peritoneal cavity for a predetermined period (dwell time) based on the child's metabolic control and acuity. The dwell time ranges from 2 to 12 hours, after which the dialysate is drained out. Fresh dialysate is instilled to complete the cycle. In PD, the dialyzing membrane for each child is exactly the right size compared with body surface area, because it is the child's own peritoneum.

The rate of solute clearance and the ultrafiltration rate in PD are determined by the amount of dialysate put into the child's abdomen, typically 30 to 50 mL dialysate per kilogram of body weight (using body surface area to calculate volume provides greater accuracy [White et al., 2006]), and the frequency of exchanges. Very sick, catabolic children requiring acute PD and intensive care, extra volume, and nutritional supplementation may require hourly exchanges, whereas otherwise healthy children on chronic PD may require fewer exchanges each day.

Commercially prepared dialysate is available in three dextrose concentrations: 1.5%, 2.5%, and 4.25%. The dextrose concentration governs the rate of ultrafiltration; the higher the dextrose concentration, the more fluid is removed during an exchange. In the acute setting, custom dialysate solutions prepared by a pharmacy may be used to provide better metabolic control.

Intermittent Peritoneal Dialysis

Intermittent PD is often used for the acutely ill child who requires a dialysis exchange every 1 to 2 hours. Their serum chemistries fluctuate and dictate frequent adjustments in the composition of their dialysate. The intermittent PD system is an open system, with air vents and other openings in the tubing. This arrangement, along with recurrent breaks in the system caused by frequent dialysate bag changes, increases the likelihood of peritonitis. Changing to a closed PD system as soon as the child's condition stabilizes helps prevent such complications.

Continuous Ambulatory Peritoneal Dialysis

Continuous ambulatory PD involves three to four exchanges during the child's waking hours, timed to fit into the child's daily schedule (Gilman & Miller, 2006). A usual schedule is to do the exchanges upon arising, after school, mid evening, and before bed. On weekends, the schedule may be adjusted to coincide with meals.

Continuous Cycling Peritoneal Dialysis

Continuous cycling PD uses an automated, programmable machine that delivers dialysate to the peritoneum, measures the dwell period, and ensures that all the dialysate and ultrafiltrate is drained from the peritoneal cavity. Prescription and compliance data can be obtained from the machine to monitor for mechanical or adherence problems. Usually, continuous cycling PD is completed at night while the child sleeps (Gilman & Miller, 2006), and most centers prescribe a last fill, with which the child ambulates through the day. When the abdominal cavity is filled with a large volume of dialysate, the liquid exerts less pressure on the abdominal wall and the inguinal canal

if the child is in a recumbent position than it does in a standing position; thus, hernias are less likely to occur with continuous cycling PD than with continuous ambulatory PD. Many practitioners use continuous cycling PD exclusively for children, believing that it lessens the burden of parental responsibility because the system is opened only twice daily: at bedtime and upon awakening. Because of the small dialysate volumes used, using continuous cycling PD machines for infants can be difficult; continuous ambulatory PD or hemodialysis may be required instead.

For all types of PD, access to the peritoneum is achieved with a Tenckhoff or other commercially available catheter (Auron et al., 2007b). The catheter is placed in the peritoneum through a midline incision below the umbilicus. The distal portion is tunneled to a lateral exit site on the abdomen where it does not interfere with the child's clothing (Fig. 19-3).

Catheter function can be compromised by poor catheter position, fibrin or omentum clogging the holes, abdominal adhesions from past surgeries, or constipation. If dialysate flows in slowly, the rate can be increased by raising the level of the inflow bag or by squeezing the bag gently to increase the rate of flow. Outflow problems are more difficult to overcome. Lowering the outflow bag by raising the child's height (e.g., picking up the child or seating the child on a taller piece of furniture) or having the child change position (roll from side to side, sit up, stand up, or walk around) are the only methods that are easily done at home (Developmental Considerations 19-1). If outflow is still a problem, the physician may prescribe an oral medication, usually sorbitol, to induce diarrhea. The increased intestinal peristalsis may change the position of the catheter to one that allows more flow. If none of these are effective, the dialysis nurse may be asked to perform forceful flushes of the catheter with normal saline using sterile technique.

If forceful flushes do not correct the outflow problem, radiopaque dye is instilled under sterile conditions and its flow is followed with fluoroscopy. If these studies show

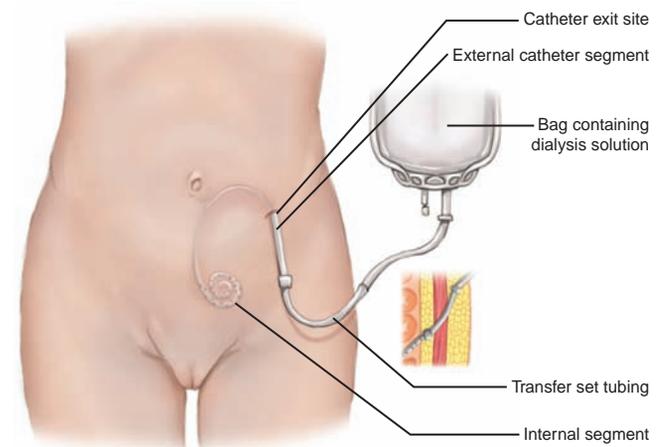

FIGURE 19-3. During PD, an implanted tube allows instillation of the dialysate fluid into the child's peritoneal cavity.

DEVELOPMENTAL CONSIDERATIONS 19–1

Participation in Peritoneal Dialysis at Home

Age	Age-Appropriate Activities
Infancy	Wears a mask during sterile procedures without distress and without removing it Tolerates catheter exit site care without undue distress
Early Childhood	Easily distracted by diversional activities during exchange procedure Same as infancy
Middle Childhood	Does not attempt to pull on catheter tubing Assists in gathering supplies or preparing the room where an exchange will be performed Fully cooperates during an exchange procedure
School-aged child	Assists in disposing of supplies after procedure Gathers supplies and prepares room where exchange will be performed Completes exchanges or sets up cyclers with parental or other adult supervision Examines effluent for cloudiness
Adolescence	Assists in disposing of supplies after procedure Gathers supplies and prepares room where exchange will be performed Completes exchanges with minimal or no supervision Disposes of supplies after procedure Informs parents when supplies are low and need to be reordered Recognizes early signs of peritonitis

that a fibrin sheath has formed around the catheter, urokinase may be used to dissolve the fibrin. A volume sufficient to fill the catheter is instilled using sterile technique, allowed to dwell for 30 to 60 minutes, then is aspirated out of the catheter. A dialysate exchange is done to check the catheter function. If outflow is still poor, surgical replacement of the catheter is the only option.

Exit site or tunnel infections are common, particularly in children who are not toilet trained (Macchini et al., 2006). Contamination of the exit site by feces can happen if the child is still wearing diapers and has a loose, runny bowel movement. Teach parents to change the dressing if fecal contamination occurs and the exit site is well healed. An occlusive dressing helps prevent contamination and decreases the need for frequent dressing changes. If a newly placed catheter dressing is contaminated, tell parents to call the dialysis nurse. Diligent exit site care can usually prevent infections. In some children, eosinophilia develops at the exit site or in the peritoneal cavity as a result of hypersensitivity to the silicone catheter. Teach the child and parents to keep the catheter immobile to avoid pulling and exit site trauma, which may lead to infection (Piraino et al., 2005) (TIP 19–2).

The major causes of morbidity with PD are catheter-related infections and peritonitis (Auron et al., 2007a; Warady et al., 2007a) (see Chart 19–2). Peritonitis can result from a break in sterile technique when changing the dialysate, from a break in the closed PD system, or

from an exit site infection migrating along the tunnel and into the peritoneal cavity.

Alert! Monitor for signs of peritonitis in a child receiving PD and immediately report them to the physician or advanced practice nurse.

Completing an exchange earlier than scheduled may be necessary to immediately evaluate the character of the dialysate. If the fluid is not cloudy and abdominal pain is not generalized, peritonitis may be ruled out by the healthcare provider. Some older children who have had peritonitis several times may be able to recognize the prodromal symptoms before the dialysate becomes cloudy (Clinical Judgment 19–2). Standardized treatment and training approaches to avoid peritonitis exist (Holloway et al., 2001).

Frequent episodes of peritonitis can lead to thickening of the peritoneal membranes and reduced ability to ultrafiltrate or remove solute. Inadequate peritoneal membrane function can mean that a child must be switched permanently from PD to hemodialysis.

Hemodialysis

Hemodialysis removes waste products and corrects serum chemistry values of the child's blood by circulating it through an extracorporeal circuit. The artificial kidney,

TIP 19–2 A Teaching Intervention Plan for the Child With a Tenckhoff Catheter

Nursing diagnoses and outcomes

- Impaired skin integrity related to effects of presence of catheter

Outcomes

- Skin at catheter entrance site remains intact and free from breakdown.
- Family performs cleaning and catheter maintenance procedures.
- Risk for infection related to catheter and dialysate exchange process

Outcomes:

- Child/family protect catheter exit site from trauma.
- Family identifies signs and symptoms of infection.
- Family verbalizes measures to prevent infection.

Teach child/family

Newly Placed Catheter (First 1–14 Days After Placement)

- Sterile exit site dressing changes will be done once per week by the dialysis nurse; schedule appointments for weekly dressing change.
- The nurse will remove the old dressing, inspect exit site/tunnel for drainage and redness (mild redness is normal), cleanse exit site, and apply a new dressing, making it occlusive around the catheter and securing it with netting/band.
- Child and family should reinforce dressing if needed, not change it. Ensure that the dressing is occlusive around the catheter; keep the catheter from dangling with netting/band at all times. Do not pull on the catheter.
- No showers

Well-Healed Catheter Site (14 Days After Insertion)

- Dressing is optional.
- Daily exit site cleaning is still required:
- Child should shower daily and not bathe in a way that allows the exit site to soak in dirty water. If

using dressing, leave dressing on until after cleaning body.

- Use regular soap on washcloth to wash rest of body.
- Remove dressing (if using) and with a new, clean washcloth with antibacterial soap (from a pump), clean around exit site.
- Rinse under shower.
- Dry rest of body with bath towel, avoiding exit site. Allow exit site to air dry or use clean 4 × 4 gauze.
- Apply new dressing if desired.
- Secure solution transfer set with tape to abdomen to prevent pulling on exit site, or secure with expandable gauze net.

Safety Concerns

- Examine Tenckhoff catheter and solution transfer set daily for signs of splits or cracks. Check that catheter adapter between Tenckhoff and solution transfer set is firmly seated and that solution transfer set is *tightly* screwed on to adapter.
- Child should avoid contact sports or games likely to affect exit site or pull on catheter or solution transfer set.
- Some dialysis centers allow children with Tenckhoff catheters to swim; others do not. If swimming is permitted, remind the child and family to swim only in well-chlorinated private pools or the ocean. Public pools, ponds, lakes, and rivers can have high bacteria counts, putting the child at risk for an exit site infection.

Contact Healthcare Provider if:

- Exit site or tunnel is hot, red, painful, or swollen
- Exit site is draining or smells bad
- Exit site is bleeding
- Any signs of splits or cracks in the Tenckhoff catheter are observed
- Child receives an injury to abdominal insertion site of catheter

or dialyzer, contains a blood compartment and a dialysate compartment. Substances in the blood but not in the dialysate, such as blood urea nitrogen (BUN) or creatinine, cross the semipermeable membrane of the dialyzer into the dialysate by osmosis and are carried away as waste. Refer to reference sources for further discussion of this highly specialized process (e.g., Daugirdas, Blake, & Ing, 2006; Fischbach et al., 2005; Kallenbach et al., 2005).

Alarms and safety mechanisms in the hemodialysis machine are triggered by problems arising in the circuit. Blood or dialysate flow shuts off if safety parameters are

exceeded; this event requires intervention by the nurse or technician. Blood lines must be selected carefully based on the volume of blood they hold.

caREminder

The total volume of the extracorporeal circuit (bloodlines plus dialyzer) should not exceed 10% of the child's circulating blood volume (Fischbach et al., 2005). If it does, then blood priming becomes necessary.

CLINICAL JUDGMENT 19–2

A Child With Chronic Renal Disease

Neal is a 6-year-old boy who has been on home PD for the past 6 weeks. His grandparents are the primary caregivers and have been responsible for managing all of his care at home. This past weekend, Neal complained of abdominal pain, especially during infusion of the dialysate. He vomited once this morning and has a temperature of 101.6 °F (38.6 °C). Neal and his grandfather come to the outpatient renal clinic for evaluation.

Questions

1. What other assessment data would be important to elicit?
2. When a child has peritonitis, what would you expect the dialysate to look like after an exchange?
3. Does Neal need to be hospitalized?
4. What measures should be instituted to reduce Neal's pain and discomfort?
5. Two days later, the home health nurse visits Neal. What data would indicate that his peritonitis is improving and that the grandparents are taking measures to prevent another infection?

Answers

1. When was an exchange last completed? What did the dialysate look like after drainage from the abdomen? When does Neal experience pain? Do any

specific events produce abdominal pain? What does the catheter exit site look like? Have the grandparents describe their technique for catheter site care, and for connecting and disconnecting the child to the dialyzer.

2. The dialysate looks cloudy. A specimen of the dialysate should be evaluated for culture and sensitivity study. Gram's stain and cell count of the fluid should also be completed to determine the infecting organisms.
3. If Neal has not demonstrated severe weight loss or signs of dehydration, and if the grandparents feel they can manage his care at home with the assistance of home healthcare, then Neal need not be hospitalized.
4. Begin antibiotic therapy immediately. Acetaminophen can be given to reduce fever and promote comfort. The dialysate should be warmed before instillation. A slow introduction of the fluid during inflow may also help reduce abdominal discomfort.
5. Neal has no fever, complaints of abdominal pain are minimal, the dialysate fluid is clear after infusion, and the grandparents demonstrate the use of aseptic techniques to clean the catheter site and to connect and disconnect the child for an infusion.

Initial studies indicate that daily home hemodialysis leads to improved growth, metabolic and blood pressure control, and fewer diet and fluid restrictions (Warady et al., 2007b), and improves health-related quality of life (Goldstein, 2007). Nocturnal home hemodialysis provides excellent biochemical and metabolic control but, compared with PD, requires more extensive training and technical expertise.

Access for hemodialysis is achieved by percutaneous catheter or by an arteriovenous fistula (AVF) or arteriovenous graft (AVG).

Percutaneous Catheter

The percutaneous catheter for acute hemodialysis can be placed in the subclavian, jugular, or femoral veins, depending on the size of the child and the size of the veins. The surgeon or nephrologist selects the site. These catheters are designed to be removed after a time, usually after a few days to a month. However, permanent catheters, most commonly placed in a subclavian vein or jugular vein, can last for many years. Maintain diligent attention to sterility when attaching the catheter to or detaching it from the hemodialysis circuit, or when performing exit site care.

Adequate functioning of the catheter is often highly related to the position of the child's body. Sometimes children with subclavian catheters must hold unusual body positions to maintain adequate blood flow through the catheter.

As with any device passing through the skin, potential complications of hemodialysis are infection at the exit site and septicemia if proper sterile technique is not observed during attachment or detachment for a treatment. Catheter kinking and thrombosis may also occur (Goldstein, 2007). Assess for signs of infection and poor flow through the catheter. Teach children with subclavian catheters not to swim, take showers, or bump or pull on the catheter or the exit site and to keep a sterile occlusive dressing over the exit site at all times.

Arteriovenous Fistula or Graft

The preferred form of vascular access for most children on maintenance hemodialysis (when hemodialysis is expected for longer than 1 year) is by AVF or AVG (National Kidney Foundation Kidney Disease Outcomes Quality Initiative, 2006).

An AVF or AVG requires time to heal and "mature" after placement surgery—typically, 3 to 6 months. A

second surgery may be needed to raise the fistula closer to the skin surface before use. Thus, if interim dialysis is needed, a catheter is also placed. After the AVF/AVG is accessed and in use, the catheter will be removed. Teach the family to assess patency daily by feeling for a “thrill,” the gentle vibration of blood flow through the AVF/AVG. Also assess by listening with a stethoscope for a “bruit,” a blowing sound. If the thrill or bruit cannot be detected, notify the physician; intervention may be required.

Fewer complications occur with fistulas than with percutaneous catheters, because they are indwelling. The infection risk is much lower. They also do not clot like catheters. The biggest complication is pain while accessing the fistula. Minimize this problem by using topical anesthetics before dialysis.

In addition to these access-specific precautions, during hemodialysis, children require vigilant assessment because they can be more unstable than adults (Fig. 19–4). Continuously monitor the child’s weight (with a metabolic scale if the child’s dry weight is less than 12 kg), check blood pressure frequently (every 1–15 minutes), and constantly observe the child for changes in hydration status or for early signs of complications. This monitoring has become much easier with the use of noninvasive monitoring devices (Patel et al., 2007). Monitor for complications such as fever, fluid overload or excessive removal, hyperkalemia, hypernatremia, hypocalcemia, and muscle cramps. Also assess for machine malfunctions, blood leaks, and allergic reactions, and address these emergencies as they arise.

Continuous Renal Replacement Therapy

Renal replacement therapy uses the same basic principles as hemodialysis; see reference resources for in-depth discussion (e.g., Dirkes & Hodge, 2007; Paton, 2003). Blood is removed from the child, pumped through a dialysis filter, and returned after removal of surplus water and wastes. The major difference is that intermittent hemodialysis removes large amounts of water and wastes in a

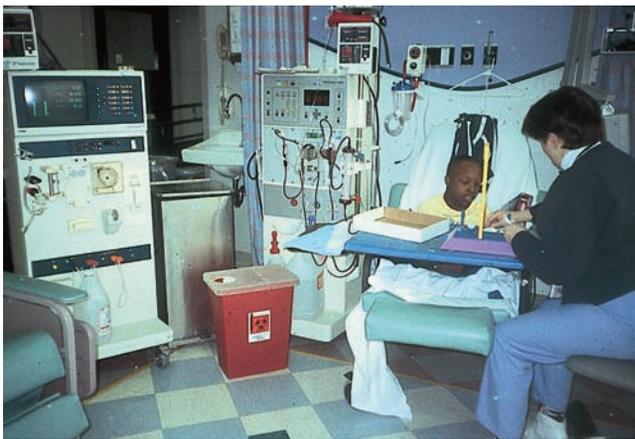

FIGURE 19–4. Hemodialysis must be performed at a specialized center where the child’s status can be constantly monitored by the specialty nursing staff.

short time, whereas continuous renal replacement therapies remove water and wastes at a slow and steady rate. Continuous renal replacement therapy is used to treat critically ill children with ARF and metabolic abnormalities.

Although hemodialysis and acute PD provide therapeutic options for critically ill children with ARF, neither may be appropriate under specific conditions (Ponikvar et al., 2002). Hemodialysis can place the child at risk for potential dialysis dysequilibrium and may be untenable because of hemodynamic instability. PD has been associated with respiratory compromise by mechanically restricting diaphragmatic movements and increasing the risk of hydrothorax. Additionally, PD may be less effective than continuous renal replacement therapy in treating inborn errors of metabolism and poisonings (Parekh & Bunchman, 1996). These issues may be compounded in treating very small infants, particularly those who weigh less than 3 kg.

Kidney Transplantation

A successful kidney transplant is the ultimate treatment goal for children with chronic kidney disease (CKD). Most centers try to accomplish it as quickly as possible by performing preemptive transplants before dialysis is needed. This approach may not be possible in some underlying diseases that require a short period of dialysis before transplant, or when a living donor is not available. Kidneys for transplant can come from either a living related, living unrelated, or deceased donor.

When determining a donor, human lymphocyte antigen typing and serum cross-match is used. Human lymphocyte antigen typing is a process that examines the white cells in serum for markers (antigens) that are involved in immune response; these markers help the immune system discriminate self from nonself. A cross-match test determines whether the serum of the potential donor reacts with that of the potential recipient. These tests are performed for living and cadaver donation. The prospective donor must also have a compatible blood type. A well-matched kidney can reduce the likelihood of rejection. The best possible kidney donor is an identical twin; next best is a human lymphocyte antigen-identical sibling. For more information, see [thePoint](#) for Supplemental Information: Kidney Transplantation: Matching Recipients and Donors.

Posttransplant Medication

Medications for immunosuppression are used to prevent the immune system from rejecting the allograft while maintaining sufficient immunity to prevent infection. Immunosuppressive medications are the only therapy available to prevent acute and chronic rejection and maintain adequate graft function. These agents can be grouped into those used for induction, maintenance, and antirejection immunosuppression.

Induction therapy starts pretransplant or immediately after transplantation. These drugs are given at high doses to prevent acute rejection. Examples are Thymoglobulin

(Antihymocyte globulin), methylprednisolone, basiliximab (Simulect), and Daclizumab (Zenapax).

Maintenance therapy is given posttransplant to maintain the graft. Examples are azathioprine (Imuran), mycophenolate mofetil (CellCept), prednisone, cyclosporine, sirolimus, and tacrolimus.

Antirejection medications are given to treat episodes of acute rejection. Examples are methylprednisolone, Thymoglobulin, basiliximab, Daclizumab, and muromonab (OKT3). Some of the medications can be given by intravenous (IV) infusion during the immediate postoperative period. By the time the recipient is discharged home, the medication can be taken orally.

Transplanted kidneys last varying lengths of time. Hyperacute rejection causes the loss of the kidney in the operating room as the transplant is being performed. Acute rejection usually occurs within the first 7 to 14 days after transplantation. Rejection can occur at any time after transplantation, particularly if the child stops taking immunosuppressive medications. Even if medications are taken as prescribed, chronic rejection—a slow, insidious process—can result in the loss of the kidney. However, the longer the transplant remains in place without complications, the more likely it is that it will never be rejected. Survival 1 year after kidney transplant is 98.2% with organs from living donors and 97.1% for deceased donors; 5-year survival rates are 95.6% for living donors and 92.6% for deceased donors (Smith et al., 2007).

Acute or chronic rejection can cause loss of transplant function. This complication is treated in the same manner as the initial loss of native kidney function: conservative management, followed by dialysis. Retransplantation at a future date is usually an option, except when hyperacute rejection occurs for an unknown cause, when the likelihood of the basic disease recurring in the transplant is too great, or with an elevated panel-reactive antibody.

Teach the child and family that immunosuppressive medications to prevent rejection of the transplanted organ must be taken, in the exact amount prescribed, for as long as the transplanted kidney is functioning. In addition, transplant recipients receive medications to prevent infections and may require medications to treat hypertension. Before discharge, teach the child and parents which medications to take, the amounts prescribed, and the effects and side effects of each medication. In addition to preventing rejection, these medications increase the recipient's susceptibility to infection and can cause other side effects including hypertension, weight gain, hirsutism, and impaired growth.

Community Care

Transplant patients are not “cured.” These children never reach a point at which they no longer require medical attention or drug therapy. However, a well-stabilized transplant patient requires only daily or every-other-day medication. Clinic visits are usually twice a week initially, but as the child continues to do well, the visits are slowly decreased to every 3 to 4 months. Monthly checks of blood chemistries, complete blood counts, and medication

levels are required to monitor kidney function and drug levels, and to detect signs of rejection. Some centers recommend periodic biopsies of the transplanted kidney to detect rejection before it has caused enough damage to change laboratory values.

caREminder

Adolescents are particularly at risk for transplant medication nonadherence, because the side effects of immunosuppressants, such as “chubby cheeks,” acne, and hirsutism, may negatively affect their body image. Talk with the teen about such feelings and reinforce the importance of the medications.

Lifelong immunosuppressive medication use puts these children at increased risk for community-acquired infections. During outbreaks of infectious illnesses, monitor these children closely and treat them aggressively because of their altered immune status. Teach parents that the child should receive a yearly influenza vaccine and be evaluated at the first sign of infectious illness.

Despite the short-term risks and the long-term side effects, successful transplantation still offers the child with renal failure the best chance at the most normal lifestyle possible (Community Care 19–1).

QUESTION: Which nursing diagnoses would be most appropriate to include in the plan of care for J. D. and his family?

NURSING PLAN OF CARE FOR THE CHILD WITH ALTERED GENITOURINARY STATUS

The nursing plan of care for a child with a genitourinary disorder should address the potentially dangerous alterations in fluid and electrolyte status that can result from these disorders (see Nursing Plan of Care 19–1). Adequate urinary and renal function is central to efficiently excreting toxins from the body. Failure to remove waste products through urinary excretion can lead to dysfunction of other body systems, such as the cardiovascular and the musculoskeletal systems.

Most children and their families find it difficult and embarrassing to discuss conditions that affect elimination patterns and competency of the genitalia. If the condition is congenital, the parents may feel guilty and question whether they could have prevented the anomaly. If the condition is acquired, family members may feel frustrated because of their inability to determine what is wrong with the child and to obtain effective treatment. The nurse plays a pivotal role in helping the child and family follow the treatment regimen that allows the child to live a full and normal life within any constraints imposed by the condition. Work with the family to help the child feel self-confident and

COMMUNITY CARE 19–1

Concerns of the Newly Transplanted Patient

Concern	Response
Can I go back to school soon and do all activities?	You will not be able to return to school for 6 weeks or until healing is complete. Driving is not allowed until healing has occurred, you are not taking pain medications, and are stable on your posttransplant medications (show no behavioral side effects). Do not lift anything heavier than 10 lb for 8 weeks.
Can I be with my friends once I get out of the hospital?	Do not participate in contact sports (e.g., tackle football, wrestling, or hockey) or sports that could severely jar the kidney (e.g., skydiving). For the first 6 weeks, you need to stay away from people, to prevent infection. A few friends can come see you during this time, as long as they do not have any signs of a cold or other illness.
Are there any restrictions on what I can eat?	You can have as much protein and fluid as you want, but concentrate on low-salt food to prevent high blood pressure. Remember, prednisone will increase your appetite, so be sure you eat healthy low-calorie snacks and keep a close eye on your weight.
Do I have to take my medications every day?	All medications must be taken every day, on time, and at the correct dose to keep your new kidney healthy. Your family will help you to remember to take these medications. When you go back to school, you will have to help the nurse remember that you need to take your medication every day.

comfortable with any changes in appearance resulting from the condition. Various support organizations can provide information and other help to the child with a genitourinary condition.

ANSWER: For J. D. and his family, appropriate nursing diagnoses would include deficient knowledge (condition, treatment, effect on functioning and appearance), anxiety related to the anomaly and impact on J. D.'s body image and functioning, and interrupted family processes related to J. D.'s anomaly, and impact on the father's view of his son and concerns about the condition.

ALTERATIONS IN GENITOURINARY STATUS

Alterations in genitourinary status have many causes, from infection to developmental, structural, and neurologic problems. Trauma can also alter genitourinary status.

URINARY TRACT INFECTIONS (UTI)

UTI is the inflammatory process that results from bacterial invasion into the sterile urinary tract. The epithelial

cells that line the urinary tract respond quickly to bacterial infiltration, flooding the area with pathogen-destroying leukocytes. Voiding rids the body of the substances; however, endotoxins released during bacterial breakdown irritate mucosal nerve endings and cause localized inflammation. White blood cells and bacteria in the urine (**pyuria** and **bacteriuria**, respectively) confirm the diagnosis of a UTI (see [thePoint](#) for Supplemental Information: Terminology Used to Describe Urinary Tract Infections).

Incidence and Etiology

UTI is one of the most common bacterial infections in childhood, second only to otitis media (Mak & Kuo, 2006). In North America, UTIs result in more than 1.1 million medical visits annually (Freedman & Urologic Diseases in America Project, 2005). UTIs occur in 8% of girls and 2% of boys by 7 years of age (Hellström et al., 1991). Among febrile infants, UTIs are more common in uncircumcised males (21.3%) than in circumcised males (2.3%) or females (5.0%) (Zorc et al., 2005). UTIs are more common in females than males after the neonatal period, and the incidence is high in sexually active adolescent females.

Escherichia coli, prevalent in the gastrointestinal tract, is the organism predominantly responsible for pediatric UTIs (Gaspari et al., 2006). Other common uropathogens include *Klebsiella*, *Proteus* (more common in boys), *Pseudomonas*, and *Enterococcus* (Whiting et al., 2006).

UTI can occur anywhere along the urinary tract, but is most often confined to the bladder (cystitis). Urethritis in

NURSING PLAN OF CARE 19–1 THE CHILD WITH ALTERED GENITOURINARY STATUS

Nursing Diagnosis: Excess fluid volume related to effects of accumulation and retention of fluids, electrolytes, and waste products.

Interventions/Rationale

- Record strict and accurate intake and output. Include incidental fluids such as those taken with medications, ice chips, and ice pops.
Accurate intake and output is necessary to determine renal functioning and fluid replacement needs.
- Weigh twice daily, always with the same scale, wearing same amount of clothing, at the same time every day.
Monitors fluid status. In older children, a weight gain of greater than 0.5 kg can indicate fluid retention.
- Monitor vital signs, especially heart rate and blood pressure.
Tachycardia and hypertension can occur because of excessive fluid.
- Auscultate lung and heart sounds.
Excessive fluid or fluid overload can lead to pulmonary edema and heart failure. Listen for adventitious breath sounds and/or extra heart sounds.
- Assess level of consciousness.
Fluid shifts can lead to accumulation of toxins, acidosis, and electrolyte imbalances.
- Monitor specific gravity.
Indicates ability of kidneys to concentrate urine.
- Monitor laboratory values (e.g., BUN, creatinine, urine and serum sodium, serum potassium, hemoglobin, and hematocrit) and diagnostic studies (chest radiographs).
Assess progression and management of renal failure or dysfunction.
- Administer medications (antihypertensives, diuretics, prostaglandins) as ordered.
Side effects of medication may alter and affect renal function. See specific medication for physiology of effects of medication.
- Monitor and assess IV site carefully, giving solution at prescribed rate and prescribed solution.
Avoids IV infiltration and helps maintain consistent infusion of fluids.

Outcomes

- Child will exhibit decreased evidence of fluid retention.
- Child will maintain stable weight.
- Child will maintain blood pressure within prescribed parameters.
- Child will maintain normal electrolyte levels.
- Signs and symptoms of fluid volume excess will be recognized promptly and treatment will be initiated.

Nursing Diagnosis: Impaired urinary elimination related to effects of condition or disease process

Interventions/Rationale

- Monitor vital signs, peripheral pulses, skin turgor, capillary refill, and oral mucosa.
Indicates fluid balance, level of hydration, and effectiveness of fluid replacement.
- Auscultate lungs, particularly noting adventitious breath sounds.
Adventitious sounds may indicate fluid overload.
- Monitor respiratory rate and effort.
May indicate developing complications such as diaphragmatic pressure.
- Monitor electrolytes, arterial blood gases, and calcium.
Impaired renal function increases the risk of electrolyte and/or acid–base problems. Increased calcium may increase risk of crystal/stone formation.
- Monitor and document urine characteristics such as specific gravity, odor, and color.
Assesses for urine infection; monitors fluid status. Provides a baseline for kidney function and presence of infection. Urine characteristics may provide information about alterations in renal function (e.g., decreased specific gravity may indicate problems concentrating urine or overhydration., hematuria may indicate bleeding).
- Visually inspect and palpate the lower abdomen for bladder fullness, suprapubic distension.
The bladder lies in the suprapubic region of the abdomen. Retention of urine can cause tissue distention of bladder and kidneys, and increases risk for infection.
- Observe for signs of bladder retention or infection (e.g., voiding small amounts, dysuria, frequency, fever).
Helps detect and treat problems promptly.
- Keep accurate intake and output; weigh daily, at same time, same scale, in same clothes.
Monitors fluid balance; helps estimate fluid-needs replacement. Fluid intake should approximate fluid losses (urine, nasogastric, wound drainage, and insensible losses).
- Assess for and follow up on reports of flank or abdominal pain.
Pain may indicate pathology and may be a medical emergency itself. Complete obstruction can cause perforation into perineal cavity.
- Assess indwelling urinary catheter, when used, for patency; irrigate as necessary; report a decrease in urine output.
Alerts nurse to inadequate output. Tubes can be occluded by stones or kinks. Failure to drain may cause urinary retention.

(Continued)

NURSING PLAN OF CARE 19–1 THE CHILD WITH ALTERED GENITOURINARY STATUS (CONTINUED)

- Ensure adequate fluid intake.
If fluid intake is not maintained, child may revert to oliguric phase.
- Facilitate access to the toilet and teach child to make scheduled trips to the bathroom.
May need to train the child to empty the bladder at specified intervals.
- Educate the child and family on signs and symptoms of overdistended bladder, adequate intake, and signs and symptoms of UTI.
Reduces the risk of infection.

Outcomes

- Child will excrete 0.5 to 2 mL/kg urine per hour.
- Child will maintain fluid balance, with intake equaling output.
- Child will not experience urinary retention or bladder distention.
- Signs and symptoms of altered urinary output will be recognized early and interventions will be initiated promptly.
- Child and family will participate in activities or adopt techniques to normalize the child's urinary elimination.
- Child and family will demonstrate skill in care and hygiene measures in response to altered urinary elimination.
- Child and family will demonstrate interventions to avoid urinary retention.

Nursing Diagnosis: Risk for infection related to effects of disease, chronic illness, medications, and invasive procedures or catheters, urinary retention

Interventions/Rationale

- Promote hand hygiene by child, family, and staff.
Reduces risk of infection by cross-contamination
- Assess for presence of, existence of, and history of risk factors such as incontinence, urine obstruction, indwelling catheters, lack of skin integrity, and types of medication.
Risk factors may weaken body's line of defense for fighting infection.
- Monitor white blood cells, increased frequency, burning on urination, bladder spasms, foul-smelling urine, and changes in output or intake.
May indicate an infection.
- Document urine characteristics.
Cloudy urine and odor may indicate infection.
- Assess nutritional intake and fluid intake, including weight and serum albumin, BUN, and creatinine levels.

Patients with poor nutritional and fluid intake may be at risk for infection.

- Encourage intake of protein and fluid, as appropriate for the child.
Maintains optimal nutritional and fluid status to fight infection.
- Teach child to take medications as ordered.
Maintains fluid and electrolyte balance and state of health.
- Demonstrate and allow return demonstrations of all high-risk procedures the child and parents will do after discharge.
Helps ascertain safe performance of procedures and may decrease the risk of infection.

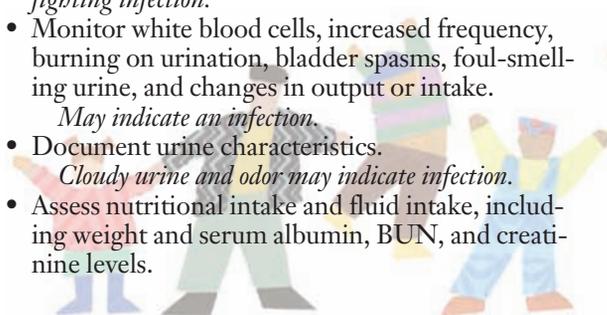

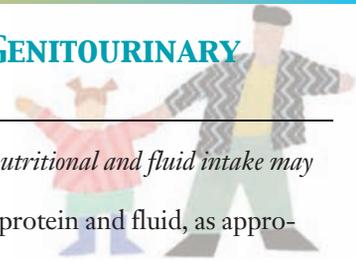

Outcomes

- Child will not develop infection.
- Child's signs and symptoms of infection will be recognized early, and interventions will be initiated in a timely manner.
- Child and family will identify signs and symptoms of UTI.
- Child and family will express their understanding of the need for prompt medical intervention if an infection occurs.

Nursing Diagnosis: Ineffective therapeutic regimen management related to complex healthcare needs and lack of understanding of importance of regimen

Interventions/Rationale

- Assess child and family's perceptions and knowledge of regime.
Allows for correction of and opportunity for increased knowledge.
- Schedule a team conference with parents and child, including teachers and friends as appropriate and approved by parents, to provide information and explore feelings and attitudes. Encourage the child to take part in the selection of conference participants.
Child becomes a comanager, and assists in having mutual support and information.
- Provide verbal and written instructions regarding regime.
Enhances and fosters adherence; provides reference for later referral.
- Stress importance of regular, frequent follow-up appointments to ensure proper healthcare needs.
Enhances opportunities to alter regime as healthcare needs improve or deteriorate.

- Explain the side effects of the medical regime, including the medications.
Nonadherence is frequently caused by not knowing what to do and by side effects of medications.
- Use a variety of teaching methods.
Children and families learn in different ways.
- Allow the child and parents to practice new skills, providing immediate feedback on performance.
Allows for enhanced retention and for making corrections of necessary skills.

Outcomes

- Child and family will show that they understand the child's healthcare needs and know how to manage current needs.
- Child and family will develop a plan to incorporate components of therapeutic regimen into their life-style (diet, medications, activities).
- Child and family will effectively manage the child's healthcare needs.

Nursing Diagnosis: Disturbed body image related to effects of illness

Interventions/Rationale

- Arrange for child and parents to meet others who have had similar experiences and managed them successfully.
Provides a support system.
- Provide openings to enable the child to express feelings by validating your observations and feelings (e.g., "You look down. How are things going?")
Assists in identification of concerns and problems.
- Be a good listener and accept what the child verbalizes. Remember not to take anger or hostility personally.
Provides the child an opportunity to discuss issues and misconceptions.
- Focus on the child's feelings and deal with the presenting behavior.
Keeping focus on the child helps him or her feel that he or she is being heard.
- Determine what the body image change means to the child and what effect the child thinks it will have on life. Do not challenge perceptions you think are unrealistic, but continue to provide opportunities for the child to share these perceptions and feelings with you.
Developmental changes normally occur as the child grows.
- Be accepting of child's body changes.
If child is repulsed or ashamed of physical changes, he or she will be watching the faces of others for negative signs, which may reinforce the child's negative feelings.
- Assist the child to normalize the change; use developmental strategies.

Child may perceive changes that are not present or real.

Outcomes

- Child will verbalize positive self-concept.
- Child and family will be prepared for potential alterations in the child's appearance caused by the disease process and treatment interventions.
- Child's peers will be prepared for the child's altered appearance and provide support for the child.

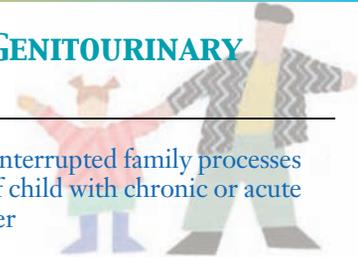

Nursing Diagnosis: Deficient knowledge: Physiology and pathology of condition and care needed by child

Interventions/Rationale

- Assess family's knowledge of the child's condition and care needs.
Assists in focusing teaching to family's needs.
- Explain condition and all treatments and procedures. Be present when other health team members give information. Reinforce and clarify information.
Helps the child and parents to understand condition and treatments, and to make informed decisions.
- Identify signs and symptoms that require further evaluation.
May assist in early detection and assist in prompt intervention of developing problems.
- Emphasize the need for ongoing medical care.
Monitors disease process, and provides opportunity for further teaching and discussions.
- Discuss potential complications related to specific therapeutic regime.
Giving appropriate strategies to deal with side effects and complications may enhance adherence.
- Provide a list of medications, with dosage and schedule; list the side effects of each; explain the importance of adhering to prescribed dosages and where and how to obtain refills; and advise not to take over-the-counter drugs unless prescribed.
Giving information and a tangible list may facilitate adherence to regime.
- Explain food and fluid restrictions, and allow the child and parents to plan daily menus and intake. Discuss the importance of maintaining an accurate intake and output as an indicator of fluid balance and renal functioning.
Giving information may enhance adherence. Promotes healing and provides energy for tissue repair.
- Instruct in daily weights, frequent blood pressure check, wearing of MedicAlert bracelet.
Self-monitoring can provide early detection of complications.

NURSING PLAN OF CARE 19–1 THE CHILD WITH ALTERED GENITOURINARY STATUS (CONTINUED)

- Initiate referrals, appointments with community support groups, mental health clinics, and so forth, as needed for continued psychosocial support.
Provides for continued support.
- Encourage regular activity and exercise as tolerated.
Immobility increases renal stasis and calcium shift out of bones.

Outcomes

- Child and family will verbalize their understanding of the physiology and pathology of the condition, its effect on urinary tract function, and its medical and surgical management.
- Child and family will state rationale for care needed and will demonstrate care and hygiene measures needed to manage the child's care.

Nursing Diagnosis: Anxiety related to child's diagnosis and uncertainty of outcomes for the child

Interventions/Rationale

- Assess the level of fear in the child and the parents. Observe for signs of denial and depression.
Assists in determining the type of interventions needed.
- Acknowledge the feelings of the child and parents; acknowledge normalcy of the situation.
Acknowledgment of feelings can sometimes help the child and parents gain control over their fears.
- Answer questions and concerns of the child and family, and provide opportunities for asking questions and voicing concerns.
Creates feelings of cooperation; assists in identification of fears and concerns.
- Encourage the child and family to participate in the care of the child.
Involvement promotes a feeling of control and feelings of usefulness.

Outcome

- Child and family will be able to manage their anxiety and perform activities of daily living.
- Child and family will verbalize their feelings of grief, loss, fear, powerlessness, or spiritual distress to an appropriate support source.

Nursing Diagnosis: Interrupted family processes related to presence of child with chronic or acute genitourinary disorder

Interventions/Rationale

- Assess family members' perceptions of problems.
Each family member has perceptions that need to be understood.
- Evaluate strengths, coping skills, and support systems.
Facilitates use of previous successful techniques.
- Consider cultural factors and incorporate into care practices as indicated and appropriate.
May decrease serious conflict.
- Provide opportunities to express concerns, fears, expectations, or questions.
Promotes communication and support.
- Assist family in setting realistic goals.
Helps family gain control over the situation.
- Encourage family to obtain information and resources.
May provide clarification.

Outcomes

- Child and family will verbalize their feelings to each other and to the healthcare team.
- Child and family will demonstrate effective decision making and mutual support activities.
- Child and family will participate in treatment activities at developmentally appropriate levels.
- Child and family will implement effective coping mechanisms to work through problems associated with the illness.
- Parents will verbalize their awareness of stressors that compromise their caregiving role.
- Parents will express their feelings regarding their child's condition and its long-term management.
- Parents will seek emotional, physical, and financial support from significant others, professionals, or other parents.
- Parents will demonstrate parenting behavior that is positive and appropriate for the age of their child.

children can result from haphazard perineal hygiene or from contact with various products, such as bubble bath solutions or soaps, that irritate the child's urinary tract. Upper tract infections (pyelonephritis) are the most common serious infection of young children.

If cystitis is left untreated, it can progress to pyelonephritis with potential for kidney damage, hypertension,

or renal insufficiency. Risk factors for UTI include anatomic and host factors. Anatomically, the female's short, straight urethra, situated in close proximity to the rectum, provides a convenient access route for invading bacteria. Female infants are especially vulnerable because of perineal colonization from fecal soiling. Urinary stasis is a prominent risk factor. Vesicoureteral reflux (VUR) is

the most commonly associated abnormality of children with UTI. Numerous studies have correlated UTI with bowel dysfunction (Bower, Sit, & Yeung, 2006; Hellerstein & Linebarger, 2003; Kasirga et al., 2006; Mattoo, 2007). This connection is believed to stem from pressure of the distended rectal segment and possibly from colonic seeding of bacteria by the hematogenic route.

Pathophysiology

Normally, the urinary tract is a sterile system, and the slightly acidic urine creates a hostile environment for most alkaline-favoring microorganisms. Bacteria that invade the urinary tract meet the first line of defense—expulsion by bladder flushing, or voiding. Anything that compromises total and frequent voiding, such as an anatomic defect, constipation, or neurologic dysfunction, increases the risk of mucosal infiltration of the bladder.

Bacterial growth triggers an immune response. Within hours, leukocytes flood the area. The affected tissue becomes inflamed and edematous. Bacteria-released endotoxins, alkaline in nature, promote disease progression. Sensitized nerve endings respond with uninhibited, painful bladder spasms in an attempt to flush out the pathogens. Localized mucosal infiltration produces hemorrhagic areas. Distorted by tissue inflammation, the ureterovesical junction may be temporarily incompetent.

If the infection is untreated, transient reflux permits it to ascend into the kidneys, resulting in pyelonephritis. Severe reflux is closely associated with permanent renal damage (Swerkerson, Jodal, Sixt et al., 2007). Chronic or recurrent pyelonephritis resulting in renal damage and scarring may progress to chronic renal disease if it continues (Downs, 1999). The cycle from initial bacterial influx to pyelonephritis can be rapid, reaching completion in 48 hours or less.

Pyelonephritis in children younger than age 2 years seems to be especially troublesome. Bladder trigone instability promotes ureterovesical junction shifting during infection, magnifying the likelihood of reflux and renal involvement. Scarring of the renal tissue and frequent UTI recurrence are more likely following initial infection. Children are at greatest risk for renal scarring during the first year of life. Early detection and treatment, coupled with long-term surveillance, are paramount to improve the prognosis for these children.

Pyelonephritis may progress to gram-negative septic shock, a response to circulating bacterial endotoxins. The child appears moribund and may experience seizures, hypotension, subnormal temperature, and loss of consciousness. Gram-negative septic shock is a medical emergency that requires life-saving treatment (see Chapter 31 for specific management).

Pyelonephritis traditionally requires hospitalization to administer IV fluids and parenteral antibiotics. This regimen provides rapid, high-dose drug therapy and fluid replacement to reduce or prevent renal parenchymal infiltration. It is appropriate for the child who is acutely ill or who is unable to maintain a high fluid intake.

Assessment

Determine the child's symptoms. Classic symptoms of UTI—urinary frequency, urgency and hesitancy, dysuria, hematuria, and stranguria (stopping and starting the urinary stream)—vary somewhat based on the child's age and cognitive level (Developmental Considerations 19–2). Constitutional symptoms, such as high temperature ($>102^{\circ}\text{F}$ [39°C]), flank pain, vomiting, lethargy, and generalized malaise, are more serious and point to pyelonephritis.

When the child's symptoms suggest a UTI, the nurse is often responsible for properly collecting and handling a urine sample. Accurate diagnosis depends on selecting a collection method with the least risk of contamination (see Tradition or Science 19–2).

Positive findings of blood and protein in the urine, using a urine Chemstrip, are suggestive of a UTI. Leukocyte esterase and nitrate readings, although accurate in adults, are problematic in children. Leukocyte esterase is an enzyme that is released during white blood cell destruction. Positive findings are closely correlated to a UTI. However, negative findings can occur even when an infection is present, because of frequent voiding and lower esterase levels in the child's blood. Urine must be in the bladder for at least 4 hours in the presence of the bacteria containing reductase so nitrate is reduced to nitrite to obtain a positive nitrate reading. Infants typically void frequently, so a positive nitrite test is often not obtained in infants with infection.

Diagnostically, a UTI is identified by the presence of white blood cells in the urine (pyuria) and by a urine culture that grows bacteria (bacteriuria) of a significant number. Cultures that grow mixed flora usually represent contamination. Obtain urine collection for culture prior to beginning antibiotic therapy and IV therapy for dehydration.

Elevated white blood cell counts, C-reactive protein, and erythrocyte sedimentation rates are often present with pyelonephritis.

DEVELOPMENTAL CONSIDERATIONS 19–2

Signs of UTI Based on Age

- Neonate: Jaundice, fever, failure to thrive, poor feeding, vomiting
- Infant: Irritability, poor feeding, fever, vomiting, diarrhea, strong odor to urine
- Early Childhood: Vomiting, diarrhea, abdominal or flank pain, fever, enuresis, urgency, frequency, new incontinence, strong odor to urine
- Middle Childhood: Fever, vomiting, flank or abdominal pain, frequency, urgency, dysuria, new incontinence, strong odor to urine

Interdisciplinary Interventions

The goal of treating UTIs is to eliminate the infection, prevent urosepsis, and reduce renal damage. Prompt intervention for UTI is necessary to provide symptomatic relief, halt the spread of infection, eliminate systemic infiltration of bacteria, and preserve the kidney. Short-term interventions combine antibiotic therapy, increased fluid intake, frequent voiding, and daily bowel movements. Long-term management involves further urinary evaluation and monitoring for recurrence.

Antibiotic Therapy

Antibiotics used to treat infection of the lower urinary tract include combined sulfamethoxazole/trimethoprim, nitrofurantoin, penicillins, and cephalosporins administered orally for 7 to 10 days. The antibiotic regimen may be altered when the bacterial sensitivity results are available, generally 48 hours after inoculation of the culture medium.

Increased Fluid Intake

A high daily fluid intake (as much as 1,000 mL for the older child) dilutes and washes out endotoxins and tissue debris. Water is the recommended fluid, along with juice, soup, milk, ice cream, gelatin, and frozen liquid desserts. Teach the child to avoid bladder irritants such as chocolate and caffeine-rich beverages. Although no studies have been replicated among children, encouraging the consumption of cranberry juice entails little risk (Tradition or Science 19–3). Maintaining a fluid record (Fig. 19–5) helps to encourage fluid intake. Children enjoy coloring the pictures and are proud to receive a reward sticker or star each day.

Another predisposing factor to bladder instability and recurrent UTI is constipation, which should be managed aggressively. Unstable bladder contractions and inability to relax the pelvic floor muscles, problems often associated with constipation, may result in incomplete bladder emptying. Adequate fluid intake can help prevent constipation.

Frequent Voiding

Most children with UTI experience uncontrolled frequency of urination resulting from detrusor hypersensitivity. However, the accompanying dysuria and bladder spasm may cause some children to withhold urine. Localized relief can be afforded by a tub or sitz bath, or with a perineal rinse during voiding. A mild analgesic, such as acetaminophen, is recommended every 4 hours for comfort. Frequent voiding decreases urinary stasis and helps prevent UTIs. Because children spend a substantial amount of time in school, work with school staff if possible to arrange schedules that allow voiding on a regular basis, every 2 to 3 hours.

Community Care

UTIs are managed at home, but when UTIs progress to pyelonephritis, hospitalization is usually required to

TRADITION OR SCIENCE 19–3

Are cranberry juice and cranberry products effective for preventing or managing UTIs in children?

MORE INQUIRY NEEDED

Historically, cranberry was used by Native Americans as a remedy for conditions affecting the urinary tract (Irvin, 2005). Cranberry was once thought beneficial because it acidifies urine, resulting in a bacteriostatic effect that destroys microorganisms. Research demonstrates that cranberry affects the urinary tract by eliminating adhesion of microorganisms to epithelial cells that are in the urinary tract (Howell, 2007; Liu et al., 2006; Reid et al., 2001).

Studies in adults demonstrate that cranberry may protect against UTIs. Two systematic reviews found positive clinical evidence that cranberry juice consumption can decrease the number of symptomatic UTIs (Jepson & Craig, 2007; Jepson, Mihaljevic, & Craig, 2004). Randomized controlled trials in women, some focusing on elderly women, have demonstrated that cranberry juice consumption can decrease the number of symptomatic UTIs over a 12-month period (Avorn et al., 1994; Stothers, 2002). Kontiokari et al. (2001) found the same results with cranberry–lingonberry juice. A small (12 women with recurrent UTIs, 8 of whom completed the 2-year follow-up), open-label study of concentrated cranberry extract tablets with a high phenolic content indicated that this preparation may prevent UTIs (Bailey et al., 2007a). There is no evidence that cranberry can treat UTI once an infection is present (Jepson et al.).

However, cranberry may be effective only in certain subpopulations. The evidence is inconclusive regarding whether it is effective in the elderly (Jepson & Craig, 2007). McMurdo et al. (2005) examined the effectiveness of cranberry juice in hospitalized elderly patients with a mean age older than 81 years. Although they did find fewer UTIs caused by *E. coli*, they caution against using the results without further study, because the number of UTIs was a secondary outcome, and the study was underpowered (McMurdo et al., 2005). The evidence does not support its effectiveness in patients with a neurogenic bladder (Jepson & Craig, 2007; Lee et al., 2007a; Linsenmeyer et al., 2004).

Although numerous studies have examined the effectiveness of cranberry products to prevent UTI/chronic cystitis in adults, particularly women, few studies have investigated the use of cranberry products in children. Kontiokari et al. (2005) examined its effects on bacterial colonization in children in a randomized, controlled trial. Children accepted the cranberry juice well, but there was no change in bacterial flora in the nasopharynx or the bacterial fatty acid composition of stools, and no effect on common infectious diseases or their symptoms (Kontiokari et al., 2005). Many parents give cranberry juice to their children with renal problems. Of 117 parents of children interviewed in a nephrology clinic, 29% gave cranberry products, and 65% gave it when children had recurrent UTIs; few discussed its use with

their physician (Super et al., 2005). One study examined the effects of cranberry juice on bacteriuria in children with neurogenic bladder who were receiving intermittent catheterization and found that cranberry concentrate had no effect on bacteriuria (Schlager et al., 1999).

Cranberry is not a substitute for antibiotics in the treatment of acute UTI. There is a strong scientific basis for recommending its use in adult women. More inquiry is needed to determine cranberry dosing, optimal preparation (e.g., concentrate, juice, capsules), and effectiveness in children.

manage fever and pain (see Chapter 11). When the diagnosis of UTI is confirmed, direct child and family teaching to include all aspects of disease progression and management. Discuss medication administration, risk factors that affect the child's potential for reinfection, and recommended prevention techniques. Give parents a home care instruction sheet to reinforce the information (TIP 19-3). Encourage parents to share this information with baby-sitters, teachers, or other adult caregivers. Emphasize the importance of long-term follow-up to identify and reduce the effects of long-term sequelae.

My doctor says, "Drink liquids!"
 Be they water, juice, or pop-
 Please make sure my cup is full,
 So my supply will never stop-
 I'll keep track of what I drink,
 A quick look at this chart will tell-
 I want to do as much as I can,
 To help myself get well!

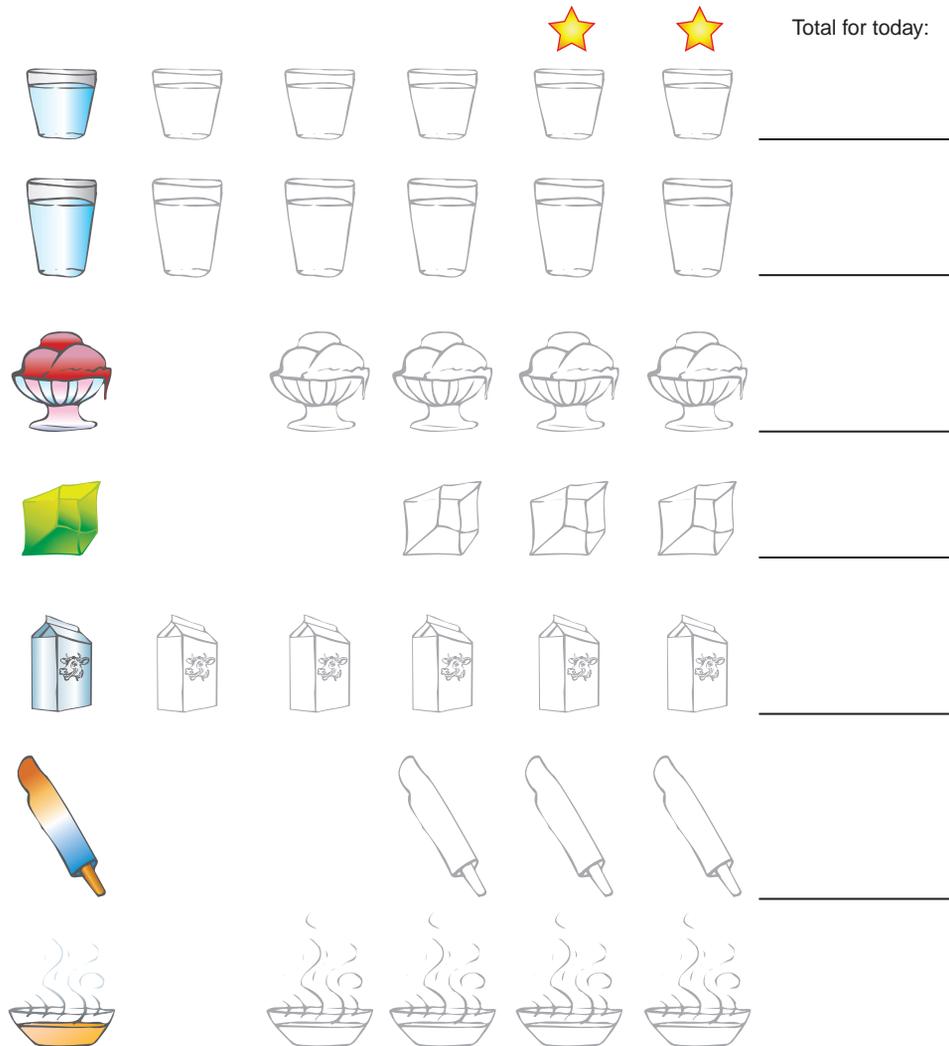

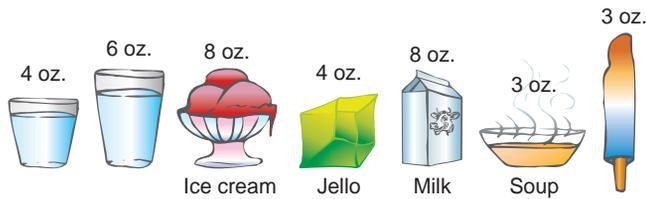

FIGURE 19-5. Having the child keep a fluid record may help motivate him or her to consume more fluids.

Follow-up Management

Three to six weeks after the infection resolves, a radiographic evaluation of the urinary tract is standard practice. Females whose first UTI occurred before age 5 years, and all males, should have a renal/bladder ultrasound and voiding cystourethrogram (VCUG) (American Academy of Pediatrics, 1999b). The ultrasound may rule out obstructive uropathy but is a poor screening tool for VUR. A standard VCUG depicts urethral and bladder anatomy and VUR. Nuclear cystography uses less radiation than the standard VCUG and can help visualize the bladder and detect VUR. Grading of VUR is less precise, however, and associated bladder abnormalities cannot be detected with nuclear cystography. Therefore, a standard VCUG is preferred as the initial study, and nuclear cystography is used in follow-up studies. A dimercaptosuccinic acid (DMSA) renal scan is the best tool for detecting tubular damage and renal scarring; unfortunately, the DMSA renal scan cannot detect VUR. Obtaining a VCUG too soon after a UTI may result in a false-positive study because of inflammation. When the DMSA renal scan is negative, VCUG may not be necessary in all young children with first UTI (Hansson et al., 2004; Tseng et al., 2007). Recent literature suggests that the rate of long-term sequelae and the need for imaging studies may be lower than previously thought (Garin et al., 2006; Hoberman et al., 2003).

A urine culture is typically obtained 48 to 72 hours after completing the antibiotic therapy to ensure that the urine is sterile. Most uncomplicated UTIs respond to treatment, and cultures are negative after 2 days of antibiotics, which has led some to argue that repeat cultures to demonstrate “cure” cause unnecessary trauma and expense (Oreskovic & Sembrano, 2007). The child with a negative urine culture should undergo repeat cultures every 3 months during the ensuing year. If a UTI recurs, the child may be given prophylactic therapy, using low-dose antibiotics. Nitrofurantoin or a combined sulfamethoxazole–trimethoprim preparation is the usual choice because of these agents’ low serum and high urine concentrations. Long-term suppressive therapy is recommended for the child with urologic anomalies until the defect is outgrown or surgically corrected.

Antibiotic prophylaxis to prevent UTI in children with low-grade VUR is being reevaluated, however. A systematic review concluded that the evidence of benefit is weak (Williams et al., 2006). Recent research indicates that antibiotic prophylaxis does not reduce incidence of UTI and increases the prevalence of resistant organisms (Conway et al., 2007; Garin et al., 2006), and that, instead of prophylaxis, increased surveillance with prompt treatment of UTI may be indicated (Faust & Pohl, 2007).

URETHRITIS

Young girls experiencing symptoms of burning, dysuria, frequency, or vaginal itching may possibly have a UTI, but more commonly the symptoms are caused by irritation

of the skin at the opening of the urethra (urethritis) or around the vaginal area (vulvovaginitis). Before puberty, sensitive urethral tissue is easily irritated by chemicals or mechanical factors (see TIP 19–3). Vaginal discharge could suggest vaginal washout resulting from the child’s position during urination, or can signal a vaginal infection or sexual abuse.

Chronic urethral and introital irritation causes some young girls to develop labial adhesions (synechiae), beginning at the posterior fourchette and advancing anteriorly. In severe cases, the vagina may be completely occluded. Labial adhesions appear as a translucent line of central fusion and act as a hood that deflects urine into the vagina, producing dysuria. Severe cases may require treatment with a topical estrogen cream and gradual separation of the labia (Pulsifer, 2005).

Although benign, urethritis is alarming, because the symptoms may be similar to those of cystitis. Differentiating cystitis from a UTI is important to prevent misdiagnosis, unnecessary medication, and overaggressive urologic evaluation. The healthcare team obtains a meticulous history and a urine sample to confirm this diagnosis (Clinical Judgment 19–3).

The symptoms of urethritis can be distressing for the child and frightening to the parents. Nursing care begins with reassuring them of the benign nature of this condition and continues with guided questioning to find the precipitating cause (e.g., bubble bath, pinworms, inadequate hygiene). The goals of treatment for urethritis are to relieve symptom and eradicate the underlying irritant. Home management is summarized in TIP 19–3.

VOIDING DISORDERS

The successful achievement of urinary bladder control is a highly anticipated childhood milestone. Delay or difficulty in achieving control after a socially acceptable age provokes a spectrum of negative responses from the child and parents: anxiety, disgrace, frustration, anger, insecurity, and lowered self-esteem. The particular age depends on the culture of the family. Uncorrected, a childhood voiding disorder can affect the child’s social and emotional development, and may lead to acting-out behaviors, childhood depression, dysfunctional family interactions, and a marked risk for child abuse. Voiding disorders are classified as dysfunctional voiding, functional incontinence, or neurogenic and anatomic incontinence.

Dysfunctional Voiding

Dysfunctional voiding is a dysfunction of the lower urinary tract in which the actions of the bladder muscle and the external sphincter are not coordinated. This dysfunction can cause incontinence, incomplete bladder emptying, inability to voluntarily start or stop voiding, or high pressure in the bladder. When no neurologic or anatomic cause can be identified, the voiding patterns in children

TIP 19–3 A Teaching Intervention Plan for the Child With a UTI or Chemical (“Bubble Bath”) Vulvovaginitis/Urethritis

Nursing diagnoses and outcomes

Urinary Tract Infection

- Impaired urinary elimination related to effects of infection

Outcomes:

- Child returns to normal voiding pattern.
- Child and family will demonstrate skill in managing protocol to treat UTI.
- Parents will verbalize signs and symptoms that indicate the child has a UTI.
- Acute pain with urination related to bladder spasms

Outcomes:

- Family will implement relief measures that ease urination.
- Child will be free from pain.
- Health-seeking behaviors: Prevention of UTI

Outcome:

- Child and family will identify methods that decrease risk of reinfection.

Urethritis/Vulvovaginitis

- Impaired skin integrity related to chemical or mechanical irritation of the genital area

Outcomes:

- Child and family will identify irritants that precipitate or exacerbate the condition.
- Child’s skin will remain free from secondary infection and will regain integrity.
- Child and family will pursue comfort measures that reduce urethral and vulvovaginal inflammation.

Teach the child/family

Cause of UTIs

- UTIs are infections of the bladder or kidneys caused by bacteria (germs) that travel up the urethra and start to grow in the bladder.
- UTIs are more common in girls, possibly because they have a short, straight urethra.
- Constipation is commonly associated with UTI.
- Causes of UTI include
 - Abnormalities of the urinary tract
 - Improper wiping after urination or bowel movement
 - Infrequent urination
 - Chemicals that irritate the urethra, including chlorine, bubble bath, soapy bath water

Cause of Urethritis/Vulvovaginitis

- Exposure to harsh soaps or chemicals causes inflammation of urethral meatus
- Bubble bath, chlorine, soapy bath water
- Use of cleansing towelettes to clean genital and rectal area
- Inadequately rinsed laundry items
- Poor genital hygiene
- Other causes
 - Itching from rectal pinworms (worse at night)
 - Wearing tight jeans or spandex pants
 - Masturbation
 - Presence of constant moisture in genital area if overweight
 - Treatment delay may lead to infection of bladder

Signs and Symptoms of UTI

- Bladder pressure/spasm before and after urinating
- Painful, frequent urination in small amounts
- Difficulty holding urine, or wetting the bed or underwear
- Cloudy, dark, or foul-smelling urine
- Stomachache
- Temperature more than 100 °F (37.8 °C)
- Vomiting or weight loss, and decreased appetite
- Diarrhea or constant diaper rash
- Crankiness or listlessness
- Poor color to skin

Signs and Symptoms of Urethritis/Vulvovaginitis

- Painful urination
- Mild frequency or avoidance of urination
- Genital rash or burning
- May experience wetting or leaking of urine during daytime
- Bed-wetting rare

Treatment of the Child With a UTI

Antibiotics

- Take _____
- Dose _____ use proper measuring spoon.
- Give medicine _____ times a day for _____ days.
- Store per pharmacy instructions.
- The child should finish all medicine, even if feeling well; do not skip doses.
- Instruct daycare, school personnel, or baby-sitter to give medication.

(Continued)

TIP 19–3 A Teaching Intervention Plan for the Child With a UTI or Chemical (“Bubble Bath”) Vulvovaginitis/Urethritis (*Continued*)

Fluids

- Encourage drinking of six to eight glasses of fluid daily, especially water.
- Give 8 oz of cranberry juice per day, which may be mixed with other juices.
- Do not give carbonated sodas, tea, and coffee.

Pain and Fever Control

- Give acetaminophen at dose of _____ every 4 hours as needed.

Diet

- Increase child’s fiber and bran intake.
- Increase child’s daily intake of fresh fruits and vegetables.

Skin Care for Urethritis/Vulvovaginitis

- Soak two times a day in basin or bathtub for 10 to 15 minutes; use plain water. Baking soda or vinegar may be added. Make sure the area is dry before donning clothes.
- *Or*, apply to irritated area compresses of witch hazel three times a day.
- *Or*, apply boric acid compresses. Mix 1 tsp boric acid powder in 2 cups of water; apply with paper towel or cotton balls three times a day.
- *Or*, apply protective ointment (e.g., A&D ointment, zinc oxide), and low-potency hydrocortisone cream (if prescribed) twice daily; symptoms should be gone after 2 to 3 days.
- If pinworms are detected, further instructions will be given.

Preventive Care

- Drink enough fluids each day to keep urine light in color.

- Monitor pattern of bowel movements.
- Teach girls to wipe carefully from front to back after urinating or having a bowel movement.
- Encourage showers.
- If baths are given, limit bath time to 15 minutes. Do not use bubble baths or soapy bath water, and do not let bar of soap float in tub. Shampoo hair at end of bath with the child standing, and rinse genital areas after the bath. Have child urinate after the bath.
- Rinse and dry genital areas after swimming in a pool. Don dry clothes; do not allow child to stay in wet bathing suit.
- Encourage urination every 3 hours during the day.
- Because the child has a high risk of another UTI, urine cultures must be checked every 3 months for 1 year.
- Child should wear cotton underpants, and should not wear tight pants or nonbreathable materials, such as spandex and nylon.
- Wash new clothes before the child wears them.
- Discontinue use of irritating laundry additives (e.g., fragrances, dyes).
- Keep child’s fingernails short and free from dirt buildup.

Contact Healthcare Provider if:

- Temperature of more than 100.4 °F (38.0 °C) develops
- Urine is pink or bloody
- Child looks sick, has a seizure, or has chills
- Child complains of back pain
- There is no improvement in child’s condition after 2 to 3 days of antibiotic therapy

with dysfunctional voiding are believed to originate from behavioral issues. These behavioral issues may evolve from adverse situations that occur around toilet training and inhibit the maturation of normal urinary control.

Dysfunctional voiding may be associated with UTI, urinary retention, or VUR and can include abnormalities in voiding patterns such as staccato voiding (interruptions in the urine flow that prolong voiding time and leave postvoid residual urine, increasing the risk of UTI), fractionated voiding (incomplete and infrequent small-volume voids), postponement of voiding, and urge syndrome. In urge syndrome, the child has overactive detrusor contractions and a small bladder capacity, resulting in frequent voiding. The child has a strong desire to void and maneuvers into squatting positions that externally compress the urethra to retain urine and avoid leak-

age. The associated incomplete bladder emptying leads to urinary stasis and infection, causing inflammatory changes in the bladder wall that stimulate overactivity of the detrusor. This voiding pattern can also be seen in children with cerebral palsy, spinal cord injury, sacral agenesis, and myelodysplasia. Conversely, a child with “lazy bladder” has a large-capacity bladder and a pattern of infrequent voiding. This child postpones responding to the urge to void with a weak or absent detrusor contraction and voids only once or twice a day, usually by abdominal straining; typically, the child feels no urge to void upon awakening in the morning. The volume voided usually exceeds the normal age-correlated capacity.

Vaginal voiding, another form of bladder dysfunction, is postvoid dribbling, which often causes external vaginal irritation or vaginal odor. It occurs in healthy girls after

CLINICAL JUDGMENT 19–3

The Child With Painful Urination

Mrs. Sternberg received a call from her daughter's teacher at preschool, reporting that 4-year-old Sally was complaining of vomiting, abdominal pain, and pain with urination, and had a temperature of 100 °F (37.8 °C). Mrs. Sternberg immediately picked up Sally from daycare and brought her to the community clinic where you work. Mrs. Sternberg thinks Sally must have a stomachache from all of the candy she ate at a party the day before.

Questions

1. What assessment data would be important to collect?
2. Which of the data in this vignette would suggest Sally has a stomachache?
3. Select a nursing diagnosis that reflects the family's need for information and home care regarding UTIs.
4. Laboratory analysis reveals bacteria present in the urine, and the diagnosis of UTI is confirmed. Based on your assessment and nursing diagnosis, what is your next plan of action?
5. How would you determine whether Mrs. Sternberg understood the plan of care?

Answers

1. Did Mrs. Sternberg notice any symptoms before today? Has Sally experienced any enuresis?

Is anyone else sick at home? Assess weight and blood pressure. A clean-catch urine specimen or a urine specimen obtained by catheterization is needed.

2. Abdominal pain and vomiting. However, in light of the other symptoms, such as fever and pain on urination, the healthcare team should suspect that Sally has a UTI.
3. Deficient knowledge: Management and prevention of UTIs
4. Teach Mrs. Sternberg the following points:
 - Importance of administering oral antibiotics for the full course of therapy
 - Need for follow-up urine culture 48 to 72 hours after initiating treatment
 - Need to monitor urine cultures every 3 months for a 1-year period
 - Need for radiographic evaluation to rule out other genitourinary conditions
 - Need to increase Sally's fluid intake, especially of water
 - Need to maintain proper hygiene and avoid irritants such as bubble baths
5. Mrs. Sternberg brings Sally in for repeat urine cultures, as requested. She reports that Sally is drinking more fluids and that she is maintaining good perineal hygiene.

toilet training. These girls complain of leaking when they stand up after voiding, or damp underwear after voiding, from urine being deflected off the labia and into the vagina, where it is temporarily trapped during micturition. This deflection occurs when the child fails to void with the legs wide enough apart to allow urine to escape freely from the introitus. It can occur in any girl, but is most common among those who are obese.

Of children with voiding dysfunction, 40% experience dysfunctional elimination syndrome, in which concomitant constipation or fecal soiling occurs (Feldman & Bauer, 2006). Dysfunctional elimination syndrome includes gastrointestinal disorders that contribute to dysfunction of the lower urinary tract, including unstable or overactive detrusor bladder muscle, infrequent voiding syndrome, or functional bowel disturbance.

Functional Incontinence (Enuresis)

Functional incontinence is a lack of urinary control beyond the developmental age when bladder control

should be achieved, usually thought to be 5 years. It is secondary to a multitude of exogenous causes. Usually called *enuresis*, functional incontinence implies mild or episodic urine leakage. Enuresis can occur during the day (diurnal) or at night (nocturnal). Children with *primary enuresis* have never achieved complete continence. In *secondary enuresis*, the child achieves continence for at least 6 months but then resumes incontinence.

The incidence of functional incontinence is age dependent. An estimated 2% to 7% of school-aged children continue to experience functional incontinence. Approximately 15% of children older than age 5 years have nocturnal enuresis, which is 50% more common in boys (Feldman & Bauer, 2006). Because most children experience spontaneous resolution of functional enuresis, it only becomes a problem when the child or the parents become concerned about the interference that enuresis exerts on their lifestyle.

Heredity is a factor in the development of enuresis, although the mechanism is unclear. The risk for a child to develop enuresis is only 15%, but risk escalates to 44%

if one parent experienced enuresis and 77% if both parents were affected (Ward-Smith & Barry, 2006).

Enuresis is thought to be precipitated or exacerbated by various interconnected factors, based on the perspective that enuresis is a symptomatic response, not a disease entity. The prevailing thinking interprets enuresis as a neuromaturational/developmental lag with superimposed familial, social, environmental, psychological, or organic mediating components.

To appreciate the concept of *neuromaturational lag* requires understanding bladder physiology. In infants, voiding occurs as a spontaneous response to the activation of stretch receptors, following the sensation of bladder filling. In spinal arc fashion, the stretch stimulus is carried to the spinal cord and rerouted along motor neurons back to the bladder and sphincter, bypassing higher neurologic centers. Micturition results from the simultaneous involuntary action of a bladder detrusor contraction and sphincter relaxation. Between age 2 and 4 years, myelination of the lumbosacral neural circuits is gradually accomplished, completing the neuromaturation of the detrusor and sphincter. The theory of neuromaturational lag proposes that enuretic children possess bladders with small capacity and also experience delayed myelination of the lower spinal nerves. The result is that these children respond with premature detrusor contractions during the filling state and cannot effectively contract the sphincter. Rather, they rely on forced constriction of the bladder neck or sphincter to remain continent during the day, but they are unable to exert sphincter pressure at nighttime to prevent bed-wetting. Because most children with functional enuresis eventually acquire complete bladder control, even without treatment, the cause is believed to be a neuromaturational delay.

Other physiologic factors may contribute to enuresis. Bladder stretch receptors may be abnormal or dulled during early childhood. As the child acquires the ability to interpret bladder fullness, he or she acquires urinary control by contracting pelvic floor muscles or by waking to void. Episodes of involuntary sphincter relaxation may allow urinary seepage. Enuretic children do not rouse to the sensation of a full bladder. They are deep sleepers (Nevés, 2003), but the depth of sleep does not relate to the severity of the enuresis (Ozden et al., 2007). Sleep patterns are similar for both enuretic and nonenuretic children, and enuretic episodes occur during all stages of sleep (Bader et al., 2002). Primary nocturnal enuresis has been shown to be associated with habitual snoring (Alexopoulos et al., 2006); treating the airway obstruction improves enuresis (Firoozi et al., 2006).

Organic factors are also known to predispose a child to enuresis. Antidiuretic hormone follows a circadian rhythm that increases at night, increasing renal tubular reabsorption of water, resulting in decreased urine output. Conditions that produce polyuria, such as diabetes mellitus, diabetes insipidus, or chronic renal disease, may be underlying causes of enuresis.

Food allergens have been periodically identified as precipitating factors in enuresis, but few studies back up this

phenomenon. Some children have experienced improvement or eradication of enuresis or urgency, with reduced sensation of bladder irritability, when chemical additives or artificial sweeteners were eliminated from the diet. These additives may exert a diuretic effect that increases urine production.

UTI and constipation, which can increase bladder irritability and reduce functional bladder capacity, can be another factor in enuresis. Eradicating bladder infection may stop bed-wetting.

Psychosocial and developmental influences can also play a part in enuresis. For example, enuresis is more common among children from lower socioeconomic groups and deprived backgrounds (Van Hoecke et al., 2003), but this relation may stem from the disorganization that often is present in these children's daily life. Psychological factors that affect the child may affect the persistence of primary enuresis or incite secondary enuresis. Children with enuresis have decreased self-esteem and are more likely to be the target of bullying behavior and to have attention/activity problems, oppositional behavior, and conduct problems (Joinson et al., 2007b). They tend to be less conscientious and more neurotic (Van Hoecke et al., 2006). As a result of enuresis, these children may not participate in age-appropriate activities, such as sleepovers or overnight camps. After successful treatment, these children report greater self-esteem and happiness, improved appearance, and reduced acting-out behaviors, suggesting that emotional disorders are expressions of distress related to the inability to control the voiding function (Ward-Smith & Barry, 2006). Enuresis has been found to be associated with relatively low IQ scores (Joinson et al., 2007a).

Neurogenic and Anatomic Incontinence

Neurologic control of the lower urinary tract (bladder, urinary sphincter, pelvic floor muscles, and urethra) involves the coordinated efforts of cerebral structures and spinal pathways. The urologic end result of lesions in these segments of the nervous system is a neurogenic bladder. Neurologic defects with detrimental effects on urologic function are wide ranging and include congenital neuromuscular disorders such as myelomeningocele, spina bifida, sacral agenesis, spinal lipoma, sacral teratoma, or tethered spinal cord, and acquired conditions such as spinal trauma, transverse myelitis, osteomyelitis, muscular dystrophy, degenerative disorders, or residual sequelae from rectal or genital surgical procedures. Generally, children with this type of incontinence experience moderate to complete loss of bladder function.

Some anatomic anomalies of the lower urinary tract may precipitate severe incontinence by distorting the sphincter mechanism. These defects include bladder exstrophy, epispadias, posterior urethral valves, ureterocele, and marked or multiple urethral strictures. Ureteral **ectopia**, in which the ureter terminates at a site within, or distal to, the sphincter, likewise causes constant dribbling.

There is no uniformity to the types of neurogenic bladder problems that children can manifest, even among those with similar neuromuscular deficits. Furthermore, the neurogenic effects may change in response to changes during growth and development. Therefore, children with a neurogenic bladder must be monitored closely to accurately assess their bladder function and response to treatment. Improper management of the child with a neurogenic bladder can have ominous consequences in the upper urinary tract. Renal damage or failure can develop from chronic ascending infection or reflux following bladder atony, which causes urinary retention.

Assessment

The evaluation of a child with a voiding disorder includes a complete health history, physical examination, and diagnostic testing.

A detailed history of voiding habits is necessary. Because parents are often unaware of “normal” voiding and age-appropriate bladder control, ask precise questions and obtain explicit details.

Assess urgency, frequency, age at onset of enuresis (primary vs. secondary), type of enuresis (nocturnal, diurnal, or combined), history of UTI, associated daytime control problems, and presence of other health problems that induce polyuria. Creating a multigenerational family tree may highlight a genetic predisposition for enuresis. The amount of urine voided during a typical enuretic episode can be estimated by evaluating the size of a wet spot or the extent to which bed linens are soaked. Discuss previous treatment measures, the child’s diet, and any concomitant bowel problems, particularly chronic constipation. Encopresis may indicate that the voiding disorder has a neurologic component.

Explore psychosocial factors such as recent lifestyle changes, the effect of the voiding disorder on the child and family, and school performance. Assess family dynamics by observing parent–child interactions for non-verbal clues. Ascertain the parents’ commitment to resolving the child’s problem, situations that may influence timing or choice of treatment, and factors that may impede adherence to a treatment regimen. For example, if the child has several caregivers, it is imperative that they all cooperate in the management plan and do not send the child contradictory messages.

A thorough voiding history is the cornerstone in differentiating voiding disorders; it also directs the treatment regimen. The following tools are useful to ensure that you gather all salient data:

- **Voiding profile:** This questionnaire is used to glean important details about the child’s voiding problem. Designed to be completed before the child’s first visit, it also helps the parent gain a clear perspective of the child’s problem (Chart 19–1).
- **Voiding diary:** This 3-day record of the child’s drinking habits, voiding/stooling pattern, daytime activities, and emotional state should include weekend days as well as school days.

CHART 19–2 CLINICAL INDICATORS OF PERITONITIS

Cloudy dialysate outflow (effluent)
 Abdominal pain
 Rebound abdominal tenderness
 Acute discomfort during fill phase of dialysis
 Fever
 General malaise
 Nausea
 Vomiting
 Increased white blood cell count of dialysate outflow
 Positive bacterial culture of dialysate outflow

- **Child interview:** Using developmentally appropriate wording, inquire about urinary habits, daytime symptoms, emotional response, and motivation level. Sample questions might include the following: “Can you tell when you need to void during the day—usually, sometimes, or never? At night?” “When you feel the urge to void, what do you do? Ignore the sensation? Try to get to the bathroom? Assume a squatting position, cross your legs, or press your thighs together to stop the urge or hold the urine?” “Is your underwear damp very often?” “How worried are you about this problem?” “What bothers you the most?” “What would change if you become dry?” A lack of motivation on the child’s part predisposes all initiatives to failure. If assessment shows poor motivation, counsel the family to delay treatment for 6 months, then reassesses the child’s readiness.

Perform a careful physical examination to detect signs of anatomic or neuromuscular abnormalities (see Focused Physical Assessment 19–1). Specifically note any genital abnormalities and palpate the abdomen for a distended bladder or for stool in the colon. Inspect the lumbosacral spine for dimpling or sacral malformation, a lipoma, a hairy patch, sinus tract, deviated or absent cephalad segment of the gluteal cleft, or a flattened buttock. If any of these signs are present, perform a neurologic assessment of lower extremity function, rectal tone, perineal and anal sensation, and intactness of the bulbocavernosus reflex. Evaluate the child’s gait and perform a developmental assessment, when applicable.

If possible, observe the child while he or she is voiding. Note a weak or intermittent stream, dribbling, or straining to initiate urination. These signs suggest organic involvement. Vaginal voiding can be detected if the girl leans backward or does not separate her legs during a void.

Diagnostic Tests

Collect a urine sample to check levels of glucose and presence of blood or protein. Measure urine concentration of the first morning void by specific gravity. Obtain a urine culture to test for bacterial infection.

At this point, all data are scrutinized and compiled to determine a diagnosis and to consider the need for further studies. If a neurologic deficit is suspected, a VCUG and renal ultrasound are performed, and serum creatinine and BUN levels are obtained to define the lower urinary tract and screen for renal dysfunction. Sacral deformities are highlighted by magnetic resonance imaging of the lower spine. Urodynamic testing of the bladder is crucial to establish the specific type of bladder dysfunction; this test is usually reserved for children in whom conservative therapy has failed (Feldman & Bauer, 2006).

Most children with voiding disorders are diagnosed with functional incontinence. An overwhelming proportion of this group consists of children with uncomplicated nocturnal enuresis—meaning, they have no history of UTI and minimal daytime symptoms. No further diagnostic studies are recommended, because the rate of organic anomaly mirrors that of the general pediatric population.

However, children with a history of UTI, significant diurnal symptoms, or encopresis are at risk for a superimposed uropathologic condition and constitute a group with complicated enuresis. They should be evaluated with VCUG, renal sonogram, and spinal radiographs to screen for effects of lower tract dysfunction. Urodynamic or renal function studies are pursued if warranted.

Nursing Diagnoses and Outcomes

Nursing Plan of Care 19–1 presents nursing diagnoses generally applicable to the child with a genitourinary condition. The following diagnoses address some more specific care needs of the child with a voiding disorder:

Impaired parenting related to child's inability to achieve continence

Outcomes: Parents will verbalize their acceptance of the child.

Parents will identify the stressors related to the voiding disorder.

Parents will use positive coping mechanisms in response to the child and the voiding disorder.

Parents will refrain from blaming the child for the voiding disorder, while encouraging the child to take responsibility in managing the consequences.

Health-seeking behaviors: Managing urinary incontinence

Outcomes: Child and parents will participate in a management protocol.

Child, parents, or both will verbalize an understanding of the therapeutic goals of managing the voiding disorder.

Child or parents will demonstrate accurate and safe use of medications.

Child, parents, or both will express realistic expectations and an appropriate time frame for completing the management protocol.

Interdisciplinary Interventions

Management of the child with a voiding disorder requires an interdisciplinary effort using medical, nursing, nutritional, and psychosocial healthcare professionals, whose skills are combined to ameliorate the child's problem, guided by the child's acceptance of and response to treatment.

Management of dysfunctional voiding and enuresis is symptomatic and may include pharmacologic agents such as anticholinergics, behavior modification techniques to modify voiding patterns, bladder retraining, bowel management (see the discussion of constipation in Chapter 18), and diet management. Management of neurogenic and anatomic voiding disorders may include surgery, pharmacologic agents, and clean intermittent catheterization.

Surgical Management

Congenital anomalies detected during the diagnostic evaluation are assessed by a pediatric urologist to determine the appropriateness of corrective or reconstructive surgery. Various procedures include reimplantation of the ureters for VUR or ureteral ectopia, bladder neck reconstruction for defects of the sphincteric mechanism, and endoscopic fulguration (destruction with electric current) of urethral webs or strictures. Implantation of an artificial sphincter has been used to manage neurogenic bladder. Bladder atrophy or a noncompliant, rigid detrusor may require bladder augmentation to increase urine capacity. Urinary diversion may be a temporary or a permanent choice in cases of massive obstructive uropathy or when sphincteric reconstruction fails, or to provide bladder access for intermittent catheterization. For the child with spinal agenesis or tethered spinal cord, neurosurgical interventions such as laminectomy is used to release neural compression. Bladder function may return fully or only partially (Guerra et al., 2006); ongoing urodynamic evaluation is necessary to monitor progress. Operation within a year of symptom onset results in the best symptom improvement (Hajnovic & Trnka, 2007).

Surgery, even when successful in correcting urologic anomalies, does not always eradicate incontinence completely. Supplemental techniques are implemented based on the residual symptoms.

Pharmacologic Management

Medications are used to treat UTI and to modify bladder activity that is detrimental to continence. Urinary antibacterials are administered when a UTI is documented; long-term suppressive therapy may be necessary for the child at risk for recurring infections. Medications that moderate neurotransmission to the lower urinary tract are used to treat urgency or to

increase bladder capacity. The anticholinergic agent oxybutynin chloride (Ditropan) exerts an antispasmodic effect on the detrusor, counteracting uninhibited contractions. This drug is effective for an unstable or noncompliant bladder. Imipramine hydrochloride (Tofranil), an anticholinergic and antidepressant drug, has mild sympathetic action on the detrusor and a strong effect on sphincteric constriction. It may also lower the sleep arousal threshold, making the child more responsive to the nocturnal filling sensation. Desmopressin acetate (DDAVP), a derivative of antidiuretic hormone, reduces the volume of urine produced during sleep. DDAVP is not considered a cure for enuresis; rather, it serves as a treatment for the symptom. It is available in a nasal spray or in tablet form. Alpha-adrenergic antagonists such as doxazosin (Cardura) inhibit detrusor contractility, improve bladder compliance, and increase bladder capacity. They may be used in children with recalcitrant voiding dysfunction and hyperreflexic noncompliant neurogenic bladders (Husmann, 2006).

Numerous studies report initial high success rates for these pharmacologic agents, but relapse rates are high when the drugs are discontinued (Glazener, Evans, & Peto, 2003, 2005). Many parents are reluctant to administer medications to their children on a long-term basis, fearing side effects or personality changes. Safety issues are a concern, particularly for imipramine, which has caused death in overdosed children. These medications appear to be most effective as adjuncts to other enuretic therapies, to enhance management of neurogenic or unstable bladder, or to offer short-term alleviation of enuresis before such experiences as camping or vacation.

Behavior Modification Techniques

Behavioral methods to treat enuresis and dysfunctional voiding include rewards for accomplishing predetermined goals or behaviors, such as dry nights, adherence to medication or diet changes, or appropriate responses to the moisture alarm; parental modeling of healthy urinary habits; timed daytime voiding or waking the child to void; and encouraging the child to assume responsibility for behavior (e.g., by changing bed linens). For enuresis, simple behavioral methods may be used initially, because they are less demanding than moisture alarms and have less risk of adverse effects than medications. In one study, almost half the patients with good adherence to timed voiding for daytime incontinence improved substantially within 4 months (Allen et al., 2007).

Moisture alarms work by applying moisture-sensing devices to the child's bed or underwear. An alarm awakens the child as wetting occurs. The child is gradually conditioned to associate the sensation of a full bladder with arousal and learns to inhibit micturition. This system is highly effective, with 66% (Glazener et al., 2005) to 79% (Cutting, Pallant, & Cutting, 2007) of users achieving dryness. In one study, initial dryness was achieved in a median time of 10 weeks, and 64% of subjects remained dry at 24 months (Cutting et al., 2007).

Alarms appear more effective than medications by the end of treatment and in the long term (Glazener et al., 2005). This effectiveness may be attributable to the behavioral change that takes place with alarms. Simultaneous use of alarms and behavioral methods may provide the best outcome (Glazener, Evans, & Peto, 2004).

Bladder Retraining

Biofeedback therapy is effective in treating children with dysfunctional voiding and enuresis (Kibar et al., 2007). It is used to retrain the pelvic muscles, promoting relaxation of the pelvic floor and improving bladder function (Liberati, 2005).

Kegel exercises are pelvic floor contractions that simulate the stopping and starting of urine flow. They can be performed as the child experiences urgency during bladder filling. Kegel exercises can be taught to children as young as 5 years but require a great deal of practice and involved support. These maneuvers effectively suppress involuntary detrusor contractions and improve nocturnal enuresis (Schneider, King, & Surwit, 1994).

Children with hyperextended bladders develop a pattern of delayed daytime voiding, up to 4 hours or longer, followed by urgency, or wetting, resulting from the desensitization of the bladder during the fill stage. They require an opposite method of therapy. Encourage these children to void every 2 hours, even before they sense bladder fullness, as a means to restore detrusor sensitivity. Alarm watches are useful reminders to void on schedule; they come in both vibrating and audible forms.

Clean intermittent catheterization permits regular, complete bladder emptying of an atonic bladder (see Treatment Modalities). In addition to preventing infection from urinary stasis, this procedure stops overflow incontinence. It also counteracts hydronephrosis, which results from a constantly filled bladder.

Dietary Manipulation

Along with the nutritional recommendations for improved bowel functioning, such as fiber, fruit, and extra fluids, eliminating foods with dyes, preservatives, and, especially, artificial sweeteners may be effective. Discourage caffeinated foods, such as cola, tea, and coffee, which exert a diuretic effect. Although many parents restrict fluids before bedtime, this precaution does not seem to reduce enuresis. Butler and colleagues (2005) found that fluid restrictions were similar in children who did and did not wet the bed.

Psychotherapy

Although most children with voiding disorders do not manifest psychopathologic symptoms, concurrent distressing life circumstances, discipline problems, depression, and family conflicts warrant assistance from mental health professionals. Successfully managing these issues is important to prevent complicating the already tenuous emotional climate for the child. Unresolved issues drain

the family's ability to formulate and adhere to a long-term, often complex, management program.

Nursing Management

Assist the child and family to manage and to cope with this condition through education about treatment options. The nurse's role in the interventions for a child with a voiding disorder is varied (NIC 19–1). All aspects of therapy require comprehension and acceptance by the child and family; therefore, child and parent education is instrumental to the success of a chosen mode of therapy.

When surgical intervention is indicated, provide preoperative, postoperative, and follow-up teaching. Teach the child and family about medications, including dosage, expected results, side effects, and home safety measures. Skin care and hygiene measures, such as the use of pro-

tective emollients and enzyme washing solutions, prevent chafing or skin breakdown related to chronic exposure to urine. Changes in diet may require creative problem solving to ensure that the child accepts them.

Developmental, temperamental, and motivational assessments provide the child and family with predictions regarding the appropriateness of a subscribed therapeutic intervention. Be alert for expressions of intolerance directed by the parents toward the child and the voiding problem; this evaluation assesses the risk for child abuse and the potential for the family's successful participation in a long-term management regimen. Offer parenting and coping techniques gleaned from feedback of other parents or from personal experience. By taking the role of a consistent resource person, the nurse can monitor progress and offer encouragement. Remind the child and parents that, in most cases, enuresis is self-limiting. The benefits derived from reducing enuresis and dysfunctional voiding can be generalized to include enhanced self-esteem, improved outlook on life, and a positive sense of self-control.

NIC 19–1 Nursing Interventions Classification: Urinary Incontinence Care: Enuresis

Definition: Promotion of urinary continence in children

Activities:

- Assist with diagnostic evaluation (e.g., physical examination, cystogram, cystoscopy, and lab tests to rule out physical causation)
- Interview parents to obtain data about toilet-training history, voiding pattern, UTIs, and food sensitivities
- Determine frequency, duration, and circumstances of enuresis
- Discuss effective and ineffective methods of prior treatment
- Monitor family's and child's level of frustration and stress
- Perform physical examination
- Discuss techniques to use in reducing enuresis (e.g., night-light, restricted fluid intake, scheduling nocturnal bathroom trips, and use of alarm system)
- Encourage child to verbalize feelings
- Emphasize child's strengths
- Encourage parents to demonstrate love and acceptance at home to counteract peer ridicule
- Discuss psychosocial dynamics of enuresis with parents (e.g., familial patterns, family disruption, self-esteem issues, and self-limiting characteristic)
- Administer medications as appropriate for short-term control

OBSTRUCTIVE UROPATHY

Obstructive uropathy is a term used to describe damage caused by a congenital or acquired condition that impedes urine excretion. Common obstructive lesions within the tubular structures (urethra or ureters) include redundant tissue leaflets (“valves”) or strictures at sites of segmental attachment. Insufficiently innervated ureteral segments halt the wavelike flow of muscular contractions from the renal pelvis to the bladder. Ureteral placement outside of the trigone affects compression of the ureteral orifice during voiding. Anomalous ureteral placement creates an ectopic orifice in the proximal urethra or in the vagina. Despite continuous dribbling, the ectopic ureteral opening is often too stenotic for complete urine drainage.

During early fetal development, the kidney originates in the pelvis. It gradually ascends to a retroperitoneal site, acquiring new vasculature while the outgrown blood vessels degenerate. An aberrant vessel remnant may constrict the ureter during the migratory process, causing obstruction. If the kidney fails to rise from the pelvis (the so-called pelvic kidney), ureteral growth may become redundant, and the ureter may kink. Likewise, kinking or twisting may occur as a result of either a sharply angled ureteropelvic junction (UPJ) or following inadequate rotation of the renal unit shortly before birth.

Pathophysiology

Forces that maintain urinary excretion originate in the renal pelvis, because accumulated urine is propelled through the ureter. Low-pressure peristaltic contractions, initiated within the pelvic musculature, transmit urine in a wavelike fashion past the UPJ to the ureter. The distal ureteral segment burrows into the bladder wall and is

tunneled within the inner bladder mucosa. The ureteral orifice emerges within the bladder interior at the trigone. Initially, a bolus of urine spurts into the empty bladder sac unimpeded; as bladder distention stretches and thins the submucosal tunnel, increasing bladder pressure eventually collapses the ureteral lumen to prevent urine regurgitation. During micturition, the sphincter relaxation is coordinated with high-pressure detrusor (bladder muscle) contractions to expel urine.

Urinary tract obstruction interferes with the normal urine drainage process, resulting in pathophysiologic changes ranging from mild to severe (Fig. 19-6). Partial urethral blockage is initially compensated for by hypertrophy of the bladder wall, necessary to generate the elevated pressure for bladder emptying. Failure of this protective effect produces retrograde ureteral dilatation and progressive loss of tissue elasticity. The most serious insult from obstructive uropathy is the visceral destruc-

tion induced by hydronephrosis. Escalated pressures within the renal tubules and glomerular structures compromise the filtration process.

Vesicoureteral Reflux (VUR)

VUR is abnormal backflow of urine from the bladder into the ureter, and sometimes the kidneys, during voiding through an incompetent ureterovesical junction. VUR is detected in as many as 38% of children with prenatal hydronephrosis (Becker & Baum, 2006). Although the incidence is more than 1% in children without urologic symptoms, an estimated 20% to 50% of children with a history of symptomatic UTI have VUR (Baskin, 2005b). Siblings of patients with known reflux may have up to a 30% chance of reflux. For this reason, routine screening of siblings of children with reflux is recommended.

VUR seems to be related to the valve mechanism of the ureterovesical junction. Primary VUR, the most common variant of VUR, results from a congenital deficiency in the formation of the ureterovesical junction and is related to a short mucosal tunnel length that compromises the flap valve mechanism. Secondary VUR occurs from decompensation of a normally formed ureterovesical junction because of neurogenic bladder, anatomic abnormality, or outlet obstruction, which results in increased bladder pressure. Managing the underlying causes often resolves reflux.

The International Reflux Grading System classifies VUR into five grades (International Reflux Study Committee, 1981), depending on the degree of retrograde filling and dilation of the renal collecting system (Fig. 19-7). The degree of grading is important to the child's management and prognosis. The more severe the reflux, the

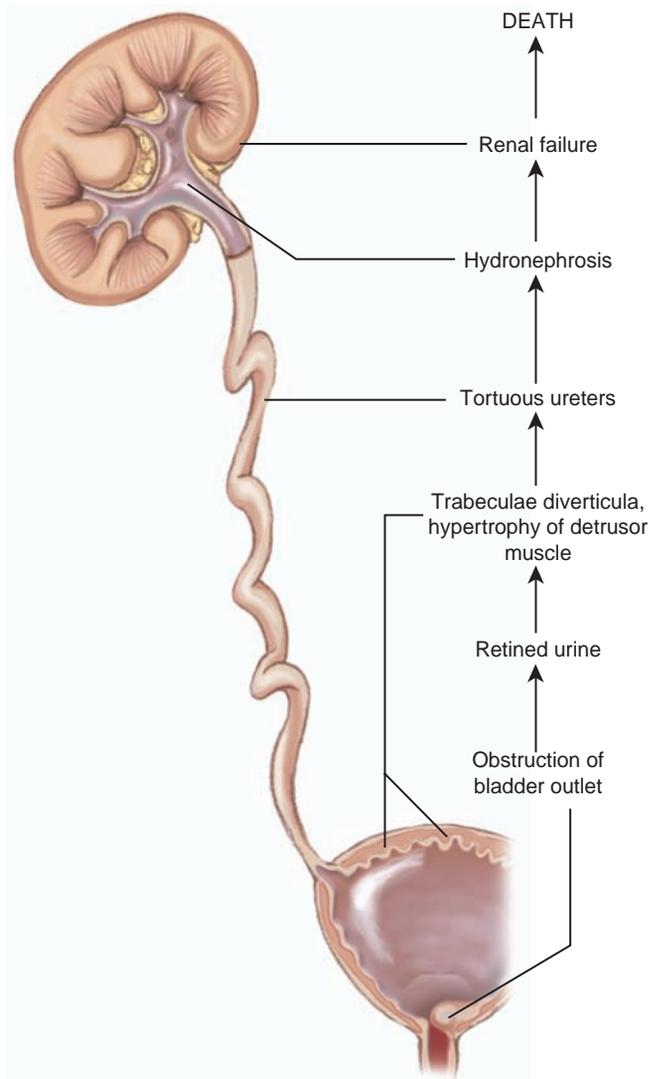

FIGURE 19-6. Urinary tract obstruction can occur anywhere in the upper or lower tract; some of the most common sites and their effects are indicated.

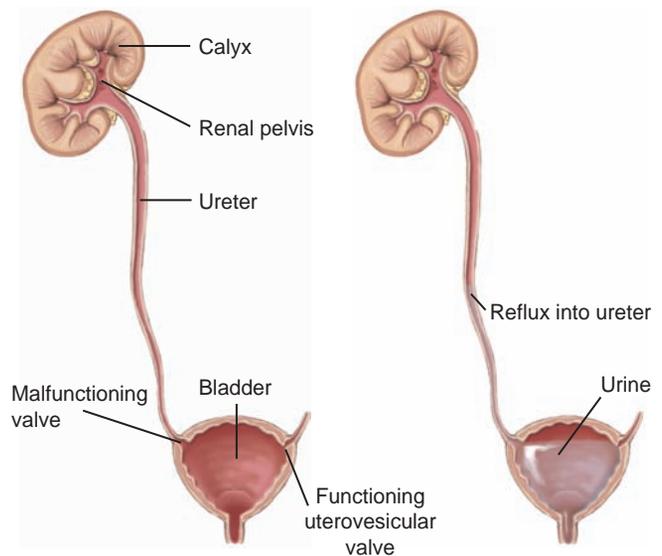

FIGURE 19-7. In vesicoureteral reflux, a defect in the vesicoureteral junction allows urine to flow back into the ureter during voiding. After voiding, the urine returns to the bladder from the ureter resulting in incomplete bladder emptying.

lower the rate of spontaneous resolution and the higher the incidence of renal scarring.

Ureteropelvic Junction Obstruction (UPJ)

UPJ obstruction is the most common cause of antenatal hydronephrosis, with an incidence of 1 in 2,000. It is more common in males than in females (3:1), more often affecting the left kidney than the right (Becker & Baum, 2006). Routine ultrasound screening during the second trimester has resulted in more infants being diagnosed with antenatal hydronephrosis.

Successful passage of urine from the renal pelvis to the ureter requires a patent UPJ. Thus, in UPJ obstruction, the intrapelvic pressure created by hydronephrosis exerts a direct negative effect on glomerular filtration. As pressures within the nephron exceed glomerular capillary pressure, reverse fluid and solute transport occurs. Concentration of urine is hampered because of restricted renal blood flow and longstanding distal tubular damage. The acceleration of fluid buildup provides a nourishing broth for bacterial colonization, and altered hydrogen excretion creates metabolic acidosis.

In its most severe form, hydronephrosis leads to obliteration of the functional renal unit. However, factors such as degree and duration of obstruction, plus the presence or absence of calculi or infection, are mediating variables in the expression of renal involvement.

Assessment

The evaluation of a child with UPJ obstruction includes a complete health history, physical examination, and diagnostic testing.

The most common sign leading to a diagnosis of obstructive uropathy is UTI; the second most common sign is the presence of a voiding disorder. Ask about the presence of flank pain. Children with obstruction, particularly UPJ defects, experience flank pain either intermittently or after high fluid intake with infrequent voiding. Also, hematuria may occur after minimal trauma. Measure height and weight, because delayed growth and weight gain may occur in the child with VUR, even when reflux is low grade and without infection. Boys with mild to moderate obstruction from posterior urethral valves (see [thePoint](#) for Supplemental Information: Obstructive Uropathy: Posterior Urethral Valves) typically void infrequently, emptying their bladders with a weak, intermittent stream or a thin, forceful one. Having experienced this abnormal voiding pattern since birth, these boys (and their parents) wrongly assume this micturition to be normal. To help detect this anomaly, obtain a detailed voiding history and observe the child's urinary stream.

Diagnostic Tests

Antenatal diagnosis of obstructive uropathy has become commonplace since the addition of ultrasonography in

routine prenatal care. Hydronephrosis, ureteral enlargement, and a “keyhole” hypertrophic bladder are signs of a major urologic anomaly. Reduced amniotic volume is pathognomonic for obstructive uropathy as well as for other genitourinary and gastrointestinal disorders. Because oligohydramnios is not apparent until 18 weeks of gestational age, a screening sonogram should be delayed until after that time. Prenatal findings suggestive of an obstructive lesion may be transient or idiopathic; therefore, radiographic evaluation should be repeated during the neonatal period to confirm the diagnosis. The value of prenatal detection rests not with its ability to predict the degree of renal function, but rather as a signal to facilitate early therapeutic intervention on a nonemergent basis.

Because VUR can delay growth and weight gain, urologic studies should be a part of the diagnostic evaluation of any child with failure to thrive. Urologic radiographic techniques are used to thoroughly investigate the nature of obstructive uropathy. The basic workup requires a VCUG and a renal bladder ultrasound. The ultrasound may not be sensitive to detect low grades of reflux; however, it is useful in detecting hydronephrosis and can be used as a baseline study to monitor kidney growth for follow-up. Nuclear cystogram may be used in follow-up evaluation in patients with established reflux. A DMSA renal scan can help to detect renal cortical scars. Some infants incur benign hydronephrosis, which is stable and causes no impairment to renal function. Differentiating physiologic hydronephrosis from pathologic UPJ obstruction can be difficult. A diuretic renogram, which uses furosemide augmentation to induce high-volume urine, helps identify which infants could benefit from surgical intervention.

Kidney function and other tests may be performed, including urinalysis, specific gravity, urine culture, serum BUN, creatinine, creatinine clearance, complete blood cell count with differential, urinary pH, and electrolytes. Unless renal function is substantially impaired, these values will be in a normal range.

Interdisciplinary Interventions

Optimal care for children with obstructive uropathy combines a mixture of medical and surgical approaches, tailored to the degree of obstruction, the child's age, and the renal status. For example, the newborn with severe hydronephrosis is critically ill from metabolic acidosis, fluid overload, uremia, and possibly respiratory compromise, and must be treated promptly to stabilize the child's condition before urologic reconstruction is begun.

Medical and Surgical Management

The primary goal of medical management is to prevent infection and renal scarring by adhering to a long-term regimen of prophylactic antibiotics. Medications of choice include nitrofurantoin (Furadantin, Macrochantin), trimethoprim-sulfamethoxazole (Septra), nalidixic acid

(NegGram), or methenamine mandelate (Mandelamine) augmented by ascorbic acid. Breakthrough infections while on suppression therapy, nonadherence to prophylactic medication, or persistence of reflux into puberty may direct a change from medical management toward surgical correction of the anomaly.

Acute relief of the urinary obstruction should be performed by placing a urinary catheter (Becker & Baum, 2006). When the infant is stable, a posterior urethral valve can be obliterated by endoscopic ablation. Temporary insertion of a catheter is used in rare cases to reduce postoperative bleeding. In most cases, the child is discharged after postsurgical recovery and an initial voiding.

When the child's condition is complicated by VUR, reimplantation of the submucosal ureteral segment can be undertaken at the same time, or the child can be reevaluated several months later to detect unresolved reflux and undergo the procedure at that time. After surgical correction, any residual negative effects on voiding or urinary continence need further attention. Medical or surgical interventions can be implemented based on the remaining symptoms (see Voiding Disorders).

The infant with high-grade urethral valve disease and severely affected upper tracts demands immediate medical attention to correct metabolic acidosis, and antibiotics to eradicate urosepsis. Surgical intervention for urinary tract decompression can be provided by bladder catheterization or temporary urinary diversion (see Treatment Modalities). Procedures such as loop-cutaneous pyelostomy, ureterostomy, or vesicostomy carry minimal surgical risk and are safe for the unstable infant. Definitive procedures such as reimplantation, bladder diverticulectomy, and valve ablation can be delayed to allow for renal rejuvenation, reduction of ureteral tortuosity, and improved bladder compliance.

Management of the child with VUR depends on the degree of reflux. For grades I through III reflux among infants and young children, many pediatric urologists adhere to a protocol of prophylactic antibiotics, resolution of dysfunctional voiding, and radiographic surveillance, expecting that the condition will resolve within 5 years (Upadhyay et al., 2003). High-grade reflux in a young child and any reflux in a child older than age 5 will probably not be spontaneously outgrown. Episodes of breakthrough UTI compound the risk of renal parenchymal scarring and usually require surgical management. Severe reflux with massive hydronephrosis and aperistaltic megaureters may be initially treated with temporary urinary diversions (see Treatment Modalities). When medical management fails, surgery may be performed to reimplant the ureter. Surgical correction of VUR involves separating the ureter from the bladder and creating a tunnel between the layers of bladder mucosa. The ureter is threaded within the tunnel, so that its opening into the bladder is within the trigone.

Endoscopic treatment of VUR by injecting a polymer is a more recent alternative to open reimplantation and long-term antibiotic therapy. During the endoscopic pro-

cedure, the child is under general anesthesia. A cystoscope aids the surgeon in identifying the ureteral orifice, where the substance is injected a few millimeters distal and medial to it.

Optimal management of VUR is unclear and evolving. Surgery provides little benefit over prophylactic antibiotics (Hodson et al., 2007a; Venhola, Huttunen, & Uhari, 2006). Endoscopic treatment requires more data on success and cost-effectiveness (Faust & Phol, 2007). Antibiotic prophylaxis does not reduce incidence of UTI in low-grade VUR, and it increases the prevalence of resistant organisms (Conway et al., 2007; Garin et al., 2006; Williams et al., 2006); increased surveillance and prompt treatment of UTI may be indicated (Faust & Pohl, 2007). Until research identifies the best therapy, consider VUR and UTI as risks for renal scarring and manage each child individually (Mattoo, 2007).

Hydronephrosis secondary to UPJ obstruction is most often treated with pyeloplasty or ureteroplasty. The focus of these procedures is to dissect the obstructive ureteral component and either anastomose the ureteral segments or suture the remaining ureter to the renal pelvis. Best results are obtained when the surgical correction is performed before the child's first birthday, because renal function may improve markedly. When the initial renal scan demonstrates less than 10% of function, the diseased organ is excised to avoid the long-term manifestation of hypertension. For the infant with severe or bilateral UPJ obstruction, a temporary percutaneous pyeloplasty can be performed with the expectation that low-pressure urinary draining will improve function. Permanent surgical repair is done after the infant is 1 year old.

In addition to open pyeloplasty repairs, laparoscopic pyeloplasty and, more recently, robotic-assisted pyeloplasty have great advantages for both the surgeon and the child. Robotic systems give the surgeon more control with the instruments by delivering highly dexterous wristlike movements. When a pyeloplasty is performed with laparoscopic technique, the child's hospitalization is shorter and the child heals faster, experiences less pain, has smaller incisions, and is able to resume normal activity sooner than with an open procedure (Lee et al., 2006).

Nursing Management

The child with obstructive uropathy will require support in the prenatal and hospital settings that continues in the home, school, and camp settings. The nurse working in these settings is uniquely positioned to support the child and family's decision making and adherence to treatment.

During the evaluation phase, expand the family's knowledge base, clarifying and supplementing information presented by other healthcare team members. Explain diagnostic studies and prepare the child and family for procedures (see Chapter 11). Parents easily become overwhelmed by the shock that an apparently healthy child has a major organ anomaly that may under-

mine a vital body function. Siblings may likewise be affected. Basic facts of urologic anatomy and physiology require constant review.

After a diagnosis has been made, the parents and the child need information and support to help them accept a management program. Educate the child and parents about medications, including therapeutic effects, dosage, side effects, and safety precautions. If surgical intervention has been recommended, assist with preoperative preparation for the child and family, and monitor the postoperative course.

Postoperative Care

Managing pain, maintaining fluid balance, keeping tubes patent, and preventing infection are important components of postoperative care.

Pain Management. Assess for pain and intervene as indicated. Incisional pain is most prominent for the first 2 days after surgery. Relief can be afforded by parenteral administration of morphine sulfate or by extradural nerve blockage in the spinal canal. Patient-controlled analgesic devices can be especially useful for the older child with a flank incision after pyeloplasty or ureteroplasty. The child who has undergone reimplantation of the ureter needs medication to subdue bladder spasms until the urinary drainage tubing is removed and full bladder reexpansion occurs, approximately 1 to 2 days later.

Fluid Balance. After the urologic obstruction is corrected, the child may experience postobstructive diuresis. During the immediate postoperative period, carefully monitor urine output and specific gravity, keeping in mind that these children have reduced concentrating ability.

Alert! Urine output that approaches the IV intake is an early indicator of diuresis, whereas an increasing specific gravity approaching 1.020 and dwindling urine output are later signs of dehydration from excessive fluid loss.

Measuring urine output for the infant with a temporary urinary diversion requires weighing stomal dressings and diapers. Maintain a bedside record showing dry and wet dressing weights to accurately assess output. Disposable diapers wrapped girdle fashion (see [thePoint](#) for Supplemental Information: Urinary Diversion Through a Stoma) around pyelostomy or ureterostomy sites are often used over sterile dressings; record their weight as well.

A bolus of IV fluids may be needed to compensate for the high urine output. Fluid balance stabilizes within 1 to 2 days, and, after removal of the IV fluids, encourage oral intake.

Urinary Tube Care. A ureteral stent, a urethral catheter, or a suprapubic tube may be used after uncompli-

cated reconstructive repairs of obstructive uropathy. If the child's surgical repair is extensive or involves ureteral tapering, stents are necessary to prevent obstruction from postoperative edema (Nursing Interventions 19–2).

Alert! In the postoperative child with ureteral, suprapubic, or urethral drainage tubes, bladder spasms may indicate a mucous plug in the tube. Monitor patency of the system, checking for urine flow and milking the tubes every 2 hours, or in accordance with the facility's policy.

Infection Prevention. Be mindful that use of urinary tubes places the child at high risk for nosocomial infection. Pay meticulous attention to incisional and urinary tube care. Observe the child's urine for cloudiness or foul odor, and note any changes in vital signs that indicate infection. Administer antibiotics as ordered to prevent gram-negative infection.

To promote wound healing, encourage the child to consume a diet high in protein and fluids. Nutritious snacks such as milkshakes or instant breakfast drinks are excellent ways to meet both dietary goals. Consult the dietitian for the child with special dietary needs, lactose intolerance, or poor appetite.

Reconstructive surgery of the genitourinary tract can be psychologically traumatic to children of all ages. Discuss with the child and family issues of body image, sexual identity, and modesty violation to alleviate negative responses to such emotionally charged concerns; collaborate with a child life specialist.

Community Care

Home care after surgical procedures to alleviate urologic obstructions is directed toward restricting activity, preventing infection, maintaining high fluid intake, and preventing potential long-term complications. Inform the child and family that any residual voiding discomfort dissipates more quickly if the child has a high fluid intake, which promotes bladder stretching. Mild analgesics are rarely needed after the child's first day or two at home. Teach the child and parent that vigorous activity, especially jumping or bouncing, is prohibited for the first week or until the first postoperative visit. The child may return to school when he or she feels comfortable, as long as activity is restricted. Baths and showers are permitted after wounds are healed. After ureteral reimplantation, antibiotics may be continued until a follow-up VCUG documents successful resolution of reflux.

Infants with ureterostomies or pyelostomies are generally comfortable at the time of discharge. Demonstrate girdle-style diapering to the parents, placing another diaper in the usual fashion for bowel movements and the occasional urine that may dribble from the bladder. This dribbling, although not harmful, may cause bladder spasms; mild analgesics, such as acetaminophen, offer adequate pain relief.

NURSING INTERVENTIONS 19–2

Postoperative Care of the Child With a Ureteral Stent

During reconstructive urologic surgery, stents are placed to divert urine from the surgical site. These devices prevent urinary extravasation through the incision and prevent urine flow obstruction caused by edema. Depending on the procedure and on surgeon preference, the stents may either exit the body through the incision and attach to external collection containers or drain into a diaper. Removal of the stent is readily accomplished shortly before the child's discharge from the hospital, and the ureteral exit site epithelializes quickly.

A ureteral double-J stent is placed at the anastomosis site of pyeloplasty. This stent passes from the renal pelvis to the bladder; it is an internal stent with no external site. The double-J stent is generally removed cystoscopically 4 to 6 weeks postoperatively.

Imaging studies are usually done 6 to 8 weeks after surgery to assess renal function and to help rule out residual obstruction. Additional imaging studies may be ordered 6 months to 1 year postoperatively to check for a silent obstruction or stricture at the anastomosis site.

To Ensure Tube Patency

Encourage high fluid intake

Monitor output; ongoing output is a good indicator of patency

Teach these techniques to the older sibling or parent and incorporate their participation in the child's care

For external drains, observe tubes for mucous shreds or debris, which may block tube; use gravity to help move these potential obstructions through the tube; check for tube kinking and straighten as needed

To Prevent Infection with External Drains

Keep the collection device below the level of incision
Observe urine for signs and symptoms of infection (e.g., foul odor, cloudiness)

Monitor the child's temperature

Aspirate urine sample for culture

Apply antibacterial ointment to tube site

Maintain a closed urinary drainage system

To Manage Bladder Spasms with External Drains

Ensure tube patency as noted earlier

Tape tubes securely to the leg or body

Medicate for spasms with oxybutynin or belladonna and opium suppositories as ordered

Prevent bladder stimulation secondary to a full rectum by completing a preoperative bowel evacuation, encouraging a high fluid intake, promoting early ambulation postoperatively, and administering a stool softener or glycerin suppository postoperatively

Stomal sites usually require minimal skin care. Soap and water cleansing is generally adequate. If irritation occurs, emollients such as zinc oxide or vitamin A and D ointments usually suffice. Chronic irritation may signal a UTI; teach the family to bring such conditions to the healthcare provider's attention. Tub bathing is allowed after clearance by the surgeon.

Prepare the child and family for ongoing urologic radiographic studies, which assess for unresolved obstruction and monitor renal function. If one kidney is severely compromised, restriction from contact sports is wise and may be mandated by the child's school system. The nurse can help the physical education department create an adaptive sports program for the child. Parents often require emotional support to alter their expectations for their child and rechannel the child's energies into other, less physical outlets.

Potential long-term ramifications of hydronephrosis include the risk of hypertension, urinary calculi, pregnancy-related infections, renal compromise, and genetic transmission of congenital defects to offspring. The

nurse's role is to present parents with strategies to prevent these complications or enable early detection, such as encouraging a lifelong habit of high fluid intake and frequent voiding, daily bowel movements, and yearly blood pressure monitoring. Teach children to ensure that every healthcare provider is aware of their urologic history and that their offspring are evaluated for congenital urologic anomalies shortly after birth.

ANOMALIES OF THE BLADDER AND URETHRA

Anomalies of the bladder and urethra include exstrophy-epispadias complex, hypospadias, patent urachus, and prune-belly syndrome. This section covers exstrophy-epispadias complex and hypospadias. For information about patent urachus and prune-belly syndrome, see [thePoint](#) for Supplemental Information: Anomalies of the Bladder and Urethra.

Exstrophy–Epispadias Complex

The bladder exstrophy–epispadias complex is a serious congenital anomaly affecting multiple organs of the urologic and musculoskeletal systems. Interrupted abdominal development during early fetal life produces an exposed bladder and urethra, pubic bone separation, and associated anal and genital abnormalities. The three variations of this complex are cloacal exstrophy, classic exstrophy, and epispadias.

Bladder exstrophy–epispadias complex is rare, occurring in approximately 1 in 30,000 to 40,000 live births. It affects males three to four times as frequently as females (Sutherland, 2005). The cause of this anomaly is unknown, but it appears to be unrelated to genetic or teratogenic exposure.

Pathophysiology

The three general variants of the exstrophy–epispadias complex share a common precipitating factor: persistence of the cloacal membrane beyond the point of expected resorption during embryologic development. During early gestational life, the embryo has an alimentary tract that terminates as an enlarged chamber—the *cloaca*. Its posterior border is the *cloacal membrane*, which runs from the umbilicus to the tail gut. A mound of tissue, the *urorectal septum*, protrudes into the upper cloacal chamber, migrating toward the cloacal membrane. The urorectal septum separates the cloaca into the anterior *urogenital sinus* and the posterior *anal canal*. Meanwhile, the cloacal membrane recedes as it is filled in with strong mesodermal tissue. In rare instances, the cloacal membrane becomes overly prominent and blocks the proliferation of mesodermal cells. Later, the membrane weakens and ruptures, leaving cloacal structures uncovered. The timing of cloacal membrane rupture determines which of the three exstrophy variations will occur.

Cloacal Exstrophy

If the cloacal membrane disintegrates before the completed cloacal division of its anterior and posterior compartments, the exposed surface is a combined bladder and rectal structure. Both ureters are lateral and have an incompetent bladder junction, whereas the internal sphincter and urethra are split. This condition results in bilateral reflux and total incontinence after initial bladder closure. This version of the defect is rare and occurs between the fourth and sixth weeks of gestational life.

Classic Exstrophy

In classic exstrophy, rupture of the cloacal membrane occurs after the anterior–posterior separation has been completed, exposing the urinary structures only. An everted bladder with lateral ureteral orifices is noted, along with a splayed internal sphincter and urethra (Fig. 19–8). Bilateral reflux and total incontinence occur postoperatively to bladder closure. Of children with exstrophy–

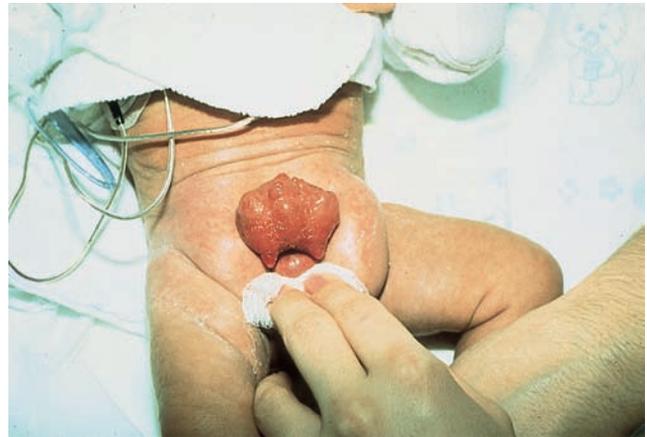

FIGURE 19–8. The bladder is open and exposed on the abdomen in classic exstrophy.

epispadias complex, 60% have classic exstrophy (Sutherland, 2005). The defect occurs during the first trimester.

Epispadias

The least involved presentation in the exstrophy–epispadias complex triad is epispadias, which results from cloacal membrane disintegration after the eighth fetal week. A urethral groove extends along the dorsal penile shaft (Fig. 19–9) or along the entire female urethra. If the internal sphincter is affected, total incontinence results.

Assessment

At birth, the infant with bladder exstrophy–epispadias complex is healthy and is physiologically normal, except for the affected structures. Classic bladder exstrophy is apparent at birth, with the inner mucosal surface of the bladder exposed in the suprapubic area, appearing red, shiny, and rugated, and constantly seeping urine. When cloacal exstrophy is present, the rectal segment protrudes within the bladder mucosa. In males, the penis is short, splayed, and exhibits dorsal curvature (chordee). Cryptorchidism is often present. In females, the urethra and the vagina are short. If primary reconstruction is delayed beyond infancy, the vagina may prolapse. Orthopedic manifestations are minimal after early pelvic ring closure. When surgery is delayed, the child may ambulate with a waddle.

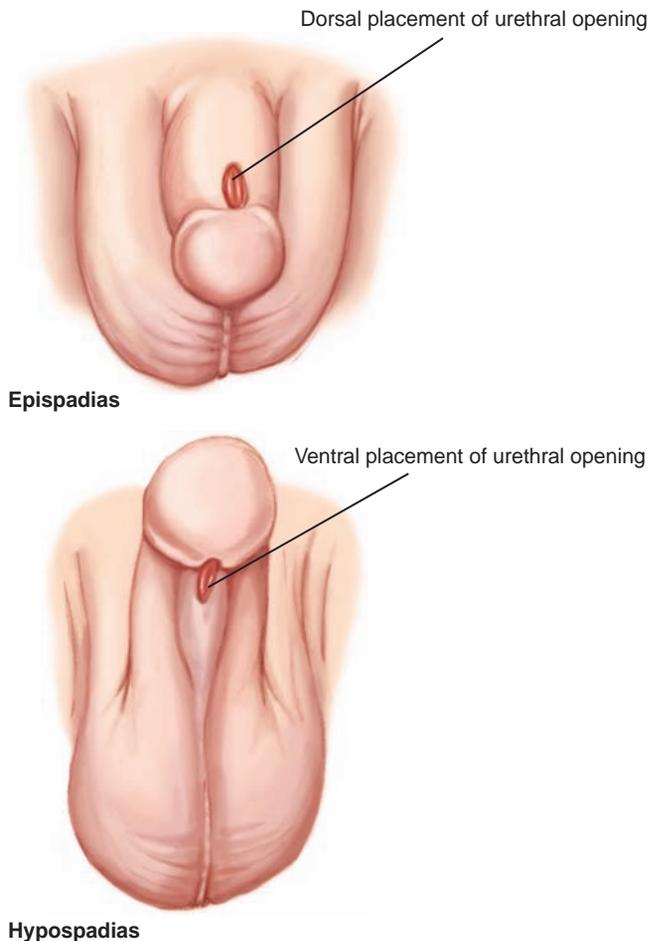

Renal structures are evaluated by a newborn ultrasound or by a renal scan. Beyond the neonatal period, an intravenous pyelogram may be substituted. A pubic computed tomographic scan highlights the severity of pubic separation.

Interdisciplinary Interventions

Management of these congenital anomalies centers on surgery to correct the defect.

Surgical Management

Surgical advances have dramatically improved the management for children with bladder exstrophy–epispadias complex. Rather than resort to urinary diversion, the focus of care is on early surgical correction. Within days

Hypospadias

FIGURE 19-9. Epispadias and hypospadias with chordee. Note the possible locations of the urethral opening.

after birth, the bladder is covered with peripheral tissue and the pelvic ring is closed. Postoperatively, the infant is placed in Bryant's traction until fibrous healing of the symphysis pubic occurs, generally after 3 to 4 weeks.

Because postoperative edema of the bladder is expected, ureteral stents and a suprapubic tube are temporarily inserted to prevent urinary obstruction. Successive surgical procedures to correct reflux, reconstruct a sphincter mechanism, close the urethra, and repair the phallus are individualized, depending on the child's anatomy and response to previous surgery.

Nursing Management

Because of the physical disfigurement of the genitalia and the parents' unfamiliarity with this anomaly, parents often react to the child's birth with this disorder with horror, disbelief, and revulsion. Provide emotional support, education, and reinforcement of the proposed medical management. In addition to routine newborn care, educate parents about skin care, diapering, and hygiene measures. Delicate bladder mucosa should be protected by a plastic wrap covering at all times. Do not use gauze, either wet or coated with petroleum jelly, which may denude the mucosal tissue, or ointments or

creams, which may occlude the ureteral orifices and impede urine flow. Soaps and powders may be abrasive and can promote bacterial growth. Therefore, all of these hygiene products are contraindicated. Clear water is best for cleansing, and a hair dryer set on a low setting effectively keeps the surrounding skin surface dry. Loosely fastened diapers may be worn. Tub bathing is avoided. Postoperative nursing care depends on the child's specific surgical procedure and on the preference of the attending surgeon. See Chapter 20 for management of the child in traction.

Community Care

Educate parents that regular evaluation studies to monitor reflux and to assess for UTI are required to conserve renal function. Urodynamic testing may be used to demonstrate bladder capacity and sphincteric activity. Urinary continence for the child with bladder exstrophy-epispadias complex may be an ongoing concern. Management of this problem often requires a multifaceted approach, incorporating pharmacologic agents, behavioral and motivational techniques, and skin care to provide optimal urine control. Pediatric-sized absorbent products and undergarments are available over the counter or in many specialty catalogues.

Negative emotional sequelae from repeated hospitalization, altered parenting response, or dysfunctional coping techniques may require psychological intervention. Assess for these problems, initiate discussions, and refer for more intensive intervention as indicated.

QUESTION: Mr. Johnson has many questions and concerns about the hypospadias and why the repair has been postponed until now. He also voices concerns about his son's appearance and how it might affect him in the future. How would the nurse respond to his questions and concerns?

Hypospadias

Hypospadias is a congenital anomaly of the penis in which the urethral folds fail to fuse in the midline, and the urethral meatus opens on the ventral surface of the penis. It can be classified according to the location of the urethral meatus along the ventral surface of the penis (glansular, coronal, midpenile, penoscrotal, perineal). Hypospadias is often associated with chordee, a condition in which a deficiency of the normal structures on the ventral side of the penis cause curvature in the penis (see Fig. 19-9). This congenital curvature of the penis may result in infertility secondary to difficulty in semen delivery. Megameatus is a variant of hypospadias in which the urethral meatus is larger than expected and hidden beneath a full foreskin.

The cause of hypospadias is not clear. Hypospadias affects 1 in 250 live male births, with an incidence of 14% in male siblings and 8% in offspring (Baskin, 2005a). Globally, incidence is increasing, possibly because of environmental exposure to endocrine disruptors (Baskin & Ebberts, 2006).

Pathophysiology

Creation of the male urethra begins with the appearance of a urethral groove in the forming genital tubercle, at about the sixth fetal week. Fusion of the urogenital folds that border this groove is initiated during week 9, proceeding along the ventral line from the perineum toward the distal shaft. Simultaneously, a glanular dimple forms at the tip and carves a notch to the corona, splitting the glans. This groove then becomes contiguous with the penile urethra and undergoes ventral fusion. The prepuce develops during week 12, following completed urethral development; scrotal fusion also occurs at this time.

Assessment

A thorough neonatal examination of the male genitalia should reveal hypospadias. In rare instances, hypospadias can be diagnosed after a completed or aborted circumcision. Infants with severe hypospadias and cryptorchidism should be investigated for intersex disorders and undergo karyotyping with endocrinologic workup. Additional testing including renal, bladder, and abdominal ultrasound may be warranted in children who have additional organ system anomalies such as cardiac murmur, imperforate anus, or pyloric stenosis.

caREminder

If any degree of hypospadias is present, a circumcision should not be performed without a urologic evaluation, because the prepuce is used for the reconstructive surgery.

Interdisciplinary Interventions

Hypospadias is treated surgically; the nurse plays a multifaceted role in postoperative care.

Surgical Management

The standard of care is outpatient surgical repair between the ages of 6 and 12 months (American Academy of Pediatrics, 1996); early initiation of the repair has many advantages. Mobility restrictions are easier to maintain before toddlerhood. Psychic trauma during postoperative care is negligible, because the child lacks a sense of modesty and has yet to acquire a sense of gender identity. If early intervention is not feasible, postponing the repair until after age 2½ years is advisable. By this age, the child can be prepared for hospitalization, can cooperate with postoperative care and restrictions, and can verbalize his needs or concerns. Two-stage procedures are often begun at age 6 to 12 months, followed by a final urethral advancement 3 to 6 months later.

The goals of surgical repair are to provide symmetric appearance to the penis and prepuce, produce a sexually functional phallus by correcting chordee and straightening the penis, advance the glans along the meatus to enable physiologically and socially appropriate ejaculation and allow the child to stand while voiding, create

urethral integrity unimpeded by residual stricture or stenosis, and make the penis cosmetically acceptable. Corrective surgery to create a new urethra is usually performed in one-stage outpatient surgery. A two-stage procedure may be necessary for proximal shaft, penoscrotal, and perineal defects (Johal et al., 2006). To improve surgical results in children with small glans, preoperative treatment with testosterone may be used, administered as testosterone enanthate, 25 mg in three injections 4 weeks apart, or testosterone cream applied directly to the penis.

Postoperative care for the child undergoing hypospadias repair focuses on urinary diversion, wound care, pain management, and activity restrictions (see [thePoint](#) for Care Paths: An Interdisciplinary Plan of Care for the Child With Surgical Correction of Hypospadias). Several bladder drainage systems may be used, including a Foley catheter, urethral stent drainage, or (rarely) a suprapubic cystostomy. (In some cases, depending on the degree of hypospadias, tissue adequacy, and the urologist's preference, the repair may be completely tubeless.) The drainage tube may be connected to a closed drainage unit or may remain as an open system, in which case a “double-diaper” technique shields the operative site from moisture, fungal infections, and breakdown in skin integrity. With this technique, the open drainage tube is sandwiched between two diapers. The bottom diaper, covering the penis, remains dry. Some urologists choose to insert a penile stent, a tube that is inserted within the penile urethra only. The stent diverts urine past the internal incision but spares the child from bladder catheterization and resultant bladder spasms. This type of stent, which extends only 2 to 3 mm past the meatus, is secured to the glans by sutures, which dissolve in 7 to 10 days. The child painlessly expels the tube during normal voiding.

Nursing Management

Assess the parents' emotional response to their son's anomaly. Parents mourn the loss of the “perfect” son and fear for his sexual ability and satisfaction, gender identity, and peer acceptance. The idea of delicate reconstructive surgery on a body part that is integral for urologic, sexual, and psychosocial response is abhorrent to many parents, especially fathers. Emphasize that the genitalia, although definitely male, is incompletely formed rather than defective or inadequate. Use illustrations of surgical procedures and before-and-after photographs to address their anxieties and promote bonding.

Nursing care for the child undergoing hypospadias correction is guided by the specific surgical procedure and by the child's age. Hospitalization can vary from less than 24 hours to 5 days. Indwelling stents are typically removed by cutting a stitch that secures the catheter to the glans. Use developmentally appropriate interventions to prepare the child preoperatively and to facilitate psychological adjustment.

Nursing care for the closed drainage catheter or stent follows the principles described for postoperative care

after reimplantation of the ureter. To ensure that the fragile urethral incision remains free from tension, the tube must be taped to angle for ventral penile exposure. Urinary retention, although uncommon, is possible if the stent malfunctions because it is blocked or kinked. Monitor urine output and assess for distention over the lower abdomen. An oral antibiotic may be administered prophylactically while the tube is in place to reduce the risk of infection. An antibiotic ointment is dabbed on the urethral meatus daily.

A compression bio-occlusive dressing is applied to the penis to reduce incisional edema and to control ecchymosis. The dressing remains undisturbed until the glanular edema visibly decreases, usually for 3 to 5 days, and is then removed. Dressing removal can be facilitated by a 30-minute tub bath, which the child can undergo even if the urinary apparatus remains in place (Gormley, Fishwick, & Whinall, 2007).

Postoperative discomfort is surprisingly minimal after hypospadias repair. Penile block and caudal block, administered during the procedure, afford adequate analgesia for most children. Postoperative pain can usually be controlled with acetaminophen with codeine. Bladder spasms in response to the tube rubbing against the bladder mucosa and trigone are controlled with oxybutynin to reduce detrusor contractility. Bowel evacuation before surgery helps to lessen this problem. Tubeless repair eliminates bladder spasms, but the child may experience painful voiding postoperatively and refuse to urinate. In such cases, catheterization is required.

The preschool-aged child who remains hospitalized after hypospadias surgery has some degree of activity restriction. Because most boys feel alert and well postoperatively, provide diversional activities to dissipate stored energy constructively. Gross motor activities and games, such as wheelchair kickball or rhythm movements, are especially important.

Because the hospital stay typically is limited to less than 24 hours, provide discharge teaching expeditiously. Demonstrate how to care for urinary drainage systems, paying particular attention to tube anchoring and patency. One or both of the parents should perform a repeat demonstration of catheter irrigation to remove a mucous plug. Emphasize that the tubing should never be clamped or kinked, and explain the “double-diaper” process. Encourage the child to eat a nutritious diet high in protein and fiber, with extra fluids. Educate about prescribed medications. Instruct the parents how to care for postoperative wound edema and explain how ecchymosis normally resolves. Explicitly describe activities that need to be curtailed until healing is complete (usually 2–3 weeks), such as rough play, swimming, and contact sports. Emphasize that the child must not play on any straddle-type toys for at least 2 to 3 weeks. Review bathing techniques, based on the surgeon’s instructions. Give parents these instructions in writing, with instructions for scheduling postdischarge visits to the surgeon.

The most common postoperative complications include urethrocutaneous fistula (communication between the new urethra and penile skin, which allows urine to drain

through two holes) or meatal stenosis (regression or scarring that narrows the meatal opening). Discuss the potential for these complications and remind parents to regularly observe the child’s voiding pattern. Indicators of problems include a thin, forceful stream, infrequent voiding, a spray-type stream, dysuria, or ventral leaking during a void. Instruct parents to report these symptoms to the surgeon. Teach older children to recognize the signs and symptoms that indicate complications and encourage them to assume self-care.

ANSWER: The nurse should first explain the anomaly and then the rationale for delaying the repair and circumcision, including the use of the prepuce for reconstructive surgery. The nurse should emphasize the advantages of repair at this age, such as easier restriction of mobility and negligible psychic trauma because child lacks a sense of modesty and has not yet acquired a sense of gender identity. In addition, the nurse needs to assess the parents’ emotional response, in particular Mr. Johnson’s response, to J. D.’s anomaly. His concerns may reveal worry about his son’s sexual ability and satisfaction, gender identity, and peer acceptance. In addition, thoughts about surgery on a body part such as the penis can be overwhelming. The nurse needs to emphasize that the genitalia is definitely male and that it is incompletely formed, rather than describing it as inadequate or defective. Using photographs of before-and-after repair may be helpful.

CONDITIONS AFFECTING THE MALE GENITALIA

Conditions that affect the male genitalia include cryptorchidism, testicular torsion, circumcision, and varicocele.

Cryptorchidism

In a normally developed male child, each testicle is secured within its sac in either side of the scrotum. Although the testicles are retractable by the cremasteric muscle when necessary for warmth or protection, each testicle should be palpable in its normal location outside the body of the child. Cryptorchidism, also called *cryptorchidia* or *hidden testicle*, is a condition in which a testicle has not descended normally.

Incidence and Etiology

An undescended testis is noted in 2% to 8% of term male infants (Virtanen et al., 2007). Spontaneous descent may occur during the first few months of life; therefore, an incidence of 1% to 2% is reported from 3 to 12 months of age (Virtanen et al.). The incidence of congenital cryptorchidism is increasing, perhaps because of lifestyle and environmental changes (Virtanen et al.). The risk of cryptorchidism among offspring whose father had the

defect is double that of the average population, although how the inheritance mechanism affects the child is unclear. Risks for undescended testes are high in premature infants with low birth weight and in multiple births.

The cause is unknown, but several hypotheses have been presented. Possible hormonal causes include inadequate testosterone production or insufficient response to the androgenic hormone. Ineffective development of the inguinal canal, abnormal epididymal development, and reduced intra-abdominal pressure represent possible structural causes.

For reasons not clearly defined, 20% to 30% of patients with testicular carcinoma in situ, which precedes germ cell tumors, have a history of cryptorchidism (Veeramachaneni, 2006). Prepubertal orchiopexy decreases the risk of testicular cancer (Pettersson et al., 2007; Walsh et al., 2007).

Pathophysiology

Cryptorchidism has etiologic roots in early fetal development. The testicular germ cells first appear along the mesonephric duct. Between 6 and 9 weeks after conception, hormones secreted by the structure stimulate cellular growth and maturation into an organized testicle. It remains in a perinephric position until a fibrous band exerts downward tension on the organ. By the end of the 12th week, the gonad has journeyed to the internal inguinal ring, where it rests until the seventh month.

During the third trimester of pregnancy, the inguinal canal opens and a hollow space is created in the scrotal sac. The testicle migrates into the scrotal sac, where it bonds to the scrotal lining. Closure of the internal ring of the inguinal canal concludes the process of testicular descent. In cryptorchidism, this process is not completed, and the testicle occupies an anomalous position.

Assessment

The diagnosis of cryptorchidism is made by physical examination. Begin assessment for testicular descent with the parental interview. Because the cremasteric reflex is weak during the neonatal period, ask about the parents' observation of testicular descent during the first 3 months after birth. Inquire whether the parents have noticed normal testicular descent when the child is relaxed, such as during a bath.

On visual inspection of the scrotum, a flaccid, nonpendulous scrotum suggests an absent testis. Observe the size, contour, and skin surfaces of the scrotum.

Scrotal palpation requires that the examiner have warm hands and that the child be relaxed. Relaxation can be encouraged by placing the toddler in his parent's lap, assuming a frog-leg position. To counteract recoil of the testes, apply pressure at the external inguinal ring (see Fig. 8–12). After the testicle is isolated, use a milking action to coax it into the sac. Coating the finger with talc or soap may ease this process. Older boys may be examined as they sit cross-legged, leaning slightly forward to facilitate palpation.

A nonpalpable testis may be absent, atrophic, or located in a position where it cannot be palpated by physical examination. Palpable testes are classified into three categories: retractile, ectopic, or truly undescended. A *retractile* testis is most often found in the inguinal area but can be palpated at any point along the pathway of descent. These testes are normally descended but are found in the extrascrotal position because of an active cremasteric reflex, usually in response to fear, cold, pain, or touch. They can usually be manually repositioned into the scrotum. An *ectopic* testis is misdirected from the normal pathway of its descent. These testes may be located in the perineal or femoral area. A *truly undescended* testis may be palpable intermittently; it may be located in the intra-abdominal region, scrotal canal, or inguinal ring.

The retractable, but normally descended, testis is equal in size to its contralateral mate, whereas the cryptorchid testis is smaller and softer. If no testicle can be discerned, examine the lower abdomen, perineum, or femoral regions for an ectopic gonad.

Interdisciplinary Interventions

Cryptorchidism is managed surgically, with orchiopexy.

Surgical Management

Surgical manipulation of the undescended testis is the treatment of choice. Spontaneous descent after 6 months is unlikely, and orchiopexy is recommended by 1 year of age (American Academy of Pediatrics, 1996; Thorup et al., 2007). Surgical placement accomplishes three goals: it preserves as much testicular function as possible, thereby potentially avoiding infertility; it offers the child a normal scrotal appearance and avoids trauma and torsion; and it facilitates regular testicular self-examinations, which could increase the likelihood of detecting cancer during young adulthood.

Management of the child with a nonpalpable testis includes a presurgical laparoscopic evaluation to ascertain the presence and viability of the intra-abdominal organ. Laparoscopy enables testicular tissue and spermatic vessels to be visualized with 90% to 100% accuracy. If the spermatic vessels are atretic (undeveloped), the gonad will be absent, and no surgery is required. A testicular prosthesis is surgically implanted when the child reaches puberty.

Intra-abdominal testes must be identified because of the risk of malignancy. Surgical options include gonadal excision or Fowler-Stephens orchiopexy in one or two stages. Fowler-Stephens orchiopexy involves division of the spermatic vessels before movement of the testis.

Some have advocated intervention with hormones such as human chorionic gonadotropin or gonadotropin-releasing hormone to encourage testicular descent or to facilitate surgical exploration by enlarging the gonad. This approach is not recommended because of poor efficacy and risk of serious side effects (Thorsson, Christiansen, & Ritzén, 2007).

Nursing Management

Nursing care for the child with an undescended testis and his family begins when the defect is first suspected. Educate parents regarding the importance of timely surgical correction and the endocrinologic consequences of cryptorchidism. Include information regarding hospitalization, preoperative and postoperative procedures, and developmentally appropriate coping techniques.

After a management plan has been provided by the urologist or surgeon, the nursing focus is to reinforce teaching and to clarify any misconceptions held by the child or his family. Use illustrations to explain the defect and the chosen treatment regimen.

Postoperative nursing care after orchiopexy is usually provided in an outpatient surgical suite. See Chapter 11 for a description of routine postoperative care.

Community Care

Discharge instructions encompass incision care and activity restriction. Most surgeons either cover the operative site with a transparent dressing or leave it open to air. No special care is necessary other than inspecting for signs of infection and promptly cleansing urine and stool off the operative site. The return to tub bathing depends on the surgeon's preference. Educate the child and family to avoid vigorous activity, straddle toys, and contact sports for 7 to 10 days.

Long-term follow-up care is imperative for the child with cryptorchidism. The parents should be referred for endocrinologic consultation if infertility or hormonal dysfunction is suspected. Counseling with a psychoendocrinologist and, in time, a reproductive endocrinologist may be necessary when the boy reaches adulthood, becomes sexually active, or considers paternity.

Because of the potential for endocrinopathy and malignancy, many urologists continue to see the child with cryptorchidism on a yearly basis.

caREminder

Monthly testicular self-examination is recommended for all males beginning in puberty, but it is essential for the male with cryptorchidism.

As a part of discharge teaching, provide the parents with an instructional brochure on testicular self-examination. Offer it to the child's father as an added reminder that he should also perform the procedure. Nurses who care for adolescents in any setting should be prepared to teach testicular self-examination as part of routine health maintenance. Also, nurses in clinic settings can display brochures on testicular self-examination in a prominent area with other health teaching publications.

Testicular Torsion

Torsion, or rotation, of the testicle constitutes one of the few urologic emergencies. This condition occurs when

the testicular suspensory apparatus, the spermatic cord, twists and obstructs circulation to the testis. In such a case, emergency medical attention is needed to prevent tissue necrosis.

Incidence and Etiology

The incidence of testicular torsion is estimated at 4.5 per 100,000 males, with a peak incidence of 8.6 per 100,000 in those 10 to 19 years old (Mansbach, Forbes, & Peters, 2005). The precipitating factor for testicular rotation is unknown, but a rising testosterone level with increased testis weight is a possible cause. The condition affects the left testicle more often than the right, possibly because it has a longer spermatic cord. No familial or racial tendencies toward the defect have been documented, nor is it associated with other congenital anomalies.

Scrotal examination of the child with testicular torsion often discloses a "bell-clapper" defect. Normally, the testis resides partially encased within a scrotal sheath, and the exposed spermatic cord–epididymal layer is securely attached to the scrotal lining. This attachment stabilizes the testicle and places it in a vertical position. In some boys, the scrotal sheath completely encases the testicle, epididymis, and spermatic cord, blocking adherence of these structures to the scrotum. This arrangement results in a loosely suspended gonad, which lies horizontally within the sac: a bell-clapper deformity (Eaton et al., 2005).

Although the anomalous testicular attachment is often bilateral, torsion is generally restricted to one testis. Because an undescended testis can also become twisted, acute abdominal pain in the child with cryptorchidism should raise suspicion of torsion.

A variation of testicular torsion involves the twisting of a testicular or epididymal appendix. Torsion of these congenital appendages usually occurs during preadolescence, but the condition may manifest at any age. Damage is confined to the appendix, sparing the testicle.

A second, rarer, form of testicular torsion occurs during testicular descent, either antenatally or within the neonatal period. Because the process is usually painless, the child undergoes treatment for cryptorchidism. At the time of surgical exploration, however, testicular atrophy is evident. The "bell-clapper" deformity is often seen in the remaining testis, which is then secured to the scrotum as a precaution.

Pathophysiology

Twisting of the spermatic cord occludes testicular circulation. The initial response is tissue congestion and testicular edema; unrelieved obstruction leads to vascular thrombosis and necrosis. If the occlusion is complete and unrelieved, tissue death occurs swiftly, possibly within 2 hours and certainly after 12 hours. Intermittent or self-resolving episodes are possible and may cause varying degrees of tissue damage. The prognosis for adequate hormonal function is consequently unpredictable.

Assessment

Acute scrotal pain, often associated with nausea and vomiting, is the hallmark sign of this disorder. Because testicular torsion can occur in association with scrotal trauma, always evaluate complaints of scrotal pain to rule out a diagnosis of torsion. During the history and the physical examination, be sure to address psychosexual issues. Reassure the child that the pain is not related to self-manipulation or to arousal from sexual fantasies.

Alert! The boy who complains of scrotal pain may be experiencing a testicular torsion. He *must* receive immediate medical attention to prevent infarction of the gland.

A history of previous inguinal or scrotal surgery does not discount the potential for torsion. Obtain historical data with the physical examination. Ask for details about the child's condition, such as onset and duration of pain, and any similar episodes of scrotal pain that resolved spontaneously. Question the adolescent male about sexual activity or urethral symptoms. Affirmative responses to these queries suggest epididymitis or orchitis. Persistent but mild scrotal discomfort is more suggestive of torsion of the testicular appendages.

Conduct the examination in privacy and assure the child that his responses are confidential. Explain that testicular torsion is a secondary effect from a congenital anomaly and that it is unrelated to sports or vigorous activity. Do not imply that the child or the parents are to blame for any delay in seeking treatment. Teens typically ignore early signs of illness, and parents are frequently unaware that scrotal pain may have such serious consequences.

Begin the examination with the boy in a standing position, to check for horizontal placement of the opposite testis. With the boy lying down, assess the abdomen for tenderness and pain or swelling in the inguinal area, especially if the boy has an undescended testis on the side corresponding to the pain.

Inspect the scrotum for edema. A blue dot suggesting torsion of the testicular appendix may be noted in light-skinned males. Stroke the inner thigh of the affected side to elicit a cremasteric sign. If it is present, testicular torsion is unlikely. On palpation, the twisted testicle is exquisitely tender throughout the organ. Torsion of the appendix, in contrast, creates localized discomfort, with a palpable upper pole nodule.

Diagnostic Tests

Microscopic urinalysis without evidence of pyuria and bacteriuria provides additional diagnostic confirmation. If the examination does not provide a clear diagnosis, high-resolution sonograms with color Doppler are used to assess testicular perfusion and intrascrotal contents. This noninvasive technique has a high degree of accuracy. A drawback to the color Doppler sonogram is that

accuracy depends on the technique and expertise of the technician (Pepe et al., 2006). Also, the sonogram may be false negative if the torsion is intermittent. If the physical examination and diagnostic studies do not conclusively exclude testicular torsion, the boy must undergo surgery.

Interdisciplinary Interventions

Suspected testicular torsion is a surgical emergency. Testicular viability diminishes dramatically after 6 hours (Mäkelä et al., 2007). Open exploration is performed through a midline scrotal incision, the testis is derotated and surgically fixed to the scrotal wall, and a contralateral orchiopexy is performed. If infarction has occurred, the necrotic gland is removed to prevent detrimental effects to the remaining testis. A pinched testicular appendage is excised for the same reason.

Nursing care after correction of a testicular torsion is directed toward enabling the child and his parents to cope with the long-term effects of the condition. If the function of the affected testis has been severely impaired, or if the organ was unsalvageable, counsel the boy to avoid high-impact contact sports. Many municipalities prohibit children with only one of a paired organ set from participating in organized sports, and, for many adolescents, the forced redirection of their energy and skills may seem punitive and unfair. The nurse can facilitate a positive adjustment by candidly discussing the issue and providing referrals to counseling facilities if necessary.

Community Care

Nurses can exert the greatest effect on this disorder within the community health sphere. The best way to ensure an optimum outcome for boys with testicular torsion is by raising public awareness of the disorder and the need to seek immediate medical care. Numerous vehicles exist to educate the public about this condition, including boys' clubs, Boy Scout troops, parent groups, religious youth organizations, school health classes, and health publications in print and on the Internet.

QUESTION: Suppose J. D. was going to have a circumcision at this age. How would his circumcision be similar and yet different from what his brother had the day after birth?

Circumcision

Circumcision, surgical removal of the prepuce (or foreskin) of the penis, is the most ancient and common operative procedure performed on males in the world for cultural, religious, or medical reasons. Although circumcision itself is not a pathologic condition, the nurse commonly encounters the procedure in the United States, and appropriate management is required.

TRADITION OR SCIENCE 19–4

Should circumcision be routine during the newborn period?

EVIDENCE-BASED PRACTICE

Multiple studies have demonstrated that male circumcision reduces the incidence of UTI (Wiswell et al., 1987; Zorc et al., 2005). Meta-analysis of research demonstrated a 90% reduction (Singh-Grewal, Macdessi, & Craig, 2005). Debate arises about the magnitude of this benefit; some argue that the benefit applies only to those at high risk of UTI (Singh-Grewal et al., 2005); others argue that the benefit of preventing renal scarring after UTI might make this benefit cost-effective (Malone, 2005).

Although Richters et al. (2006) found that circumcision was unrelated to acquiring a sexually transmitted infection (STI), many studies have found that circumcised men are less likely than uncircumcised men to acquire STIs. Circumcision may reduce the risk of acquiring an STI by 48% (Fergusson, Boden, & Horwood, 2006). Circumcision reduced the incidence of acquiring syphilis, cancer, and genital herpes (Weiss et al., 2006); risk of chlamydial infection in female partners by 82% (Castellsagué et al., 2005); and the incidence of human papillomavirus (Baldwin et al., 2004; Castellsagué et al., 2002), the causative agent in cervical and penile cancer. Circumcision also reduces the risk of candidal infections (Richters et al., 2006).

Women are more likely to acquire cervical cancer from uncircumcised partners (Castellsagué et al., 2002; Drain et al., 2006). The risk of penile cancer is greatly reduced in circumcised men (Daling et al., 2005; Maden et al., 1993; Schoen et al., 2000).

Circumcision reduces transmission of HIV. Systematic reviews and meta-analysis of observational studies provide evidence of this association (Siegfried et al., 2003, 2005; Weiss, Quigley, & Hayes, 2000). Randomized, controlled trials of male circumcision in Africa demonstrate that it provides a protective effect against HIV infection of more than 50% in these high-risk populations (Auvert et al., 2005; Bailey et al., 2007b; Gray et al., 2007). Contrary to this strong evidence, Turner et al. (2007), after adjusting for other risk factors, reported no protective effect of circumcision associated with women's risk of acquiring HIV, although findings suggest that further investigation of the effect in high-risk women is warranted. Controlling viral load in HIV-positive men may reduce transmission to female partners (Wawer et al., 2005).

Although complications are generally rare in developed nations, parents must be educated about them as they consider circumcision for their child. The complication rate after neonatal circumcision is 0.2% (Wiswell, & Geschke, 1989) to 0.34% (Ben Chaim et al., 2005). In one study of Nigerian infants, the complication rate was 20% (Okeke et al., 2006). Complications of circumcisions in boys younger than 15 years in England occurred

in 1.2% (Cathcart et al., 2006). Men in Africa between 18 to 24 years old had a complication rate of 1.8% (Krieger et al., 2007). Most complications are minor; they include bleeding, wound infection, redundant foreskin from inadequate removal, and penile-glandular tissue bridge. Major complications include urethral fistula, concealed penis (excision of shaft epithelium with adhesions), penile necrosis, hypospadias, and penile amputation.

Some argue that the medical benefits of circumcision are small and not sufficient to recommend routine circumcision (American Academy of Pediatrics, 1999; British Medical Association, 2006; Canadian Paediatric Society, 1996; Royal Australasian College of Physicians, 2004), and most children who are not circumcised (which includes most males globally) do well medically (Lerman & Liao, 2001). Research negates some concerns regarding possible negative effects of circumcision. Neonatal circumcision does not disrupt breast-feeding (Fergusson, Boden, & Horwood, 2008). In the United States, circumcision during the neonatal period is more cost-effective than later procedures (\$165 vs. \$1,921) (Schoen, Colby, & To, 2006). Research has not shown a difference in sexual satisfaction between those who are or who are not circumcised (Collins et al., 2002; Senkul et al., 2004).

Aside from religious or cultural beliefs, routine male circumcision has generated extensive debate. Evidence demonstrates that circumcision has a protective effect against some diseases. Because of the ethical and cost-benefit issues that the topic engenders, circumcision remains a choice that requires consideration of individual beliefs and risks.

WORLDVIEW: The practice of circumcision varies dramatically worldwide. Approximately 25% of males are circumcised (Steadman & Ellsworth, 2006). Male circumcision is common among Jews and Muslims (Rizvi et al., 1999), and in the East Cape of Africa (Meissner & Buso, 2007). Circumcision rates approximate 61% (Nelson et al., 2005) to 85% (Schoen, 2006) of male neonates in the United States, 90% of Filipino men (Lee, 2006), and 87% of males in Nigeria (Okeke, Asinobi, & Ikuerowo, 2006). Male infants from Central and South America, Europe, or Asia, however, likely will not experience the procedure (Steadman & Ellsworth, 2006).

Many pediatric organizations do not recommend routine circumcision of newborns (American Academy of Pediatrics, 1999a; British Medical Association, 2006; Canadian Paediatric Society, 1996; Royal Australasian College of Physicians, 2004). This stance has been challenged (Dickerman, 2007; Morris et al., 2006; Schoen, 2006), making routine circumcision one of the most controversial issues in modern pediatric healthcare (Tradition or Science 19–4).

Pathophysiology

Creation of the foreskin begins during the third fetal month. Originating at the base of the glans, the prepuce proceeds distally to envelop the penile tip, and the adjacent tissue layers become adherent. As fetal growth nears completion, clefts of cells resembling holes in a sponge develop within the preputial–glanular layer to begin the separation process. At birth, only 4% of males have a retractile prepuce, but by age 3 years, the foreskin is retractable in 90% of boys.

In children, smegma is a by-product of preputial separation. As the epithelial cells degenerate, they form white clumps, which are expelled normally during micturition. During puberty, sebaceous cell secretions mix with epithelial cells to lubricate the glans.

Two pathologic conditions are related to foreskin development: phimosis and paraphimosis. Phimosis is an unretractile foreskin. Because most infants exhibit physiologic phimosis, the description among young males is confined to foreskin constriction that obstructs urine flow. A foreskin that balloons during urination indicates phimosis. Ulceration of the glans resulting from this phenomenon may lead to balanoposthitis, an infectious condition of the glans. Phimosis can be treated with topical steroids, and circumcision need only be used if steroid treatment fails.

Paraphimosis is a painful condition resulting from forced retraction of a tight or stenotic foreskin below the coronal ridge, usually during an overzealous attempt to clean the glans before separation is complete (Fig. 19–10). The resulting constriction creates pain, distal edema, and difficulty replacing the foreskin. Emergency medical intervention is needed to relieve the obstruction through manual compression of the edematous glans or, in severe cases, surgical release of the constricting foreskin with a dorsal slit.

Assessment

Detailed scrutiny of the genitalia is necessary before neonatal circumcision. Signs suggestive of a congenital anomaly include chordee, a hooded prepuce, or meatus

FIGURE 19–10. Paraphimosis. Note the swollen prepuce.

dislocation. A newborn with bilateral undescended testes and severe hypospadias should be evaluated for an intersex condition. A male infant with an apparently small phallus should also be examined by a urologist before a decision regarding circumcision is made. Palpate the bladder for distention and assess voiding.

Alert! Examine the infant for signs of a bleeding dyscrasia, such as unexpected ecchymotic spots or prolonged bleeding after newborn testing.

Administer vitamin K, as ordered, before the procedure to offset potential bleeding complications. Also, question the parents regarding a family history of coagulation disorders. If the history is positive, circumcision should be deferred until it is determined that the child does not have a bleeding disorder.

Interdisciplinary Interventions

With well-baby education condensed into shortened hospital stays after delivery, many parents have little opportunity to make a thoughtful decision about circumcision. Nurses have ample opportunity to provide anticipatory guidance during prenatal visits and childbirth education programs. If the parents choose not to have their son circumcised, provide instructions for proper genital care (TIP 19–4).

Circumcision is ideally performed within the first 48 hours after delivery, but it can be performed anytime through the first month of life without general anesthesia. The procedure begins with a thorough cleansing of the glans, then the inner preputial epithelium is separated from the glans. A dorsal slit is made through the foreskin, which allows a clamp mechanism to be applied over the glans. The prepuce covering the clamp is excised. Hemostasis is provided where needed, and a lubricated gauze pad is wrapped circumferentially over the raw edges. Circumcision for the older infant or child is similar, but sutures are needed to approximate the skin edges.

Pain management during and after circumcision is necessary, because newborns likely experience even more pain than an adult would with the same stimulus. Therapeutic options include caudal block, dorsal penile block, and topical analgesics (e.g., EMLA, LMX4), all of which offer continued relief for 4 to 8 hours after the procedure. Also use sucrose and nonnutritive sucking (see Chapter 10). Discomfort after circumcision in infants may persist for 24 to 48 hours. Mild analgesics are generally adequate to extinguish pain (Garry et al., 2006).

After circumcision, observe the child's penis for bleeding or signs of infection. In many cases, the first sign of a blood dyscrasia is prolonged oozing after the procedure. Although most infants void within 6 hours after circumcision, an excessively tight dressing may induce urinary retention. Reapply the bandage to correct the problem.

Community Care

Discharge teaching includes providing parents with information about wound care. Instruct them to reapply

TIP 19–4 A Teaching Intervention Plan for a Boy Who Is Uncircumcised

Nursing diagnoses and outcomes

- Deficient knowledge: Normal preputial separation

Outcome:

- Parents will express an understanding of appropriate hygiene measures, which vary by age of the child.
- Risk for infection related to inappropriate hygiene measures

Outcomes:

- Parents will adhere to recommended hygiene measures and teach them to the child.
- Child will gain independence in adopting a consistent hygiene regimen.

Teach the child/family

Hygiene Measures: Birth to 3 Years

- The foreskin and the glans (the end of the penis) are normally fused during these years.
- No specific care of the foreskin is recommended.
- Occasionally retract the foreskin to check for separation.

- The foreskin should *only* be retracted with gentle pressure until resistance is felt.

After Complete Foreskin Separation

- Retract the foreskin fully to expose the glans.
- Cleanse the glans with a mild soap and water, and dry completely.
- Return the foreskin to its normal position.
- Perform this routine daily.

Adolescence

- White discharge, called *smegma*, needs to be removed daily.
- Retained smegma can be irritating and may be a source of infection.
- When sanitation facilities are inadequate (such as long hiking trips) or in hot, humid climates, disposable wash towelettes may be used.

Contact the Healthcare Provider if:

- The glans becomes sore or excoriated
- There is an unusual odor, rash, or discharge around or from the penis
- The foreskin cannot be retracted

the dressing for 1 to 2 days; parents can use petroleum-coated gauze bandages and apply them to the tip of the penis. This dressing helps prevent the circumcised area from rubbing against the diaper or sticking to the diaper as the healing process is occurring. Teach the parents that the penis will appear edematous and ecchymotic during the process of wound healing. If the child is not an infant, caution the child and parents to avoid straddle toys and vigorous play for 3 to 4 days. Tub baths may be instituted after the fifth day to help the sutures dissolve.

ANSWER: Care for the older infant or child having a circumcision is similar to that for a newborn. However, sutures are needed to approximate the skin edges. Pain management as well as parent teaching related to wound care and monitoring for signs and symptoms of bleeding and infection are key for a child at any age. Tub baths can be used after the fifth day to help dissolve the sutures in the older infant or child.

Varicocele

A varicocele is a scrotal mass resulting from engorgement of the spermatic vein and scrotal vasculature. Blood return from the scrotum into the renal vein is impeded,

producing antegrade vascular dilatation and stasis. The pooled blood raises the temperature around the testicle, with potentially adverse effects on the organ.

Varicoceles are seldom evident before the second decade of life, reaching their peak incidence by the mid teens. The prevalence of scrotal varicoceles is 11% to 14% in males 11 to 14 years old and 11% to 19% in males age 15 to 19 years (Cayan & Woodhouse, 2007). Varicoceles are clinically detectable on the left side in 90% of boys and are bilateral in 10% (MacLellan & Diamond, 2006). No genetic, racial, or congenital risk factors are associated with the phenomenon.

The etiologic basis for a varicocele rests with a discrepancy in the attachment angles of the right and left spermatic veins to their corresponding renal vein. The right spermatic renal junction is obliquely angled, allowing unobstructed circulation, whereas the left junction is a 90-degree angle, which reduces blood velocity. It is probable that anatomic changes in relative renal position and vascular configuration, secondary to the pubertal growth spurt, trigger the development of the varicosed venous network.

Pathophysiology

By the time the child reaches mid to late adolescence, the deleterious effects of a varicocele can be noted. Increased

glandular volume, which normally occurs during puberty, is delayed in the affected testicle. Histologic evaluation of the affected gonad demonstrates delayed maturation and decreased spermatogenesis. These changes are progressive into adulthood, reducing the density and motility of spermatozoa. The presence of a varicocele is a common cause for male infertility, and its effects are cumulative.

The youth's response to surgical correction of the varicocele seems to depend on the severity and duration of the condition. Studies suggest that correction in older adolescents results in catch-up growth of the testis and markedly improved sperm concentration and motility (Cayan & Woodhouse, 2007). Although evidence that catch-up growth affects fertility is limited (Cayan & Woodhouse; Diamond, 2007), varicolectomy may improve fertility; further study is needed (Werthman et al., 2007).

Assessment

The cardinal sign of a varicocele is a palpable scrotal mass of veins, typically described as a “bag of worms.” The defect is noted when the boy is in an upright position, and it resolves when the adolescent is examined in a supine position. Occasionally, boys describe a heavy or dragging sensation to the scrotum, but most varicoceles are asymptomatic. They are usually detected as a scrotal fullness during a routine scrotal examination or when teaching the child to perform testicular self-examination.

When a varicocele is palpated, determine testicular volume, monitoring for a discrepancy between the affected gland and its mate. Measure testicular volume on a regular basis with an orchidometer or by ultrasound. A reduction in the volume of the affected testicle is an indicator of testicular damage.

Hormonal tests are not indicated unless the child has signs of hypogonadism (Cayan & Woodhouse, 2007). Follicle stimulating hormone and testosterone levels vary as boys go through puberty. Gonadotropin-releasing hormone stimulation test may help identify early testicular dysfunction, but a normal test does not indicate absence of risk for future infertility, and an abnormal result does not indicate future infertility (Cayan & Woodhouse).

Interdisciplinary Interventions

Early detection of the varicocele and vigilant monitoring for testicular changes are necessary to avoid testicular damage.

caREminder

Institute thorough genital examinations when the boy enters puberty and repeat yearly, along with monthly testicular self-examination.

Surgical correction is recommended when signs of testicular impairment are present, such as abnormal semen

analysis (Diamond, 2007) or testicular hypotrophy (>20%) compared with the unaffected side (Cayan & Woodhouse, 2007). The recommended procedure is ligation of the varicosity and removal of the spermatic vein, as either an open or laparoscopic procedure.

Nursing care for the adolescent undergoing a varicolectomy includes routine postoperative stabilization, pain relief, and wound assessment. The hospital stay is minimal, and home instructions focus on activity restrictions for 10 to 14 days.

Community Care

Important components of discharge teaching by the nurse are to review the possible postoperative complications with the child and his family, and to stress to the boy himself the necessity of performing monthly testicular self-examination. Long-term problems, although infrequent, include the development of a hydrocele or the recurrence of a varicocele arising from varicosed collateral vessels. A postoperative hydrocele is asymptomatic and is typically left unrepaired. A recurring varicocele requires additional surgery to ensure that the affected testicle will catch up to its contralateral mate in volume size.

RENAL FAILURE

The kidneys are vital in regulating fluid and electrolyte balance in the body. Kidney failure may result from acute or chronic processes that cause kidney injury, congenital conditions, or acquired disease.

Acute Renal Failure (ARF)

ARF, also called *acute kidney injury* (American Society of Nephrology, 2005), develops rapidly, over days or weeks. It can be classified according to the site of injury to the kidney:

- Prerenal, resulting from impaired blood flow to or oxygenation of the kidneys
- Intrinsic renal (or parenchymal), resulting from glomerular, tubular, or interstitial injury
- Postrenal, resulting from obstruction of the urinary flow at some level between the kidney and the urinary meatus

Prerenal ARF may be abated with early supportive treatment and correction of the low flow state. Intrinsic renal ARF may require pharmacologic intervention. Postrenal ARF usually requires physical removal of the obstruction. All have the potential for requiring dialytic intervention if nonamenable to supportive or corrective intervention. Longstanding pre- or postrenal ARF may lead to intrinsic ARF.

Incidence and Etiology

ARF most commonly results from prerenal causes secondary to systemic illness (Radhakrishnan & Kiryluk,

2006; Vachvanichsanong et al., 2006). Infants are most vulnerable because of their immature kidneys and large body surface area compared with body mass. The most common causes of prerenal ARF are related to excessive fluid losses from trauma and bleeding or losses from the gastrointestinal, genitourinary, or integumentary systems. In developing countries, prerenal ARF is primarily caused by infections such as gastroenteritis and malaria (Radhakrishnan & Kiryluk). In children, the causes of intrinsic renal ARF vary by age. In infancy, multiple factors can contribute to failure, including hypoxic insults, drug toxicities, renal artery and venous thrombosis, and congenital renal malformations. In school-aged children, glomerular diseases are the most common causes. Glomerular diseases can affect adolescents as rapidly progressive forms of glomerulonephritis, but trauma also contributes in this age group (Benfield & Bunchman, 2004). Postrenal ARF in younger children is commonly caused by congenital defects. The incidence of ARF in critically ill children is estimated to be 4.5% (Bailey et al., 2007c) to 82% (Akcan-Arikan et al., 2007); this wide range may stem from lack of a standardized definition of ARF.

Pathophysiology

Prerenal ARF results from the kidneys' protective responses to diminished renal blood flow in an effort to regain normal intravascular volume, blood pressure, and renal perfusion. In the first response (the myogenic reflex), the glomerular afferent arteriole dilates to maintain glomerular blood flow. With the second response (glomerulotubular feedback), constriction or dilation of the afferent arteriole is further regulated by sodium and chloride delivery to the macula densa area of each nephron. During the third response, decreased blood pressure in the kidneys causes release of renin, which leads to production of angiotensin, a potent vasoconstrictor, and increased aldosterone synthesis, which increases sodium resorption from the distal tubule. Also, vasopressin secretion is increased, which results in more water being resorbed from the distal tubule. These protective responses work for a limited time, but unless the initial insult is resolved, the compensatory mechanisms become overwhelmed. This eventuality results in decreased glomerular blood flow and decreased glomerular filtration rates (GFRs), which may not be reversible.

In intrinsic renal ARF, the pathology can be identified by the area of renal injury: vascular, glomerular, or tubular. In vascular injury, an embolism causes a direct injury, or malformed platelets cause endothelial damage as occurs in hemolytic-uremic syndrome (HUS). Malignant hypertension can also damage the renal arteries, causing vascular injury. Glomerular injury is caused by rapidly progressive ARF that causes microvasculature changes. Tubular injury is most often caused by contrast nephropathy or by pigment nephropathies including rhabdomyolysis, crushing injuries, and underlying myopathies (Benfield & Bunchman, 2004).

Ureteropelvic junction (UPJ) stricture, posterior urethral valves, calculi, tumors, or compression of the ureters

or the urethra may cause postrenal ARF. However, deposition of substances such as uric acid crystals, xanthenes, or casts in the tubular lumens can also cause postrenal ARF. Renal blood flow increases in early hours after an obstruction occurs, but it slowly declines with prolonged obstruction from renal vasoconstriction; therefore, rapid identification of the cause, and repair, are imperative.

The prognosis and recovery of the child with ARF depend on the underlying cause. Mortality is often related to comorbid conditions and not directly to the renal failure itself.

Assessment

The symptoms of ARF have a sudden onset and are related directly to the lack of kidney function. Assess for **oliguria**—production of less than 0.5 mL urine per kilogram body weight per hour in children; less than 1 mL/kg/hour in infants—which may be the first sign of ARF. Anuria, essentially no urine production, is a less common sign of ARF. Children can also have ARF and have normal urine output or nonoliguric renal failure. A stratification system has been proposed to evaluate acute kidney injury in children: pRIFLE (pediatric Risk, Injury, Failure, Loss, End-stage) (Akcan-Arikan et al., 2007). Severity of renal injury increases as estimated creatinine clearance and urine output decreases.

Assess for hypertension, edema, or shortness of breath, which may indicate volume overload resulting from retained fluid. Monitor also for gastrointestinal disturbances (anorexia, nausea, vomiting, diarrhea), cardiac arrhythmias, altered level of consciousness (lethargy, drowsiness, coma), or central nervous system disturbances (headache, seizures), which may be signs of acidosis or serum electrolyte imbalance.

Assess for the first sign of recovery from the oliguria of ARF, which is usually diuresis marked by polyuria. This phase is heralded by a slow increase in urine volume, often greatly exceeding normal volumes, followed by slow decline in serum creatinine and BUN.

Alert! Assess for electrolyte imbalances and dehydration during the polyuric phase of ARF. Massive urine output can quickly cause electrolyte or fluid imbalance.

Diagnostic Tests

Renal failure can affect the results of various laboratory tests. Elevated serum BUN and creatinine are most diagnostic. With decreasing renal function, severe electrolyte imbalances can occur, most notably hyperkalemia and acidosis. Hypocalcemia and hypoalbuminemia can also be noted.

Interdisciplinary Interventions

The goals in treating ARF are to reduce symptoms and to provide supportive care until renal function returns.

Treatment can range from conservative management to some form of dialysis, depending on the severity of the symptoms (see Treatment Modalities at the start of this chapter). Medication, dietary restrictions, or dialysis may be needed to control fluid overload, acidosis, electrolyte imbalance, or central nervous system disturbances. Erythrocyte-stimulating agents (e.g., epoetin alfa [Epo-gen, Procrit], darbepoetin alfa [Aranesp]) should be administered to prevent the anemia of renal failure. Teach and model good hygiene practices, such as diligent hand hygiene and daily baths, to prevent infections.

Chronic Kidney Disease (CKD)

CKD is a progressive loss of kidney function. In children, the more prevalent causes of CKD are uropathies (31%) and glomerular disease (27%) (Wong et al., 2006). The National Kidney Foundation Kidney Disease Outcomes Quality Initiative (2002) guidelines define CKD as (1) kidney damage (either pathologic abnormalities or markers of damage, including abnormalities in blood or urine tests or imaging studies) for longer than 3 months, with or without decreased GFR; or (2) GFR less than 60 mL/minute/1.73 m² for longer than 3 months, with or without kidney damage.

A CKD staging system (Table 19–1) was developed to help the care provider understand the severity of renal dysfunction, address changes in medical management, and make referrals to appropriate medical teams to prevent or delay adverse outcome of CKD. Children can remain at a specific level of GFR, or their overall function may progressively worsen.

Pathophysiology

CKD in children has many causes. It can be related to an inherited disorder, congenital abnormalities, injury during the neonatal period, glomerulonephritis, nephritic syndrome/NS, tubulointerstitial disease, or renal transplant. Although many different diseases can cause CKD, morphologic changes associated with the progression to end stage renal disease (ESRD) are somewhat standard. Sclerotic glomeruli with proliferative matrix changes as well as interstitial fibrosis are common. Chronic interstitial inflammation and tubular atrophy are also seen. The few remaining functional glomeruli may develop hypertrophic tubules as the kidney attempts to compensate for lost function. As kidney function deteriorates, secondary complications arise, because the kidneys are unable to meet the body's physiologic demands (see Table 19–1).

Assessment

Obtain a detailed prenatal and antenatal history. Antenatal findings may include polyhydramnios, oligohydramnios, and abnormal antenatal ultrasound.

Signs and symptoms of CKD in children are vague and differ by stage of disease. With the benefit of laboratory and radiographic studies, children are presenting earlier for long-term follow-up care. Overall symptoms

of chronic progressive kidney disease can include, but are not limited to, fatigue, exercise intolerance, delayed growth and sexual maturation, dry itchy skin, hypertension, headaches, renal osteodystrophy or bony changes, muscle cramps or myopathy, and generalized malaise. Decreased renal function also increases susceptibility to infection. In young children, findings may include failure to thrive or short stature. Older children and adolescents may present with delayed puberty and poor school performance.

Assess the child and the family for their responses to CKD. As with any other chronic condition, the psychological effects of CKD on the child and family can be devastating. Both the diagnosis and the treatment cause stress for all family members. Parents mourn the loss of their “normal, healthy” child and experience anger, denial, and hopelessness. Even though they intellectually understand that CKD can progress and lead to ESRD, parents still may repeatedly question the necessity of recommended treatments and ask for second opinions. Children, too, mourn the loss of their good health. If nephrectomy is necessary, they mourn the loss of this body part, even if no normal kidney function remained. Some children believe that being “bad” has brought on the illness and that only being “good” will result in a cure. Explain the condition, as age appropriate, and provide frequent reassurance to decrease fright and increase the child's sense of well-being. Ask about the child's school performance. Multiple factors contribute to poor performance: anemia, uremia, absences, and depression; intervene as indicated.

If the cause is a hereditary disease, guilt is a common parental feeling. Parents who believe that the disease may result in the child's death may become distant and less supportive of the child because they are experiencing anticipatory grief. See Chapter 12 for a discussion of the effects of chronic conditions on the child and family.

Diagnostic Tests

The gold standard measurement of GFR is creatinine clearance. This test requires a 24-hour urine collection and a serum creatinine level drawn during, or at the end of, the urine collection. This cumbersome task is not feasible in younger children who are not toilet trained. An *estimated* GFR is commonly calculated instead, using the Schwartz formula:

$$\text{Height (in centimeters)} \times \text{CF/serum creatinine} = \text{GFR (in milliliters per minute per 1.73 m}^2\text{)},$$

where CF is the coefficient factor (0.45 in infants, 0.55 in children, and 0.7 in adolescent males).

Improved formulas to estimate GFR are under development (Furth et al., 2006).

caREminder

Creatinine is a measure of muscle breakdown, so results can be misleading in very thin or malnourished children.

TABLE 19-1
Stages of Chronic Kidney Disease, Complications and Interventions

Description	Secondary Complications	Interventions
<i>Stage I</i>		
Normal or increased GFR (≥ 90 mL/min/1.73 m ²)	No complications caused by kidney dysfunction because kidney function does not decline; kidneys may even be hyperfiltering	Provide interventions to prevent progression of disease by managing proteinuria and hypertension. Provide teaching to reduce risks of cardiovascular disease, including regular aerobic exercise, healthy weight, and heart-healthy diet.
<i>Stage II</i>		
Mild decrease in GFR (60–89 mL/min/1.73 m ²)	May occur when kidney is unable to keep up with the body’s demands Alterations in electrolyte balance from decreased kidney filtration of blood, typically acidosis and hyperkalemia The kidney produces the hormone erythropoietin (EPO), essential in the formation of red blood cells. Declining GFR reduces the kidney’s ability to produce adequate amounts of EPO, causing renal anemia. As a result of the reduction in growth hormone secretion, alterations in growth patterns can begin	Preventive measures as noted earlier. Monitor for electrolyte imbalances. Dietary intervention (low potassium) Medications for acidosis (sodium bicarbonate) Monitor for anemia. Medications to supplement iron and EPO EPO requires subcutaneous injections. Monitor growth velocity. Rule out alternative causes for growth failure (acidosis, poor nutrition, endocrine abnormalities). Dietary restriction of phosphorous
<i>Stage III</i>		
Moderate decrease in GFR (30–59 mL/min/1.73 m ²)	Further alterations in bone metabolism and growth can occur. The kidney excretes 70% of dietary phosphate intake; as function declines, hyperphosphatemia develops. A decrease in calcium absorption in the gut leads to hypocalcemia. Phosphorous–calcium imbalance affects the parathyroid gland. A decrease in the number of calcium receptors on the parathyroid gland in individuals with CKD occurs.	Monitor and manage as noted earlier, plus monitor for bone disease. Monitor growth velocity. Restrict phosphorous. Medicate to treat bone disease/growth failure <ul style="list-style-type: none"> • Phosphorous binders • Vitamin D • Growth hormone (daily subcutaneous injection) Anticipatory teaching and planning for renal transplant
<i>Stage IV</i>		
Severe decrease in GFR (15–29 mL/min/1.73 m ²)	The previous alterations become more pronounced and more difficult to control.	All of the interventions mentioned earlier, plus begin anticipatory teaching and planning for renal replacement therapy.
<i>Stage V</i>		
Kidney failure/end-stage renal disease (GFR <15 mL/min/1.73 m ²)	Signs and symptoms of uremia typically present	Requires renal replacement therapy <ul style="list-style-type: none"> • Peritoneal dialysis • Hemodialysis • Kidney transplant

Adapted from National Kidney Foundation Kidney Disease Outcomes Quality Initiative (2006) guidelines.

Multiple lab values are monitored, based on the child’s stage of CKD. These include serum electrolytes; complete blood counts; iron stores; calcium; phosphorous; intact parathyroid hormone levels; cholesterol panels;

and nutritional parameters such as albumin, total protein, and prealbumin levels. Intermittent measurements of serum creatinine can guide treatment but cannot predict the rate of decline or likelihood of renal failure.

Nursing Diagnoses and Outcomes

The slow onset of CKD and the anticipation of dialysis and transplantation in the future govern the selection of diagnoses, which reflect the child's psychosocial needs. Nursing diagnoses and outcomes typically applicable to the child with renal disease are presented in Nursing Plan of Care 19–1. The child and family require extensive teaching to prepare them for each different phase of the child's disease progression. Evaluate nursing diagnoses that can be applied to direct the child's psychosocial care needs, including those related to activity intolerance and body image disturbance. In addition, the following nursing diagnoses may be applicable to reflect alterations in family and individual coping:

Compromised family coping related to the effects of the presence of chronic condition and ongoing care requirements of child

Outcomes: Child and family will demonstrate effective decision making and mutual support activities.

Child and family will share ongoing concerns with one another and with members of the healthcare team.

Child and family will participate in treatment activities at developmentally appropriate levels.

Grieving related to response to loss of kidney function and restricted lifestyle

Outcomes: Child and family will verbalize feelings of grief and accept these responses as appropriate to the situation.

Child and family will seek support from appropriate resources to assist in dealing with grief.

Plan nursing care to address the child's current level of kidney function, to slow progression, and to treat secondary issues that arise out of decreased function.

Interdisciplinary Interventions

Treatment for CKD ranges from conservative medical and dietary management to dialysis or kidney transplantation. All treatment modalities for children require a major investment of parental time and energy as well as commitment from an interdisciplinary care team. Each discipline must address family members' knowledge deficits and support the other disciplines in caring for the child and family. Because work overlaps significantly, schedule regular team meetings to discuss care plans, which permit consistent care and a unified approach to the child and family.

During the early stages of CKD, regular observation of the child's condition may be all that is required. However, when a child is first diagnosed with kidney disease requiring treatment, explain all the appropriate treatment modalities to the parents and to the child, as developmentally appropriate. Include extended family or significant others who support the family and assist in caring for the child. As the child progresses into stage IV, begin planning for transplantation and renal replacement therapy. Planning ahead reduces anxiety and decreases the need for emergent decision making if a rapid decline in function occurs.

Nursing care of the child with stage V CKD includes teaching the child and family about the long-term impli-

cations of each treatment option (TIP 19–5). Assess family coping mechanisms and intervene if indicated. Educate both the child and family of the consequences of not adhering to the prescribed treatment regimen; help the family to focus on promoting the most normal lifestyle possible. Close interaction with a social worker and renal dietitian are imperative at this stage of kidney disease. Children may need assistance in school scheduling to accommodate dialysis and frequent medical appointments. Adherence to dietary management can be very difficult, especially in the teenage population; provide ongoing reeducation. Child life specialists help provide coping skills and diversion during dialysis.

Conservative Management

Conservative management is used for children with impaired renal function before dialysis is required. The main focus of conservative management is to treat the symptoms of CKD and prevent further damage. Controlling blood pressure is a priority. Teach the family how to measure blood pressure, what their child's normal blood pressure is, and at what level to contact their healthcare provider about elevated or low measures. Facilitate obtaining automatic blood pressure devices as indicated (e.g., for infants when it is difficult to obtain accurate readings).

Teach families how to give injections (see Chapter 9 and [thePoint](#) for Procedures/Interventions for Medication Administration: Subcutaneous). Children with CKD may require erythropoietic stimulating agents to treat anemia. These injections are given from three times weekly to as infrequently as monthly with the new longer acting erythropoietic stimulating agent formulations. Children may also require recombinant human growth hormone injections, which are given daily at bedtime. Frequently assess child and family coping, and proper injection technique; inspect injection sites.

When caring for a child undergoing conservative management, frequently assess the child's nutritional status by appetite, weight and height measurements, and activity level. Nausea and vomiting are common symptoms of renal failure, particularly as the child gets closer to requiring dialysis. These symptoms are thought to result from the body compensating for protein load or may be related to an altered taste pattern. If medications are vomited, instruct the family to consult the healthcare provider to determine whether they should be readministered.

Although laboratory tests are a good method to monitor serum chemistries, laboratory tests should be kept to a minimum. Decrease the trauma associated with laboratory tests as much as possible. For instance, drawing blood from a child's heparin lock or implanted venous access device eliminates the need for multiple needle sticks. Use topical anesthetics for needle procedures (see Chapter 10).

Alert! Renal failure affects the body's ability to form blood clots. Children who have been in renal failure for a while are at risk for prolonged bleeding. Teach families to control excessive bleeding from laboratory tests or injuries by applying ice and direct pressure.

TIP 19–5 A Teaching Intervention Plan for the Child With Renal Disease

Nursing diagnoses and outcomes

- Excess fluid volume related to excess sodium intake or fluid retention

Outcomes:

- Child maintains fluid intake within ordered parameters.
- Child maintains baseline weight.
- Child and family demonstrate skill in monitoring child's fluid intake and sodium intake.
- Risk for impaired skin integrity related to delayed healing, pruritus, edema, and/or Tenckhoff catheter insertion

Outcomes:

- Child's skin remains intact.
- Child and family institute measures to monitor and maintain skin integrity.
- Delayed growth and development related to effects of disease and medications

Outcome:

- Child demonstrates age-appropriate skills and behaviors to the extent possible.

Teach the child/family

Fluid Intake

- If fluids need to be encouraged, offer small amounts (30–60 mL) of the child's favorite fluid every hour while the child is awake.
- Keep a chart of the fluids consumed to assist in monitoring intake.
- If fluids are restricted, pour out the day's fluid allotment in a single container to be kept in the refrigerator. Set aside enough fluid to consume with medications.
- Any food substance that melts (e.g., ice cream, ice, gelatin dessert) counts as liquid intake.
- Ensure that all fluids have some calories in them to maximize the number of calories that the child receives. Do not offer low-calorie and diet drinks unless the child is significantly overweight.

Nutrition

- If the child is in renal failure, protein intake is restricted to recommended daily allowance for age group.
- If the child is receiving peritoneal dialysis, protein intake may be up to 100 g/day.

- A potassium-restricted diet (2 g/day) is generally recommended. High-potassium foods include citrus fruits, dried fruits, bananas, potatoes, chocolate, nuts, and tomatoes.
 - No-added-salt diet
 - No more than 4 g sodium/day
 - Do not use table salt at all
- Low-salt diet
 - No more than 2 g sodium/day
 - Do not use table salt at all
- Encourage intake of high-carbohydrate and/or high-fat foods, such as hard candy, bread, and butter, and add Polycose or vegetable oil to formulas.
- Calcium supplements should be given to prevent bowing of the long bones and joint swelling (renal rickets).

Skin Care

- Because healing times are prolonged, monitor skin integrity daily and provide routine skin care.
- Clean the Tenckhoff catheter, hemodialysis access catheter, or urinary diversion tube site daily.
- Itching is common in renal failure. Keep the child's nails trimmed to prevent scratching, and use a moisturizing cream (e.g., Eucerin) to help minimize itching.

Health Maintenance

- Practice proper hand hygiene to prevent infections in the child with immunosuppression.
- Ensure that immunizations (especially varicella vaccine) are current before kidney transplantation.
- Platelet function is decreased. Observe child for bleeding. If bleeding occurs, apply direct pressure to the site, elevate the affected area, and apply a dressing or ice to the site.
- Promote good dental hygiene to prevent cavity formation and the need for extensive dental work.

Developmental Considerations

- Encourage independence and activities appropriate to the child's developmental level.
- Encourage school attendance.
- Set behavioral limits and reward desired behaviors.
- Give the child choices, allowing some participation in decisions about his or her care.

Renal failure causes immunosuppression. Teach the child and family to avoid exposure to contagious diseases, to avoid skin breakdown, and to take antibiotics as ordered.

Dietary Management

The diet recommended for a child with renal failure is individualized and designed based on the child's level of CKD. In stages I to IV, the renal diet consists of restricted amounts of protein, low potassium and phosphorus, and low to moderate sodium. Permitted levels may be modified, depending on the child's requirements. To achieve fluid balance, the child's underlying disease process is considered. For children in stages I through IV, fluids are not usually restricted, and in fact they often are told to "push" fluids.

The diet for a child in stage V CKD is essentially a balanced diet, but in contrast to the diet in stages I through IV, a more liberal protein intake is allowed, because of the catabolic nature of dialysis, and fluids are restricted. Educate the family regarding dietary restrictions and suggest ways to help the child adhere to the regimen. Grandparents or friends, if they are unaware of the scope of restrictions, may inadvertently sabotage the diet by handing the child a candy bar or a banana.

Encourage the child with CKD to live as normal a life as possible. Attending school, after-school activities, sports, scouting, and camp is important. Assist the child and parents, as requested, to explain dietary limitations to school and camp personnel. Most institutions can adjust menus for children with dietary restrictions.

Support the family in developing practices to prevent the child with renal failure from feeling different or deprived because of dietary limitations. Having the whole family eat the renal-failure diet at home helps the child to normalize the diet. In addition, the family's food preparer avoids the stress of preparing two different menus at each meal; salt, spices, or butter can be added to individual portions after they have been served.

The child on a limited-potassium diet must limit intake of citrus fruits, bananas, potatoes, chocolate, nuts, dairy products, and tomatoes, which are all high in potassium. Dried fruits of all kinds are also high in potassium, because the dehydration process concentrates the substance.

Alert! Many salt substitutes use potassium as their main ingredient. These substances exacerbate hyperkalemia in children with CKD.

Renal Replacement Therapies

If conservative measures fail to manage the child's condition, some form of renal replacement therapy is necessary. The child with severe hyperkalemia, hyponatremia, increased BUN levels, fluid retention, and metabolic acidosis is a candidate for dialysis (see Treatment Modalities). Monitor for symptoms or complications of uremia such as anorexia, nausea and vomiting, poor growth, lethargy, and an inability to concentrate, which are also

indications to begin dialysis. Specific serum creatinine and creatinine clearance values and other criteria have been established as indications for dialysis in adult patients. However, such specific criteria have not been adopted for children, because serum creatinine levels depend on the child's muscle mass. Thus, because of the disparity in muscle mass, a serum creatinine level of 3 mg/dL in a newborn may demonstrate the same need for dialysis shown by a level of 8 mg/dL in an adolescent. Creatinine clearance may be more useful in determining the need for dialysis in smaller children. Symptoms of ESRD are sufficient reason to begin dialysis, even if laboratory values do not indicate that it is needed. For children with ARF, the rapidity of onset, duration, severity of abnormalities, and symptoms govern the decision to begin dialysis (Table 19–2).

CONGENITAL RENAL DISEASE

Congenital renal disease results from improper embryonic development of urinary tract structures. It occurs in several forms. Agenesis is the complete absence of kidney tissue. If agenesis is unilateral, it may not be discovered until later in life. At birth, the contralateral kidney is stimulated to undergo compensatory hypertrophy to maintain normal renal function. As long as renal function in the sole kidney is normal, children can grow and function normally, with no adverse effects to the single kidney. Usually, the left kidney is absent, and the right kidney is normal. The condition predominates in males (Schwaderer et al., 2007).

A small kidney with fewer nephrons than normal is called a *hypoplastic kidney*. Like other congenital malformations, hypoplasia can be unilateral or bilateral. Bilateral hypoplastic kidneys is a leading cause of ESRD during the first decade of life (Elder, 2007).

Dysplastic Kidneys

Aplastic and *dysplastic* are terms that are often used interchangeably to describe kidneys that have not developed normally. Aplastic or dysplastic kidneys can occur bilaterally or unilaterally. Dysplasia often occurs along with a functional obstruction of the collecting system, such as neuropathic bladder (González Celedón, Bitsori, et al. 2007), posterior urethral valves, or prune-belly syndrome.

Pathophysiology

Dysplastic kidneys show abnormal differentiation of renal tissues, with primitive glomeruli and tubules, cysts, and nonrenal tissues, like cartilage. Altered gene expression or obstruction in the renal system can contribute to development of renal dysplasia (Jain et al., 2007; Shibata & Nagata, 2003).

Assessment

The function of dysplastic kidneys varies as widely as the types of anomalies do. Presenting signs and symptoms

TABLE 19-2

Comparison of Dialysis Modalities

Modality	Advantages	Disadvantages
Peritoneal dialysis	<ul style="list-style-type: none"> Easy to start Easy for staff to learn Liberal diet Liberal fluids Consistent therapy Most normal lifestyle, can usually attend school uninterrupted No heparinization Can travel with/have equipment shipped to destination 	<ul style="list-style-type: none"> If rapid results are desired, this method produces slow, gentle fluid removal and solute correction Not appropriate if recent abdominal surgery Unrelenting, must be done 7 days per week Risk of peritonitis, tunnel and exit site infections More responsibility on family
Hemodialysis	<ul style="list-style-type: none"> Rapid fluid and solute chemistry correction Therapy three to four times a week Less work at home 	<ul style="list-style-type: none"> Expensive equipment Trained and experienced staff required Blood vessel access required Heparinization required Diet and fluid restrictions Intermittent therapy/missed school time Travel time/expense to dialysis unit Extracorporeal circuit required
Continuous renal replacement therapy	<ul style="list-style-type: none"> Slow, gentle fluid removal and solute correction for the hemodynamically unstable patient 	<ul style="list-style-type: none"> Blood vessel access required Requires high staff-to-patient ratio with highly trained and experienced staff Heparinization required Extracorporeal circuit required Continuous arteriovenous hemofiltration requires mean arterial pressure more than 60 mm Hg

can be apparent (flank mass, UTIs, hematuria, proteinuria) or can be somewhat concealed by other conditions, such as failure to thrive.

Children with dysplastic kidneys can show the signs and symptoms of CKD. The degree of renal impairment often progresses as the child grows and is related to degree of proteinuria, number of febrile UTIs, presence of hypertension, GFR rate at onset of deterioration, and puberty (González Celedón et al., 2007). Bilateral dysplastic kidneys may have enough function to maintain a newborn but are not able to keep a larger child healthy. If a child has unilateral dysplasia, the contralateral side may develop well, hypertrophy, and provide normal renal function.

Dysplastic kidneys can be seen on ultrasound; their size can be measured, and any scarring can be noted. However, a kidney biopsy is needed to differentiate between dysplastic and hypoplastic tissue.

Interdisciplinary Interventions

As the child with dysplastic kidneys progresses through the stages of CKD, first conservative management, then some form of renal replacement therapy will be required (see Chronic Kidney Disease).

Polycystic Kidney Disease

Polycystic kidney disease is an inherited disease characterized by diffuse cystic lesions in both kidneys (Torres & Harris, 2006). Polycystic kidney disease has no ethnic or gender predilection. Two types of polycystic kidney disease exist: autosomal dominant and autosomal recessive. Autosomal dominant polycystic kidney disease (ADPKD) is the most common inherited human kidney disease; incidence is 1 in 500 to 1 in 1,000 live births (Boyer et al., 2007). Autosomal recessive polycystic kidney disease (ARPKD) predominantly presents in infancy, occurring in 1 in 20,000 live births (Torres & Harris, 2006).

Pathophysiology

In addition to the renal cysts in ADPKD, cysts are present in other organs, such as the liver, pancreas, seminal vessels, and arachnoid membranes. Other abnormalities can be present, such as intracranial aneurysms, aortic root dilatation and aneurysms, mitral valve prolapse, and abdominal wall hernias (Torres, Harris, & Pirson, 2007). ADPKD is less aggressive than ARPKD, and progression to ESRD in childhood is rare; however, many progress to ESRD as adults (Torres et al., 2007).

When renal insufficiency appears, the GFR typically decreases at a rate of 4.4 to 5.9 mL/min/year (Torres et al., 2007).

In addition to the renal cysts in ARPKD, some degree of biliary dysgenesis and hepatic fibrosis is always present (Goilav et al., 2006). Kidney and liver transplantation are needed if polycystic liver disease accompanies ADPKD. If a child with ADPKD dies, the cause is usually attributed to cirrhosis, portal hypertension, or ruptured esophageal varices resulting from liver disease.

Long-term prognosis is variable. The earlier the disease manifests, the greater the number of nephrons affected and the poorer the prognosis. About 30% of newborns die from lung hypoplasia with oligohydramnios sequence (Bisceglia et al., 2006). In ARPKD diagnosed in an infant, decreased GFR is usually evident early, but can remain stable or even slightly improve during the first year of life. Most children require renal replacement therapy before adolescence (Goilav et al., 2006). Much of the morbidity associated with ARPKD is related to the hepatic disease rather than the renal disease. With advances in renal transplantation, renal survival rates are high.

Assessment

Manifestations of ADPKD may not appear until late childhood or even adolescence, but occasionally they may affect neonates. An abdominal mass, flank pain, hematuria, hypertension, and (less frequently) renal insufficiency, may be the presenting symptom (Boyer et al., 2007).

ARPKD typically presents during early infancy as bilateral flank masses that do not transilluminate. The presence of respiratory distress, infantile hypertension, and a history of oligohydramnios is highly suggestive of the disease.

ADPKD and ARPKD may be diagnosed by prenatal ultrasound that demonstrates renal cysts. Renal ultrasonography is often used for assessment and diagnosis; computed tomography or magnetic resonance imaging may be used.

Interdisciplinary Interventions

Treatment of either type of polycystic kidney disease is symptomatic. In addition to treatment of hypertension, congestive heart failure, respiratory distress, or other symptoms of CKD, surgical removal of the polycystic kidneys is often necessary. Maintenance dialysis is then required until renal transplantation is successful (see Treatment Modalities).

Because polycystic kidney disease is hereditary, older children with the disease and their parents should receive genetic counseling along with teaching about dialysis and transplantation. This preparation permits them to make informed decisions about reproductive choices.

GLOMERULAR DISORDERS

Injury to the glomerulus leads to impaired kidney filtration. As a result, blood components normally excluded

(e.g., red blood cells, protein) can pass into the urine and be excreted. The type and severity of the defect determines the degree of functional impairment.

Various renal disorders are grouped under the larger diagnosis of glomerulonephritis. There is proliferation and inflammation of the glomeruli and evidence of both hematuria and proteinuria. Many of the glomerulopathies are believed to be a direct result of an immune mechanism. For more information, see [thePoint+](#) for Supplemental Information: Causes of Glomerulonephritis. A kidney biopsy is the only way to identify the type of glomerulonephritis. A specific diagnosis is essential in determining treatment for the underlying disease, in assessing the likelihood of retaining or regaining normal renal function, and for assessing the probability that disease will recur.

Nephrotic Syndrome (NS)

NS is characterized by a sudden onset, with edema as its first presenting symptom and a diagnostic triad of proteinuria, hypoalbuminemia, and hypercholesterolemia. Idiopathic nephrotic syndrome can be differentiated by different pathologic lesions found on renal biopsy, including minimal change nephrotic syndrome, focal segmental glomerulosclerosis, and mesangial proliferation (Vogt & Avner, 2007).

Annually, NS develops in 2 to 3 per 100,000 children (Vogt & Avner, 2007). Most cases develop in 2- to 6-year-old children; boys are affected twice as often as girls (Vogt & Avner, 2007). Minimal change nephrotic syndrome is the most common cause (85%) of idiopathic NS in children (Vogt & Avner, 2007). Minimal abnormalities are found on renal biopsy, and these children have the highest likelihood of complete disease resolution by their early teens. The incidence of focal segmental glomerulosclerosis appears to be increasing (Borges et al., 2007), which is clinically important because focal segmental glomerulosclerosis is the lesion most likely to be a precursor to CKD (Reidy & Kaskel, 2007).

Pathophysiology

The primary pathophysiologic event in NS is increased permeability to albumin in the glomerular basement membrane. This permeability results in massive albumin loss into the urine and hypoalbuminemia, causing circulating fluid volume depletion and decreased intravascular oncotic pressure. Compensatory physiologic mechanisms result in sodium retention (renin-angiotensin-aldosterone) and free water retention. Hyperlipidemia in NS is thought to result from hypoalbuminemia stimulating hepatic protein synthesis, including lipoproteins, and loss of lipoprotein lipase into the urine. Nonalbumin proteins lost in the urine include immunoglobulins, clotting factors, and several important binding proteins in the plasma, including several hormonal binding proteins. As a result of the loss of immunoglobulins, a child with NS is prone to infection even before immunosuppressive therapy is initiated, and severe ascites may be complicated by spontaneous bacterial peritonitis. Thrombotic events

have been reported in the portal vein, sagittal sinus, and various limb vessels (Schachter, 2004).

Categorizing NS by response to therapy helps to delineate prognosis and treatment plans. Steroid therapy is the first-line treatment, and response is categorized as steroid resistant, steroid responsive, or steroid dependent. Steroid resistance is diagnosed after no response is obtained after 12 weeks of steroid treatment. These children require renal biopsy and second-line agents for treatment. In steroid-responsive children, the amount of protein in the urine decreases to negative or trace amounts within 10 to 15 days after initiation of steroid therapy. Steroid-dependent children relapse when alternate day therapy is begun or within 2 weeks after all steroid therapy has been discontinued. Most children are steroid responsive and respond to prednisone therapy within 2 weeks.

Assessment

Typically, the first sign of NS is periorbital edema, and it is often originally thought to be an allergy. Periorbital edema is most noticeable on arising, but subsides as the child is upright during the day; however, it may shift to peripheral, scrotal, or vaginal edema. Weight gain usually occurs, but parents may mistake it as being caused by growth. Urine becomes diminished, foamy, or frothy. Ascites and pleural effusion may develop from the fluid shifts. Blood pressure is usually normal to slightly decreased.

The child is as edematous on the inside of the body as on the outside. Gastrointestinal edema can cause diarrhea, anorexia, and poor food absorption. If the protein loss is prolonged, signs of malnutrition, such as hair changes, pallor, or shiny skin with prominent veins, may ensue. The child may be irritable from the swelling, lethargic, fatigued, and increasingly susceptible to infection, especially pneumonia, peritonitis, cellulitis, and septicemia.

Interdisciplinary Interventions

Treatment aims to decrease urinary protein loss (thus controlling edema), balance nutrition, restore normal metabolic function, and prevent or treat any infection (see [thePoint](#) for Care Paths: An Interdisciplinary Plan of Care for the Child With Nephrotic Syndrome). Children with steroid-sensitive NS should be treated for at least 3 months with corticosteroids (Hodson, Willis, & Craig, 2007b). The child is usually hospitalized for the first episode of NS so that the diagnosis may be confirmed, therapy can be initiated, and the family can be taught about the disease and its management. Recurrences can usually be managed at home; however, severe edema causing respiratory distress, ascites, skin breakdown, or massive scrotal swelling requires hospitalization.

The child may ambulate as tolerated and is given a low-sodium, well-balanced diet with fluid restriction only if the edema is severe. Hydrotherapy is often helpful to assist in fluid shifting. Instruct the child to soak in a warm bath or swim in a pool to aid in mobilizing fluid back into

the intravascular space. Elevate the lower extremities or scrotum if indicated to reduce fluid pooling. Monitor for skin breakdown, a particular risk with marked edema, and intervene as indicated. Peritonitis is the most common infection in actively nephrotic children. Because steroid therapy may suppress physical findings of infection such as fever, carefully assess the child. Severe abdominal pain that impedes activity should be evaluated emergently.

Community Care

Most children have had their childhood immunizations by the time NS first develops. After NS is diagnosed, consider the child's current use of steroids when making decisions to immunize. Educate the parents that if the child is not receiving steroids, immunizations should occur at regular intervals, with the understanding that they may cause the child's NS to relapse. The risk of contracting a preventable disease likely far outweighs the risk of NS relapse. Immunizations administered to a child taking steroids may not evoke adequate response and therefore may not fully protect the child from illness.

Viral illnesses, especially upper respiratory infections, are an unavoidable part of childhood. If an NS relapse occurs because of viral illness, instruct parents to seek medical care so that steroid treatment can be reinitiated.

Educate parents on the importance of treating the child normally, particularly during periods of remission, and of having age-appropriate expectations of the child (e.g., discipline, chores).

Proteinuria

Many healthy children excrete protein in their urine; 150 mg every 24 hours is the upper limit of the normal range (González-Buitrago, Ferreira, & Lorenzo, 2007). The causes of proteinuria can be classified into three main categories. In *postural*, or *orthostatic*, proteinuria, a nonpathologic form, children excrete normal or slightly increased amounts of protein when they are recumbent. When they arise, however, protein excretion may increase 10-fold or more (Vogt & Avner, 2007). *Nonpathologic transient* proteinuria can occur with a temperature of 101 °F (38.3 °C) or more, after vigorous exercise, with heart failure, with seizures, after exposure to cold, or with emotional stress. *Fixed* proteinurias are more likely to be pathologic. The abnormal proteinurias are caused by glomerular or tubular disorders, overload of protein in the blood, and alterations in intrarenal blood flow.

Pathophysiology

Glomerular proteinuria results from changes in the electrostatic charge or size of the pores of the glomerular capillary membranes, which increase membrane permeability. Increased levels of plasma proteins in the filtrate result. In tubular proteinuria, normal levels of smaller molecular weight proteins are filtered but are not reabsorbed from the proximal tubule as they should be.

Overload proteinuria occurs when excessive amounts of low-molecular-weight proteins, present because of a disease process, are present in glomerular filtrate. The levels exceed the resorptive capacity of the proximal tubules. The compensatory changes in a single functioning kidney give rise to altered blood flow within that kidney and can lead to proteinuria.

Assessment

Protein in urine can sometimes be detected by a “foamy” appearance, but this is an unreliable indicator. A dipstick test, a turbidimetric test with sulfosalicylic acid, or both types of tests are required for accurate detection. The accuracy of dipstick testing can be affected by the concentration of the urine. If proteinuria is detected first by dipstick, it must be verified by laboratory measures of actual protein excretion. Measurement of protein-to-creatinine ratio in a first-morning urine sample correlates to the 24-hour protein excretion value (Rashman et al., 2006; Xin et al., 2004).

Interdisciplinary Interventions

Children with pathologic proteinuria should have a physical examination, urinalysis with microscopic examination, a first-morning protein-to-creatinine ratio, urine culture, serum albumin, BUN, creatinine, and C3 levels. If hematuria, hypertension, or impaired renal function is found, a kidney biopsy is necessary.

If a child loses less than 1 g of protein in the urine every 24 hours, no treatment is required. The child should have a yearly well-child visit including a first-morning protein-to-creatinine ratio and blood pressure check.

A child who excretes more than 1 g of protein every 24 hours, in whom the cause is not orthostatic proteinuria, should have a kidney biopsy. Prolonged proteinuria can cause glomerular scarring and accelerate progression of CKD.

Hemolytic–Uremic Syndrome (HUS)

HUS is the most common cause of acute renal failure in children younger than age 3 years (Fiorino & Raffaelli, 2006). The disease itself is characterized by hemolytic anemia with fragmented red blood cells and thrombocytopenia. The specific renal pathology is thrombotic microangiopathy, in which platelet–fibrin thrombi form in the kidneys. Typically children present in renal failure as a result of the disease.

Assessment

Childhood HUS can be divided into two entities, according to clinical presentation and outcomes. About 90% of HUS cases in children have a prodromal illness involving diarrhea caused by Shiga toxin-producing *E. coli*—typically, 0157:H7 (Oakes et al., 2006). Prognosis is generally good, although lethargy, oliguria, dehydration, and high white blood cell count ($>20 \times 10^9$ cells/L) and hematocrit levels ($>23\%$) upon presentation are associated with mor-

tality (Oakes et al.). CKD or death occurs in about 12% of cases, and 25% of survivors have renal sequelae (Garg et al., 2003). The second category, children with no diarrheal prodrome, encompasses a heterogeneous group of disorders, and prognosis is often poor (Waters et al., 2007; Zimmerhackl et al., 2006). Some are caused by genetic mutations that predispose to HUS, such as mutations in complement regulatory proteins (Sellier-Leclerc et al., 2007). HUS may also be associated with infections caused by *Streptococcus pneumoniae* (Waters et al.).

From 5 to 10 days after onset of the prodromal illness, HUS begins, with the child manifesting a sudden onset of pallor, bruising or purpura, irritability, and oliguria. The child usually has a slight fever, anorexia, abdominal pain, vomiting, watery and blood-stained diarrhea, and mild jaundice. Signs of circulatory overload also may occur. With central nervous system involvement, lethargy and seizures develop (Clinical Judgment 19–4). Between days 4 and 7, renal manifestations peak and can range from mild renal insufficiency to ARF that requires dialysis.

Alert! Immediately refer a child with vomiting and watery, bloody diarrhea who develops purpura or pallor to the primary healthcare provider for workup for HUS.

Interdisciplinary Interventions

Supportive therapy should begin early (see [thePoint](#) for Care Paths: An Interdisciplinary Plan of Care for the Child With Acute Renal Failure Resulting From Hemolytic–Uremic Syndrome). Frequent dialysis and transfusions of packed red blood cells to maintain the hemoglobin level usually result in recovery. For survivors, screening for microalbuminuria may facilitate early recognition of renal sequelae and intervention (Lou-Meda et al., 2007). Children who develop CKD are managed accordingly.

Community Care

Educate families about the importance of cooking meat fully, because HUS may be transmitted in undercooked ground beef containing *E. coli* bacteria. Also reinforce good hand hygiene to reduce fecal–oral contamination and transmission of *E. coli* bacteria.

Acute Poststreptococcal Glomerulonephritis (APSGN)

APSGN is one of the most common acute renal syndromes. The child has symptoms of varying severity 1 to 2 weeks after a throat or skin infection with certain nephrogenetic strains of group A streptococci. In cold weather, the precipitating infection is most likely to be pharyngeal; in warm weather, skin infections (impetigo, infected insect bites, or varicella sores) predominate.

CLINICAL JUDGMENT 19–4

The Child With Hemolytic-Uremic Syndrome

Leo is a 3-year-old with HUS. He presented in the emergency room with a temperature of 100.4 °F (38 °C), lethargy, vomiting, abdominal pain, and watery, blood-stained diarrhea. His skin is pale, slightly jaundiced, and bruises easily. Within several hours after admission to the hospital, a decision is made to initiate PD. The physician explained the purpose of dialysis and the need for surgery to place a Tenckhoff catheter. As you enter the child's room, the mother is crying and asks, "Is my baby going to die?"

Questions

1. During your health assessment, what additional information would be beneficial to elicit to clarify the diagnosis?
2. Why does Leo's skin appear pale, with slight jaundice, and have evidence of bruising?
3. What should be the focus of your nursing plan of care at this time?
4. What actions would you take to implement your plan?
5. How would you determine that the parents understood the treatment plan?

Answers

1. Has Leo recently had a bacterial or viral illness? HUS is commonly associated with these conditions.
2. Leo is pale as a result of anemia, which results from damaged red blood cells. The jaundice and easy bruising are results of thrombocytopenia.
3. Providing comfort to the parents, addressing the parents' concerns by reemphasizing and clarifying the plan of care as explained by the physician, and determining what other concerns the parents may have
4. Show parents pictures of the Tenckhoff catheter and PD process. Discuss how they can help support their child and hold him during dialysis. Help parents select diversionary activities for their child. Review with parents the clinical indicators that the healthcare team will be evaluating to determine when kidney function is returning.
5. Parents verbalize that they understand the plan of care, they are able to discuss the plan of care with their child and other family members, and they select activities to keep the child calm and content during dialysis treatments

Pathophysiology

APSGN results from the immune response to streptococcal antigens, with circulating immune complexes triggering complement and the inflammatory process (Rodriguez-Iturbe & Batsford, 2007). Biopsy specimens from children with poststreptococcal glomerulonephritis show that pathologic findings vary with the severity of the disease. Mild cases show minimal to moderate proliferation of mesangial cells and matrix. In severe cases, mesangial cell, matrix, and endothelial cell proliferation, as well as infiltration with polymorphonuclear cells and monocytes can be so extensive that the capillary lumens are occluded. In fact, severe disease is called *diffuse endocapillary exudative glomerulonephritis*.

The disease usually runs its course in about 1 month. Prognosis is excellent; more than 95% of children recover completely (Davis & Avner, 2007). Serum complement levels may remain low for 12 to 16 weeks. Mild proteinuria may last for several months, and microscopic hematuria may be present for up to a year. In some children with oliguria, rapidly progressive glomerulonephritis develops; in others, chronic glomerulonephritis develops more slowly. In general, children with prolonged proteinuria and an abnormal glomerular filtration rate (GFR) have a poor prognosis.

Assessment

Severe clinical manifestations may include ARF with sudden onset of gross hematuria, edema, hypertension, and renal insufficiency. However, up to half the children are asymptomatic, with only microscopic hematuria. A typical case might show the sudden onset of mild proteinuria, hematuria, and periorbital edema. The urine is tea or cola colored from the presence of red blood cells. The child is usually irritable and complains of flank or midabdominal pain, general malaise, and fever. Hypertension can cause headache, vomiting, somnolence, and other central nervous system symptoms, including seizures. Fluid overload can cause cardiovascular symptoms such as dyspnea and tachypnea as well as an enlarged, tender liver.

Laboratory testing for serum creatinine, albumin, hemoglobin, hematocrit, and complement levels; and urine testing for complete urinalysis and urine protein excretion help identify the presence of disease. Kidney biopsy is the only way to distinguish between the various types of glomerulonephritis. The biopsy specimen is examined by both light microscopy and electron microscopy, and it is stained for immunofluorescence.

Interdisciplinary Interventions

Treatment of acute poststreptococcal glomerulonephritis is symptom specific. Dietary restrictions of fluid, sodium, and potassium are recommended. Bed rest, antihypertensives, and diuretics are also helpful in treating this condition. Early treatment of streptococcal infections with antibiotics does not always prevent development of the disease, but an evidence review noted some protection (Del Mar, Glasziou, & Spinks, 2006). The affected child and all other family members with positive cultures should undergo antibiotic treatment for 10 to 14 days (Community Care 19–2). See Chronic Kidney Disease for information on supportive care for renal sequelae.

Hereditary Nephritis (Alport's Syndrome)

Of the several types of hereditary glomerulonephritis, Alport's syndrome is the most common, accounting for approximately 3% of cases of ESRD in children (Kashtan, 1999). Mutations in the genes for type IV collagen, the major constituent of basement membranes, cause this syndrome. About 80% of children have the X-linked form, 15% have an autosomal recessive form, and 5% have an autosomal dominant form (Kashtan, 2007).

Pathophysiology

In children younger than age 5 years with Alport's syndrome, biopsies are normal except for a few fetal glomeruli. As the child grows older, microscopic changes occur in the glomeruli: mesangial cells and matrix proliferate, capillary walls thicken, and tubules atrophy or dilate. These changes usually start to occur during the teenage years, but presentation of the disease can vary widely. Progression to renal failure may occur.

Assessment

The presenting symptom of Alport's syndrome may be a persistent asymptomatic microscopic hematuria or an episode of gross hematuria after an upper respiratory infection. Some children with Alport's syndrome have progressive bilateral sensorineural hearing loss that begins in the high frequencies and progresses to total deafness. Most also have eye disorders, such as whitish or yellowish flecks around the macula and anterior lenticonus (Kashtan, 2007).

Interdisciplinary Interventions

For children with hearing or vision loss associated with Alport's syndrome, facilitate their obtaining hearing aids and glasses as needed. Genetic counseling helps both the parents and the child make informed reproductive choices in the face of this hereditary disease. If Alport's syndrome progresses to ESRD, as it generally does in males, then dialysis and transplantation are the usual treatments.

Renal Calculi

Renal calculi (urolithiasis) are relatively uncommon in children. They can be broadly classified into three categories, defined by the precipitating condition: infection-related calculi, calculi resulting from a metabolic imbalance, and pharmacologically induced calculi. For more information, see [thePoint](#) for Supplemental Information: Renal Calculi.

Renal Trauma

Renal injury usually occurs in conjunction with abdominal trauma, although it can occur as an isolated event.

COMMUNITY CARE 19–2

Preventing Acute Poststreptococcal Glomerulonephritis

In children with streptococcal infection:

- All children who have had a sore throat, tonsillitis, otitis media, or impetigo caused by streptococcus should have a urinalysis 2 weeks after the infection to monitor for APSGN
- Teach children who are prescribed penicillin or other antibiotics for a streptococcal infection to complete the entire course of the treatment regimen

For contacts of a child diagnosed with APSGN:

- All people living in the home should have throat cultures completed to evaluate for the presence of streptococci

- Any individual who has a positive throat culture should have a course of penicillin therapy. It can be given by mouth for 10 days, or benzathine penicillin can be administered intramuscularly once.
- Community contacts generally do not need to be tested for streptococcal infection
- Prophylactic therapy with penicillin to prevent further streptococcal infections is not necessary because APSGN tends not to recur with subsequent infections

Damage to the genitourinary tract is a component of 1.7% of all pediatric trauma cases (Cooper et al., 2007). The overwhelming majority of injuries occur after blunt-force trauma, such as occurs in passenger or pedestrian motor vehicle accidents, falls, recreational activities, or abuse (Broghammer et al., 2006). Renal trauma rarely causes death but may compound the effects of other life-threatening injuries.

Certain characteristics of the child's renal structure increase its susceptibility to damage. The child's kidney fills proportionately more space in the abdomen compared with the adult organ. Its position is lower in the retroperitoneum, and it is less protected by fat and fascia. Supporting structures have greater elasticity, which allows for excessive renal motion after bodily force. Immature ossification of the encircling ribs further compromises protection to the kidney. Congenital anomalies or an aberrant renal location (e.g., hydronephrosis, fused kidneys, or a pelvic kidney) increase the potential for damage after even minimal force (Onen et al., 2002).

Pathophysiology

Blunt abdominal trauma can compress the renal unit against skeletal structures (i.e., ribs or vertebrae), rupturing its surrounding renal capsule or causing a subcapsular hematoma. In situations such as a bicycle–automobile accident, the child's increased kidney motility can create an acceleration–deceleration injury, which can shear or thrombose the vascular attachment site or can disrupt the UPJ. Penetrating forces, such as a bullet, a knife, or a rib, can cause injury by puncturing or shattering a renal segment. Iatrogenic injuries can occur during invasive procedures such as biopsy, tube placement, or stone manipulation.

Most children who sustain renal trauma heal completely, with little or no residual negative sequelae. The child's long-term prognosis is more closely dependent on the severity of other wounds (Broghammer et al., 2006).

Assessment

Assess any child who sustains a compressing, penetrating, or blunt wound to the abdomen, chest, flank, or spine for renal trauma. Hematuria may be gross or microscopic, but is not always diagnostic of renal trauma. Carefully evaluate the liver and spleen, additional potential sources of hematuria. Other indications of renal trauma include tenderness or pain to the flank or upper abdomen, ecchymosis of the trunk, palpable abdominal mass, nausea and vomiting, and hypotension. Elevated BUN and creatinine, oliguria, and anuria that accompany a history of trauma are also indications of severe renal injury.

Diagnosis of renal trauma is best determined by computed tomographic scan, which provides detailed views highlighting organ involvement (Lee et al., 2007b). Renal injury is classified based on extent of injury: grade I, contusion or subcapsular hematoma; grade II, shallow cortical laceration or confined perirenal hematoma; grade III, deep cortical injury without extension into the medulla; grade IV, laceration extending into the medulla and

collection system or a vascular injury; grade V, shattered kidney or avulsion of the renal hilum, which devascularizes the kidney (Moore et al., 1989). This classification system has useful predictive value for management, need for surgical intervention, and follow-up care.

Interdisciplinary Interventions

Emergency care and stabilization is the first priority for the child with multiorgan trauma. After this goal is accomplished, results of the renal computed tomographic scan direct management of this injury. Reattachment of renal vessels or the ureter, evacuation of blood clots, and closure of renal lacerations are surgical goals for major injuries that involve the collecting system or major blood vessels and branches with hemodynamic instability.

Conservative treatment, the management of choice (Buckley & McAninch, 2006), necessitates bed rest. The child is hospitalized, and fluids are increased by IV therapy or by mouth if tolerated. Monitor urine for volume and degree of hematuria, and vital signs for indications of hemorrhage and shock. Fever can be treated with increased fluids and antipyretics. Control discomfort by implementing pain interventions such as medications, positioning the child to keep pressure off the affected site, and applying ice packs to the affected area. Diversional activities are extremely important during this phase, because resolution of gross hematuria may require confinement of a week or longer. The healing progress is monitored by computed tomographic scans, and hospital discharge is considered when gross hematuria fades. Out-patient follow-up with activity restrictions continues until microscopic hematuria disappears.

When conservative treatment is chosen, monitor the child for the following complications: infection, persistent or recurring bleeding, perirenal bleeding or hematuria, urinary leakage or obstruction, or renal necrosis. Be alert for changes in vital signs, decreased urine output, increasing level of hematuria, or increased flank or abdominal pain, all of which are clues to potential problems.

Community Care

At discharge from the hospital, review with the parents the need for long-term follow-up. Late complications include hydronephrosis, hypertension, renal atrophy, or arteriovenous fistula (AVF) or aneurysm, conditions that generally develop slowly and silently. Blood pressure monitoring should occur periodically during the ensuing year to monitor for hypertension. For the child who underwent a nephrectomy or who has a severely compromised residual kidney, restriction from contact sports may be prudent as well as legally mandated, although review of the evidence demonstrates that cycling causes more than three times more kidney injuries than football and that such restriction may be unwarranted (Grinsell et al., 2006). Focus child and family counseling around acceptable low-impact sports and help plan the child's physical education program at school, in daycare, or in extracurricular sports settings.

The Child With Altered Musculoskeletal Status

Case History

Remember the Whitworth family and Cory, who we introduced in Chapter 6 and featured in Chapter 11? Cory has several older brothers: Ken, Collin, Chris, and Chase, the fourth brother. Cory's scoliosis was diagnosed by radiograph obtained as a component of his presurgical assessment. Cory is now in kindergarten and is receiving no treatment for his scoliosis. He has a strong family history of scoliosis; his mother and his brother Chase also have scoliosis. Chase's scoliosis was diagnosed when he was 13 and in the seventh grade. At first, there were no interventions and he saw the physician every 6 months. Then his back began to hurt anytime he had to sit for a length of time, such as going to a movie and in school. Now he is in the eighth grade and growing rapidly. He has a brace, which was made for him and which he wears at home and at night, but he does not have to wear it to school. Chase

has had his brace for almost a year and he hates it. It is uncomfortable, he has trouble falling asleep in it, and he sweats in it. It is embarrassing to wear to anyone's house if he is sleeping over with friends. Chase often removes his brace in the middle of the night.

Chase's older brothers enjoy teasing and tormenting him. Collin, a very athletic senior in high school, was taunting him when Chase lost his temper and punched his brother. Collin turned so that the punch landed on his shoulder. Pain shot up through Chase's fist. He could not clench and open his fist. When the pain would not subside and his hand began to swell, Chase had to tell his mother that he might have broken a bone in his hand from hitting his brother. His mother took him to the emergency department, where radiograph verified that he had broken the fifth metacarpal, often referred to as a *boxer's fracture*. A cast was placed on his right hand.

CHAPTER OBJECTIVES

1. Recognize clinical signs and symptoms that would indicate a musculoskeletal disorder or injury.
2. State the interdisciplinary interventions that are commonly used for each musculoskeletal disorder or injury.
3. Explain nursing care interventions to promote healing and prevent further injury and skin breakdown in the child receiving treatment for a musculoskeletal disorder or injury.
4. Provide family education regarding home care, activity, and dietary modifications for the child with a musculoskeletal disorder or injury.
5. Describe measures to protect children from musculoskeletal injury.

See [thePoint](#) for a list of Key Terms.

The musculoskeletal system provides the framework for the human body. The symmetry of muscle and bone propelling a body through space is apparent in elite athletes. Not as visible to the naked eye is the force it takes for a child to walk across a room for the first time. Bone is resilient and, particularly in children, has a remarkable ability to remodel itself.

This chapter focuses on various congenital and hereditary disorders that alter this balance. It also explores trauma, infection, sports injuries, and growth-related disorders specific to pediatrics.

DEVELOPMENTAL AND BIOLOGIC VARIANCES

Many anatomic and physiologic differences exist between the musculoskeletal systems of children and those of adults. Just as children should not be treated as “little adults,” children’s bones and muscles cannot be treated like adult bones and muscles (Fig. 20–1). Differences also occur throughout the various stages of childhood. These variances affect both the types of musculoskeletal illnesses seen in children and the treatments used.

Bones

Anatomically, much of the skeleton in an infant or young child consists of preosseous cartilage and growth plates called **physes**. The child’s bones are more flexible, have a higher porosity, and have a lower mineral count. The osteogenic **periosteum** is thick and strong, producing **callus** more rapidly and in greater amounts than in adults. Because of these structural differences, a child’s bone absorbs more energy before breaking, and may even bow rather than break (fracture) when trauma occurs. When fractures do occur, the thick periosteum is likely to remain intact. Therefore, femoral fractures in nonambulating infants, particularly spiral fractures, are believed to be highly specific for inflicted injury.

Alert! A child younger than age 1 who presents with a fracture should be evaluated for possible physical abuse or an underlying musculoskeletal disorder that would cause spontaneous bone injury.

The young bone can bend to a 45-degree angle and then straighten when the bending force is removed. This flexibility accounts, in part, for the high incidence of greenstick fractures seen in young children. As the child matures, the type of fracture reflects the porosity and strength of the affected bone.

Young children have an active growth area at each end of the long bones (humerus, radius–ulna, femur, and tibia–fibula) known as **physeal** or **epiphyseal plates**. Longitudinal growth of the long bones takes place through a process known as *endochondral ossification*. The epiphyses at the ends of each bone are cartilaginous in infants and become more ossified with time.

caREminder

The calcium deposits in bones make them appear white in radiographs. Cartilage, like many soft tissues, is not visible on radiographs. Therefore, because of the cartilaginous nature of their skeletal systems, fractures may be difficult to detect in young children.

Bones in infants not yet completely ossified, thus increased amounts of cartilage; bones fully ossified in the teen years.

Ligamentous laxity in infant girls, due to maternal hormones, (possibly accounting for a higher incidence of DDH in females).

Toddlers have immature gait until age 3 thus trip and fall more easily than adults.

Toddlers’ knees closer to their ankles, making torsional problems more obvious, likely turning the foot inward.

Bone age of a child is predicted by a radiograph of the left wrist.

Bowing of the legs common under the age of 2 years, usually straightens by itself.

Knock-knee common between the ages of 2 and 7 years.

Flat feet normal variance in children; by age 2–3 most have formed normal foot arch.

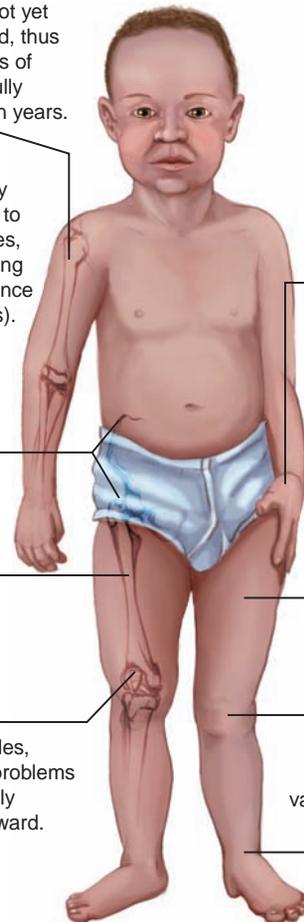

FIGURE 20–1. Developmental and biologic variances in the musculoskeletal system.

The process of converting cartilage to bone continues until skeletal maturity is completed during adolescence. At that time, increasing levels of androgenic hormones produced during puberty cause the growth plates to gradually stop functioning. Alterations in the growth of a child's bones can occur as a result of trauma, nutritional deficits, metabolic disorders, and soft-tissue disorders. The epiphyseal plate is an area of vulnerability and structural weakness in the bone. The physes are not as strong as metaphyseal or diaphyseal bone (mature calcified bone). Ligaments frequently insert into the epiphyses. Thus, traumatic forces that are applied to an extremity may be transferred to the physes, causing injury. Trauma to the growth plate can result in complete or partial closure. Consequently, angular deformities or shortening of the bone can occur, depending on the physes involved and the amount of remaining growth.

When a child injures a bone, healing follows the same processes as in adult bone. In a child, however, the thick periosteum has an abundant blood and nutrient supply. The metabolically active periosteum, combined with the child's growth potential, creates a more rapid healing process in the child. During adolescence and with further skeletal maturity, the rate of healing slows to that of the adult.

Remodeling is the process by which correction of the fracture site occurs through a combination of periosteal reabsorption and new bone formation. Factors that affect remodeling include the child's age, proximity of the fracture to a joint, and relation of the angular deformity to the plane of the joint axis of motion. If the child is young, the fracture occurs adjacent to a physes, and the deformity is in the plane of motion; therefore, the remodeling potential is great. Thus, for certain pediatric fractures, **reduction**—restoring proper anatomic alignment—is not necessary.

Children often outgrow many of the abnormalities in structure seen in the young, immature skeleton. For instance, in utero positioning can cause physiologic alterations in the child's musculoskeletal status that may take up to 4 years to completely resolve. Normal newborns have 20- to 30-degree hip and knee contractures, which usually resolve by age 4 to 6 months. The infant frequently has inward rotation of the lower leg, creating a bowed appearance in which the feet may be turned slightly inward. This bowed appearance results from the legs and feet being tucked close to the body while the fetus is developing in the uterus. Metatarsus adductus (intoeing or pigeon-toed) is a common finding in infants and toddlers. For some children, medical management is used to correct the malformation if it does not spontaneously resolve as the child's bones and muscles grow.

At birth, the child's spine has a C-shaped appearance. Spinal curvature undergoes several changes as the child gains the ability first to hold the head erect, then sit, and finally stand and bear weight. The child's weak abdominal musculature contributes to a "pot-bellied" or hyperlordosis appearance that is common in young toddlers.

Muscles

Voluntary muscle control changes as the child's overall development proceeds in a cephalocaudal fashion. The primary protective reflexes seen in the infant (e.g.,

rooting, palmar grasp, stepping) are replaced by the purposeful movements associated with an intact, growing nervous system and an increasing muscle mass. The infant's muscles account for only 25% of total body weight, whereas they account for 40% to 45% in an adult. Muscle mass increases with use and as innervation proceeds. In children with cerebral palsy, or other conditions in which connections between nerve fibers and muscle fibers are abnormal, muscle development is abnormal. Muscle atrophy and contractures are common.

During adolescence, muscle growth is influenced by hormonal changes, primarily the increased production of androgenic hormones. Higher levels of androgen and testosterone are partly responsible for more extensive muscle growth in males than in females. Androgen excess, as seen in young athletes taking anabolic steroids, can accelerate muscle development and skeletal maturation. This practice can result in short stature, interfere with normal testosterone levels, and impair spermatozoa production.

The incidence of sports injuries increases dramatically in adolescents. The young child has resilient soft tissue, so dislocations and sprains are unusual occurrences. However, an adolescent's increased participation in athletics increases the opportunity for fractures, dislocations, and ligamentous tears. In addition, rapid bone and muscle growth may contribute to the appearance of "clumsy" and awkward motions of the adolescent who is trying to adjust to new body dimensions. These factors, combined with the risk-taking attitude of many adolescents, can lead to a higher rate of personal injury.

ASSESSMENT OF THE CHILD WITH ALTERED MUSCULOSKELETAL STATUS

Assessment is based on a focused health history, beginning with the birth of the child to his or her presenting complaint, and physical assessment aided by diagnostic imaging.

Focused Health History

QUESTION: Referring to the case study, what are the aspects of the focused health history that reveal the most pertinent information related to Chase's scoliosis and the most pertinent information for the metacarpal fracture?

Assessment of the musculoskeletal system begins with a history of the child's past health concerns from the prenatal period to the present (Focused Health History 20–1). Start with a history of the birth and delivery. The type of delivery (vaginal or cesarean) and the condition of the infant at birth, including Apgar score, will aid in identifying potential orthopedic disorders. Certain orthopedic problems are congenital (e.g., polydactyly and limb deformities), developing in utero as the fetus matures.

FOCUSED HEALTH HISTORY 20–1

The Child With Altered Musculoskeletal Status*

Current history	<p>Reports of musculoskeletal or neuromuscular pain including onset, what makes it better or worse, does it interfere with sleep</p> <p>Noticeable deformity</p> <p>Stiffness or swelling of a joint or extremity</p> <p>Gait changes (e.g., limping)</p> <p>Recent accident or injury, including description of event (e.g., speed of the car or bicycle), and any report of a snapping sensation felt or heard before or after the injury or fall</p>
Past medical history	<p>Prenatal/Neonatal History</p> <p>Maternal exposure to teratogens, infections, medications, or illegal drugs or alcohol</p> <p>Type of delivery (vaginal or cesarean) and complications</p> <p>Positioning of the child in utero, presentation (e.g., cephalic, breech)</p> <p>Neonatal history (e.g., Apgar scores, periods of anoxia)</p> <p>Previous Health Challenges</p> <p>Any chronic conditions or congenital anomalies</p> <p>History of surgery, hospitalizations, fractures, or bone and joint infections</p> <p>History of hyperactivity or attention deficit disorder</p> <p>Childhood Illnesses</p> <p>Polio</p> <p>Tuberculosis</p> <p>Conditions that can affect the spine</p> <p>Immunizations</p> <p>Status of current immunizations, especially polio and <i>Haemophilus influenzae</i> type b (Hib)</p> <p>Date of last tetanus shot</p> <p>Allergies</p> <p>Medications</p> <p>Latex, especially in children with myelomeningocele or with indwelling shunts</p> <p>Current Medications</p> <p>Medications that may affect bone density, wound healing, or bleeding time</p>
Nutritional assessment	<p>Use of medications for calcium deficiency or rickets</p> <p>Recent weight change or decreased appetite</p> <p>Use of vitamin supplements</p> <p>Intake of calcium-containing foods</p>
Family medical history	<p>History of developmental dislocated hip, clubfoot, or other skeletal or neurologic disorders</p>
Social and environmental history	<p>Any exposure to unsafe physical or structural settings</p> <p>Consistent, proper use of car seat</p> <p>Use of safety gear with activities (e.g., helmet with bicycling; wrist supports, knee pads, and elbow pads when skateboarding or roller blading)</p> <p>Child's interaction with friends; risk taker; history of thrill-seeking behavior</p> <p>Cultural practices influencing musculoskeletal development (e.g., use of papoose board)</p>

(Continued)

FOCUSED HEALTH HISTORY 20–1

The Child With Altered Musculoskeletal Status* (Continued)

Growth and development	Physical milestones First time for crawling, walking, running Previously achieved developmental milestones that the child no longer is able to accomplish Developmental milestones School grade for child Child's participation in age-appropriate activities Habits Activities when not in school Games child likes to play Usual bedtime; usual awakening time Involvement in sports; number of hours per week of practice or competition
------------------------	---

*This history is focused on the musculoskeletal system. See Chapter 8 for a comprehensive format.

Orthopedic injuries (e.g., a brachial plexus injury or a fractured clavicle) may occur during the birthing process. For example, breech delivery has been highly associated with the diagnosis of developmental dysplasia of the hip (DDH) (Gelfer & Kennedy, 2008). Other orthopedic disorders may be noted only as the child grows or may be acquired as a complication of another primary illness such as polio, tetanus, or an infection in a bone.

Note whether the child has reached appropriate developmental milestones (see Chapters 4–7). Primitive reflexes that persist longer than 3 months of age may indicate a fixed motor–brain defect. In the older infant or child, missed milestones may be the first clue that a child has a musculoskeletal disorder such as cerebral palsy or some other degenerative disease.

Explore the family history for any hereditary disorders. The presence of scoliosis, clubfoot, hip or skeletal dysplasia, or neuromuscular disorders in family members may help in diagnosing genetically linked orthopedic disorders.

Alert! Children who have had repeated exposures to latex during hospitalizations and surgery are at higher risk than others for latex allergies. Investigate the possibility of a latex allergy in all children with a suspected musculoskeletal disorder, especially in those who have had surgical procedures.

Obtain a thorough history of the current problem, including the onset and duration of symptoms, extent of the disability, and any home remedies or medical treatments that already have been used. Common concerns include pain, swelling, deformity, clumsiness, weakness, stiffness, and limitation of movement (Tradition or Science 20–1).

ANSWER: The strong family history, with Chase's mother and brother both having scoliosis, is pertinent information. So is the information that Chase's back is uncomfortable when he sits for any length of time. Because he was involved in an acute incident, the description of the incident and the physical symptoms are most pertinent.

TRADITION OR SCIENCE 20–1

Do adolescents really experience “growing pains?”

EVIDENCE-BASED PRACTICE

Growing pains, first identified in 1823, are experienced by an estimated 4% to 34% of young adolescents. Criteria for diagnosis include limb pain of at least 3 months' duration, intermittent pain with symptom-free intervals of days or months, pain occurring bilaterally not related to joints, pain severe enough to interfere with regular activities, and normal physical examination and laboratory findings (Baxter & Dulberg, 1988; Evans & Scutter, 2004). The cause of growing pains remains unclear; however, psychosocial factors may be indicated. A pronated (or flat) foot posture is not correlated to growing pains (Evans & Scutter, 2007). Headaches and abdominal pains often coexist in adolescents with growing pains. Nocturnal bone growth is related to growing pains (Noonan et al., 2004). Growing pains are physically benign, with resolution occurring within 1 to 2 years. Treatment interventions include massage, heat application, and use of nonsteroidal anti-inflammatory medications. Further research is indicated to explore the factors that may contribute to this condition (Kim, 2003, Noonan et al., 2004).

FOCUSED PHYSICAL ASSESSMENT 20–1

Musculoskeletal System

Assessment Parameter	Alterations/Clinical Significance
General appearance	<p>Observe child undressed except for diapers or underclothes</p> <p>Level of irritability, fever, pain may indicate general state of well-being</p> <p>Café-au-lait spots suggest neurofibromatosis</p> <p>Maculopapular rash may indicate juvenile rheumatoid arthritis (JRA)</p>
Musculoskeletal system	<p>Gait</p> <ul style="list-style-type: none"> • Observe walking, sitting, climbing up on the examination table • Difficulty running, waddling gait, frequent falls, using hand to walk up legs (Gowers' sign) may suggest muscular dystrophies • Limp: unequal leg lengths, pain, muscle or joint weakness or injury • Infancy and early childhood: septic arthritis, osteomyelitis, DDH, child abuse or neuromuscular disease • Middle childhood: septic arthritis, osteomyelitis, Legg-Calvé-Perthes, juvenile rheumatoid arthritis, cancer, sickle cell crisis, trauma or neuromuscular disease • Adolescence: fractures, tumor, slipped capital femoral epiphysis osteomyelitis, Osgood-Schlatter, scoliosis, tarsal condition, JRA, trauma <p>Neck</p> <ul style="list-style-type: none"> • Observe for alignment and ROM • Tilt of head to one side with chin pointing to opposite side in a newborn may indicate torticollis <p>Shoulders and upper extremities</p> <ul style="list-style-type: none"> • Decreased movement or ROM, or guarding, may indicate clavicular fracture, nursemaid's elbow; pain or tenderness at the elbow or wrists may be caused by inflammation, infection, or fracture • In the newborn or very young child: pseudo-paralysis of arm on affected side may indicate clavicular fracture or brachial plexus injury • Infant or child does not voluntarily use arm: look for radial head subluxation, nursemaid's elbow, or congenital dislocation • In the older child with history of trauma secondary to fall with the arm outstretched or falling on the shoulder; observe for pain, tenderness, bruising and swelling at the fracture site (clavicle) <p>Wrists and fingers</p> <ul style="list-style-type: none"> • Decreased movement, decreased ROM, or guarding may indicate arthritis, sprain, strain, or infectious process • Decreased sensation or impaired motor function may indicate ulnar, radial, or medial nerve injury or compromise, especially when cast or splint is applied • Amount of swelling usually reflects severity of injury • Tenderness or swelling in wrist or elbow may indicate joint disruption • In the newborn, look for webbing of digits, lack of digits, or duplication of digits • Joint swelling or effusion, limitation of joint motion and tenderness, pain with motion, and increased heat or warmth of joints may indicate JRA <p>Spine</p> <ul style="list-style-type: none"> • Alignment: spinal curvature, rib hump, asymmetric rib cage, tenderness at spinal processes may indicate scoliosis, infection, arthritis, sprain, strain, or neoplasm • Newborn: observe for hairy patches in the sacral area or a dimple in the gluteal fold, may indicate spina bifida occulta • School age, 8 years and older: scoliosis screening at each well-child visit and group screening in the schools • Tingling or decreased sensation in fingers may indicate spinal cord injury (such as that seen in cheerleaders, wrestlers, gymnasts, or those engaging in other sports in which whipping motions, flips, or cervical compression are common) <p>Hips</p> <ul style="list-style-type: none"> • ROM, extra skin fold in groin or buttock area, decreased ROM with adduction may be indication of DDH, septic arthritis, or JRA • Newborn or infant: shortening of femur in flexion (Galeazzi sign), shortening of limb in extension, Ortolani's sign, Barlow's sign may indicate DDH

Focused Physical Assessment

QUESTION: Describe the focused assessment related to Chase's scoliosis. What would be included in the focused assessment related to the metacarpal break in his right hand?

Physical assessment of the musculoskeletal system includes inspection and palpation, range of motion (ROM) evaluation, and neurologic examination (Focused Physical Assessment 20–1). In the newborn, assess ROM of the head (to look for congenital torticollis, a condition in which the head is tilted to one side) and palpate the clavicles for tenderness or lumps, especially if the history shows that delivery was difficult. Assess the hips, with the diaper removed, for dislocation. Examine the limbs for any syndactyly or webbing.

Assess older children unclothed, except for undergarments, to ensure visualization of all aspects of the

musculoskeletal system. Examine younger children while they sit on a parent's lap or move around the examination room. Observe movements such as gait, mobility, arm swing, hand preference, guarding, climbing, and playing. During inspection, note the degree of symmetry of size and configuration between limbs, as well as the child's ability to move them. Unequal growth, paralysis, or spasticity in a limb may be subtle. Note any absence of parts, duplication of parts, or abnormal swelling. Assess ROM of all joints, either passively or actively. To analyze gait, ask the child to walk down a hall or to follow a parent who is walking and note any limp, tiptoeing, or foot drop.

Palpate the limbs to detect any areas of tenderness swelling, masses, crepitus, or warmth. Begin the examination at the most distal joints (the toes) and work up to the hip joint or begin with the fingers and work up to the shoulders. Estimate the size of any bony or soft-tissue masses. Palpate the spine and examine it for any dimples or hairy patches; note the general contour of the spine. Look for hip or shoulder asymmetry.

NURSING INTERVENTIONS 20–1

Neurovascular Assessment

Assessing circulation to an extremity is done frequently for the first 24 hours after a cast has been applied, after surgery has been performed on an extremity, or when nerve injury is suspected. After that time assessment every 4 to 8 hours is sufficient if there is no neurovascular compromise. The categories for assessment include the following

- **Pain**—Ask the child if they have pain in an extremity. Pain is common at the injury site. If the pain is not relieved by narcotics, or pain becomes worse when the finger or toes are flexed the child may have compartment syndrome and the physician should be notified immediately.
- **Sensation**—Determine if the child can feel touch on the extremity. Two-point discrimination is decreased when there is neurovascular compromise.
- **Motion**—Ask the child to move his or her fingers or toes; lack of movement may signal nerve damage.
- **Temperature**—Assess if the extremity for temperature (warm versus cool). Compared to unaffected limb a cool extremity may become warm if a blanket is placed over it and the extremity is elevated. If these actions do not warm the extremity, there is poor circulation.
- **Capillary refill**—Apply brief pressure to the nail beds and note how quickly pinkness returns. Sluggish capillary refill signals poor circulation.
- **Color**—Note the color of the extremity and compare the color of the injured extremity with the other one.
- **Pulse**—Check pulses distal to the injury or cast. This may not be possible if the cast covers the foot or hand. If the pulse is difficult to locate, check it with a Doppler machine and mark it with an “X”.

caREminder

If injury has occurred, examine that area last and be gentle when palpating the injury site.

Perform a neurovascular assessment of the extremities (described in Nursing Interventions 20–1). Compare the affected extremity with the unaffected one for neurovascular status and strength. Extremities should be pink, warm, with strong (+2) pulses. The child should be able to move the extremity and sense pinpoint discrimination. Frequent assessments for changes noted early will aid in identifying potential complications and guiding treatment.

Examine limb ROM to assess hip flexion, contractures or spasm of the extremities, and limitation of motion. Test muscle strength to assess for neuromuscular problems such as poliomyelitis and muscular dystrophy. To assess motor ability, ask the child to bend his or her arm and to push and pull against your hand; then, using his or her foot, ask the child to push down and pull up against your hand. Test superficial and deep tendon reflexes in each extremity.

Observe the child as he or she stands up from a sitting or lying position. If you note abnormal reflexes or muscle weakness, encourage the family to talk to the primary healthcare provider.

ANSWER: Inspection and palpation should be used to assess Chase’s spine. Ask Chase to bend at the waist to determine whether the scapula and posterior iliac crests are symmetric. Palpate along the spine to assess the location of curvature. Inspection, limitations of movement, and gentle palpation should be incorporated into Chase’s assessment of

the metacarpal break in his right hand. Inspect the degree of swelling, comparing right and left. Ask Chase to open and shut his fist and observe the limitations. Gently palpate along the metacarpals for swelling.

Diagnostic Criteria

QUESTION: Which of the described diagnostic tests are most applicable for each of Chase’s musculoskeletal problems?

Blood, joint fluid, and bone analyses are diagnostic tests used to evaluate musculoskeletal alterations. In addition, diagnostic imaging techniques also are very useful (Tests and Procedures 20–1). The sensitivity and specificity of each test may vary with the disease process and the child’s age. A regular radiograph (plain x-ray) is often acquired initially and guides the selection of additional imaging (Fig. 20–2).

Alert! If the child has a history of trauma, maintain cervical spine precautions during diagnostic testing until the physician rules out a cervical spine injury.

ANSWER: For both of Chase’s musculoskeletal problems, a radiograph will confirm the diagnosis. Both problems are related to the bone, not the surrounding soft tissue, and are readily visible on a radiograph.

Tests and Procedures 20–1 Evaluating Musculoskeletal Conditions

Diagnostic Test	Purpose	Findings and Indications	Healthcare Provider Considerations
Complete blood count	Blood sample analysis to evaluate several indicators (e.g., infection, anemia)	Normal range, 6,000 to 11,500/uL Elevated white blood cell count found in presence of infection, septic arthritis, osteomyelitis.	Explain to child and family that this test helps to evaluate conditions that may alter normal ranges of components of the blood.
C-reactive protein (CRP)	Measures a protein in the blood that is released when infection is present	Normal, <1.0 mg/dL Level >0.9 mg/dL may indicate infection, septic arthritis, inflammatory bowel disease, rheumatoid arthritis, or lupus	Explain that CRP level rises as an inflammatory process worsens and falls as healing occurs. Urge the child/family to avoid aspirin, acetaminophen, or ibuprofen before test, because these drugs may lower CRP levels.
Calcium and phosphorus levels	Tests amount of these minerals in blood sample; assists in diagnosis of renal and skeletal diseases	Normal ranges: <ul style="list-style-type: none"> • Calcium, 8.5 to 11 mg • Phosphorus, 3.0 to 4.5 mg/dL Low levels may indicate rickets, malabsorption syndrome, and starvation Increased levels may indicate bone tumor, healing fracture, skeletal disease, high milk intake, bone metastasis of cancer	Explain that the test evaluates the balance of chemicals in the body, specifically calcium and phosphorus. Handle specimen gently, to avoid hemolysis.
Rheumatoid factor (Rh)	Measures the body's autoimmune response to an antigen	Negative, <60 IU/mL May indicate juvenile arthritis, systemic lupus erythematosus	Ensure that specimens are tested as soon as possible or within 72 hours of collection. Keep in mind that gold therapy decreases the Rh titer.
Erythrocyte sedimentation rate (ESR)	Evaluates presence of an inflammatory process; does not assist in revealing the site or cause of inflammatory process	Normal range, 0 to 10 mm/hour Indicates how much inflammation in the body	Keep specimen at room temperature. If the ESR is elevated, anticipate that other diagnostic studies will be completed. If the ESR is elevated and the child is already being treated for a known disease, expect a change or increase in medications or therapy.

Diagnostic Test	Purpose	Findings and Indications	Healthcare Provider Considerations
Blood culture and sensitivity	Diagnoses bacteremia or septicemia; identifies pathogenic microorganisms present in blood and determines their sensitivity to antimicrobial agents	Causative organisms seen with bacteremia or septicemia; positive blood culture in 40% of children with septic arthritis	Use strict aseptic technique to gather specimen. If more than one culture is ordered, the specimens should be drawn separately at no less than 30 minutes apart to rule out the possibility of transient bacteremia. Be aware that antimicrobial therapy given prior to blood collection may result in false-negative findings. Allow a minimum of 24 to 72 hours for culture reports to identify pathogens. Some pathogens, such as fungi and mycobacteria, may take weeks to incubate and provide identifiable growth.
Bone biopsy	Allows microscopic examination of bone tissue; usually performed to diagnose a lesion found by radiograph examination	Normally, no abnormal cells or tissue Abnormalities possibly indicate infection, malignant tissue	Obtain informed consent. Anticipate administering intravenous antibiotics prebiopsy to prevent postoperative infection. Assist in providing conscious sedation and pain medication. Explain that discomfort at the site will persist for several days after the test.
Fluid aspiration from joints	Determines cause and type of joint disorder and effusion; allows for fluid drainage from a joint or to administer local pharmacologic therapy	Increased or abnormal levels possibly indicate noninflammatory abnormalities (e.g., traumatic arthritis), inflammatory abnormalities (e.g., rheumatoid arthritis, systemic lupus erythematosus), septic abnormalities (e.g., septic arthritis), or hemorrhagic abnormalities (e.g., trauma)	Obtain informed consent. Assist in providing local sedation and pain medication. Explain that discomfort may be felt when the needle enters through the synovial membrane into the joint capsule. Apply ice packs for 24 to 36 hours after test to decrease pain and swelling. Apply elastic bandage after test to maintain good joint stability. Observe site for erythema, tenderness, warmth, or exudate.
Arthrography	Uses fiberoptic endoscope to visualize selected joints for injuries or abnormalities; assists in monitoring degenerative processes or joints; aids in	Abnormal findings possibly indicate tears, injury, dislocation, fracture, subluxation, or synovial abnormalities	Obtain informed consent. Check for allergies and monitor for reaction to contrast medium. Assist in providing local sedation and pain medication. Explain that discomfort may be felt when the needle

(Continued)

Tests and Procedures 20–1 Evaluating Musculoskeletal Conditions (Continued)

Diagnostic Test	Purpose	Findings and Indications	Healthcare Provider Considerations
	evaluating effects of medical or surgical interventions; may also be used to perform minor surgical repair		enters through the joint cavity and from pressure of the tourniquet. Administer intravenous antibiotic if ordered, to prevent infection of the bone after manipulation. Assess joint areas for rashes or sign of infection after procedure.
Bone scan	Detects early bone disease from cancer and metastasis of cancer to the bone (highly sensitive); measures the response of bone tissue to therapeutic interventions	No differentiation between benign and malignant processes; directs attention to areas of the skeleton that may need further study	Obtain informed consent. Explain that there is some radiation exposure to entire body. A large scanning camera is positioned over the child and moves slowly above and around the body, taking 1 to 3 hours for completion of the scanning. Determine whether child is claustrophobic or unable to remain still for long periods of time. Administer sedation, if ordered. Inform child and parents that test takes about 4 hours to complete. Ensure intravenous access necessary to administer contrast agent. Inform child and parents that contrast medium takes 2 to 3 hours to be absorbed in the bone tissue prior to test. Have child void prior to test; a distended bladder will decrease visibility of the pubic bone. Encourage fluids after test to facilitate renal clearance of contrast agent.
Computed tomography	Evaluates and diagnoses a large number of clinical conditions of the musculoskeletal system with radiographs taken at multiple angles to provide cross-sectional anatomic display	Abnormalities visualized include tumors, cancer, lesions, abscesses, fluid collection, and inflammation	Obtain informed consent. Assess for allergies to contrast agent, which may be used; observe for reaction to contrast media. Determine whether child is claustrophobic or unable to remain still. Administer sedation if ordered.

Diagnostic Test	Purpose	Findings and Indications	Healthcare Provider Considerations
Magnetic resonance imaging	Detects structural, circulatory, and metabolic abnormalities in the body; visualizes hard and soft tissue, and bone marrow	Abnormal findings include tumors, edema, hemorrhage, abscesses, skeletal abnormalities, intervertebral disk abnormalities, spinal cord compression, and muscular disease	Obtain informed consent. Determine whether child is claustrophobic or unable to remain still. Administer sedation if ordered. Remove all metal objects from child's body. If parents allowed to stay with child during procedure, ensure they remove all metal objects from their bodies. Explain to child that machine makes various noises as the radio waves are turned on and off. Provide child with earplugs if necessary.
Plain film radiograph	Examines bones to evaluate child's pain or discomfort and confirm suspected injury or disease; provides a two-dimensional view; visualizes most fractures well; does not visualize cartilage and other soft tissues well	Abnormalities may indicate fracture, osteomyelitis, growth plate abnormalities, injury, cancer, infection, nutritional alterations	Keep in mind that radiographs are an easily available and inexpensive testing method. Inform child and parents that the child will need to be positioned properly.
Ultrasound	Aids in verifying other diagnostic tests to verify or confirm presence of musculoskeletal abnormality; provides good view of soft-tissue masses and cysts	Abnormalities may indicate a mass, inflammation, abscess, or tumor	Tell the child and parents that no sedation is needed. Explain that the test is painless. Explain that an ultrasound lubricant will be applied to the area being viewed. Remove the lubricant after test is completed.

TREATMENT MODALITIES

QUESTION: Of the following treatment modalities, which is traditionally used for scoliosis and which for fracture? Compare the nursing care associated with each treatment modality.

Various treatment modalities are used to manage musculoskeletal alterations. These may include heat and cold applications, brace and splint applications, serial manipulation, casting, traction, external fixation, and continuous passive motion (CPM). Surgical intervention is also common. To implement or support these healthcare interventions, be sure to understand their principles and mechanics. Also, allow the child to be involved in his or

her own care as much as possible. For a child too young to manage self-care, encourage other family members or caregivers to manage or assist. By involving the family, the healthcare team can achieve better cooperation from the child and family, and improve adherence to treatment (Developmental Considerations 20–1).

Cold and Heat Applications

Simple application of cold and heat has long been used as therapy for soft-tissue injuries. In some cases, both may be used.

Cold Application

By decreasing tissue temperature, cold can cause vasoconstriction; diminish pain, metabolism, and muscle

FIGURE 20–2. A radiograph is a noninvasive diagnostic procedure that most children will complete in a cooperative manner.

spasm; minimize the inflammatory process; and aid recovery after soft-tissue trauma. After injury, ice is primarily used to reduce metabolism, thereby minimizing the degree of tissue damage. During rehabilitation, it is used primarily to relieve pain. Ice is often used in combination with compression and elevation. Application of ice is recommended for the first 24 to 48 hours after injury to reduce edema. It is usually applied as crushed ice in a bag, applied over a thin layer of cloth, or by immersing the injured part in cool water (55° F) for 20 minutes every 2 to 3 hours (Bleakley & McDonough, 2004).

Cold therapy is not recommended for persons with hypersensitivity to cold or with impaired circulation. Assess the child's skin for changes in color, integrity, sensation or any other signs of injury before and after cold application. After the treatment, dry the skin well.

KidKare ■ Gel packs cool skin faster than an ice bag and should be applied for no more than 10 minutes. Ice can be applied for 20 minutes, but should also be monitored carefully to prevent skin and tissue damage.

Heat Application

Heat is generally used for subacute or chronic conditions to warm muscle groups, cause vasodilation, relieve inflammation, and relieve pain from muscle stiffness or spasm. Application of heat allows the muscles to stretch further and increases the circulation of oxygenated blood to muscles and joints.

Heat therapy can be used in a dry or wet form. Dry heat is provided by means of infrared lamps, heating pads, electric heating blankets, and commercial hot packs. Tub baths, immersion in a hot tub, compresses, and hot water bottles are sources of wet heat. Do not apply heat for more than 20 to 30 minutes at a time. Do not place the extremity on top of the heat source; rather, place the heat source on top of the extremity. After an hour of heat therapy, capillary vasoconstriction occurs as a secondary effect, making the therapy more destructive than beneficial. For this reason, do not reapply heat sooner than 1 hour after the initial application.

KidKare ■ When using electrical sources of heat, the caregiver should not make a point of showing the child how plugging in the apparatus makes the light come on or the dial glow. A young child is likely to consider this a game and may want to play with the plug after the caregiver leaves the room.

During heat therapy, evaluate the skin for changes in color, integrity, and sensation. Monitor the child for profuse sweating or an increase in respirations or pulse rate, which indicate the need to immediately stop the therapy. Do not allow electric sources of heat to become wet or let the child go to bed with a heating pad in place. Heat lamps are not recommended for home use with children because of the risk of burns.

caREminder

The child should never be left unattended during a tub bath. A child who is feeling weak, ill, or lethargic may not be able to support him- or herself adequately in the tub.

Braces and Splints

Braces and splints are devices made from a solid material, such as molded plastic. Straps (Velcro, or leather with buckles) hold the splint or brace in place. The device is either custom made for the child by a trained orthotist or therapist, or is a standard-sized device that is adjusted to fit the child. The purpose of a splint or brace is to immobilize a body part to provide support for weak limbs or to prevent deformities by maintaining optimal functional position of the joints.

A brace or splint can be removed for bathing, sleeping, or exercise, in contrast to a cast. The amount of time each day that the child must wear the brace or splint is dictated by the type of device and the medical reasons for the treatment. For instance, a child with scoliosis may need to use a Milwaukee or Boston brace. These plastic braces must be worn between 16 and 23 hours a day. For some children, the brace is removed only for bathing. The Pavlik harness is a cloth brace used in children with DDH. This brace must be worn at all times for 4 to 6 weeks. A wrist or knee splint may be applied to immobilize an area

DEVELOPMENTAL CONSIDERATIONS 20-1

Age-Appropriate Self-Care Activities for the Child With a Musculoskeletal Condition

Infancy

Parents or caregivers provide all self-care needs. Diversionary activities may be needed to prevent infants from pulling at straps, pins, and wires. Child indicates pain and discomfort in a manner recognizable to primary caregivers.

Early Childhood

Child wears or uses supportive devices without disturbing the integrity and safety of the device. Child learns to be mobile with use of assistive devices as needed and as physically capable. Child takes medications with assistance. Child indicates pain and discomfort in manner recognizable to primary caregivers.

Middle Childhood

Child uses walker, crutches, or wheelchair to assist in mobility. Child verbalizes feelings of pain and discomfort related to condition. Child takes medications as instructed. Child selects biobehavioral methods to manage pain and discomfort.

Child performs pin care. Child selects foods to eat that provide a well-balanced diet. Child wears clothes that are easy to put on and take off given the restrictions of his or her condition.

Adolescence

Child uses walker, crutches, or wheelchair to assist in mobility. Child administers own medications. Child verbalizes feelings of pain and discomfort related to condition, and independently implements or seeks assistance in implementing biobehavioral methods to manage pain and discomfort. Child selects activities that enhance mobility and do not cause additional pain or discomfort. Child performs pin care. Child selects foods to eat that provide a well-balanced diet. Child monitors diet to prevent weight gain. Child selects clothes that enhance body image and self-esteem.

during the acute phase of an arthritic condition or after an athletic injury. In these cases, the child may select not to wear the splint during periods of inactivity.

Priorities for care of a child with a splint or brace focuses on ensuring that the device is fitted and used correctly to achieve its maximal effects and on maintaining skin integrity. If the device does not fit properly, the skin can become irritated and can break down. Wearing cotton clothing underneath the brace or splint can minimize skin irritation. Daily baths or skin care followed by thorough drying of the skin helps to maintain cleanliness, stimulate the skin, and minimize skin irritation. Give the child or the child's parents verbal and written instructions regarding how and when to apply the device, how it should look on the child, what activities should be allowed and prohibited during the treatment, and how to care for and clean the device.

The child who wears a splint or brace may feel self-conscious about his or her physical appearance. This feeling may negatively affect adjustment and adherence to the treatment regimen. Encourage the child to participate in all care decisions surrounding brace or splint wear. Assisting the child to select appropriate and attractive clothes to wear over the brace is helpful. Encourage the child to verbalize feelings associated with brace or

splint wear. Direct the child toward positive coping behaviors and remind him or her of the positive eventual outcomes of therapy.

Serial Manipulation

In serial manipulation, passive ROM exercises are used to manipulate a joint or muscle group. The purpose of serial manipulation is to restore joint alignment or to maintain functional mobility of a joint. The passive movements of the joint should not cause pain. An example is passive manipulation during diaper changes, used for the child with metatarsus adductus to attempt to straighten the child's forefoot. Serial manipulation may also be used in conjunction with other techniques such as casting. For example, the child with clubfoot may use serial manipulation techniques to stretch the foot by hand, and then use a cast to hold the position of the foot in place. The casts serve to help stretch the soft tissues of the foot. Every few weeks, the cast is removed, serial manipulation is again performed and a new cast is placed on the foot.

Serial manipulation of a joint or muscle group is not recommended for all musculoskeletal disorders. The treatment is usually taught to the family by a physical

therapist. Parents should be aware that the treatment might not be successful, and that other therapies, such as a brace or casting, might be required.

Casting

Casts hold fractured extremities in alignment, prevent or reduce contractures, and provide postoperative immobilization. Casts, made from either plaster or synthetic materials, can be made to fit an extremity or the trunk. The location of the musculoskeletal problem and the degree of immobility needed to achieve healing or correction determine the type of cast to be applied (Fig. 20–3; see also [thePoint](#) for Procedures: Cast Care).

Casts are generally applied and removed in an acute care setting or specialized outpatient clinic by a trained physician or orthopedic technician. Unless the child has an illness or injury that requires extensive hospitalization, after cast application the child promptly returns home, where cast care must be managed by the child and family (see [thePoint](#) for Supplemental Information: Teaching Information for the Child with a Cast).

KidKare ■ Fiberglass casts are available in a variety of colors and designs, such as neon, stripes, and camouflage. Ask the child or parents what design they prefer before the cast is placed.

Neurovascular compromise, skin breakdown, and misalignment of a fracture can occur if the cast is not properly fitted. Careful assessment aids in prompt recognition and treatment of these complications. Family members need to learn neurovascular assessment and cast maintenance techniques; other aspects of home care include maintaining good nutrition and modifying activities as needed to promote the healing process.

ANSWER: The text identifies braces as a common treatment modality for scoliosis and casting as a treatment modality for fractures. Both of these treatments immobilize the child and have the potential to apply pressure to the skin and tissue. Critical nursing interventions for both treatment modalities include assessment of perfusion and skin integrity to identify areas of potential skin breakdown.

Traction

Traction is defined as the application of a pulling force to an injured or diseased part of the body or extremity whereas countertraction pulls in the opposite direction (see [thePoint](#) for Procedures: Traction Care). Traction is used for four primary purposes:

1. To reduce or prevent spasm or contracture of muscles and relieve pain
2. To immobilize a part of the body or a joint to promote rest and healing of bones and soft tissue
3. To reduce a subluxation, dislocation, or fracture and maintain alignment
4. To prevent, lessen, or correct deformities

Traction and suspension are required to override the natural muscle tension and to restore alignment. Several basic traction principles must be maintained to enable the traction to work effectively. First, *countertraction* is provided as sandbags, metal weights, or the child's body weight. Second, the prescribed *line of pull* is maintained. This principle requires a child to lie still in one position—a challenging task. Third, the traction is *continuously applied*. Fourth, there must be *prevention or reduction of friction* that interferes with the effectiveness of the traction.

Three types of traction are used: manual, skin, and skeletal. *Manual traction* uses force applied to the bones by a physician, nurse, or technician to keep them in

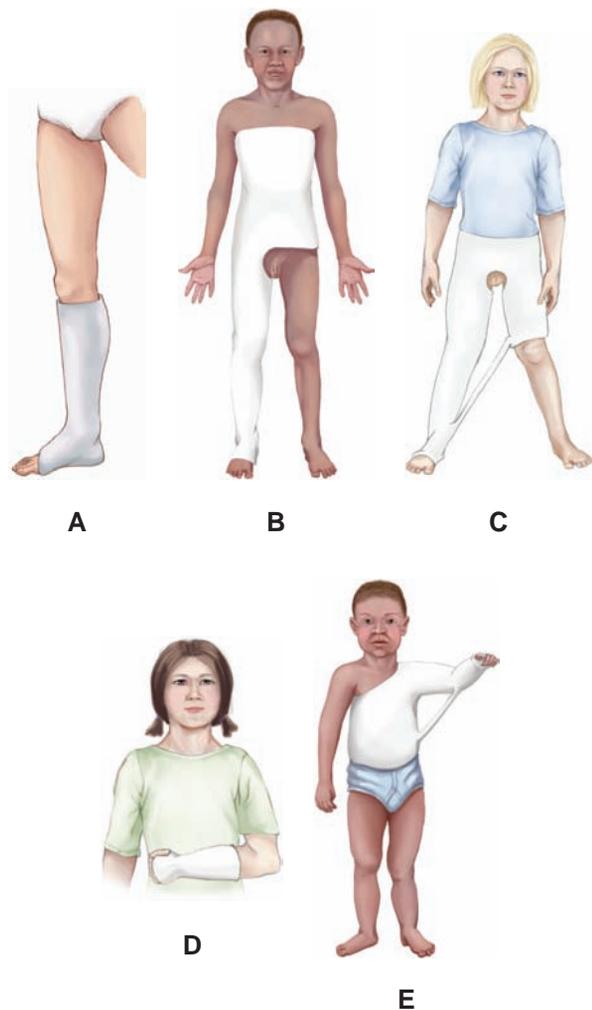

FIGURE 20–3. Types of casts. (A) Short leg cast. (B) Unilateral hip spica cast. (C) One and one-half hip spica cast. (D) Short arm cast. (E). Shoulder spica cast.

alignment. Manual traction is used in cases of stable fractures or dislocations to reduce the bone or realign joints before splinting or casting (see [thePoint](#) for Supplemental Information: Types of Skin Traction and Types of Skeletal Traction).

Skin traction is applied to the skin using skin adherents, Ace wraps, commercial traction tapes, or special foam boots, to which the pull is applied (usually a 1- to 5-lb weight for children). Weights applied to skin traction should not exceed 3.5 kg or 8 lb. Intact skin integrity is essential, because this type of traction cannot be applied over an open wound or when the skin is at high risk for impairment. Assessment of neurovascular and motor status is also essential prior to traction application, so that changes from baseline can be noted. Assess neurovascular and motor status at least every 4 hours, or more frequently for children at risk for neurovascular impairment. Skin traction may be intermittently removed by physician order.

Skeletal fracture refers to any traction apparatus where the pull force is applied directly to the skeleton via pins, wires, screws, and/or tongs that are inserted into the appropriate area of bone. Weights applied can be 4.5 kg or 10 lb, up to 11.5 kg or 25 lb. Skeletal traction is beneficial for unstable or fragmented fractures that are not amenable to surgical intervention. Skeletal traction would also be used if there were skin damage associated with the fracture. Skeletal traction carries a risk of pin tract infection and osteomyelitis. Frequent skin and neurovascular assessments are important components of care for a child in skeletal traction, as well as pin site care (Tradition or Science 20–2).

Never remove or add traction weights without specific physician orders. Do not allow weights to touch the floor

or drag on the bed parts; keep weights hanging free (Bowden & Greenberg, 2008).

External Fixation

External fixation uses a system of percutaneous pins, rods, and wires connected to a rigid frame, placed on the outside of the body to hold fractured bones in place while they heal. It is used to treat complex, unstable fractures of both upper and lower extremities. An external fixator can hold the bone fragments much more rigidly than a cast. It is usually left in place for 6 weeks, and continued splinting is required for some time after removal.

An external fixator may also be used to lengthen bones or correct angular or rotational defects. In these cases, the wires, rings, and telescoping rods allow limb lengthening to occur by the process of distraction: two opposing bone ends are separated, and new bone regeneration occurs to fill in the gap.

Care of the child with an external fixator device involves maintaining skin integrity and preventing infection or injury. Skin and neurovascular assessments are needed. Skin care is similar to that for a child in skeletal traction. Pin care must be completed daily to prevent infection. To prevent dryness, lotions can be applied to skin away from the entry sites of pins and wires. Activities in which the fixator might be hit or bumped are restricted during the treatment. In some cases, the child may be able to bear weight on the affected limb.

Teach the child not to pick at or manipulate any of the wires or pins. The child may wear baggy sweatpants or skirts over the device. Velcro can be sewn into the seams of pants to allow them to easily slip over the fixator device.

TRADITION OR SCIENCE 20–2

Should pin care be completed daily and, if so, what cleansing solution should be used?

EVIDENCE-BASED PRACTICE

The National Association of Orthopaedic Nurses completed evidence-based practice guidelines for skeletal pin site care. The guidelines make four specific recommendations:

1. Pins located in areas with considerable soft tissue should be considered at greater risk for infection.
2. At sites with mechanically stable bone–pin interfaces, pin site care should be done on a daily or weekly basis (after the first 48–72 hours).
3. Chlorhexidine 2 mg/mL may be the most effective cleansing solution for pin care.
4. Patients and their families should be taught pin site care before discharge from the hospital. They should be required to demonstrate whatever care must be done and should be provided with written instructions that includes signs and symptoms of infection (Holmes, Brown, & Pin Site Care Expert Panel, 2005).

Surgical Interventions

Pediatric musculoskeletal surgery is performed for two main reasons: (1) to correct a deformity or broken bone and (2) to prevent a deformity. The goal in either case is to enable the child to live a functional life. Surgical interventions aim to restore mechanical balance to the body through bone fusions, bone lengthening or shortenings, muscle realignments or releases, joint reconstruction, or even amputations. Internal fixation is a method to position and support a fractured bone until it is strong enough to bear weight. Materials such as stainless steel or, more recently, cobalt and titanium are used to support the body. These materials are compatible with tissue and rarely cause an allergic reaction. The most common types of internal fixation are wires, plates, rods, pins, nails, and screws.

Nursing care of the postoperative child is discussed in Chapter 11. ROM exercises or restrictions of movement may be necessary to protect the surgical area. For instance, logrolling is used to turn the child who has had a spinal fusion, whereas continuous passive ROM machines may be used on the adolescent who has had knee surgery. Postoperatively, the child is likely to

experience significant pain. The assessment and management of pain in children is discussed in Chapter 10.

Continuous Passive Motion

CPM is a treatment method used to provide early controlled motion after surgery or injury of an upper or lower extremity. Joint motion is provided passively by a device, to diffuse synovial fluid without compromising the integrity of the repaired tissue. The goals of CPM are to decrease edema and pain while maintaining ROM. CPM can be used for elbows, knees, hips, ankles, and fingers. Some are adaptable for use in children.

The physician specifies how many hours the patient must use the device, the ROM (both extension and flexion), and the speed of the cycle. Most devices have a small, handheld keypad that is programmed either by the nurse or physical therapist. The nurse or physical therapist places the patient in the machine with the joint properly aligned. The nurse also monitors patient adherence and skin integrity, and adjusts the settings as ordered. When the CPM machine is used at home, the patient and family must be taught how to properly position the joint in the machine and how to adjust the ROM settings.

Ambulatory Devices

The child may need assistance with ambulation after surgery, injury, or immobilization of a lower extremity. The ambulatory device transfers a portion of the body weight to the arms and provides additional support during walking. The device can also help the child get up from and down to a sitting position. The type of device selected is based on the child's age, overall functional ability, degree of strength in the arms and legs, balance, and ability to maintain an upright position. A physical therapist works with the child and family to choose the most appropriate device, and teaches the child how to use the device correctly and how to best achieve an effective gait pattern.

The types of ambulatory devices that children can use include canes, crutches, and walkers. A *cane* is used to widen the base of support on the side of the affected limb. The cane is held on the same side as the affected leg and is moved in coordination with the affected leg. A regular cane has a single base; a quad cane has a four-pronged base of support. When a cane is used, the affected leg experiences partial weight bearing. Canes are more effective for school-aged and older children who have good gait and upper extremity coordination.

Crutches relieve weight bearing from the affected limb by transferring body weight and gait control to the arms and hands. The muscles of the arms, shoulders, back, and chest are all used during crutch walking. Exercises may be initiated before crutch use to strengthen these muscles. Instruction regarding the position and proper manipulation of the crutches is essential to prevent further injury to the child. To prevent nerve palsy, the top of the crutches should be between two and three finger breadths below the axilla. The position of the crutches during periods of rest and movement is important to

ensure that stability is maintained and gait is not compromised (Fig. 20–4). Gait is described in terms of the number of points in contact with the floor. For instance, a three-point gait occurs when the two crutches and the unaffected limb are touching the floor.

Walkers are useful ambulatory devices for young children and those with limited functional abilities. A walker uses a four-legged base to provide support during ambulation. A parallel stationary walker requires the child to lift and advance the entire walker when ambulating, which may be difficult for the child with more severe musculoskeletal challenges. The rolling walker has two to four wheels attached to the base and merely requires the child to gently push the device to assist in ambulation. This type of walker is less stable, however, especially on wet or slippery surfaces.

Prosthetic Devices

Children with limb deformities and those who have experienced permanent loss of a body part may elect to use a prosthetic device to enhance mobility and body image. Prostheses are individually fitted to the contour of the remaining body part. The prosthetic device can be a completely formed body part such as a hand or foot, or it can be a device with myoelectric controls that enable the child to move and use the extremity.

Experience has indicated that children who have been fitted with prostheses earlier than 4 years of age function better than those fitted at a later age. Fitting an artificial limb within a year after birth or traumatic injury is optimal. Frequent adjustments will be needed for growth,

FIGURE 20–4. Crutches are placed under the child's arms. To avoid shoulder nerve injury, the child should not lean on the crutches. The crutches are placed approximately 1 ft in front of the child, and the child's legs should swing up to, but not beyond, the crutches.

evaluation may be needed every 3 to 4 months, and a new prosthesis may be needed as frequently as every 18 months. Each child's physical condition, aspirations, and life circumstances are reflected in the prosthetic prescription and treatment plan. Management is a team effort, with special attention to effects of growth and changes that characterize childhood. Parental education is extremely important in managing prosthetic training, applying the prosthesis, monitoring skin tolerance, and promoting good maintenance of the prosthetic device to prevent wear and tear.

Prevention of Complications of Immobilization

Conditions that affect a child's muscles, bones, or connective tissues generally lead to immobility. A primary focus of the interdisciplinary team is to prevent formation of contractures, loss of muscle tone, or fixation of joints during immobilization. The immobilized area may be limited to a specific body part, or immobilization may affect every aspect of the child's activities and mobility. Immobility can also be hazardous to the child if the healthcare team and the family do not take measures to prevent systemic complications and disability. Nursing Interventions 20–2 summarizes the hazards of immobility and the interventions to prevent these hazards.

Nutritional Interventions

QUESTION: Chase is a rapidly growing 13-year-old boy with a broken hand and scoliosis. How can he meet his calcium and vitamin requirements?

Children with musculoskeletal disorders do not generally require any special dietary considerations unless the child is immobile or acutely injured. In most cases, a healthy, well-balanced, age-appropriate diet provides for the nutritional needs of the child (see Chapters 4–8). Foods high in calcium and phosphorus are of particular importance in promoting the development of strong bones and teeth (Table 20–1). Also, adequate calcium intake during childhood and adolescence is a key strategy in preventing osteoporosis and skeletal fractures in later life. Vitamins A and D are also needed to regulate absorption and deposition of calcium and phosphorus, thus aiding bone growth and contributing to bone strength.

When the child is immobile and has a low caloric expenditure, weight gain may become a concern. The child's diet can be modified to reduce the number of calories ingested while continuing to provide vitamins and minerals to promote growth.

Children who have experienced an acute injury to the bone, skin tissues, or muscle may require increased intakes of calcium, phosphorus, vitamins, and minerals. Calcium and phosphorus promote bone formation and growth to damaged areas. Vitamin A is needed for the creation of collagen, scar formation, and growth of new epithelial

cells. Vitamin C is necessary for collagen synthesis, to improve resistance to infection, and to form capillaries to bring blood to the damaged musculoskeletal areas. Minerals such as zinc, copper, and iron also assist in the synthesis of collagen (Lanou, Berkow, & Barnard, 2005).

ANSWER: Between the ages of 9 and 18 years, 1,200 to 1,500 mg calcium are recommended per day. Parents need to be aware that given how food is labeled, this means 120% to 150% of the recommended daily allowance. During this critical period of rapid growth, teenagers store calcium in their bones and establish the bone density for their adult years. Medical studies also show that there may be a relationship between inadequate calcium intake and broken bones. A variety of foods are needed for vitamin requirements, but four 8-oz glasses of milk will meet a teenager's calcium requirements. Some fruit juices are also calcium fortified, but read the nutritional labels carefully.

Pain Management

Sources of pain and discomfort for the child with a musculoskeletal disorder include diagnostic and surgical procedures, muscle spasms, development of contractures, injury to the bone and tissues, joint inflammation, swelling, stiffness, and the processes of healing. Children want to move and explore their world. Even in the presence of pain, children are likely to find ways to adapt their movements and motion to remain as active as possible.

Providing pharmacologic and biobehavioral measures are essential to ensure the child's comfort, maintain the integrity of the child's musculoskeletal status, and promote continuing achievement of developmental milestones. Because motion is so crucial to the child, the child's mobility must not be negatively affected by pain. Chapter 10 provides a summary of pain management techniques that are effective in children.

Diversional Activities

The child's physical activities are based on the amount of motion allowed and the child's need for stimulation, peer interaction, and opportunities to promote normal development (Fig. 20–5). When a child is immobilized, passive and active ROM exercises should be completed three or four times a day to maintain functional ability. In the acute care setting, the child life therapist can provide age-appropriate toys to place around the bed. Children should be provided with a playroom setting, when possible. Photographs of family members or the child's favorite movie or TV characters can be taped to the crib and traction bars to provide visual stimulation. If necessary, social services personnel can provide assistance for parents who stay with their child during the hospitalization, and they can assist with the family's anticipated needs on discharge.

NURSING INTERVENTIONS 20–2

Promoting Healing and Preventing Complications of Immobility

Nursing Diagnosis	Clinical Manifestations	Nursing Interventions	Rationale
Ineffective breathing pattern	Slow, shallow respirations Pooling of secretions Decreased cough reflex	Evaluate respiratory status each shift. Encourage child to cough and breathe deeply. Initiate use of an incentive spirometer and chest physiotherapy as needed. Mobilize patient as soon as possible.	Immobilization leads to decreased lung expansion, decreased respiratory effort, decreased cough reflex, and pooling of secretions. Baseline assessment provides data for early interventions. Pulmonary status is evaluated to prevent atelectasis. Early interventions reduce respiratory complications.
Ineffective tissue perfusion: Cardiopulmonary	Circulatory stasis Venous dilation in dependent parts Decreased thoracic and abdominal pressures Decreased cardiac rate, circulatory volume, and arterial pressure	Turn the patient. Encourage active and passive ROM activities. Apply elastic stockings to lower extremities. Mobilize the patient as soon as possible.	Vasodilation and impaired venous return may result from muscular inactivity and response to injury.
Risk for peripheral neurovascular dysfunction	Decreased capillary refill Pain, pallor, pulselessness, paresthesia, and/or paralysis of extremities Changes in extremities, including increased or decreased temperature, increased swelling, decreased sensation and movement	Assess the child's extremities for clinical manifestations of neurovascular dysfunction, comparing affected and unaffected extremities. Monitor motor function and ROM by having the child move fingers and toes.	The unaffected extremity can be used as a baseline for assessment. Starting the examination on the healthy limb may calm the child. Normal capillary refill is 1 to 3 seconds. Longer than 3 seconds indicates inadequate arterial supply. Swelling peaks within 24 to 48 hours unless tissue damage is extensive. Document responses indicating sensation as present, absent, or abnormal. If the child's nerves are intact, sensation should be felt at areas of innervation above and below the injury. Document motion distal to the fracture as normal ROM, painful, or minimal.
Hyperthermia	Increase in body temperature	Monitor child's temperature for fever.	Elevated temperatures may indicate infection. Fever

Nursing Diagnosis	Clinical Manifestations	Nursing Interventions	Rationale
	Flushed skin Increased respiratory rate and heart rate Warm to touch	Monitor laboratory values for elevated white blood cells or elevated erythrocyte sedimentation rate.	of 101 °F or higher should be reported. Elevated white blood cell count and elevated erythrocyte sedimentation rate are indications of infection and or inflammation.
Impaired physical mobility	Decreased muscle mass and strength Decreased bone mass and strength	Encourage active and passive ROM activities. Encourage isometric and isotonic exercises. Mobilize patient as soon as possible.	Imbalance between osteoblastic and osteoclastic activity leads to calcium and phosphorus loss, resulting in decreased muscle tone and decreased bone stress.
Imbalanced nutrition: Less than body requirements	Decreased efficiency in using nutrients Increased potassium and calcium excretion Decreased appetite	Give small, frequent meals. Give increased fiber, protein, vitamin C, and acidifying foods. Limit calcium intake. Mobilize the patient as soon as possible.	Inactivity will result in decreased basal metabolic rate and oxygen consumption. Nitrogen loss and negative nitrogen balance can occur because of protein loss from loss of muscle mass. Balanced nutrition is needed to promote healing.
Impaired skin integrity	Increased potential for skin breakdown	Inspect the child’s skin for rashes, redness, irritation, or pressure sores. Avoid positions that put pressure on bony prominences. Turn the patient regularly. Keep the patient’s skin clean and dry. Apply lotion to dry skin areas. Apply pressure-equalizing and pressure-reducing devices.	Skin assessment includes looking at the bony prominences and at any area that is in contact with the traction or suspension apparatus, cast, and bedding material. Continuous pressure on bony prominences can compromise skin integrity.
Constipation	Constipation Urinary retention Renal calculi Anorexia	Evaluate the individual’s established elimination patterns for amount, consistency, and frequency of bowel movement and urination. Encourage fluid intake and roughage. Encourage small, frequent meals. Provide privacy for elimination. Administer stool softeners or suppositories as ordered.	General muscle weakness and atrophy with inactivity slow peristalsis and cause urinary stasis in the renal pelvis. Promote intake of water and juices; limit milk intake to maintain bowel and bladder function, because constipation and renal calculi are both related to immobility. Privacy is especially important to children who are school age through adolescence.

(Continued)

NURSING INTERVENTIONS 20–2

Promoting Healing and Preventing Complications of Immobility (*Continued*)

Nursing Diagnosis	Clinical Manifestations	Nursing Interventions	Rationale
Acute pain	Discomfort Observed evidence of pain Sleep disturbance Guarding behavior Changes in appetite and eating	Monitor urine output and characteristics of urine every shift. Offer acidic juices such as apple or cranberry. Assess for cause of pain. Use pharmacologic and biobehavioral measures for pain management. Position for comfort.	A stool softener or suppository helps facilitate bowel movements. Actual or potential tissue damage can cause pain. Pain may indicate compartment syndrome.
Deficient diversional activity	Boredom Irritability Regressive behaviors	Provide a stimulating environment with age-appropriate toys, posters, and music. Provide age-appropriate toys or activities for the child in traction. Encourage a family member to stay with the young child. Allow friends and classmates to visit. Have classmates telephone or write letters to the hospitalized child. Encourage movement by having the child perform appropriate self-care. Enlist child life specialist and physical therapist in providing activities that will encourage movement without disrupting traction. A hospital or school tutor can be contacted to continue the school-aged child's schooling. Encourage age-appropriate behavior. Allow for regressive behavior without punishment. Provide methods by which the child can express anger appropriately.	Imposed immobility associated with musculoskeletal conditions and traction can cause disruptions in patients' independence, body image, and self-esteem. Stress and changes in role can bring about anxiety and fear. Sensory deprivation can lead to boredom and a sense of being forgotten. Peer interactions are especially important to school-aged children and adolescents. Move the bed to the playroom daily to change the environment. An immobilized child may regress to an earlier developmental level.

TABLE 20-1
Important Nutrients to Promote Strong Bones

Nutrient	Food Sources	Results of Deficiency on Musculoskeletal System
Calcium	Milk, cheese, yogurt, cottage cheese Clams, oysters Broccoli, cauliflower, cabbage Molasses	Improper bone growth (rickets, bowed legs, osteomalacia, osteoporosis) Porous bones Tetany and muscle spasm
Phosphorus	Milk, cheese, egg yolks Meat, fish Nuts Whole-grain cereals Legumes	Rickets, bowed legs Porous bones Stunted growth
Vitamin A	Liver and liver sausage Butter, cream, whole milk, egg yolks Green and yellow vegetables, yellow fruits Ripe tomatoes Fortified margarine Fish liver oils	Poor bone formation
Vitamin D	Vitamin D-fortified milk Butter, egg yolk, liver, and saltwater fish (small amounts) Fish liver oils	Soft bones Bowed legs Poor posture

Attendance at school, when possible, is strongly encouraged. The school nurse can work with the family to adapt the child’s environment, schedule, and physical activities as necessary. If the child is unable to attend school, diversionary activities in the home or in the acute care setting must be incorporated into the daily plan of care. The child can become easily bored and regress socially, personally, and academically. Providing age-appropriate activities and encouraging visits from friends can help the child adapt to the immobilized state.

short-term lifestyle modifications. However, the active young child or the adolescent concerned with body image issues may have difficulty meeting the demands of the treatment regimen. The nursing plan of care addresses the impaired or altered mobility and movement that the child may experience. In addition, concerns regarding body image and achieving optimal levels of growth and development are likely to emerge. The nursing plan of care should reflect these concerns. Most musculoskeletal disorders or injuries are managed in the home. Formulate the plan of care to address the teaching, family support,

NURSING PLAN OF CARE FOR THE CHILD WITH ALTERED MUSCULOSKELETAL STATUS

QUESTION: Using Nursing Plan of Care 20-1, what is the nursing diagnosis most appropriate for Chase? Select a nursing diagnosis that is applicable to Chase, but is not found in Nursing Plan of Care 20-1.

The child with a musculoskeletal disorder or injury faces challenges in mobility and movement. Such challenges may require long-term adaptation by the child and family to change the environment, their daily living activities, and their developmental expectations to complement the child’s abilities. When temporary injury has occurred, alterations in the child’s lifestyle usually require only

FIGURE 20-5. The immobilized child should be provided with age-appropriate toys and diversional activities.

and resources that will be required to manage the child's illness at home, in school, and as the child participates in community activities (Nursing Plan of Care 20–1). For some children, the musculoskeletal condition may be lifelong, with periods during which symptoms are exacerbated and the child may need hospitalization. The Nursing Plan of Care in Chapter 12 addresses the care needs of the child with a chronic condition and the child in need of rehabilitation or habilitation services. Nursing Plan of Care 11–1 provides the plan of care when the child's condition requires hospitalization for acute management.

ANSWER: The nursing diagnosis that is relevant for both the fractured metacarpal and Chase's scoliosis is impaired skin integrity related to surgical incision, wounds, or application of treatment devices such as casts, braces, and external fixators. Another appropriate diagnosis is related to the fact that Chase is not wearing his brace for the amount of time required to effect change in his spine. An appropriate diagnosis is ineffective self health management noncompliance with therapeutic regimen.

ALTERATIONS IN MUSCULOSKELETAL STATUS

Alterations in musculoskeletal status can result from congenital disorders, growth-related disorders, inflammatory or infectious disorders, or traumatic injuries.

Congenital and Hereditary Disorders

Disorders that are caused by an inherited gene or that occur within the intrauterine environment are referred to as *congenital disorders*. The child is born with the disorder, although it may not be apparent at birth. For example, a clubfoot is visible, whereas children with mild osteogenesis imperfecta (OI) may escape detection until they become active and experience numerous fractures.

Metatarsus Adductus

Metatarsus adductus, also known as metatarsus **varus**, or in-toeing, is a mild deformity in which the bones of the forefoot turn inward. It is a common congenital problem that occurs in approximately 1 to 2 per 1,000 live births (Gore & Spencer, 2004). It occurs in both males and females and presents bilaterally in 50% of the cases. It is defined as a transverse plane deformity in the tarsometatarsal joint in which the metatarsals are deviated medially. The cause of metatarsus adductus is unknown, although many affected children have a family history of it. Intrauterine positioning, especially with breech positioning, may also play a role, because the feet are tucked medially in utero. Prone sleeping posi-

tion of the baby may increase the tendency of the feet to turn inward. Absence of a medial cuneiform or abnormal growth of the medial cuneiform has been considered to affect development of metatarsus adductus. In addition, arrest of normal rotation of the foot during fetal development plays a role in the development of metatarsus adductus. Children with metatarsus adductus have an increased incidence of hip dysplasia.

Approximately 85% to 90% of cases spontaneously resolve by 1 year (Ryan, 2001). The ultimate goal is to straighten the forefoot so that it is aligned with the heel, soft-tissue vertical crease is present, the deformity is structural and rigid or “nonflexible.” Whether the foot is flexible or nonflexible will guide treatment decisions.

caREminder

To differentiate metatarsus adductus from clubfoot, hold the infant's heel in one hand and with the other hand try to position the foot to midline. If you are able to straighten the foot, the child has metatarsus adductus, not clubfoot.

Radiographs are not usually necessary. However, radiographs are acquired if passive correction indicates the metatarsus adductus is inflexible, to determine whether other deformities exist.

Interdisciplinary Interventions

Treatment of flexible metatarsus adductus in the infant consists of gentle, passive manipulation, performed by the parent during diaper changes, and stretching exercises. The parent holds the child's heel still with one hand while attempting to straighten the forefoot with the other hand. The child may also benefit from slightly overcorrecting the position of the foot by wearing splints or reverse-last shoes. The splints or shoes are worn 22 hours a day, and the child's condition is reevaluated in 4 to 6 weeks (Hosalkar, Spiegel, & Davidson, 2007).

Flexible deformities that persist beyond 8 months or rigid deformities need serial casting. Serial casting, done as often as biweekly, gently molds the foot into position. After casting, a straight or reversed shoe may be worn to maintain the foot in the correct position. Surgical correction is rare, but may be indicated in persistent rigid adductus. Persistent adductus deformity does not appear to cause disability or degenerative arthritis.

Teach the family passive manipulation, correct infant sleeping positions, and cast care, if indicated (see [thePoint](#), for Procedures: Cast Care). Reassure parents that the deformity need not interfere with the child's development and ability to participate in full activities.

Clubfoot

Clubfoot, or *talipes equinovarus*, is a congenital deformity that typically has four main components: inversion and adduction of the forefoot, inversion of the heel and hindfoot, equines (limitation of extension) of the ankle and

NURSING PLAN OF CARE 20–1: FOR THE CHILD WITH ALTERED MUSCULOSKELETAL STATUS

Nursing Diagnosis: Acute or chronic pain related to musculoskeletal condition or treatment regimen

- See Nursing Plan of Care 9–1 for a complete description of pain management interventions.

Nursing Diagnosis: Impaired physical mobility related to restriction of movement/activities, physical and cognitive impairments, traction, deformity, or brace

Interventions/Rationale

- Assess for muscle strength in all extremities.
Rehabilitation and habilitation will be geared toward maximizing the strength of unaffected extremities, and maintaining and potentially maximizing strength of affected extremities.
- Assess for complications of immobility (e.g., ineffective breathing pattern, constipation, imbalanced nutrition), and use interventions to prevent and treat complications.

Even children on temporary bed rest or with restricted physical mobility can experience the complications associated with immobility. Ongoing assessments, preventive care, and prompt intervention when complications are apparent will minimize additional impairment.

- Assist the child or encourage the child to perform ROM exercises twice daily, or as prescribed; praise correct performance of exercises and positive attitude.

ROM exercises promote venous return, prevent stiffness, and maintain muscle strength and endurance.

- Turn and position the child every 2 hours or as needed. Ensure limbs are maintained in functional alignment, using pillows, wedges, and so forth. Support feet in dorsiflexed position. Use other antipressure devices as needed (e.g., specialty beds, sheepskin mattress).

Optimizes circulation to all tissues and relieves pressure on skin and bony prominences. Prevents foot drop.

- Allow child to perform tasks at his or her own rate while also encouraging and facilitating early ambulation and other age-appropriate activities of daily living.

Child may be fearful of initiating activities, given mobility restrictions. Early mobilization will enhance long-term recovery and reduce debilitating effects of immobility.

- Place necessary items within easy reach of the child. Alter environment to ensure the child's belongings are accessible and easy to use and operate, given the child's mobility restrictions. Keep side rails up and the bed in the low position.

Promoting a safe environment for child to perform self-care activities will prevent further injury and will support mobilization.

- Provide a list of restricted activities based on condition (e.g., for a child with scoliosis, no weight lifting, trampoline, or gymnastics).

Restricted movement caused by a cast or brace and restriction of some activities might discourage or limit participation in beneficial physical activities.

- Review with the family, school officials, and other community personnel (as identified by the family) practical changes for school and home environment (e.g., modifications to enable participation in physical education class, access to classes without going up stairs).

Ensures that the child's mobility limitations are communicated to the family, school, and other community agencies so that a safe environment can be provided for the child, and ensures that the child's ongoing plan of care can be implemented and supported.

Expected Outcomes

Child will maintain muscle strength, endurance, and joint flexibility in unaffected extremities.

Child will remain free from the complications of immobility.

Child will be as mobile as possible as soon as possible, using assistive devices if needed.

Child will perform as many activities of daily living as possible.

Nursing Diagnosis: Risk for peripheral neurovascular dysfunction related to the effects of the musculoskeletal disorder

Interventions/Rationale

- Frequently monitor all extremities for pulses, sensation, movement, color, capillary refill, edema, ROM, and complaints of pain, and compare findings bilaterally.

Frequent monitoring provides baseline data to recognize early development of complications. Prolonged bed rest, restrictive devices such as casts and braces, reductions in muscle strength and function, and decreased mobility may all contribute to changes in neuromuscular and neurovascular status, including the development of compartment syndrome.

- Assess for developing thrombophlebitis (e.g., calf swelling, Homans' sign, redness, localized swelling, and increased temperature).

Prolonged bed rest or immobility can promote clot formation.

- Assist child or encourage child to perform ROM exercises twice daily, or as prescribed; praise

(Continued)

NURSING PLAN OF CARE 20–1: FOR THE CHILD WITH ALTERED MUSCULOSKELETAL STATUS (CONTINUED)

correct performance of exercises and positive attitude.

ROM exercise promotes venous return, prevents stiffness, and maintains muscle strength and endurance.

- Monitor fit of casts, braces, and appliances to ensure that devices are not causing constriction that would lead to neurovascular compromise.

Ill-fitting braces and appliances may constrict blood flow and sensation to the extremities. Peripheral swelling and edema will alter fit of appliances. Normal physical growth of the child will alter fit of appliances over time.

Expected Outcomes

- Child will exhibit signs and symptoms of adequate neurovascular function.

Nursing Diagnosis: Impaired skin integrity related to surgical incision, wounds, or application of treatment devices such as casts, braces, and external fixators

Interventions/Rationale

- Conduct a complete assessment of the skin, including evaluating for signs and symptoms of skin breakdown and infection. Assess skin for color, texture, moisture, general appearance, signs of redness, and appearance of wounds and incisions. Assess vital signs.

Assessment provides baseline data about the skin to allow for early detection and prompt intervention should problems such as signs of infection as evidenced by increased temperature and heart rate occur.

- If child is on bed rest, change position, logroll, or assist child to turn every 2 hours; check for correct position of feet and forehead when in prone position.

Frequent position changes prevent pressure areas from developing and prevent tissue from breaking down.

- Keep skin clean, dry, and free from irritants.
Skin breakdown may be caused by shear, friction, and irritation.
- Inspect pressure areas and bony prominences.
Visual inspection helps identify areas at risk for breakdown as well as areas that are beginning to break down.
- Apply pressure relief device to bed as appropriate.
Flotation devices, air mattresses, and so forth, assist in preventing the development of pressure areas.
- Teach the child how to assess for proper fit of brace or appliances.

A poorly fitting cast or brace may rub against the skin, causing skin breakdown.

- Teach care of wound or incision site, including assessment of site for signs of infection (e.g., redness, odor, excessive drainage).

Surgical procedures and breaks in the skin (e.g., pin sites) provide potential sites for infection.

Expected Outcomes

- Child will remain free of any signs of skin breakdown or infection.
- Child will exhibit signs and symptoms of healing to regain skin integrity of wound or incision site.
- Child or family will demonstrate skill in care of wound, incision, or treatment devices to maintain or enhance skin integrity.

Nursing Diagnosis: Constipation related to decreased activity level and impairments in musculoskeletal status

Interventions/Rationale

- Assess the child's usual patterns of elimination and compare with current pattern, including frequency, color, and quality of stool. Assess dietary patterns. Evaluate current medication usage that may contribute to constipation.

Baseline data provide information about deviation from normal stool patterns. Constipation may result from decreased metabolic need, changes in nutritional patterns, inactivity, and use of certain medications.

- Encourage a high-protein, high-fiber diet with small, frequent meals and increased fluid intake. Encourage the child to consume “natural” cathartics such as prunes, beans, or green leafy vegetables.

Protein will enhance the healing process, and protein and fiber add bulk to stool to make defecation easier. Too little fluid can cause constipation.

- Manage environmental conditions to enhance regular elimination patterns (e.g., encourage a regular time for elimination, provide adequate privacy, assist child in bathroom or in using bedpan).

Children will often avoid going to the bathroom (even when they feel the urge) if they think others may be able to see them while they eliminate, if the toileting equipment is not familiar to them, and if they feel it will “hurt” when they have to defecate.

- Give bulk fiber (e.g., Metamucil), stool softeners, laxatives (e.g., milk of magnesia, Citrucel, or mineral oil), and suppositories as needed as ordered; record effectiveness.

A variety of over-the-counter agents can be used to change the bulk of intestinal contents, soften stool, lubricate intestinal mucosa, and/or stimulate rectal mucosa.

Expected Outcomes

- Child will pass stool according to his or her usual elimination pattern.
- Child will demonstrate an increase fluid and fiber intake.
- Child will report easy and complete elimination of stool.

Nursing Diagnosis: Impaired urinary elimination related to effects of immobility**Interventions/Rationale**

- Monitor bladder function daily. Observe for signs of urinary retention, incontinence, or infection (e.g., voiding small amounts, dysuria, frequency, fever).

Urinary tract infections are hazards of immobility, because a recumbent position may cause urinary stasis in the renal pelvis. Increased calcium excretion from inactivity causes alkaline urine, which promotes bacterial growth.

- Record intake and output. Ensure hourly urine output is 1 to 2 mL/kg/hour.

Intake and output provide evidence of the adequacy of fluid balance. Urine output less than 1 to 2 mL/kg/hour indicates dehydration.

- Assess need for intermittent or Foley catheterization.

The incontinent child or the child with decreasing urinary output may require catheterization to ensure accurate measurement of urinary output.

- Explain the necessity of high fluid intake. Collaborate with the child and parents to encourage fluid consumption.

Increasing fluids will reduce the likelihood of urinary tract infections and constipation.

Expected Outcomes

- Child will maintain normal urinary elimination patterns postoperatively and while mobility is restricted.

The child will remain free of signs and symptoms of a urinary tract infection.

Nursing Diagnosis: Delayed growth and development related to lack of stimulation, immobility, physical limitations of musculoskeletal condition (e.g., joint stiffness, limitations in ROM)**Interventions/Rationale**

- Perform complete developmental screening and compare with norms for age of child.

Developmental screening provides baseline data to determine areas of fine motor, gross motor, language, and social skills that need enhancement.

- Collaborate with the family to determine factors that may impede the child's participation in age-appropriate activities and self-care activities.

The child's health status, environmental conditions, overprotection by family members, and child's own fears may be issues that impede participation in activities. A comprehensive assessment of these factors will assist in determining which of these factors can be managed or changed to better support achievement of developmental milestones.

- Collaborate with child life services and school services to determine age-appropriate play activities for the child that enhance developmental skills. Share strategies with the child and family. Encourage the child to do as much for him- or herself as possible; assist in resuming as many normal activities as possible.

Children on forced bed rest and forced immobility (braces, casts) have restricted activities, thereby limiting routine opportunities for growth and development.

- Work with the child and family to develop a plan for involving the child in self-care activities and self-management of the treatment regimen (e.g., learning to put on a brace, self-administering medications) as age appropriate. Refer to rehabilitation services as needed.

The child should be encouraged to perform skills at a level appropriate to their assessed abilities. Over time, the child should become more independent in managing the chronic condition.

Expected Outcomes

- Child will demonstrate skills appropriate for developmental stage and age.
- Family members will demonstrate an understanding of child's special needs.
- As the child matures, the child will demonstrate increasing responsibility for maintaining the treatment regimen.

Nursing Diagnosis: Chronic or situational low self-esteem related to physical manifestations of condition, use of devices such as braces or splints, disturbed body image, feelings of powerlessness, and unrealistic self-expectations**Interventions/Rationale**

- Provide openings to enable child or adolescent to express feelings. Be a good listener and accept what the child or adolescent verbalizes. Be accepting of the child's body image changes and limitations related to the child's condition.

Allowing the child to talk provides an outlet to discuss their frustrations and concerns. Listening to the child provides an opportunity to validate their concerns and discuss ways to help build their self-esteem. Visual differences such as a body cast or brace may contribute to low self-esteem.

- Schedule a team conference with the parents, child, teachers, school nurse, and healthcare team members to provide information and explore

NURSING PLAN OF CARE 20–1: FOR THE CHILD WITH ALTERED MUSCULOSKELETAL STATUS (CONTINUED)

feelings and attitudes; encourage the child to take part in selecting conference participants.

Team conferences facilitate open discussion among all family members. Active listening and open acceptance of the child's physical changes will model acceptance of the child and will assist family members, including the child, to accept changes.

- Give the child a sense of control by providing realistic decision-making opportunities.

The child may feel powerless, further adding to feelings of low self-esteem.

- Assist the child or adolescent to develop strategies to enhance self-esteem (e.g., changing physical appearance, participating in enjoyable activities in which the child can excel, developing new friendships).

Appropriate strategies help the child or adolescent to explore new methods for developing positive feelings about him- or herself.

- Arrange for the child and parents to meet others who have a similar condition or experiences and who have managed these issues successfully.

Meeting others provides an opportunity for the child or adolescent and parents to identify with someone who is experiencing the same type of situation. It also provides an opportunity to learn new coping strategies and to have realistic perceptions of how others have managed their condition over time.

Expected Outcomes

- Child will verbalize positive statements about self.
- Child will discuss concerns related to feelings about self and body.
- Child will maintain age-appropriate interaction with peers.

Nursing Diagnosis: Deficient knowledge: Child's condition, treatment, exercises, and care of appliances and assistive devices

Interventions/Rationale

- Provide instruction regarding treatment plan (e.g., exercises, restriction of activities, proper application of braces or appliances, frequency of follow-up appointments, diet, and skin care).

If deficient knowledge exists, the child and parents cannot appropriately adhere to treatment, manage the appliance, or detect signs of complications.

- Allow time for questions, provide a written summary of what the healthcare team has said about the child's condition and recommended plan of treatment, and reinforce or repeat initial explanation as needed.

Questioning provides opportunities to clarify misconceptions, and ensures that the child and family are able to manage care when in the home environment.

- Observe the child and parents demonstrate home care skills.

Return demonstration provides an opportunity to ensure the child and family can independently perform the skill in a safe and accurate manner.

- Make appropriate referrals to community service agencies (e.g., home health, physical therapy, education, mental health counseling) as needed.

Many musculoskeletal conditions require ongoing, long-term management to assist the child in achieving maximum developmental abilities.

Expected Outcomes

- Child and family will describe the illness, identifying the child's specific manifestations and the planned treatment regimen.
- Child and family will demonstrate necessary skills for care.

subtalar joint, and internal rotation of the leg. Clubfoot is a complex, multifactor deformity with genetic and intrauterine factors, although the etiology of idiopathic clubfoot remains unknown (Gore & Spencer, 2004; Morcuende, 2006). It is common (1.24 per 1,000 live births), occurring twice as often in males as in females, with a higher incidence in persons of Hispanic and Asian heritage (Morcuende, 2006). Approximately 80% of all children born with clubfoot live in developing countries, and many of these children and their families lack the financial and medical resources to seek treatment (Penny, 2005).

Pathophysiology

The exact mechanisms that results in the anatomic abnormalities of clubfoot are unknown. Several hypotheses exist regarding mechanism of injury, including uterine constriction; abnormalities of the bones, joints, and/or connective tissues; distal limb vasculature; muscle migration; and presence of underlying developmental or neurologic abnormality or arrest. It has been demonstrated that severe club foot resembles an embryonic foot at the beginning of the second month of fetal development and, because the deformity is accompanied by underdevelopment of the bones and muscles, this implies that the

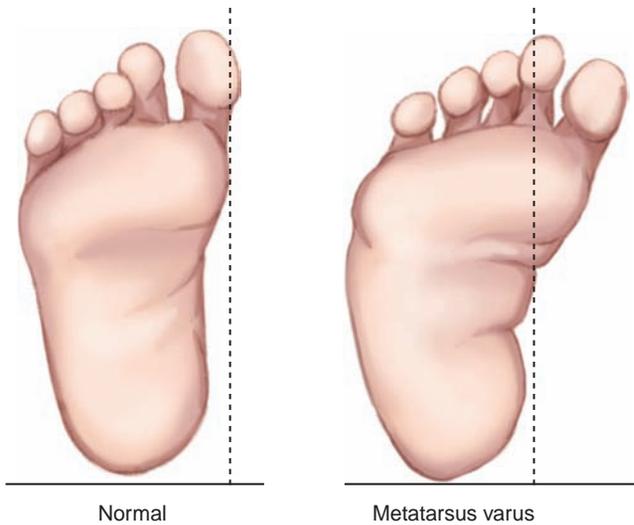

FIGURE 20-6. Metatarsus varus is graded according to the degree of inward toeing that passes beyond the medial border of the foot. Metatarsus adductus is evident in the foot in which the great toe is widely separated from the other toes and the foot angle turns inward.

abnormality may occur between 9 and 38 weeks of gestation (Miedzybrodzka, 2003; Morcuende, 2006).

The clubfoot malformation, which can be unilateral or bilateral, is usually obvious at birth. The main anatomic components of clubfoot are a flexed ankle, a turning in of the heel, and adduction of the forefoot (Fig. 20-7). Clubfoot can be classified into extrinsic (supple) type, which is essentially a severe positional soft-tissue deformity; and intrinsic (rigid) type, in which manual reduction is impossible. The type of clubfoot determines the specific treatment.

Assessment

On examination, the foot appears small, with a flexible, soft heel, because the calcaneus is hypoplastic. The heel is usually small and internally rotated, making the soles of the feet face each other in the case of bilateral deformity. Physician evaluation of the foot includes measuring foot size and shape, ROM of the joints, and radiographic evaluation. Radiographs reveal roughly parallel axes of the talus and calcaneus.

Interdisciplinary Interventions

The ideal treatment protocol for clubfoot remains disputed and controversial (Hsu et al., 2007). In the case of supple or extrinsic clubfoot, the treatment may consist of a casting and manipulation technique known as the *Ponseti technique*. In rigid (intrinsic) clubfoot, casting followed by surgery may be the treatment of choice. In either type, the treatment begins immediately after diagnosis.

With the Ponseti technique, specific manipulation and casting is performed weekly in the physician's office for 6 to 8 weeks. At the end of that period, the child undergoes a small surgical procedure (percutaneous Achilles tenotomy) under local anesthesia to lengthen the heel cord.

Then, a long plaster cast is applied for 3 weeks (Morcuende, 2006; Pitner, Klingele, & Beebe, 2008). When correction has been achieved, a foot abduction brace is used until the child is 6 months of age. Part-time use of the abduction brace is recommended during sleep until the child is 3 to 4 years of age.

For a rigid clubfoot that does not respond to treatment, surgery is recommended. The goal of surgery is to obtain a straight, painless, plantigrade (child stands with the sole of the foot on the ground, not on his heels or the outside of his foot), and mobile foot with normal radiographic appearance (Ippolito, Farsetti, Caterine, & Tudisco, 2005). The two surgical procedures most widely performed are Achilles tenotomy and arthrodesis, which is performed for more severe cases with residual varus and forefoot adduction. The Achilles tenotomy is performed before the child is walking, and the second procedure is done if the tendon release does not allow the foot to be in a functional position. Surgery requires brief hospitalization. Nursing care includes postoperative pain management, neurovascular assessment of the involved foot, and cast care teaching for the parents. A below-the-knee cast is applied for up to 12 weeks, with a cast change every 4 weeks. After cast removal, follow-up is usually done at 6-month intervals.

Depending on the treatment protocol, teach parents cast care procedures and, as treatment progresses, care and application of foot braces (see Treatment Modalities). Ensure the parents understand the importance of daily assessment of the child's skin to monitor for skin breakdown from cast or brace wear or infection from surgical incisions. Treatment of this condition extends over several months. Encourage parents to be diligent with regard to following the treatment protocol and to complete all follow-up appointments. The ultimate goal of therapy is to restore the look and function of the foot, thus allowing the child to walk correctly; and to prevent any long-term disabilities.

Developmental Dysplasia of the Hip (DDH)

DDH is a condition in which the femoral head has an abnormal relationship with the acetabulum. The term

FIGURE 20-7. The child with clubfoot has a flexed ankle, a turned heel, and an adducted forefoot.

includes **luxation** (frank dislocation; complete loss of contact of the femoral head with the acetabulum), **subluxation** (partial dislocation; femoral head able to move within or outside the confines of the acetabulum), instability, and a number of radiologic abnormalities that demonstrate inadequate formation of the acetabulum (American Academy of Pediatrics, 2000; Cady, 2006). Hip dysplasia can occur in utero, perinatally, or during infancy or childhood. Because, in some cases, the condition may not be apparent at birth, the term *developmental dysplasia of the hip* has replaced the term *congenital dysplasia of the hip*. However, the earlier a dislocated hip is detected, the more simple and effective the treatment.

DDH is one of the most common defects in the newborn infant, with incidence influenced by genetic and racial factors. The incidence of DDH in developing countries ranges from 1 to 20 per 1,000 births. Variances of incidence by race include a higher number in the Sami people and Native Americans, and a decreased number in African American children (Phillips, 2007; Shipman, Helfand, Moyer, & Yawn, 2006). Dislocation of the left hip is four times more common than the right, which is thought to result from the left occiput anterior position of most nonbreach infants (Cady, 2006). A family history positive for DDH may be found in 2% to 33% of affected patients (Storer & Skaggs, 2006). Eighty percent of children with DDH are females (Storer & Skaggs, 2006). The greater incidence in females may reflect the fact that they are more susceptible to the maternal hormone relaxin, which may contribute to ligamentous laxity.

Pathophysiology

At birth, the femoral head and the acetabulum are primarily cartilaginous. The acetabulum continues to grow postnatally. The growth of the fibrocartilaginous rim (the labrum) that surrounds the bony acetabulum deepens the socket. This continued development of the femoral head and acetabulum is needed to form a normal adult hip joint.

In general, hip development is normal during the fetal period and then gradually becomes abnormal for a variety of reasons. These reasons may include fetal position in utero, presentation at birth (e.g., breech), and generalized ligamentous laxity of the hip joint (Hart et al., 2006).

Assessment

Current clinical guidelines include screening of all newborns' hips by physical examination. Thanks to aggressive screening, late presentation of DDH is becoming less common.

Obtain a information about the type of delivery and any family history of DDH to aid in determining the newborn's risk. Examine the infant while the child is relaxed and laying on a firm surface. Look for apparent limp length discrepancy and restricted or diminished motion, especially with abduction of the affected side. With the infant supine and the pelvis stable, abduction to 75 degrees and adduction to 30 degrees should be possible. Limitations in abduction may indicate DDH. Also perform Ortolani's and Barlow's tests (see Nursing Inter-

ventions 8–4 and Fig. 8–16 for an illustration and explanation of these maneuvers). A newborn with a positive Ortolani's or Barlow's sign at the 2-week examination should be referred to an orthopedist. At 3 to 4 months of age, the capsule laxity decreases, and muscle tightness increases, making the two maneuvers no longer reliable indicators of DDH.

In the 3-month-old infant, limited adduction of the affected hip is the predominate sign when the hip becomes fixed in the dislocated position. Asymmetric thigh folds and a positive Galeazzi sign (one femur shorter than the other when measured with the hips and knees flexed) are physical findings that may be an indication of acetabulum abnormalities. Examine the hips at every well-baby visit until the infant is walking. Document all findings. If the physical findings arouse suspicion of DDH or if strong family history or concern exists, refer the child to an orthopedist for age-appropriate imaging.

Frequent hip examinations are recommended during the first year of life for all children (Cady, 2006; Storer & Skaggs, 2006). After the child starts walking, the presence of gait abnormalities may raise the suspicion of DDH. These abnormalities may include a short-limb gait or limb or a waddling gait pattern (Hart et al., 2006). Another indication of DDH in the walking child is a positive Trendelenburg's sign, indicating weak hip abductors. When the child is asked to stand on the affected leg, the examiner will visualize that the pelvis drops to the opposite side and the trunk leans to the affected side (Hart et al., 2006).

caREminder

If a child's hip is known to be dislocated, do not repeatedly assess it, because repeated manipulation of the joint may increase risk of vascular compromise.

Diagnostic Tests

Accurate diagnosis of abnormalities in the acetabulum requires imaging. However, imaging has limited value in the newborn, because the femoral head is composed of cartilage. By 4 to 6 months of age, radiographs become more reliable, as the femoral head undergoes increased ossification. The use of ultrasound to detect DDH is becoming more widespread, but hip sonography requires training and expertise. A few studies have recommended using ultrasound in all infants age 4 to 6 weeks, but cost-benefit analysis does not support this recommendation; ultrasound is currently recommended only as an adjunct to the clinical evaluation.

Interdisciplinary Interventions

If DDH is diagnosed early, simple and effective noninvasive treatment options usually result in excellent long-term anatomic and functional outcomes. Early detection of DDH limits malformation of the joint, and early treatment allows the hip to remodel and form properly. Remodeling is facilitated by maintaining the hips in a

position of flexion and abduction using a Pavlik harness. Delayed diagnosis increases the risk of complications from treatment. Infants diagnosed after 6 to 8 months may require surgery for a closed reduction, followed by spica casting. Closed or open reduction and casting may also be needed when the child's condition does not improve after Pavlik harness treatment. As a child grows, the dislocation produces secondary changes in the shape of the hip. These changes can be corrected only with a surgical procedure to recreate a socket that is similar to a normal hip joint.

Although rare, complications from DDH and its treatment do occur. One common complication is lack of concentric reduction, which necessitates further operative procedures. Avascular necrosis, or loss of blood supply to all or part of the head of the femur, is another potential complication. In some cases, the legs will not be the same length after surgery. The child will need to be monitored until age 17, when the adolescent growth spurt is complete.

Bracing

The Pavlik harness is the most common device used for newborns or infants younger than 6 months of age (Cady, 2006; Gelfer & Kennedy, 2008). This harness promotes hip flexion and abduction by prohibiting hip extension or adduction, while allowing some kicking and movement. It consists of a chest strap, held at the nipple line by two shoulder straps. The leg and foot are adjusted with anterior and posterior straps, which hold the hips in proper position. Hip flexion is set to 100 to 110 degrees, and abduction is set at 50 to 70 degrees. Treatment is continued until the hip joint stabilizes or ultrasound or radiographs are normal. The Pavlik harness has been found to be effective in about 90% of the infants treated during the first 6 months.

The harness must be applied by a physician and adjusted throughout the course of treatment. A poorly adjusted harness may make the dislocation worse and is associated with other complications (Fig. 20–8). Skin breakdown can occur underneath the harness or in groin folds if skin is not kept clean and dry. Tightly or poorly fitting shoulder straps can compress the brachial plexus, and improperly positioned leg straps can lead to subluxation of the knee and hyperflexion of the hips.

Traction

In cases in which DDH is not corrected by the harness, or when a late diagnosis is made, traction is used for about 2 weeks, followed by closed reduction and a body cast for 8 to 12 weeks. One type of traction, Bryant's traction, aims to stretch the soft tissues around the hip and allows the femoral head to move back into the hip socket (see [thePoint](#) for Procedures: Traction Care). After 1 to 3 weeks in traction, the child is taken to the operating room, where the hip is reduced manually and a hip spica cast is applied. Often an arthrogram is done at the same time, to confirm that the hip has been reduced.

The spica cast is worn for 3 to 6 months. The position of the hip is checked periodically to make sure it remains satisfactory. Computed tomography may be used to get a three-dimensional view.

caREminder

Unless the crossbar (as found in some spica casts) has been specifically reinforced so that it can be used for lifting or turning, do not use it for these purposes. Check with the physician or orthopedic technician if you are unsure about the safety of using the crossbar.

Surgical Interventions

If traction does not adequately stretch the muscles, surgical intervention may be indicated. In the child older than 2 years of age, if the hip has been dislocated for some time, the muscles around the hip shorten and become contracted. In such children, surgical intervention is recommended (Hart et al., 2006; Weinstein, Mubarak, & Wenger, 2003). A percutaneous adductor **tenotomy** consists of cutting an adductor tendon of the hip to decrease the risk of avascular necrosis (a potential complication of forced reduction and abduction) by taking pressure off the hip joint.

An open reduction of the hip consists of an **osteotomy** (incision or transaction of the bone) of the acetabulum or femur and removal of soft tissues. This operation cuts the bone and realigns it, allowing the hip to be concentrically placed so that it can continue to grow correctly as the child ages. After an open reduction, the child is placed in a hip spica cast for 6 to 8 weeks and then in an abduction splint for up to 3 more months.

FIGURE 20–8. The Pavlik harness is used to maintain the hips in a position of flexion and abduction. (Wheaton Pavlik Harness. Courtesy of Wheaton Brace Co. Reprinted with permission.)

CLINICAL JUDGMENT 20–1

The Child With Developmental Dysplasia of the Hip

Lauren is a 2-month-old female who comes to the community health clinic with her mother for her immunizations. During her physical examination, you note that the fat folds in her thighs are not even. When interviewing the mother for the birth history, she says that Lauren is her first child and that she was delivered via cesarean section because of her breech presentation.

Questions

1. During your assessment, what other information would help you to determine the problem?
2. What diagnostic studies would help you to determine the problem?
3. The mother is upset that the condition has not been noted sooner. What could you say to her at this time?
4. How can DDH be treated?
5. How would you determine that the harness is keeping the hip in the correct position?

Answers

1. Is there any family history of DDH or of joint laxity? Were Lauren's hips examined at birth or at any other time before this visit?
2. Ultrasound of the hip, possibly a plain radiograph. Ortolani's and Barlow's maneuvers would help to confirm the diagnosis.
3. The condition can be missed during the initial assessment of the child. Now that it has been noted, corrective therapy can begin and the child should have very good outcome.
4. Use the Pavlik harness for a few months. If this does not work, traction and casting, or possibly surgery, may be needed.
5. Ultrasound of the hip or a plain radiograph of the child while she is in the Pavlik harness

This surgery is painful, and children generally are in the hospital for 2 to 3 days afterward. Intravenous narcotics are required for the first day after surgery, and oral narcotics are often needed for several days thereafter. Reassure the parent that the incision will heal even though it is under the cast.

Community Care

Beginning in the outpatient setting, parental education and support are key. The parents may experience a variety of reactions to the diagnosis, including shock, fear of the potential risks of surgery, feelings of loss and anger at the unexpected news, and uncertainty and anxiety about the future. Parents are often reluctant to hold the baby or change a diaper for fear of hurting the hip. Also, mothers tend to blame themselves for causing the dislocated hip. Seeing a small baby placed in a Pavlik harness for the first time can be upsetting. When the parents realize that the harness does not hurt the child and the baby can still move, some of their fears and anxieties may lessen (Clinical Judgment 20–1).

If the diagnosis of DDH is made when the child is older, the parents often become angry with their health-care provider for not finding the disorder earlier. The stress may be compounded by hospitalization of the child for traction or surgical procedures and by long-term follow-up.

After the plan of treatment is established, instruct the parents on proper application of the Pavlik harness, skin

care, and other activities of daily living such as diaper changing (TIP 20–1). Provide referrals to community resources as necessary to help the family cope with the child's care, such as frequent transportation between the home and clinic. Children do not need specialized transportation unless they cannot fit into a car.

Additional parental education and modifications to the home environment may be necessary if the child is placed in a spica cast. Before surgery, prepare the parents for how the child's lower extremities are placed and how the cast is applied to ensure abduction of the hips. Other important areas for teaching include handling the child in a cast; petaling or waterproofing the cast; and feeding, dressing, and bathing the child in a cast (see [thePoint](#) for Procedures: Cast Care). Car seats and high chairs may be unusable or may require modification for a child with a spica cast. For infants, a bouncing seat can be used as a feeding chair, and car seats that have been adapted for children in hip spica casts can be purchased or rented. Strollers, wagons, or reclining wheelchairs also provide mobility for the child.

Congenital Limb Defects

Congenital malformations of the limbs are typically classified into seven categories:

1. Failure of formation (absent parts)
2. Failure of differentiation (lack of part separation)

TIP 20 –1 A Teaching Intervention for the Child With a Pavlik Harness

Nursing diagnoses and outcomes

Deficient knowledge: Care of the child requiring a Pavlik harness

Outcome:

- Parents will demonstrate measures to care for the child with a Pavlik harness.

Risk for impaired skin integrity related to the use of a Pavlik harness

Outcomes:

- Parents will demonstrate proper skin care techniques to maintain the child's skin integrity while a Pavlik harness is being used.
- Child will exhibit intact skin without redness, irritation, or breakdown.

Teach the Family

Positioning of the harness

- Explain the purpose and function of the Pavlik harness.
- Ensure that the harness remains in place on the child at all times until the hip is stable (unless otherwise instructed by the physician). For this reason, only one harness is distributed and it is applied at the physician's office or clinic.
- Instruct the parents in how to correctly reattach the buckles or straps of the harness they should loosen or become detached.
- Use indelible ink to make black lines to show where the straps should pass through the buckles.
- Use letter coding to match the straps to their respective buckles.
- Fasten diaper tapes under the straps to prevent any pull on the straps.

Care of the harness

- Sponge the harness clean with mild soap if it becomes soiled.

- If needed, place the harness in the washing machine for cleaning on cold water/gentle cycle and then line dry. (This necessitates that a second harness be obtained and placed on the child by a person trained to do so.)
- Do not remove the harness unless otherwise instructed by a healthcare provider.

Skin care

- Give the child a daily sponge bath, paying close attention to the skin under the straps and stirrups.
- Check the skin under the harness daily for irritation, and gently massage the skin to stimulate circulation.
- Do not use powders or lotions that will cake and irritate the skin.
- Use padding beneath the shoulder straps to prevent discomfort at pressure points.
- Unfasten the shoulder straps to slip a shirt on the child. This should not affect hip position.
- Provide perineal care in the usual manner, because the harness does not affect it and there are no straps covering that area.
- Do not pull the legs when changing the diaper, because of the possibility of forced dislocation. Instead, lift the child from under the buttocks and slide the diaper under the bottom.
- Try using disposable diapers with elastic around the legs (recommended) to prevent the brace from becoming wet or soiled.

Contact the Healthcare Provider if:

- Harness becomes heavily soiled and needs to be replaced
- Skin underneath the harness becomes red or swollen, or if areas of skin breakdown are noted
- Child appears to be in pain
- Harness comes off

3. Duplication
4. Overgrowth
5. Undergrowth
6. Congenital constriction band syndrome
7. Generalized abnormalities

The most common congenital defects are absence of limb, duplication of fingers or toes, overgrowth or undergrowth of a limb, and amniotic band syndrome. Amniotic band syndrome is a set of congenital birth defects believed to be caused by entrapment of fetal parts (usually a limb or digits) in fibrous amniotic bands while in utero.

Syndactyly, or webbing of two digits, is common, as is polydactyly (Fig. 20–9).

Pathophysiology

Chapter 3 describes the normal development of bone formation and the development of the extremities in utero. Altered growth and development patterns are likely to result in impairment of function and malformation of the anatomic structure of the limb. Abnormal in utero positioning may cause congenital deformities. Malformations

FIGURE 20-9. This infant with polydactyly has additional toes on each foot.

may also be associated with genetic syndromes, such as trisomy 13, trisomy 18, trisomy 21, Carpenter's syndrome, and orofacioidigital syndrome. Risk factors that may increase the likelihood of congenital limb defect include conditions that affect the developing fetus, such as maternal exposure to chemicals, viruses, or specific medications while pregnant.

Interdisciplinary Interventions

Early diagnosis and management of congenital anomalies is mandatory to prevent progression of certain deformities, to detect any limb-threatening conditions when there is neurovascular impairment, and to provide early psychological support to the child and the parents. No standard interventions or treatments have been identified for congenital limb defects. If the child is functioning well, no treatment interventions may be instituted. Many children with limb deformities learn to adapt to their condition and do not consider themselves limited in performing any normal developmental skills and abilities. A limb deformity does not necessarily prohibit a child from participating in any age-appropriate activities. As the child matures, encourage parents to support the child's independence and self-care abilities.

Prosthetics may be selected to equalize limb lengths, correct malrotation, and improve body mechanics (Fig. 20-10). A prosthesis is expensive and requires maintenance. For the growing child, the prosthetic device must be replaced every year until age 5. Thereafter, annual assessment determines when the size of the prosthesis needs to be altered again. Some families choose not to obtain the prosthesis and to teach the child to function without it.

Surgical procedures are used to create a stump that is amenable to prosthetic fitting, to lengthen a deficient bone, or to improve limb function. In some cases, the defect can be repaired with a minor surgical procedure. Children with more severe defects may need several corrective procedures over time. The ultimate goal of

FIGURE 20-10. The child with a limb deformity and prosthesis should be encouraged to participate in age-appropriate activities to the limit of his or her abilities.

surgery is to provide the child with a limb that has good function and appearance. Function usually takes precedence; a hand that looks good but does not work correctly is of little help to the child. Rehabilitative services are used to optimize function of the limb after surgery.

Community Care

Child and family education, and coordination of needed healthcare services are key components of community care. If the child has a prosthesis, the family must learn to assess the skin for redness and irritation. The child is most likely to experience these complications with a new brace or prosthesis. Teach the parents to report any signs and symptoms. For example, if the skin becomes irritated, the brace or prosthesis needs adjustment; in cases of severe skin breakdown, wear may need to be discontinued for a time. Care of the stump is also important. Rubbing alcohol can be applied to toughen the stump skin. However, lotions or oils are avoided. A cotton sock or other piece of clothing can be worn underneath the brace or prosthesis to absorb the moisture from perspiration.

Physical and occupational therapy can assist the child to become independent in activities of daily living and in the use of the prosthesis. Social services can provide the family with information regarding where to find assistive devices, alternative funding opportunities, and support groups. Children with limb deformities are fully capable of adapting to this condition, such that it does not affect their ability to pursue competitive and

noncompetitive physical activity. Support from parents, the healthcare team, and community groups will assist these children in achieving any dream they choose to follow.

Osteogenesis Imperfecta (OI)

Often referred to as *brittle bone disease*, OI is an autosomal dominant inherited disorder (see Fig. 3–3) characterized by bone fragility and low bone mass. Occasionally, a child will develop OI through a spontaneous genetic mutation. OI occurs in all racial and ethnic groups, and is equally prevalent in males and females. The incidence ranges from 1 in 10,000 to 1 in 20,000 live births (Devogelaer & Coppin, 2006).

Pathophysiology

This genetic condition stems from a variety of mutation of the genes COL1A1 and COL1A2, which encode the $\alpha 1$ and $\alpha 2$ chains that, when organized into a triple helix, constitute type I collagen (Devogelaer & Coppin, 2006). Collagen is the major protein of the body's connective tissue and is the framework upon which bone and tissue are built. Children with OI produce less collagen, or a poorer quality of collagen, than healthy children do. Subsequently, this defect leads to bone fragility (the bones fracture easily), low bone mineral density, short stature, fractures, blue sclerae, dentinogenesis imperfecta (poor tooth development), joint laxity, and deafness later in life (Cheung & Glorieux, 2007; Zeitlin, Fassier, & Glorieux, 2003).

A classification system has been developed that identifies four main types of OI. Type I is the most common and mildest form. Children with type I have bones that are predisposed to fractures. Other than spinal curvature, bone deformity is minimal. Type II is the most severe type and is frequently lethal at or shortly after birth. Types III and IV are more serious than type I but not as lethal as type II. More recently, researchers have reported two additional types of OI that do not involve a defect of type I collagen (National Institutes of Health, 2005). Type V is moderate in severity and similar to type IV, and is characterized by hypertrophic calluses that develop at the site of fractures or surgical procedures. Type VI is extremely rare and only diagnosed by bone biopsy (National Institutes of Health, 2005).

Assessment

OI is often diagnosed through physical examination. The assessment starts with a review of family medical history. Physical examination commonly reveals major characteristics such as bone fragility leading to fractures, **osteopenia** (insufficient bone tissue), short stature, and progressive skeletal deformity. Additional clinical manifestations include blue sclera, dentinogenesis imperfecta, joint laxity, and maturity-onset deafness. A unique feature of a fracture in a child with OI is lack of bruising or swelling at the fracture site. However, the child has tenderness at the site of the fracture.

caREminder

When the child is first noted to have multiple fractures, accusations of child abuse may be made by people who are not familiar with OI. Healthcare providers must be sensitive to this differential diagnosis if a young child is admitted with frequent fractures.

Alert! When taking blood pressures, guard against inflating the blood pressure cuff too tightly, because this could lead to bruising or fractures in patients with severe OI. Do not use an automatic blood pressure cuff because the cuff inflation pressure is preset and cannot be controlled. Avoid obtaining a blood pressure in an extremity that has repeatedly fractured and/or has a bowing malformation, because the bone in the limb may be especially predisposed to fracture (National Institutes of Health, 2005).

Laboratory tests will confirm the diagnosis and rule out diagnosis such as rickets and hypophosphatasia. Biochemical tests can evaluate the collagen, and molecular testing can confirm the genetic pattern and type of OI. Radiographs reveal multiple normal callus formations at new fracture sites, generalized osteopenia, evidence of previous fractures, and skeletal deformities.

As children grow older, many become disabled by their severe deformities. Children with OI have normal intelligence, but social development may be delayed because of increased dependence on parents and decreased social interactions.

Interdisciplinary Interventions

OI cannot be cured. Thus, management focuses on preventing injury and providing prompt and aggressive orthopedic management. Early treatment and correction of fractures or bowing and bending of the bones helps to maximize mobility and prevent deformities. Fractures are a part of life for these children, and hoping to completely eliminate fractures is not realistic.

When a fracture occurs, acute management consists of precise alignment to prevent deformity and application of a lightweight cast or splint for immobilization. Early return to weight-bearing activity is crucial to stimulate formation of new bone. Often, splints and braces are used on the lower extremities to assist with ambulation and to protect against fractures (see Treatment Modalities earlier in this chapter).

Surgical Interventions

Children with OI often require surgery to reduce fractures, correct spinal deformities, and straighten long bones. A common procedure is intramedullary “rodding” with solid or telescoping rods. Solid rods are easier to insert, but they do not “grow” with the child and must be replaced every 2 to 4 years. Telescoping rods require more extensive surgery, but they can be adjusted as the child grows. Placement of the rods is not a perfect solution, because the small diameter of the bone and the abnormal collagen can cause complications. However, intramedullary rodding can provide stability to a deformed bone and help prevent progressive deformities.

Postoperative care includes pain management, neurovascular checks, assessing for bleeding at the surgical site, and special attention to positioning as a result of the child's limited ROM and the potential for fractures and skin breakdown. Children with OI are prone to have slightly higher than normal body temperature, sensitivity to heat and cold, excessive sweating, and pseudo-malignant hyperthermia after anesthesia (National Institutes of Health, 2005). The exact cause of these symptoms is unknown, but are believed to be the result of an increased metabolic rate. Therefore, intravenous fluid therapy initiated preoperatively is continued postoperatively. Adequate hydration must be ensured throughout hospitalization, with frequent weight checks and careful monitoring of intake and output. The use of warming blankets and heavy drapes (during surgery) and blankets (during recovery) should be avoided, to prevent hyperthermia. The length of the recovery period is dependent upon the extent of the surgery, the child's age, and the child's previous activity level. After surgery, the limb is supported by a lightweight cast or splint for about 4 weeks. Bracing may be used after the cast is removed to provide additional support for standing and walking as the child continues to heal.

Physical Therapy

Physical therapy is a mainstay of treatment for children with OI and focuses on ROM and muscle-strengthening exercises. After a fracture or surgical intervention, the physical therapist helps the child to regain mobility. The presence of deformities may require the child to use ambulatory devices such as a walker or a wheelchair. The physical therapist ensures that the child can use the device safely.

Pharmacologic Interventions

Bisphosphonates are a class of drugs being prescribed “off label” (see Chapter 2) to treat OI in adults and children. The U.S. Food and Drug Administration has approved the drug for treatment for osteoporosis and Paget's disease of bone in men and women. However the use of a second-generation bisphosphonate called *pamidronate* is now being used by investigators to treat OI. In most cases, chronic bone pain disappears after the first infusion cycle, bone density increases, and mobility improves (National Institutes of Health, 2005). Bisphosphonates are thought to exert these effects by inhibiting bone reabsorption. Use of these medications has been shown to be safe and effective for 4 to 5 years. Long-term effects are still being investigated. Adverse effects of therapy include decreased appetite, low-grade fever, myalgia, irritability, and decreased energy (Cheung & Glorieux, 2007; Devogelaer & Coppin, 2006).

Nutritional Interventions

Nutrition and diet are important to maintain a healthy weight and to support overall health. Although no food or vitamin supplement has been shown to reverse or pre-

vent symptoms, calcium and vitamin D are essential to maintaining strong bones and helping to prevent osteoporosis.

Community Care

Most families are unaware of the different types of OI, of the prognosis for the disorder, and of the special care needs of a child with OI. Genetic counseling is aimed at primary prevention. Ensure that information given to parents is specific to the child's type of OI. Parents are anxious about the possibility of causing a fracture in their child. Provide specific instructions on how to hold, change, and position the infant to reduce fractures, and to help decrease parental anxiety. Parents of children with OI must achieve a delicate balance between protecting the child and allowing the child to have normal life experiences (Community Care 20–1).

caREminder

Signs of a fracture, especially in an infant, are important items to teach parents. In an infant, these signs include general symptoms such as fever, irritability, and refusal to eat.

Older children with OI become aware that if they injure themselves, they need to be evaluated for a possible fracture. Symptoms of a fracture in an older child include pain, swelling, and possibly deformity at the site.

Muscular Dystrophy

The muscular dystrophies are a group of genetic diseases characterized by progressive weakness and degeneration of the skeletal muscles that control movement. These disorders vary in age of onset, hereditary pattern, and area of weakness. Most dystrophies begin during childhood or adolescence, and all are progressive to some degree. The most common type of muscular dystrophy is Duchenne muscular dystrophy (DMD), also known as *pseudohypertrophic dystrophy*. Other types include limb-girdle (involving weakness of the pelvic and shoulder girdles) and facioscapulohumeral (involving the face and shoulder girdle).

DMD is the most common X-linked recessively inherited disease, occurring in approximately 1 in 3,500 newborns. An estimated one third of cases result from new mutations, with no family history (Manzur, Kinali, & Muntoni, 2008). DMD is predominately a male disease; females are the carriers. In the rare instance that a female has the disease, it is usually a milder form with a slower progression. Genetic counseling should be considered for females in the family. The accuracy of carrier detection has improved significantly during recent years.

A steady and progressive increase in weakness and disability occurs with DMD. Walking becomes increasingly difficult, and many children resort to crawling. On average, most children with DMD are wheelchair dependent by age 10 to 12 years. As the trunk muscles continue to

COMMUNITY CARE 20–1

Recommendations for Promoting Health and Safety for the Child With Osteogenesis Imperfecta

In the Home

Encourage active ROM exercises for children of all ages. Avoid jerking or pulling when moving the child. The child should be allowed to move independently whenever possible.

Fractures can occur. Watch for signs of a fracture, which include pain, swelling, or deformity at the site.

Encourage the child to wear rubber-soled shoes to assist with traction while ambulating.

Remove throw rugs from the floors to help prevent falls.

Monitor toys placed on the floor to prevent the child from tripping on them.

If a wheelchair is needed, the home may need ramps installed to permit easy transportation.

Encourage the child to do as much self-care as possible.

The Osteogenesis Imperfecta Foundation has literature, support groups, social gatherings, and conferences for the children and their family members.

In the School

Encourage the child to attend regular school if possible.

Arrange for home tutors during periods of hospitalization and home recovery.

Discourage participation in contact sports.

Recommend activities such as swimming, arts, crafts, and computer activities.

Body image disturbances are common. Evaluating the child's acceptance of self and acceptance by others, and provide interventions to support positive peer interactions.

Evaluate hearing annually to ensure that no loss has occurred, which may affect school performance.

After an Injury

If the parent or child suspects a fracture, the child should see a healthcare provider immediately.

Before transportation of the child, immobilize the affected area.

Continue treatment measures instituted by the healthcare team (e.g., splinting, braces) until follow-up care reveals no further need for these interventions.

Consider ordering acetaminophen for pain after an injury.

Dietary Needs

Inactivity and short stature may lead to obesity. Recommend, a low-fat, high-fiber diet, with a reduced number of calories.

Encourage fluid intake to prevent dehydration from increased diaphoresis.

Oral Care

Encourage yearly dental checkups. Teeth are frequently prematurely eroded or broken. Teeth may need to be capped.

Complete dental hygiene after every meal.

Skin Care

Because of the problems with diaphoresis, advise the child to wear lightweight clothes that allow ventilation.

Use a sheepskin or softly padded mattress on all bedding.

atrophy, scoliosis often occurs. The scoliosis exacerbates already poor respiratory function caused by thoracic muscle weakness. Death results from cardiac or respiratory failure sometime during the late teens or early 20s. Currently, DMD has no cure. Gene therapy techniques are being investigated as a technique to prevent muscle degeneration and as a potential cure (Manzur, Kinali, & Muntoni, 2008).

Glucocorticoid corticosteroids (prednisone and deflazacort) have been shown to benefit DMD patients. In randomized, double-blind, controlled trials, both of these corticosteroids significantly increased muscle strength, pulmonary function, and functional abilities in these patients. Prednisone is administered to help increase muscle mass and thereby decrease muscle degeneration.

Monitor the child receiving corticosteroid therapy for expected side effects such as weight gain, growth retardation, moon face, hirsutism, cataracts and changes in behavior. Dosing adjustments may be necessary to help minimize side effects.

Pathophysiology

In DMD, the defect on the X chromosome results in a deficiency or absence of the protein dystrophin. This protein, which is thought to help strengthen the muscle cell membrane, is a part of the complex of interacting proteins in the dystrophin–glycoprotein complex. The dystrophin–glycoprotein complex may play a key role in the cascade of events that lead to muscle cell

necrosis. Dystrophin can be found on the surface membrane of muscles and in the brain. Without dystrophin, the sarcolemma membrane is prone to tearing during muscle contraction, which allows muscle cells to break open and their contents to enter the bloodstream. An increase in creatinine kinase levels indicates that muscle damage is occurring. Creatinine kinase levels are high in DMD patients at birth, and high levels persist throughout life.

Assessment

Neonates typically display no clinical symptoms. However, occasionally an infant with DMD displays mild delay in attaining milestones as an early symptom. In most cases, the symptoms of DMD become apparent between ages 2 and 3 years, often more noticeable after a child begins to walk. Note the child's gait; children with DMD appear clumsy and have difficulty climbing the stairs. The classic finding for DMD is Gowers' sign (Fig. 20–11). Because of the muscular weakness in the pelvis and legs, children must use one or both hands to brace the lower extremities and to raise themselves off the floor from a sitting or prone position. Tiptoe walking is also common.

Apparent hypertrophy of the calf muscles marks the progression of DMD and is the reason for the term *pseudohypertrophic muscular dystrophy*. Although the calf muscles look big and strong, fat and fibrous tissue have infiltrated

the muscle, actually making it weaker. Deep tendon reflexes eventually diminish or disappear. However, the child with DMD does not lose sensation in the extremity.

Diagnostic Tests

An elevated creatinine kinase level is the hallmark laboratory value in children with DMD. Severely elevated levels as high as 15,000 to 20,000 U/L reflect the primary damage at the sarcolemma membrane as creatinine kinase leaks out of the muscle fibers. Serum creatinine kinase elevation can be detected at birth, but the test is rarely done at that time, because infants lack symptoms. Electromyography is sometimes used if creatinine kinase levels are not elevated. The most definite diagnosis is made on the basis of either muscle biopsy or DNA analysis. The characteristic muscle biopsy demonstrates scattered groups of regenerating and necrotic muscle fibers. DNA analysis reveals the defect on the X chromosome.

Interdisciplinary Interventions

Management of the child with DMD requires an interdisciplinary team consisting of a nurse, orthopedist, neurologist, pediatrician, geneticist, physical therapist, occupational therapist, orthotist, dietitian, social worker, and psychologist. When possible, follow-up should be done at a specialty clinic where the team approach is best

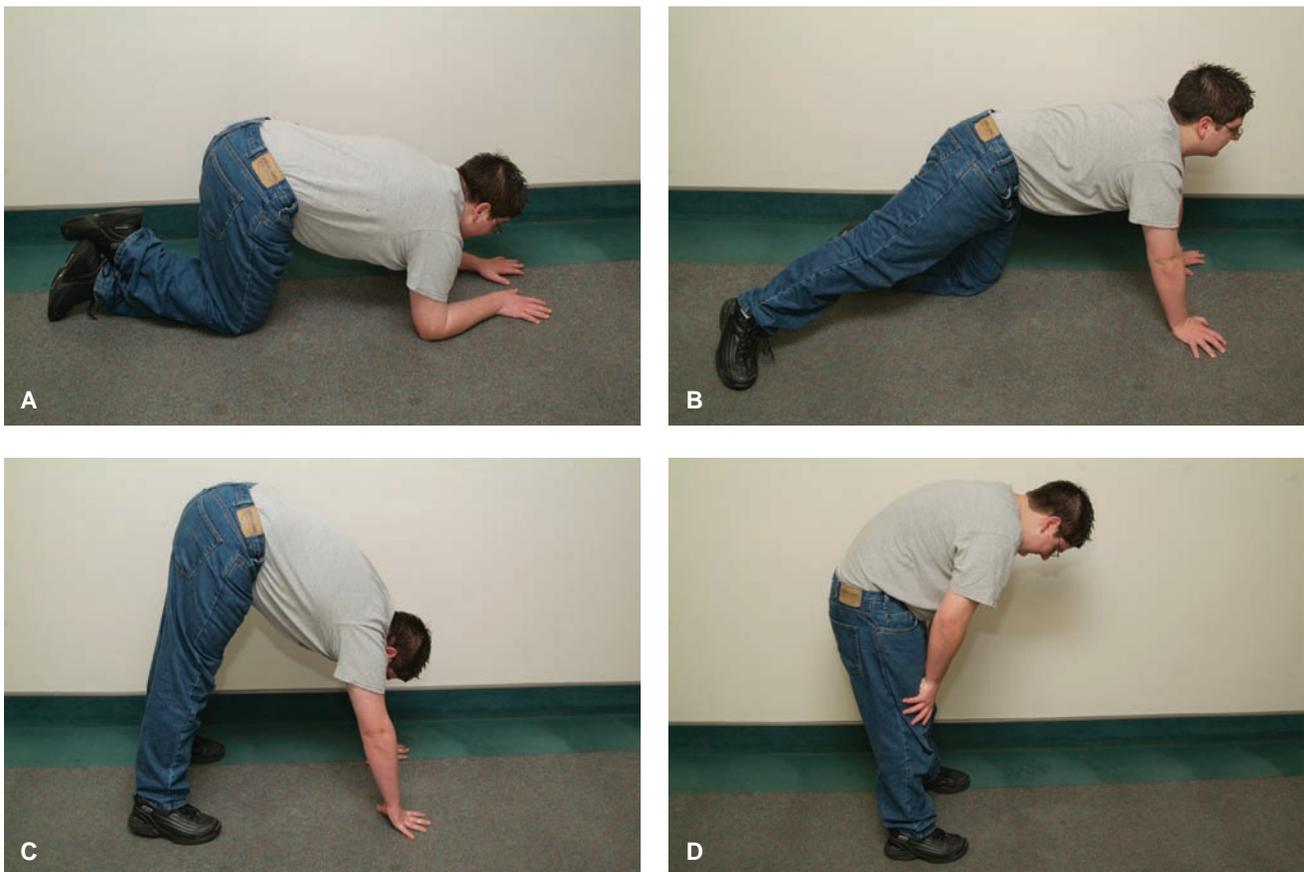

FIGURE 20–11. (A–D) Gowers' sign. The adolescent must use one or both hands to brace the legs and then raise himself off the floor to a standing position.

facilitated. The goals of treatment are to maintain daily functioning for as long as possible and to prevent deformities, which can further disable the child. Good supportive care can increase comfort and the life expectancy of the child with DMD.

Pharmacologic Interventions

Glucocorticoid corticosteroids (prednisone and deflazacort) have been shown to benefit DMD patients. In randomized, double-blind, controlled trials, both of these corticosteroids significantly increased muscle strength, pulmonary function, and functional abilities in these patients. Prednisone increases strength by increasing muscle mass and decreasing muscle degradation. The major long-term benefit of prednisone is prolonged independent or braced ambulation. Unfortunately, side effects include growth retardation, weight gain, moon face, hirsutism, cataracts, and behavior changes. The most common reason for discontinuing therapy is weight gain (King et al., 2007; Manzur et al., 2004).

Supportive Interventions

Conservative treatment for DMD generally begins with resting night splints to slow ankle contractures, followed by long leg braces to delay progression to a wheelchair. Progressive scoliosis and contracture formation may require surgical intervention. Spinal fusion to correct scoliosis may be done, depending on progression of spinal deformity. Ankle contractures may be corrected with heel cord release, and muscle transfers (such as posterior tibialis muscle transfer) may be considered to preserve functional ability.

As the child ages, the teenage years may be marked by respiratory and cardiac complications, and the progressive development of scoliosis. Each of these conditions requires referral to an appropriate medical specialist for treatment. Cardiomyopathy occurs in as many as 90% of DMD patients older than 18 years old (Manzur, Kinali, & Muntoni, 2008). Respiratory complications and sleep hypoventilation develop as a result of weak respiratory muscles, obstructive apneas, and hypoxemic dips during sleep. Scoliosis may develop during the pubertal period, especially after loss of walking. Progression of curvature of the spine affects respiratory function, feeding, sitting, and overall comfort. Surgical spinal fusion may be indicated. The goals of treatment are to keep the child independent and at a high functioning level for as long as possible.

Community Care

The impact of the diagnosis of DMD on a family cannot be underestimated. All members of the family will be affected by the care needs of the child. Encourage the family to seek support and healthcare assistance from the many local, state, and national resources available for children with muscular dystrophy. See Chapter 12 for more information on intervening for a family of a child with a chronic illness.

Promotion of Independence and Self-Esteem

Letting children with DMD be as independent as possible is important to their self-esteem. Children with DMD often have problems with pressure ulcers, particularly if they are obese and wheelchair dependent. An enterostomal therapy nurse can be consulted for specific cases when more complex strategies to manage skin breakdown need to be used. Obesity not only decreases the child's functioning, but also makes it more difficult for parents to lift the child. Nutritional counseling is also important, both to ensure an adequate diet and to control constipation. Neurogenic bowel can be a complication of DMD.

caREminder

Obesity related to inactivity is common in the child with DMD.

Appropriately selected activities can boost self-esteem, provide social interaction, and normalize life for the child with DMD. Children attend school until they are not able to sit up. When the child cannot attend school, a home tutor can be arranged. School personnel meet with the family and selected members of the healthcare team to develop an individual education program to meet the child's educational needs. (See Chapters 2 and 12 for more discussion of individual education programs). Activities such as arts and crafts, board games, and computer games are favorites. Many children with DMD attend camps for children with disabilities and participate in wheelchair sports. Many options are available for the wheelchair athlete, including tennis, swimming, rowing, skiing, and track and field (Fig. 20–12). Teams are organized at the state level and through rehabilitation programs. Local tournaments and national championships provide opportunities for all levels of athletes to participate.

Supportive Therapies

Physical therapy and occupational therapy are an important part of the life of a child with DMD. Physical therapy initially focuses on stretching tight muscles. As weakness progresses, physical therapy can provide appropriate equipment and assistive devices to maintain functional mobility. Occupational therapy assists with activities of daily living and includes special clothing, eating utensils, toilet seats, and mobility devices. A speech therapist can help with issues related to dysphagia and aspiration risks as the child gets weaker. A recreational therapist can help the family to connect with resources within the community, such as the parks and recreation department for activities, groups that provide adaptive physical education, and disabled student service organizations. The Muscular Dystrophy Association can be a great social and financial support to families (see [thePoint](#) for organizations).

Anticipatory guidance is ongoing. As the child's status deteriorates, the family and child will most likely need

FIGURE 20–12. Wheelchair sports provide an opportunity for the child with muscular dystrophy to enjoy physical activity and interact with peers.

counseling related to decision making for placement of a tracheostomy tube for positive-pressure ventilation, and airway and secretion management. Early education on the progression of the disease can assist the patient and family with decision making and advance directives.

GROWTH-RELATED DISORDERS

Growth-related disorders become evident as the musculoskeletal system matures. Multiple diagnoses are related to delayed or accelerated growth. Many of these conditions are associated with endocrine or metabolic disorders (e.g., growth hormone deficiency, hypothyroidism, hypophosphatemia, rickets) (see Chapters 26 and 27). Growth disorders may also be secondary to other chronic conditions such as cystic fibrosis, renal disease, and cardiac disease. Many growth-related disorders are self-limiting; as the child grows, the disorder resolves itself. In other cases, such as with Legg-Calvé-Perthes (LCPD) disease or scoliosis, a joint is destroyed, or the child is left with a permanent disfigurement. In all these cases, the cause is either not known or not fully understood.

Torsional Deformity: Femoral Anteversion

A torsional deformity is a musculoskeletal condition in which the bone is “twisted.” Such twisting can occur in the femur or tibia. In femoral anteversion, also called *internal femoral torsion*, the femur is medially rotated (Fig. 20–13). It is often associated with metatarsus adductus, neuromuscular disorders (e.g., cerebral palsy, myelodys-

plasia), LCPD, and DDH. It is postulated that femoral anteversion increases the likelihood of development of osteoarthritis in adulthood. Torsional deformities affect females twice as often as males, and a familial tendency has been noted.

Pathophysiology

The rotational and angular alignments of the legs change during a child’s growing years. Children begin life with the femurs anteverted. In most children, femoral anteversion will remodel (resolve spontaneously) by age 8 (Gordon et al., 2005). In a child with a neuromuscular problem, however, resolution may not occur as a result of the underlying neurologic defect and/or the musculoskeletal sequelae of the disorder, and treatment is needed.

Assessment

Begin the assessment by asking the parents if they have any concerns regarding their child’s gait. The history of the problem, including onset, progression, and any previous management, plus information about the perinatal period and motor development, are essential. Next, evaluate the child’s gait by having the child walk the length of a hallway unclothed except for underclothing. Observing gait provides information on muscle strength, coordination, and foot angle. Assessment of femoral anteversion frequently includes a subjective complaint that the child is walking “pigeon-toed” or seems to trip over his or her feet when running (running may accentuate dysfunction or rotation).

Upon physical examination, the child’s thighs medially rotate, and the knees and patellae turn inward. The legs

FIGURE 20–13. In femoral anteversion, the thighs rotate medially and the knees and patellae turn inward. Braces can be used to correct this problem. (Courtesy of Wheaton Bracing System).

appear bowed when the feet are pointed straight ahead. Clinical measurements determine medial and lateral rotation of the hip. In children with femoral anteversion, measurement shows decreased lateral rotation of the femur and increased medial rotation. Radiologic examination may be done to rule out other pathology, such as acetabular dysplasia.

Interdisciplinary Interventions

Normally, no treatment is necessary because of spontaneous remodeling of the femoral anteversion. If femoral anteversion is severe (limiting participation in normal activities of daily living or sports) and does not resolve spontaneously, or the child has a neuromuscular disorder, derotation femoral osteotomy may be done to correct alignment. An osteotomy involves a cut through the femur; the bone is then rotated to the desired position, and screws are used to hold it until the bone heals. A hip spica cast is then applied for approximately 6 weeks.

Assure the parents and child that this problem often resolves on its own. When surgery is necessary, educate the family on caring for the hip spica cast and arrange for a wheelchair rental and a home tutor. In most cases, postoperative physical therapy is not needed.

Torsional Deformity: Tibial Torsion

The most common cause of in-toeing in toddlers is internal tibial torsion, which is a medial twisting of the tibia along the axis of the tibia, and has been attributed to position in utero or in sleep. Pressure from the uterus or mattress on the legs as the fetus or child tucks the legs under the body is thought to twist the tibia. Medial torsion causes an in-toeing gait; lateral torsion causes an out-toeing gait. Alignment problems of the lower extremities are related to alterations in normal limb development and rotation of the hip, femur, and tibia in utero.

Abnormal medial tibial torsion rarely occurs as a single deformity. It is commonly associated with femoral anteversion, congenital metatarsus varus (in-toeing), or developmental genu varum (knock-knee). It occurs in approximately 5% of adult females and 3% of adult males. The degree of tibial torsion varies with the child's age. At birth, the tibia rotates medially, but with normal growth and development, it spontaneously derotates.

Assessment

The child with medial tibial torsion usually presents with a history of being “pigeon-toed.” Often, a family history of medial tibial torsion is noted.

Lateral tibial torsion is seen as an out-toeing gait. Children usually do not have a positive family history for lateral tibial torsion. Unlike medial torsion, which may improve during late childhood, lateral torsion usually worsens. Worsening results from a contracture of the iliotibial band, the congenital deformity that has caused the torsion.

Diagnosis is made by physical examination. Two methods can be used to screen for tibial torsion. First, the

child sits with the knees at a 90-degree angle, and the examiner palpates the malleoli. Normally, the medial malleolus lies farther forward than the lateral malleolus. Second, with the child lying prone, the examiner measures the thigh-foot angle (see Fig. 8-15). The parent will often report that the child has in-toeing. Radiographs are not very useful in diagnosing tibial torsion in young children. Most cases spontaneously resolve with growth. Persistent tibial rotation in an older child requires referral to an orthopedic surgeon.

Interdisciplinary Interventions

No treatment is indicated in most patients with internal tibial torsion. Occasionally, a Dennis Brown bar (a rigid bar, attached to the bottom of the shoes that rotates the feet in an out-toeing position) is used for the child younger than 18 months of age to alter the patient's sleep position. Corrective shoes for daytime wear are not indicated.

If the in-toeing gait is persistent, surgery—specifically, an osteotomy—is performed. Generally the surgery is not done until 8 to 10 years of age, so that normal physiologic remodeling can occur.

Legg-Calvé-Perthes Disease (LCPD)

LCPD is a common pediatric hip disorder that causes pain and decreased hip motion, possibly leading to a femoral head deformity. It has an incidence of 1 per 1,200 live births, with some hereditary factors influencing incidence. LCPD occurs four times more often in males than in females and rarely occurs in African American children. The peak age range for occurrence is 4 to 8 years, although it has been seen in children as young as 3 years. Generally, LCPD occurs unilaterally; however, 10% to 12% of cases are bilateral (Hosalkar, Horn, Friedman, & Dormans, 2007a).

Pathophysiology

LCPD is a form of avascular necrosis of the proximal capital femoral epiphysis (growth plate) in children. The precise cause is unknown. LCPD progresses into four distinctive phases:

1. Avascularity: Interrupted blood supply to the femoral head, cessation of bone growth with no change in bone density and intact surface cartilage
2. Revascularization: Restoration of blood supply to the femoral head with reabsorption of dead bone with laying down of immature new bone; possible remodeling of femoral head in a deformed position
3. Reossification: Laying down of new bone with continued remodeling
4. Residual deformity: Completion of healing; hip normal or deformed forever

Assessment

The first symptoms of LCPD typically include pain, limping, and decreased ROM in the affected hip. These symptoms usually have been plaguing the child for

months, with no history of trauma, before the child complains. The child will report hip or groin pain, which may be referred to the knee or thigh. Pain increases with activity and decreases with rest. Diagnosis usually occurs during the second phase, when the child begins to have symptoms such as pain.

On observation, the child may hold the leg in slight flexion, and a hip contracture may be present. Limited hip motion, especially internal rotation and abduction, is a classic sign of LCPD. The limited abduction is secondary to synovitis and muscular spasm. Most children with LCPD walk with a limp that becomes more pronounced during later stages of the disease. Additional findings include leg length discrepancy, thigh atrophy on the affected side, and a positive roll test. The roll test is done with the child lying supine. The examiner rolls the hips of the affected extremity into internal and external rotation. The maneuver will evoke guarding or muscle spasm in the affected child during the acute phase of the disease.

Diagnostic Tests

Radiographs are the standard technique for diagnosing LCPD and evaluating treatment. Based on the location and degree of involvement of the epiphysis, the disorder is classified using the two basic classification systems: the Catterall system, used retrospectively; and the Salter-Thompson classification system, which aims to predict outcome. For example, involvement of only the posterior epiphysis has a good prognosis. When the entire epiphysis is involved, the prognosis is poor, because the growth plate is often severely damaged, further increasing the risk of residual deformity.

Bone scans are particularly useful in diagnosing the early stage of LCPD, when changes may not be evident on radiographs. A bone scan shows decreased uptake of dye in an affected femoral head and more clearly demarcates the area of avascularity; magnetic resonance imaging (MRI) and arthrography also may be performed.

No laboratory studies are relevant for LCPD. Although a complete blood count and an erythrocyte sedimentation rate (ESR) may be done to rule out infectious or inflammatory processes.

Interdisciplinary Interventions

The goals of treatment for LCPD are to achieve and maintain ROM, relieve weight bearing, and position the femoral epiphysis within the acetabulum with traction. The earlier that treatment begins, the less risk there is of residual deformity to the hip joint. Also, children whose LCPD is diagnosed at a young age tend to have fewer long-term problems. Approximately 80% of children have a good recovery, although they may have difficulty later in life with hip degeneration.

Pain Relief Interventions

The first step in treatment is to regain motion around the hip joint and relieve pain resulting from **synovitis**

(inflammation of the synovial membrane) or muscle spasm around the hip. Nonsteroidal anti-inflammatory drugs (NSAIDs) help decrease inflammation and pain. Some physicians place the child in Buck's traction (see [thePoint](#), for Procedures: Traction Care) at home or in the hospital until ROM improves and pain diminishes (approximately 1–2 weeks). The child must be on strict bed rest, and even sitting in bed (except to eat meals) is discouraged. When the child is placed on home traction, a home care company provides the traction equipment, trains the parent to set up traction, and sends nurses or physical therapists to the home periodically. Home traction requires an enormous time commitment from the family, and the child will need home tutoring. Also, staying in traction may be an issue for some children at home. Children who are younger or whose disease is detected early may require only observation and follow-up, with radiographs obtained every 2 to 4 months.

Containment Interventions

After the inflammation in the hip has decreased and ROM has improved, the next goal, containment, can be addressed. Containment involves holding the femoral head in abduction to prevent the edge of the acetabulum from denting the head. However, some movement of the hip is desirable to mold the soft head round.

Containment can be achieved in a variety of ways, and the treatment chosen depends on the stage of the disease and physician preference. Nonsurgical options for containment include braces and Petrie casts (thigh-to-ankle casts connected by a brace that holds the legs apart). The most commonly used brace is the Atlanta–Scottish Rite orthosis, which enables weight bearing. A child may be placed in Petrie casts for a few weeks and then braced, or the child may be put in a brace immediately. Both options have advantages and disadvantages, but both maintain the hips in abduction.

To be effective, bracing must be used for 6 to 18 months. The brace is worn constantly, except for bathing. Children can wear the brace over regular clothes and some can even participate in other activities, such as baseball, while wearing the brace. The child must be monitored routinely. Some physicians prefer to treat the child with physical therapy or no brace at all.

Surgical options for containment of the hip are reserved for children with severe deformity. Surgical options achieve containment via an osteotomy of the femur. A pelvic osteotomy can be used to increase abduction and correct the various existing deformities, alleviating the associated symptoms. The child is hospitalized for approximately 3 days and is discharged home in a hip spica cast for 6 to 8 weeks. When the cast is removed, no further treatment is needed. The advantages of this treatment method are that the child is restricted in a cast for only 2 months and that the hip containment is permanent. The disadvantages are those related to any surgery and the possibility of a leg length discrepancy as a result of the osteotomy. As an adult, the child may be at higher risk for degenerative joint disease.

Community Care

Community care begins with educating the parents and child about the disease process and the use of corrective devices (i.e., traction, casting, or bracing). Despite the healthy appearance of the affected child, parents and other caregivers must come to understand the seriousness of this disease and the importance of adhering to the treatment regimen. The treatment for LCPD can span a few years, which can be a stressful time for families emotionally as well as financially. Social services can assist families to find the resources they need to manage long-term care.

If home traction is required, the parent must learn the principles of traction and immobilization. Assist with arranging home healthcare services to monitor the child's progress and to evaluate the family's ability to manage the traction device. If both parents work, the home health agency may be able to assist in locating a daytime caregiver for the child. Home tutoring arrangements should be made with the child's school so that the child does not fall behind in schoolwork.

If casting is used, be aware that these types of casts vary widely (see Treatment Modalities at beginning of this chapter). Fitting through the door of a house or car may be impossible unless the child turns sideways. A reclining wheelchair allows some mobility, although it is limited. Special transportation services in a van or ambulance can be arranged by social services or the home care nurse if required.

If the child is in a brace, he or she may attend school and participate in many of the activities with other children. The child is given specific instructions regarding how and when to wear the brace. If the brace becomes soiled, instruct parents to wash it with a damp cloth. If the brace breaks, urge the parents to contact the company that issued the brace promptly to provide an immediate replacement.

Slipped Capital Femoral Epiphysis (SCFE)

SCFE is defined as a posterior and inferior slippage of the proximal femoral epiphysis at the femoral neck, occurring through the physal plate (Fig. 20–14).

SCFE is the most common hip disorder, with onset during the prepubescent growth phase; it almost never occurs in girls after menses has begun. The average age of occurrence is 12 years in girls and 13½ years in boys. Although the condition is usually unilateral, SCFE is bilateral in 25% to 40% of affected children. One half of those with unilateral presentation will later develop the condition in the opposite hip, usually within 18 months. Incidence is two to five times higher in males than in females and is greater in the eastern United States, in Polynesians, and in African Americans (Katz, 2006; Loder and Greenfield, 2001). With prompt treatment, many children do well after a slip. Barring the complication of avascular necrosis, the prognosis is good. However, the child is at risk for degenerative hip arthritis later in life, a risk that increases with the severity of the slip.

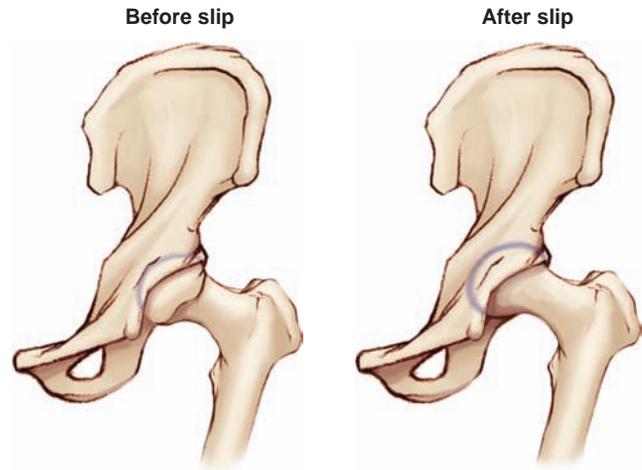

FIGURE 20–14. In slipped capital femoral epiphysis, the femoral head moves upward and forward while the capital epiphysis becomes displaced backward and downward.

Pathophysiology

The exact cause of SCFE is unknown. Numerous theories have been proposed, but none have been proved. A genetic component has been noted, and the most plausible theory is that SCFE is related to an endocrine abnormality. Idiopathic SCFE may be caused by many factors, including obesity, physal orientation, abnormalities in physal architecture, and hormonal changes during adolescence that affect physal strength. Some researchers believe the incidence of SCFE is related to the child's place of residence in the world and the seasons of the year (Tradition or Science 20–3). Obesity results in increased shear stress across the physal plate, which is already orientated more vertically and posteriorly in children than in adults.

Trauma also has a role in the development of a slip. If a heavy child's growth plate is already weak, and the child falls on the weakened hip, SCFE may result. Other conditions associated with SCFE include hypothyroidism, renal osteodystrophy, and postradiation therapy.

SCFE is classified by the stage and the severity of the disease, which in turn influence prognosis (Table 20–2). Complications that can occur as a result of SCFE are chondrolysis (acute necrosis of the cartilage of the hip) and avascular necrosis (loss of blood supply) of all or part of the femoral head.

Assessment

Typically the child with SCFE has a history of intermittent limp and pain for several weeks or months in duration, which may be in the hip, groin, or knee. A vague history of trauma often exists. As the epiphysis continues to slip, the child loses hip motion, including internal rotation, flexion, and abduction. The gait is often **antalgic** (limping on the affected side). Although the knee examination and distal neurovascular examination are normal, the child often refuses to move the hip. The hip may be held in external rotation at rest, whereas, normally, the

TRADITION OR SCIENCE 20–3

Is seasonal variation evident in the onset of SCFE symptoms?

EVIDENCE-BASED PRACTICE

Several researchers have been interested in the relationship between the seasons and the onset of SCFE symptoms. Furthermore, seasonal variation has been examined as it relates to gender, ethnicity, and geographic location. Study data remain inconclusive. Lehmann et al. (2006) found that slips occurred significantly more often during the summer north of 40° latitude and during the winter south of 40° latitude in the U.S. Brown (2004) found significantly more seasonal variation in the northern United States, in both boys and girls, than in the southern United States, but less seasonal variation occurred among blacks than among whites. Maffulli & Douglas (2002) completed their work in Scotland and determined that for male patients, seasonality was significant, with an autumnal peak that was highest in November. No significant seasonal variation was present among female patients, although there was a trend similar to that in male patients, again with the highest incidence in November.

Why this interest in seasonal variation of SCFE? Although the cause of seasonal variation in SCFE remains unknown, the effect is believed to differ by latitude and skin pigmentation, suggesting a possible link to impaired vitamin D synthesis. More research is indicated to strengthen the associations indicated between seasonal changes and the physiologic rhythms that may affect the onset of SCFE.

hip is typically held in a position of flexion, internal rotation, and abduction. In a moderate or severe slip, the affected leg also may be shorter, with an atrophied thigh muscle. Radiographs of the pelvis are the best tools for diagnosing SCFE.

Alert! Do not attempt ROM evaluation in a child with a suspected acute slip, because this evaluation could worsen displacement.

Interdisciplinary Interventions

Distinguishing between stable and unstable SCFE is important in directing care. In stable SCFE, ambulation is possible, with or without crutches; in unstable SCFE, ambulation is not possible, with or without crutches. The patient with an unstable hip has a poorer prognosis, because this condition carries an increased risk of avascular necrosis.

The goal of treatment for SCFE is to prevent further slippage and to achieve closure of the physal plate. When SCFE is diagnosed, the child should stop all weight-bearing activities, be placed on crutches or use a wheelchair, and be referred to an orthopedic surgeon. The most widely accepted treatment for SCFE (90% of cases) is internal fixation—a surgical intervention that pins the hip together with a single central screw. Results of this type of surgery are excellent, and blood loss and complications are minimal.

After internal fixation, the child is discharged with crutches; after 1 week, the child can fully bear weight on the affected leg. The pin is removed later. Children with SCFE are monitored by their physicians until they have reached skeletal maturity, to ensure that they do not develop contralateral SCFE or experience residual deformity and pain of the femur (Katz, 2006).

Assist the child and family in adjusting to sudden hospitalization, no weight-bearing activity, and surgery. Manage postoperative pain with oral or intravenous narcotics. Monitor the neurovascular status of the affected extremity closely (see Nursing Interventions 20–1). The physical therapist instructs the child in crutch walking.

KidKare ■ Instruct the child that safe crutch walking starts with wearing low-heeled, rubber-soled shoes (sneakers are ideal). The child should not try to move quickly on crutches, because a fall may result.

TABLE 20–2

Classification of Slipped Capital Femoral Epiphysis

Stage	Severity
Preslip phase: The child complains of weakness in the leg, and pain in the hip or knee when standing or walking for prolonged periods of time.	Grade I (preslip): The physis widens without actual displacement of the epiphysis.
Acute slip: A child falls and then reports hip pain.	Grade II (minimal slip): The femoral neck is displaced from the femoral head by up to one third.
Chronic slip: The femoral head gradually slips off the femoral neck and remodels.	Grade III (moderate slip): The femoral neck is displaced by more than one third, but less than one half of the femoral head.
Acute on chronic slip: Slow, progressive slippage becomes more displaced when a child falls.	Grade IV (severe slip): The epiphysis is displaced by more than 50%.

Community Care

The child is ready for discharge from the hospital when he or she can ambulate safely with crutches and when the pain is well controlled with an oral narcotic such as acetaminophen with codeine. Crutches will be needed for ambulation for 3 to 6 months postoperatively. The child may then gradually resume normal activities, including running and contact sports. The child is closely monitored for 6 to 12 months for hip, groin, or knee pain in the nonaffected leg as a result of the high incidence of bilaterality seen in SCFE.

Osgood-Schlatter Disease

Osgood-Schlatter disease is one of the most common causes of knee pain in the adolescent. The diagnosis requires consideration in a child who presents with pain, swelling, and tenderness at the anterior tibial tuberosity. The typical patient is a 13- to 14-year-old boy or an 11-year-old girl. It can occur unilaterally, but presents bilaterally in about 30% of cases.

The prognosis for Osgood-Schlatter disease is very good. Symptoms can be expected to resolve about the time that the child's skeletal growth ceases (in boys, around age 17; girls, age 15). This condition does not result in long-term complications; however, many patients with Osgood-Schlatter disease may have pain on kneeling as an adult.

Pathophysiology

The underlying cause is believed to be a partial traumatic avulsion of the proximal tibial tuberosity at the insertion of the patellar tendon. The patella is particularly susceptible to trauma during rapid growth spurts, when the tibial tuberosity is susceptible to strain as a result of repetitive, submaximal stress from the quadriceps muscles.

Assessment

The child will often give a history of participation in sports that requires repetitive quadriceps contractions, such as football, basketball, soccer, gymnastics, and ballet. Discomfort is exacerbated with running, jumping, kneeling, and going up and down stairs. The child will often report pain relief with rest. The diagnosis is made by examination. The major clinical manifestations include visible soft-tissue swelling, and tenderness to direct pressure over the proximal tuberosity at the site of the site of the patellar tendon insertion. Upon palpation, a soft mass can often be felt in the area.

Osgood-Schlatter disease has been rated as grades 1 through 3, according to severity. Grade 1 involves pain after activity that resolves within 24 hours, grade 2 involves pain during and after activity that does not limit activity and resolves within 24 hours, and grade 3 consists of constant pain that limits sport and daily activity. Grades 1 and 2 require conservative treatment for a short time. Grade 3 may require conservative treatment for 3 to 6 months.

KidKare ■ Asking the child to squat or extend his or her knee against resistance usually elicits pain and is a good indicator of Osgood-Schlatter disease.

Irregularity of the tibial tuberosity is often seen on radiographs; however, they are usually unnecessary for diagnosis.

Interdisciplinary Interventions

In most cases, Osgood-Schlatter disease is self-limiting and can be managed by the primary care physician. Conservative management is directed at limiting physical activities that require frequent knee bending, jumping, or repetitive motion of the knee. Analgesics are recommended for pain, and anti-inflammatory agents are used to reduce inflammation. Ice may be applied during the acute phase. Exercises during the rehabilitation phase include quadriceps isometrics, straight-leg raising, and isotonic resistance exercises for the hamstring. Occasionally a splint or protective padding is applied, especially when the child has difficulty restricting activities.

In the rare cases when a child develops a painful ossicle in the distal patellar tendon, surgical excision may be recommended. Displaced avulsion fracture, a very rare complication, typically requires surgical repair.

Treatment of Osgood-Schlatter disease requires up to 3 months before the child can resume full sports involvement. Support the child and family at this time. A note from the physician or nurse to the school is needed if the child participates in a physical education program. If a child participates in multiple sports activities, choosing one sport to remain involved in will enable the child to recover and feel that he or she has some control. Involvement of the team coach may be needed to increase adherence to rehabilitation. Treatment should continue until the child can enjoy activities without discomfort or noticeable pain afterward. Too rapid a return to sports will cause symptoms to recur. If symptoms are not controlled by conservative management, the child will need referral to an orthopedic surgeon. The parents need to be advised that the child may have a permanent bump on the anterior knee; this bump can be especially problematic with girls, for cosmetic reasons.

Scoliosis

QUESTION: Chase has idiopathic structural scoliosis. Chase and his parents want to know if he might need surgery for his scoliosis. How would you explain the rationale for surgical versus nonsurgical intervention for idiopathic scoliosis appropriate for Chase?

Scoliosis is defined as spinal curvature in the coronal plane greater than 10 degrees. The primary deformity is

a lateral flexion plus rotation of the involved vertebrae around a vertical axis.

Scoliosis can be idiopathic or congenital. Idiopathic scoliosis is present in 2% to 4% of children between 10 and 16 years of age. Females are affected more often than males. Congenital scoliosis, caused by a malformation of the vertebrae, occurs less often than idiopathic scoliosis. Of all children with congenital or idiopathic scoliosis, fewer than 10% require medical intervention (Lonstein, 2006).

Scoliosis is classified as nonstructural or structural, according to magnitude, location, direction, and cause. In nonstructural scoliosis, the spine is structurally normal with a lateral curvature, no spinal rotation, and no truncal asymmetry. Causes of nonstructural scoliosis include postural compensation for leg length discrepancy and irritation of the sciatic nerve. Structural scoliosis involves both a lateral curvature and rotation of the vertebrae. Causes can be cerebral palsy, poliomyelitis, muscular dystrophy, metabolic abnormalities, birth defects, or connective tissue disorders. A third type, neuromuscular scoliosis, is defined as a coronal and sagittal plane deformity of the spine with abnormalities in the myoneural pathways and curves of greater than 50%. In many cases the cause is idiopathic.

Kyphosis and *lordosis* are two terms used to describe a spinal curvature in the sagittal plane. Kyphosis is commonly described as a “humpback” or excessive forward concavity of the spine. Lordosis is a “swayback” or excessive backward concavity of the spine. Both curves are present in the normal spine, but when they become excessive, families may seek treatment. Lordosis, usually of the lumbar spine, is not a major deformity in children. Kyphosis and lordosis are not as commonly seen as scoliosis. The following discussion focuses on scoliosis.

Pathophysiology

Current theories hold that scoliosis is a multigene-dominant condition with variable phenotypic expression. The severity of scoliosis can vary widely from parent to child and sibling to sibling. When both parents have scoliosis, the risk of their children needing treatment is 50 times greater than the risk in the general population (Reamy & Slakey, 2002). Four major curve patterns occur in children with idiopathic scoliosis: thoracic, lumbar, thoracolumbar, and double major (Fig. 20–15).

The age at onset and the location of the curve affect the prognosis of scoliosis considerably. The younger the child at the time of diagnosis, the greater the degree of curvature, because of the amount of growth remaining. Adolescents with a curvature less than 30 degrees at the time of bone maturity are unlikely to experience further progression. Adolescents with a curve from 30 to 50 degrees are likely to progress an average of 10 to 15 degrees of curvature after bone maturity. Curves greater than 50 degrees will progress at about 1 degree per year.

Curvature tends to progress more severely in females than in males. Congenital curves are also more likely to progress and to cause respiratory compromise. Life-

threatening effects on pulmonary function increase as the curve angle worsens.

Assessment

When obtaining the history, include questions about family history of scoliosis and presence of pain or neurologic changes, including bowel or bladder dysfunction. The presence of severe pain or neurologic symptoms would be atypical of scoliosis. Include the date that the curve was first noticed and the history of progression of the curve. A slowly progressing curve is less worrisome than a sudden increase in severity of a curve.

Alert! If pain is reported as a symptom of the child's scoliosis, investigate immediately. Pain is not a normal finding for idiopathic scoliosis, and the presence of this particular symptom could signal an underlying condition, such as a tumor of the spinal cord.

Physical examination should include an assessment of Tanner stage (see Figs. 3–16 and 3–17) and a complete neurologic examination. Peak curve progression occurs during Tanner stage 2 or 3. If neurologic signs such as a limp, weakness, or change in gait pattern are evident, pursue a full neurologic workup. Observe gait, measure leg length, and assess overall physical maturity.

Scoliosis screening is done routinely in schools and during well-child physicals by nurses. A scoliometer or “humpometer” can be used during screening to obtain a rough measurement of the curvature and to help identify scoliosis. The child bends forward at the waist while holding the palms together with arms extended (Fig. 20–16). The examiner looks along the horizontal plane of the spine from the back and side to detect an asymmetry in the contour of the back, known as the *rib hump* (the hallmark of scoliotic curves); those greater than 10 degrees require referral to a physician for radiography.

Diagnostic Tests

Abnormalities on physical examination require radiographic evaluation with a single standing, posteroanterior radiograph to enable measurement of the curve using the standardized Cobb or Risser grading scale. MRI is indicated for a left thoracic curve, pain, or positive neurologic examination.

Nursing Diagnoses and Outcomes

Many of the nursing diagnoses and outcomes for the child with a musculoskeletal disorder presented in Nursing Plan of Care 20–1 apply to the child with scoliosis. In addition, the following nursing diagnoses may apply to the newly diagnosed child and the child undergoing surgical intervention:

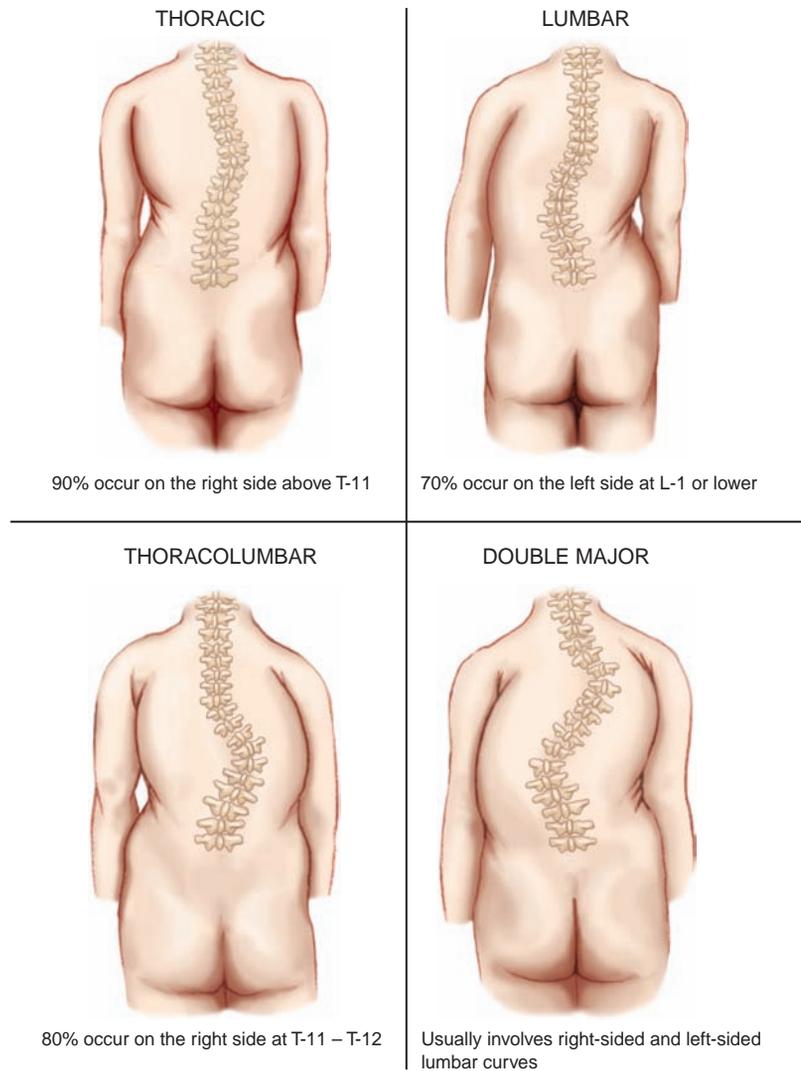

FIGURE 20–15. The four major curve patterns in idiopathic scoliosis.

Ineffective breathing pattern related to effect of curvature on ventilation and mobility

Outcome: Child will achieve maximal lung expansion with adequate ventilation.

Acute pain related to surgical intervention to treat scoliosis

Outcomes: Child will experience minimal pain during the postsurgical recovery period.

Child will identify measures effective in relieving pain.

Parents will express awareness of the child's pain and perform measures to comfort the child.

Interdisciplinary Interventions

Education is an important component of the care for a child with scoliosis. At the time of diagnosis, many children and families are often upset and scared. Basic explanations and truthfulness are the best approach with teenagers. Progression of a curve is the basis for deciding whether the child will need treatment. The selected treatment regimen then is based on the child's age, the

degree of curvature, and the child's willingness to adhere to the treatment program. Treatment options for scoliosis fall into two groups: nonsurgical and surgical interventions.

Nonsurgical Interventions

Bracing has proved effective to alter the natural curve progression of scoliosis, if the brace is worn as prescribed. The effectiveness of other approaches, such as physical therapy, chiropractic care, biofeedback, and electrical stimulation, has not been proved.

If the curve of the child's scoliosis is less than 20 degrees, most physicians observe the child for any further progression of the curve. The child is assessed approximately every 6 months on an outpatient basis until the physician determines either that the curve is progressing or more aggressive treatment is needed.

When the scoliosis measures between 20 and 39 degrees of curvature, and evidence of progression exists, bracing is generally the next course of action. During the past

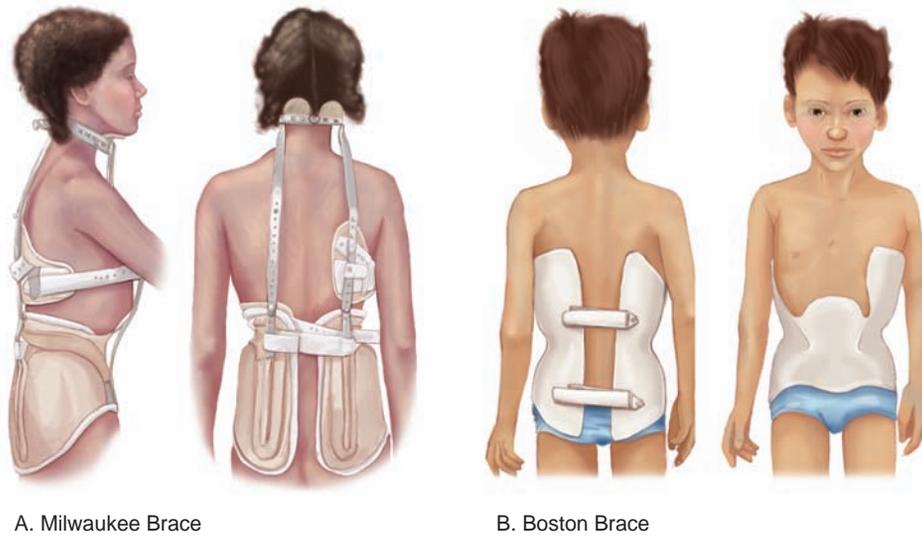

FIGURE 20–16. Scoliosis screening is performed by the school nurse. (A) The examiner begins by viewing the child from the back, looking for symmetry of the shoulders, scapulae, and waist creases. (B) Next, the child is asked to place her hands together and bend forward. The examiner uses a scoliometer to obtain a rough estimate of the degree of spinal curvature. (C) The examiner looks from the front for anterior chest deformity or asymmetry. (D) When the child bends forward toward the examiner, particular curves may become more visible. (E) Observing the child from the side allows the examiner to assess for kyphosis and lordosis.

50 years, a variety of braces, or orthoses, have been developed to treat scoliosis. The Milwaukee brace is the most familiar brace, although in recent years the Boston brace (the most common form of the thoracic–lumbar–sacral orthosis brace) has become more popular. This is likely a result of its acceptance by teenagers because it is not visible when worn under clothing. However, the Boston brace is not effective for high thoracic curves. A brace

also may be custom-designed specifically for a child (Fig. 20–17).

KidKare ■ If the child expresses strong resistance and noncompliance with wearing a brace, a surgical approach to care may be required.

A. Milwaukee Brace

B. Boston Brace

FIGURE 20-17. (A) Milwaukee brace (side and back views). (B) Boston brace (front and back views).

If the child must wear a brace, the schedule for wearing the brace should be convenient yet fulfill the required number of hours, generally at least 16 hours a day. During brace treatment, children are seen in the physician's office every 4 to 6 months. After the child reaches skeletal maturity, the time for wearing the brace is tapered. When braces work, they prevent progression of the curve by holding it in place until the child reaches skeletal maturity. The ideal candidate for a brace is the child who is immature skeletally and who has a curve with a high risk for progression. TIP 20-2 summarizes a teaching intervention plan for the child with a brace. Despite adherence to a bracing regimen, however, the curve does progress in some children, necessitating surgical intervention.

Surgical Interventions

Most experts believe that if a spinal curve reaches 40 degrees or more, surgery should be considered because the possibility is great that the curve will worsen. With a curve measurement of more than 50 degrees, surgery is almost always needed. Each case is considered for neurologic status, bone age, diagnosis, curve size, physical and psychological effect of the deformity, and readiness for a major surgical intervention.

The goals of scoliosis surgery are to fuse the vertebrae so that the spine cannot bend, and to correct the deformity. The most common surgical approach for idiopathic scoliosis is posterior spinal fusion (Table 20-3). This procedure consists of a long, straight midline incision extending to two levels above and below the segments of the spine to be fused. Iliac crest bone graft is used to augment the fusion (see [thePoint](#) for Care Path: An Interdisciplinary Plan of Care for the Child With Posterior Spinal Fusion.)

Surgical intervention for the child with neuromuscular scoliosis is different because it often occurs at a younger age, and the fused portion of the spine is longer. The surgical technique is anterior and posterior, to enable increased stabilization of the spine and sacrum. To obtain the desired outcomes, rods, sublaminar wires, or a combination are used. Postoperative care is more challenging because these children need pulmonary support, fluid status monitoring, and nutritional support in addition to routine postoperative monitoring.

As an adjunct to surgery, if a child has severe deformities, halo-gravity traction is used preoperatively and postoperatively in children with severe trunk decompensation, failed previous spinal fusion, or severe pulmonary compromise. This process can be long and costly, and can be a drain on the family. The halo traction is in place for a few weeks before surgery and for up to 6 weeks after surgery. Potential complications of loose pins and wound infections add risk during the perioperative and postoperative courses.

Preoperative Care

Preoperatively, the healthcare team reviews the surgical plan with the family. Education begins with explaining the degree of the curve, the surgical procedure, possible surgical complications, and duration of hospital stay. The teaching includes postoperative dressing change, bracing needs, pain management, activity level, and home care needs. See Chapter 11 for additional information on preoperative and postoperative care of the child.

Immediate Postoperative Care

After surgery, children may go either to the intensive care unit for one night or to the pediatric unit. Care during

TIP 20–2 A Teaching Intervention Plan for the Child Wearing a Brace for a Back Condition

Nursing diagnoses and outcomes

Noncompliance related to discomfort and alteration in body image from brace

Outcome:

- Child will wear brace for prescribed period of time.

Risk for impaired skin integrity related to presence of brace

Outcome:

- Child will exhibit intact skin without evidence of pressure areas or skin breakdown.

Risk for injury related to presence of brace

Outcome:

- Child will remain safe and free of injury.

Teach the Child/Family

Schedule for brace wear

- Inform about the amount of time the child is to wear the brace each day. The number of hours the brace must be worn depends on the type of brace.
- Encourage wearing the brace during sleep to use up the most hours.

Skin care and comfort

- With a new brace, gradually increase wearing time so that the skin can develop tolerance for the pressure of the brace.
- Bathe or shower each day.
- Wear a 100% cotton T-shirt underneath the brace to absorb moisture.
- Do not use powders or lotions under the brace.
- Watch for areas of redness that do not disappear in 20 minutes, tingling, and numbness.
- Cover the chin pad (if present) with a smooth cloth to preserve skin integrity.
- Wear the brace as tightly as possible; if it is loose, it will rub the skin and cause skin breakdown.
- Consult the orthotist who made the brace if the brace does not seem to fit well. Fit and comfort are important factors.
- Loosen the brace during meals if necessary.

- Urge the child to avoid sitting in one position for long periods of time.

Appearance

- Select loose clothing that will camouflage the brace.

Brace care

- Clean the brace each day by hand with mild soap and water, and allow it to air dry completely. Once a week, wipe the brace down with rubbing alcohol.
- Examine the components of the brace regularly. Contact the physician and/or orthotist if there are any signs of “wear and tear” that may affect the function of the brace.

Activity and safety

- Check the home for possible environmental hazards. Normal defense mechanisms and mobility are altered in a brace. Either remove hazards or find ways to avoid them.
- Urge the use of safety precautions and devices (e.g., handrail when using stairs).
- Allow bicycle riding while in the brace.
- Do not allow participation in swimming, gymnastics, skating, skiing, or contact sports while in the brace.
- Complete exercises as prescribed by the physical therapist. These exercises help adapt to the brace, encourage the active correction of the spinal deformity, and maintain the trunk musculature. Exercises focus on actively shifting laterally in the direction of the correction (away from the brace pad), extending the trunk while in the brace, and taking deep breaths.

Contact the Healthcare Provider if:

- Signs of redness, numbness, or tingling persist under or around the brace
- Brace seems to become uncomfortable, despite having fit well in the past
- Parts of the brace become loose, cracked, or broken
- Child is not wearing the brace for the prescribed amount of time each day

the first 24 to 48 hours focuses on optimizing respiratory status, monitoring fluid volume shifts, and managing pain. Subtle changes in vital signs such as decrease in blood pressure and increase in pulse rate may be early indicators of hypovolemia. Occasionally, the child needs

mechanical ventilation for a brief period to assist with breathing and to optimize respiratory status. Often, chest tubes are necessary after anterior spinal surgery. The tube is usually left in place until postoperative day 3, when it is removed by the surgeon.

TABLE 20-3
Types of Surgery for Posterior Spinal Fusion

Type of Instrumentation and Description	Indications	Area of Fixation	Early Postoperative Positioning	Brace Needed
Harrington: single rod with two hooks	Scoliosis, not commonly used	Top and bottom of curve	Logroll and bed rest for 1 week until casted; do not logroll to convex side of thoracic curve	Yes; or cast
TSR/CD (Texas Scottish Rite Hospital/Cotrel-Dubousset): double rod with multiple hooks and crossbars	Idiopathic scoliosis, lordosis	Segmental	Head of bed up 30 to 45 degrees Hip flexion over crease of bed Logroll until ambulating Bed flat when on side No overhead frame	No
Luque: double rod with wires	Neuromuscular disease (scoliosis, muscular dystrophy, cerebral palsy)	Segmental	Logroll Head of bed up 30 degrees	No

Preventive pulmonary care is essential to avoid pneumonia. Such care may include oxygen by nasal cannula or mask, and coughing and deep breathing along with the use of an incentive spirometer and chest physiotherapy. Pulse oximetry is useful for monitoring respiratory depression resulting from the surgery or analgesics. Respiratory therapy may be required to assist with mobilizing secretions.

Ongoing Postoperative Care

After the child is transferred to the pediatric care unit, ongoing postoperative assessments for a child with a spinal fusion include evaluating fluid balance (intake and output), monitoring wound healing and drains, assessing neurovascular status of the extremities, and facilitating ambulation. Because of the amount of muscle exposed during surgery, children tend to have more blood loss than other orthopedic procedures. Monitor vital signs and hemoglobin and hematocrit levels to determine the need for blood transfusions after surgery.

Turn the child using a logroll technique (Fig. 20-18), every 2 hours to decrease pooling of secretions in the lungs. Encourage coughing and deep breathing. The incentive spirometer and early ambulation are also important in preventing pulmonary complications. Assess bowel sounds and gradually progress fluid and diet intake as bowel motility is fully restored.

The wound from a spinal fusion is closed with dissolvable sutures on the inside and Steri-Strips or staples on the outside. It is then covered with gauze bandages and a pressure dressing. The incision is kept covered with a dressing for 2 to 3 days. Assess the area for bleeding and

note any unusual drainage on the dressing. A Hemovac or similar surgical drain may be used to help evacuate excess blood from under the skin. Output from the Hemovac is generally greatest during the first 24 hours, gradually tapering off during the next few days. The drain usually is discontinued at about postoperative day 2 or 3. Monitor the amount of accumulated drainage and also assess the child for infection at the incision site.

FIGURE 20-18. The logrolling technique is used after back surgery to prevent the child from flexing the back while being turned from side to side in bed.

CLINICAL JUDGMENT 20–2

The Child After Spinal Fusion

Whitney is a 13-year-old black female who is admitted to the hospital for a posterior spinal fusion for idiopathic scoliosis. She is brought to your unit from the postanesthesia care unit (PACU) after her surgery. She has an intravenous line in her left hand, a nasogastric tube set to low intermittent suction, and a Foley catheter. Her orders state that she is NPO, on strict intake and output, and must logroll every 2 hours. Her vital signs are as follows: temperature, 99.5 °F; pulse rate, 90 beats per minute; respiratory rate, 28 breaths per minute; and blood pressure, 135/78 mm Hg. She is moaning.

Questions

1. During your assessment, what other data would be important to elicit from the PACU nurse who is giving you the report?
2. What are some of the important aspects of care you will want to evaluate in this postsurgical child?
3. Is Whitney in pain currently?
4. How can her pain be managed?
5. What factors would indicate that her pain is well controlled?

Answers

1. How much blood was lost in the operating room and how much blood did Whitney receive? How much fluid did she receive in the operating room? Assess the appearance of the wound and the amount of drainage in the Hemovac. Note the type of procedure that was done and any complications that occurred in the operating room. Also, check pain medication orders. When was the last pain medication given, and is the dose appropriate for her weight?
2. Fluid balance, pain management, and respiratory status
3. She is probably in pain as evidenced by increased pulse, respirations, and blood pressure. Whitney should be asked to rate her pain to validate your assessment.
4. Intravenous or epidural infusion of opioids via patient-controlled analgesia pump or bolus
5. Whitney is able to logroll easily, she is sleeping, she verbalizes relief of pain, and her vital signs return to baseline

The administration of prophylactic antibiotics for the first 72 hours postoperatively is a common practice to prevent infection. Stool softeners or a laxative may be needed to prevent constipation, which is a common side effect of pain medications.

Syndrome of inappropriate antidiuretic hormone (SIADH) is common in spinal fusion patients after surgery because of a number of factors, including change in blood volume, anesthetic medications, and the physical and emotional stress of the surgical procedure itself (see Chapter 26). The body responds by releasing antidiuretic hormone to retain fluids. The first sign of developing SIADH usually is a decrease in urine output, with an associated increase in urine specific gravity. Measure the serum level of sodium. Monitor blood pressure; if it decreases, administer additional fluids or blood transfusions as ordered. In mild hyponatremia with minimal symptoms, the treatment is to restrict fluid. SIADH usually resolves spontaneously in 2 to 3 days, as the patient starts diuresis.

Pain after a spinal fusion cannot be eliminated, but it can and should be controlled (see Chapter 10). For some patients, especially nonverbal ones, a continuous intravenous infusion of opioids works well. Patient-controlled analgesia is very effective in managing pain and is a common method of pain treatment. Other children benefit from an epidural infusion of a local anesthetic or opioids,

placed in the incision during surgery, to block transmission of pain impulses. After approximately postoperative day 3, the child can be switched to oral pain medications (Clinical Judgment 20–2).

Early mobilization helps to prevent pulmonary emboli, phlebitis, and skin breakdown. Assess the child's level of pain and provide pain relief as needed before turning or ambulation. Physical therapy after surgery assists the child in ambulation training, including teaching how to step and make transfers. Encourage parents to accompany the child to therapy. Remind children to move their extremities while they are on bed rest; the physical therapist can also teach strengthening and isometric exercises to the child who is bedridden. Children who are wheelchair bound may need their wheelchair adjusted to conform to their new shape. If the child has a brace or cast after the surgery, review brace or cast care and general skin care before discharge. Ensure that parents can correctly demonstrate how to apply the brace. Make brace adjustments before the child goes home.

Community Care

Although special equipment is usually not needed after a spinal fusion, some children require an elevated toilet seat, hospital bed, or a shower chair in their home after discharge. These needs can be assessed in the hospital as

COMMUNITY CARE 20–2

Activity Guidelines for Children After Back Surgery

Time Frame	Activities Encouraged	Activities Discouraged	Activities Restricted
Discharge from hospital to 4 to 6 weeks	Walking Quiet activities Study with home tutor; may start back to school in 3 to 4 weeks Riding in car, but not driving Swimming	Lifting more than 5 lb Running Diving in a pool Playing contact sports Riding dirt bikes, all-terrain vehicles, or mountain bikes	Gymnastics Parachuting Bungee jumping Motorcycle riding Trampoline jumping
6 weeks to 3 months	Same as above, but driving is allowed	Same as above	Same as above
3 to 6 months	Riding a bike Light jogging Lifting 5 to 10 lb	Same as above	Same as above
6 months to 1 year	Return to most of the normal activities done before surgery Bowling, skiing, skating, aerobics, golfing, horseback riding, diving, racquet sports, lifting weights	Playing contact sports until 1 year from surgery Water park amusement rides or roller coasters until 1 year after surgery	Same as above unless approved by physician

the child's activity progresses. Plans must be made regarding supervision of the child at home and to ensure that the child is able to continue with school studies during the recovery period at home. The child can usually return to school within 4 to 6 weeks.

During the home recovery period, children should avoid activities that require twisting, bending, or lifting heavy objects. The child should not participate in contact or high-impact sports for up to 2 years. Swimming and cycling are encouraged, however, and can be resumed within 3 to 4 months (Community Care 20–2).

Good nutrition is an important aspect of wound healing and general health. By the time of discharge, children are eating a regular diet. Some children need iron supplementation after surgery because of anemia caused by blood loss during surgery. Vitamin C and protein are important for healing; thus, the child should be encouraged to eat foods that contain those dietary elements. Extra calcium intake is not needed if the diet is well balanced. If the child has constipation caused by decreased activity and medication, encourage eating foods high in fiber and increasing fluid intake. A stool softener such as docusate sodium (Colace) may also be necessary.

The diagnosis of scoliosis often happens at an emotionally vulnerable time: the teenage years. Because body image is at the forefront of a teenager's mind, the hump on his or her back may be considered enormous. Anything that makes a teenager feel different from his or her peers is stressful. Contact with another teenager who is undergoing the same problems can be helpful.

Parents also need to be supported with counseling, because they can be frightened by the unfamiliar situation as well. Difficulties can arise when the parents and teenager disagree on the type of treatment to be undertaken. Most teenagers comprehend what is happening to their bodies and should be included in decision making from the start. (See Chapter 2 for more information on informed consent, autonomy, and self-determination issues.)

ANSWER: An example of an explanation for surgical versus nonsurgical interventions appropriate for Chase is, "If you are wearing your brace and it is slowing down the rate your spine is curving, then you might not need surgery. If the curvature in your back becomes more than 40% or the rate of curvature increases quickly, then you probably will need to have surgery. The good news for you is that boys tend to have less progression of curvature than girls."

INFECTIOUS AND INFLAMMATORY AND DISORDERS

Musculoskeletal disorders classified as inflammatory or infectious affect the bones and joints. The most common inflammatory disorders of children are juvenile arthritis (JA) and systemic lupus erythematosus (SLE). Infections generally are caused by bacteria that invade bones or

joints. Osteomyelitis and septic arthritis are the most common infectious disorders.

Osteomyelitis

Osteomyelitis is an infection of the bone and the tissues around the bone. The two most common types in children are acute and subacute hematogenous osteomyelitis.

Alert! All types of osteomyelitis require immediate treatment if suspected, because they can cause massive bone destruction and life-threatening sepsis.

Osteomyelitis occurs in 2 cases per 10,000 children. Approximately 50% of cases occur in preschool-aged children (Auh, Binnis, & Katz, 2004; Kocher, Lee, Dolan, Weinberg, & Shulman, 2006).

Osteomyelitis most often involves the long bones of the lower limbs, although it can occur in any bone of the body. Numerous organisms cause osteomyelitis. The most common cause of acute hematogenous osteomyelitis is *Staphylococcus aureus*. Group A beta-hemolytic streptococci are the next most common organisms, followed by *Streptococcus pneumoniae*, *Haemophilus influenzae* type b, and *Kingella kingae*. As a result of the widespread use since the late 1980s of conjugate vaccine against *H. influenzae*, acute hematogenous osteomyelitis caused by this organism has been virtually eliminated. With increased use of the 7-valent conjugate vaccine against *S. pneumoniae*, incidence of invasive infections caused by this organism is expected to decrease. However, *Candida lusitanae* is emerging as an opportunistic causative pathogen in premature infants.

Before antibiotics became available, the infection would progress, necessitating amputation of the affected limb. Today, if osteomyelitis is treated promptly with intravenous antibiotics, prognosis is good.

Pathophysiology

Organisms causing osteomyelitis can gain access through a variety of routes, including an open fracture, penetration of the skin by a contaminated object, spread from a septic joint or infected wound, or spread from a bacterial infection somewhere in the body, such as dental caries or ear infection. Blunt trauma also may precede osteomyelitis, because the hematoma formed from the trauma acts as an entry port for microorganisms. Premature infants, infants with birth complications such as ventilator dependency, central line and umbilical catheter placement (Kocher et al., 2006), children with sickle cell disease, and children with malignancies or juvenile arthritis who are taking immunosuppressive agents and are malnourished have the highest incidences of osteomyelitis.

Osteomyelitis results in inflammatory destruction of bone, bone necrosis, and new bone formation. In children older than 1 year, infection starts in the metaphyseal

sinusoidal veins and is contained by the growth plate. The joint is spared unless the metaphysis is intracapsular. In infants younger than 1 year, some metaphyseal vessels may transverse the epiphyseal plate and permit spread of infection to the epiphysis and adjacent joint.

The infection spreads laterally and breaks through the cortex, lifting the periosteum to form a subperiosteal abscess. The presence of vascular connections between the metaphysis and the epiphysis makes infants particularly prone to infection in the adjacent joint. The cortical bone of neonates and infants is thin and loose, consisting predominately of woven bone, which permits pressure caused by infection to escape, and promotes rapid spread of the infection into the subperitoneal region. Two common areas of osteomyelitis are the proximal tibia and the distal femur (Kocher et al., 2006; Listerneck, 2003).

Assessment

Children with acute osteomyelitis often present with complaints of pain in an extremity. Some children may have fever. The child is irritable and will not use the painful limb. If the child is an infant, irritability and lethargy, decreased motion of the limb, and edema and joint effusion may be noted. Note parental reports of a recent infection, such as a cold or otitis media. Alternatively, the child may have a history of falling or trauma to an extremity.

Also investigate the duration of symptoms and any history of prior bone infection after surgery or trauma. The child with chronic osteomyelitis exhibits symptoms similar to those of acute osteomyelitis but the history reveals symptoms persisting for longer than 3 weeks or prior bone infection weeks or months ago. Due to the increased awareness of the need for prompt, aggressive treatment for acute osteomyelitis, the incidence of chronic osteomyelitis in children is decreasing.

Physical examination of the affected area reveals localized tenderness, redness, warmth, and pain on palpation of the area. Occasionally, children have soft-tissue swelling around the area.

Diagnostic Tests

Radiographs usually only show soft-tissue swelling, but they can be useful in distinguishing osteomyelitis from bone tumors, fractures, or old fractures. A bone scan will show increased osteoblastic activity in the infected bone and it distinguishes osteomyelitis from deep cellulitis. MRI is a sensitive tool that can be used to detect bone marrow inflammation (Listernick, 2003; Pineda et al., 2006).

Laboratory studies that may aid in the diagnosis are a WBC count, C-reactive protein, and ESR. The white blood cell count is elevated in about half the patients, and C-reactive protein and ESR are almost always elevated. A blood culture can be used to identify the causative agent. Bone marrow aspirations may be completed to identify the pathogens and to tailor antibiotic therapy.

Nursing Diagnoses and Outcomes

Nursing diagnoses, nursing interventions, and desired patient outcomes for the child with a musculoskeletal disorder are presented in Nursing Plan of Care 20–1. Depending on the assessment data, the following nursing diagnoses may also apply to the child with osteomyelitis:

Risk for injury related effects of infectious process on bone mass

Outcomes: Child will maintain the affected extremity in proper alignment.

Child will refrain from bearing weight on the affected extremity.

Child will complete entire course of antibiotic therapy to promote full recovery.

Risk for imbalanced body temperature related to the infectious process

Outcome: Child's body temperature will remain within normal range.

Interdisciplinary Interventions

Interdisciplinary interventions for both chronic and acute osteomyelitis are the same and focus on eradicating the infection via antibiotic therapy, ensuring the child's comfort, and promoting growth and development.

Antibiotic Therapy

Blood cultures initially are obtained, and empiric broad-spectrum parenteral antibiotics (such as nafcillin, vancomycin, clindamycin, or cefazolin) are started intravenously to provide adequate coverage for common pathogens. In the neonate, nafcillin with tobramycin or cefotaxime is used. When blood culture or aspirate results are obtained, antibiotic therapy is tailored to the causative organism. After the patient demonstrates a response to antibiotic therapy (usually within 2–3 days) and final blood cultures obtained are negative, the parenteral medication is stopped and the patient is switched to oral antibiotics, usually for 4 to 8 weeks. However, children who do not respond well initially to intravenous antibiotics may remain on intravenous antibiotic therapy much longer. To determine the child's response to antibiotic therapy, ESR, which decreases as the infectious process resolves, is measured weekly.

caREminder

The antibiotics used to treat osteomyelitis are caustic to veins. Be diligent about diluting the medication and infusing it slowly.

Monitor the intravenous site closely for signs of infiltration. Usually, the child with osteomyelitis receives long-term antibiotic therapy. Duration of treatment is based on the type of infection, and no standard length of treatment has been determined. Four to 6 weeks of therapy is not atypical, although a longer period of time may be needed if infection persists. Whenever possible, advocate for the patient to have a long-term intravenous line inserted, such as a peripherally inserted central catheter (PICC). Because frequent laboratory tests can also be

drawn from a PICC line, the child will receive fewer needle sticks. (See Chapter 17 for a more complete discussion of care of the PICC line.)

Comfort Interventions

Making the child comfortable and ensuring relief from pain are key for the child with suspected or known osteomyelitis. Splinting the involved extremity may be helpful during the first few days of treatment (see Treatment Modalities earlier in this chapter). However, splinting should not be used indefinitely, because they may discourage use of the affected extremity. If required, oral analgesics such as acetaminophen, ibuprofen, or narcotics can be given to relieve pain. After antibiotics have been administered for at least 24 hours, bone and tissue pain should start to subside.

Child Life Specialist Interventions

The hospitalized child can become easily bored and frustrated by the limitations imposed by lengthy intravenous therapy. The involvement of a child life specialist can be extremely helpful in providing age-appropriate diversions and activities that do not compromise the intravenous site or cause the child pain in the affected limb. These activities also can help to foster growth and development.

Community Care

Some children with osteomyelitis are discharged on a regimen of home intravenous antibiotic therapy. Discuss this option with the family at the start of treatment. Collaborate with home care nursing services to ensure the family has the education, supplies, and support personnel to manage home intravenous therapy. The nurse helps in assessing whether a family can maintain a child on home intravenous antibiotics and teaches the family intravenous therapy skills. If the antibiotics can be scheduled every 8 to 12 hours, adherence increases. A parent who is administering one or two antibiotics every 4 to 6 hours can easily become sleep deprived.

Some children may return to school while they are receiving intravenous antibiotics at home, depending on the schedule for administration, such as administration every 12 hours. Other children use a home tutor until they have completed the medications. ESR is monitored by the physician to determine the response to antibiotic therapy. Instruct the family to notify the physician if the child becomes febrile or experiences pain in the affected area.

The child with chronic osteomyelitis may benefit from increased psychological support to help deal with depression associated with physical limitations and frequent hospitalizations. Treatment is prolonged, painful, and frustrating for the child and family.

Septic Arthritis

Septic arthritis, a bacterial invasion of a joint space, can occur in any joint in the body. Septic arthritis occurs in

all age groups, although the most common age of occurrence is 1 to 2 years. Methicillin-resistant *S. aureus* is the most common causative organism, followed other methicillin-resistant organisms (Goergens, McEvoy, Watson, & Barrett, 2005). Before antibiotics became available, the mortality rate among children with septic arthritis was 50%. Septic arthritis is a medical and surgical emergency that must be treated as soon as possible.

Pathophysiology

The process of septic arthritis begins when bacteria enter the joint space. The organism can invade the joint through hematogenous seeding (transmitted by the bloodstream), by extension of an adjacent bone infection (osteomyelitis), by seeding from a distal site of infection (otitis or upper respiratory infection), or by a penetrating wound or foreign body in the joint. An inflammatory reaction occurs resulting in fluid and white blood cells entering the joint. The white blood cells release an enzyme that breaks down the surface of the articular cartilage. Scar tissue replaces the articular cartilage, restricting joint motion. If not treated promptly and aggressively, septic arthritis results in permanent loss of function. Large joints are more commonly affected than small joints. Approximately 60% of cases affect the knee or hip (Matthew & Coakley, 2008). Other sites for septic arthritis, in decreasing order of incidence, are the ankles, elbows, wrists, shoulders, and pelvis.

Assessment

Typically, assessment of the child with septic arthritis reveals a 1- to 2-week history of pain in the affected extremity, with decreased activity tolerance and passive ROM. Warmth, tenderness, and swelling over the joint are common. The child usually complains of pain in an extremity and often has a limp that is associated with pain. If the hip joint is the affected area, the child may exhibit slight flexion, abduction, or external rotation of the affected extremity. An infant may present with or without fever, symptoms of irritability, failure to eat, and crying when handled.

The child may resist or guard the joint when asked to move it. If the hip or lower extremities are involved, the parent usually reports that the child will not walk or crawl. History may reveal reports of a recent ear infection, cold, or joint trauma. Any history of a bite or penetrating wound, such as with a needle or thorn, is also important to note when trying to ascertain the cause for the septic arthritis.

Diagnostic Tests

Laboratory tests used in diagnosing septic arthritis include a complete blood count with differential for white blood cells, neutrophil count, band cell count, ESR or Westergren sedimentation rate, and blood cultures. The white blood cell count may be normal or elevated, with an increased neutrophil count. Blood cultures will reveal the causative organism. The Westergren sedimentation rate test is used to rule out other

disease processes such as rheumatoid arthritis, collagen disease, and neoplasms.

Radiologic tests for septic arthritis include a plain radiograph, ultrasound, and bone scan. Radiographs may show a subtle increase in the joint space, or soft-tissue changes (such as swelling), and can rule out any lesions. Ultrasound may be done, especially if the hip is affected, to observe for fluid in the joint. Although bone scans are ineffective in demonstrating septic arthritis, they may be helpful in ruling out osteomyelitis as the cause of the child's symptoms.

Definitive diagnosis requires joint aspiration using fluoroscopy to obtain fluid for cultures and determine white blood cell count. A fluid sample that contains more than 100,000 white blood cells and 75% neutrophils confirms the diagnosis.

Interdisciplinary Interventions

The goals of treatment of septic arthritis are to prevent destruction of the articular cartilage and to retain motion, strength, and function. Care of the child with septic arthritis also includes managing pain, reducing body temperature, and ensuring consistent medication administration.

Procedural Interventions

In septic arthritis, the inflammatory process, not the bacteria itself, causes damage to the joint. Thus, the inflammatory exudates that cause the damage to articular surfaces must be released. This may be accomplished with needle aspiration of the fluid. If the fluid continues to accumulate, then arthroscopy can be used to clean out the joint and obtain a synovial biopsy. In certain joints such as the hip or shoulder, an **arthrotomy**, or surgical opening into the joint, is needed. The fluid and biopsy samples are sent for laboratory examination to ascertain the causative organism.

Perform wound management of an open arthrotomy site. Secure the dressing, note the color and amount of secretions, and change the dressing if necessary.

Infection Management

The administration of antibiotics for a 4- to 6-week period is an important aspect of the treatment plan. Broad-spectrum intravenous antibiotics are started after a culture has been obtained. After an organism has been identified, the antibiotic may be changed to one that is specific for the causative organism. If the causative agent is not identified, broad-spectrum intravenous antibiotics are continued for the entire course of therapy. If the causative agent is identified and if the child has a good response to the treatment regimen (decreased pain and swelling, a downward trend in laboratory values, and fever resolution), the child may be switched to oral antibiotics for 3 to 6 weeks or the length of time it takes for the ESR to return to normal, and will then be discharged home. ESR levels are monitored by the physician to determine the response to antibiotic therapy.

During the acute phase of the infection, monitor the child's temperature frequently. Administer antipyretics as

ordered. Implement other cooling measures, such as a tepid sponge bath and removing blankets or clothing. To prevent dehydration secondary to fever, encourage fluids.

Pain Management

If the child is uncomfortable, administer oral pain medications and monitor their effectiveness. Give analgesics before beginning daily activities or treatments that may cause discomfort.

If necessary, initially splint the affected limb or joint for comfort. The splint can be removed after a few days. Observe the child to note the extent of joint mobility, voluntary movement, and weight-bearing capabilities. Encourage the child to participate in daily activities as he or she feels able. Provide assistive devices such as crutches or a walker as needed to support ambulation.

Community Care

Intravenous antibiotic therapy can be managed by home care when it is determined that the ESR level is decreasing and the antibiotics are effective. Before discharge, teach the family about administering the child's medication, and collaborate with home care services as needed to ensure the child receives daily medication. Emphasize the importance of not missing scheduled doses and the need to continue administering the medication (whether intravenous or oral) even if the child feels better. Insufficient treatment can result in permanent damage to the articular cartilage or in chronic osteomyelitis. Follow-up care is needed to assess the effectiveness of the treatment.

Families require support during the acute and home management phases of the child's illness. With a diagnosis of septic arthritis, concern about loss of joint function is paramount. If treatment was delayed, the parent may feel guilty about not seeking medical attention earlier. Encourage the parent to seek support from family members, social services, clergy, and friends.

Juvenile Arthritis (JA)

JA, also referred to as *juvenile rheumatoid arthritis* and *juvenile idiopathic arthritis* is the most common chronic inflammatory condition in children. It is defined as a continuous inflammation of one or more joints, lasting at least 6 weeks, for which no other cause can be found. The inflammation causes pain, stiffness, and swelling in the affected joints.

Approximately 294,000 children younger than 18 years of age in North America are affected by JA (Sacks et al., 2007). Onset of JA may occur as early as age 6 weeks; however, peak incidence of onset is from 2 to 15 years of age.

Pathophysiology

The cause of JA and the mechanisms that lead to the chronic synovial inflammation are unknown. Heredity is thought to play some part, but researchers believe that something in the environment triggers the disease. JA is considered to be an autoimmune disorder. It occurs when

the body's immune system mistakenly identifies the body's own tissue as foreign and attacks the tissue, as if trying to rid the body of an invader. Although the clinical onset of JA may follow an acute systemic infection or physical trauma to a joint, no research supports a direct cause-and-effect mechanism.

JA starts with an inflamed synovial membrane and adjacent joint capsule. The inflammation of the synovial tissues produces increased amounts of fluid, which are secreted into the joint. The increased fluid volume causes the joint to become swollen and boggy, a condition termed *joint effusion*. The joint feels edematous and warm to the touch. The synovial membranes become infiltrated with lymphocytes and plasma cells, which cause the normally clear joint fluid to become cloudy. Prolonged synovitis can erode joint structures and narrow joint spaces. Eventually, bone deformity, subluxation, and **ankylosis** (immobility and consolidation) of joints occur. Growth disturbances adjacent to the affected joint can cause overgrowth or undergrowth of the affected part.

The joint pain and stiffness associated with JA are initially caused by the pressure applied to sensory nerves in the area of the edematous membranes. As the disease progresses, pain and discomfort may also be a result of joint destruction or contractures, which lead to stiffness and immobility.

There are three major subtypes of JA, defined according to the symptoms at disease onset: pauciarticular, polyarticular, and systemic (Table 20-4). Polyarticular JA is divided further as seropositive (subtype I) and seronegative (subtype II) based on the presence or absence of the rheumatoid factor (RF) in the blood. RFs are autoantibodies that have formed in the body after long-term exposure to an antigen. Pauciarticular JA is also further divided into an early- (type I) and late-onset (type II) group. Although the JA classifications are based on symptoms at disease onset, the course of the disease is also critical in directing treatment.

Some familial tendencies have been demonstrated in early-onset pauciarticular JA and RF-positive polyarthritis. Siblings appear to be at increased risk for development of JA. Some genetic markers (e.g., human leukocyte antigen [HLA]-B27, -DR5, -DR8, and -DR4) can be linked to certain types of JA. However, more research is needed in this area.

Assessment

Physical manifestations of JA vary according to the type (see Table 20-4). Most commonly, family members state that the child has become "cranky" or "irritable." The child may tire easily, have a poor appetite with scant weight gain, and demonstrate some growth delays. Ask questions about the child's daily activities and comfort. Children with JA have a difficult time getting out of bed in the morning because of joint stiffness. They may not participate in play or sports activities that are painful to them. The child's gait may be altered to avoid putting pressure on a distal joint.

In the pauciarticular type, the most common and mildest form, the child may present with pain; warmth; and

TABLE 20-4

Types of Juvenile Arthritis

Type	Age at Onset and Gender Predominance	Systemic Manifestations	Laboratory Tests	Prognosis
<i>Pauciarticular: Four or fewer joints for the first 6 months after disease onset; only affects the knee in some patients</i>				
Type I	Early onset: 2 to 6 years Female	Chronic iridocyclitis Modest hepatosplenomegaly Lymphadenopathy Mucocutaneous lesions Mild anemia	Less than 5% have positive RF ANA present in 90% HLA-DR8, -DR5, and -DR6	At least 60% go into remission. Ten to 50% will have ocular damage from iridocyclitis.
Type II	Late onset: 10 to 15 years Male	Acute iridocyclitis Ankylosing spondylitis Sacroiliitis is common	RF negative ANA negative HLA-B27	Disease responds well to therapy. Patients generally will not have crippling disease.
<i>Polyarticular: Five or more joints involving both upper and lower extremities, especially cervical spine</i>				
Subtype I	RF-positive disease occurs at any age during childhood Female	Low-grade fever Malaise Rheumatoid nodules Inflammation of internal organs (uncommon) Adenopathy Weight loss Growth retardation Anemia Vasculitis	RF positive ANA present HLA-DR4	Fifty percent will have disabling arthritis.
Subtype II	RF-positive disease occurs later in childhood Female	Low-grade fever Malaise Rheumatoid nodules Inflammation of internal organs (uncommon)	RF negative ANA may be present	Ten to 15% will have disabling arthritis.
<i>Systemic: Arthritis with a characteristic intermittent fever; any joint affected</i>				
	Occurs at any age during childhood (median age, 5 years) Male	Temperature more than 39.5 °C, spikes one or two times daily Evanescent, pale red, non-pruritic, macular rash present Leukocytosis, severe anemia Joint problems may be mild at onset Myalgia Pleuritis Enlarged spleen Enlarged liver Enlarged lymph nodes Severe anemia	RF positive in 5% Elevated ESR Rarely positive ANA	Fifty percent will completely recover. Fifty percent will have severe, chronic arthritis.

ANA, antinuclear antibody; HLA-B27, human leukocyte antigen-B27; RF, rheumatoid factor.

swelling of knees, ankles, wrists, or elbows. About 20% of these children will develop uveitis and should have annual slit-lamp examinations.

Children with systemic JA often present with a history of spiking fevers with temperatures more than 103 °F (39.5 °C) daily for 2 weeks in conjunction with a rash that comes and goes with the fever. They often have swollen lymph glands and an enlarged liver and spleen; they may also have pleuritis or myocarditis. They will be listless and unwell during the fever and become more engaged when the temperature returns to normal. During the course of the fever spikes, the child may complain of weakness, lose weight, and suffer from anemia. During the early stages, no signs of joint inflammation may be evident. The joint involvement may occur up to 6 months after the febrile illness.

Spondyloarthritis generally affects the child older than 10 years and is more common in males. It involves fewer joints in the lower limbs, hips, and spine. This form of arthritis may progress to pain and stiffness in the back. It is one of the few types of arthritis that may be hereditary and run in families. Many of these children carry a protein called HLA-B27 on their cells. Eye involvement is more common in this group of children.

During physical assessment, inspect and palpate each joint for redness, swelling, warmth, and tenderness, and note any nodules on the joints that may be present in polyarticular-onset JA. To assess for limping or guarding behavior, observe the child walking down a hall. Children with JA tend to keep their joints flexed, which can cause contractures. Accurate measurement of height and weight is also essential, because JA can retard growth.

In addition to examining the musculoskeletal system, assess the child for other systemic changes resulting from the inflammatory process. Carditis, pleurisy, pneumonia, and organomegaly are typically manifestations of progressive illness. Inflammation of the iris and ciliary body, called *anterior uveitis*, *iritis*, or *iridocyclitis*, may occur. This complication is most typically seen in young girls with pauciarticular onset. The inflammation can cause eye pain and diminished vision; in some cases, permanent blindness occurs. Remind parents to seek medical treatment if visual changes are noted that could indicate iridocyclitis, such as sensitivity to light, blurred vision, or redness of the eye. Encourage annual ophthalmologic examination including slit-lamp examination to promote early detection and treatment.

Diagnostic Tests

Diagnosis of JA is often made on the basis of the child's constellation of symptoms. Some nonspecific indicators of inflammation may be noted, including elevated white blood cell count, ESR, and C-reactive protein level. Some children will be seropositive for RF.

Radiographs do not show any changes until late during the disease course, but they are useful for comparing bone growth or damage from the time of diagnosis onward. Other radiologic tests such as MRI, computed tomography, or bone scan may be performed to rule out other diagnoses.

Nursing Diagnoses and Outcomes

Nursing diagnoses and outcomes for the child with a musculoskeletal disorder are presented in Nursing Plan of Care 20–1. The following nursing diagnoses should also be considered for the child with JA, especially for the child with a subtype of JA in which fever is a frequent occurrence:

Risk for imbalanced body temperature related to inflamed synovial tissues

Outcomes: Child will maintain normal body temperature. Child will remain free of joint swelling and pain.

Deficient fluid volume related to fever

Outcome: Child will maintain normal fluid volume as evidenced by good skin turgor, moist mucous membranes, and adequate urine output.

Imbalanced nutrition: Less than body requirements related to anorexia, dietary inadequacies, drug–nutrient interactions, limitations in physical activity, mechanical feeding difficulties, and susceptibility to food fads and quackery

Outcomes: Child will exhibit weight gain appropriate to his or her age, height, and physique.

Child and parents will implement measures to ensure that the child consumes adequate amounts of nutritious food.

Interdisciplinary Interventions

The desired outcomes for children affected with JA are to prevent deformities, minimize discomfort, promote mobility, and preserve the ability to perform activities of daily living. Drug therapy and physical therapy are mainstays of treatment for JA. The healthcare team in the acute setting may encounter the child when he or she is experiencing a severe exacerbation of illness that requires intense physical therapy and nutritional support, when a change of medications is required, or when surgical intervention, such as muscle or tendon release, is needed to treat severe musculoskeletal complications. However, most children are cared for at home. The interdisciplinary team collaborates to ensure continuity of care regardless of the setting for treatment. Implement an interdisciplinary teaching plan to provide family members with the knowledge and skills needed to attend to the child's care needs at home (TIP 20–3). Review the plan with the child periodically so that, as the child grows and matures, he or she can continue to learn more about the condition and accept increasing responsibility for managing self-care.

Pharmacologic Interventions

Various drugs are used to treat JA. These include NSAIDs, disease-modifying antirheumatic drugs, and glucocorticoids.

Nonsteroidal Anti-inflammatory Drug (NSAIDs)

Treatment usually starts with NSAIDs, which include a variety of medications that affect the processes involved in inflammation. A reduction in pain, swelling, and

TIP 20–3 Teaching Intervention Plan for the Child With Juvenile Arthritis

Nursing diagnoses and outcomes

Risk for impaired physical mobility related to joint inflammation, swelling, and pain

Outcomes:

- Child will take medications as ordered.
- Child will follow daily exercise program.
- Child will moderate activity with adequate periods of rest and relaxation.
- **Chronic pain related to joint inflammation and contracture**

Outcomes:

- Child and family members will describe interventions to reduce pain and discomfort associated with the child's condition.
- Child will experience no pain or acceptable levels of reduced pain as evidenced by play and participation in daily self-care activities.
- **Delayed growth and development related to physical limitations, discomfort, and clinical progression of the child's condition**

Outcomes:

- Child will maintain a normal weight for age and height.
- Child and family will acknowledge the importance of well-balanced meals and rest periods.
- Child will participate in age-appropriate activities that are modified as needed based on the child's current status.

Teach the child/family

Medications

- Administer anti-inflammatory and analgesic medications per healthcare provider orders to maintain a therapeutic blood level and reduce the likelihood of joint pain and swelling.
- Reduce gastric irritation associated with medication administration by taking salicylates with food or milk.
- Review adverse side effects of prescribed medications, and report any adverse signs and symptoms to the healthcare provider.

Activity and Safety

- Encourage the child to participate in low-impact exercises, especially swimming.
- Avoid overexercising and stimulating swollen joints, which aggravate pain.
- Assist child to complete exercise program daily at home, at school, or at another community location.

- Incorporate exercise program into daily play activities such as throwing a ball, riding a bike, or molding clay.
- Encourage child to attend regular school.
- Schedule daily rest periods for the child.
- Encourage the child to participate in daily self-care activities and tasks around the home.
- Utilize splints, sandbags, or casts to maintain position of function and to prevent muscle contractions.
- Provide assistive devices such as elevated commodes and handrails to aid in body mechanics.
- Choose clothing that is easy for the child to put on and take off.
- Modify eating utensils, brushes, combs, and toothbrushes for easier grasp.
- Ensure the child is evaluated by an ophthalmologist for slit-lamp examination and routine eye care on a regular basis.

Pain Management

- Encourage the child to take a warm bath for 20 minutes upon awakening in the morning.
- Use an electric blanket if a bath is not feasible to warm and relax the muscles and joints.
- Use warm moist packs and heating pads to relieve joint discomfort.
- Use paraffin baths to reduce joint pain.
- Use a firm mattress and lie flat in bed to reduce flexion deformity.

Nutrition

- Provide a well-balanced diet to avoid weight gain or weight loss.
- Select foods high in iron if anemia is a concern.
- Monitor weight on a weekly basis. If the child becomes overweight, an extra burden can be put on weight-bearing joints.
- Monitor the child's hematocrit level on a regular basis to assess for anemia, which can be associated with the inflammatory process.
- During febrile periods, monitor the child for adequate hydration and encourage intake of fluids.

Psychosocial

- Encourage the child to ventilate his or her feelings regarding the condition.
- Encourage the child to meet other children with JA.
- Encourage independence. Do not do for the child what the child can do for himself or herself.
- Encourage the child to participate in therapy and treatment decisions to promote self-care, sense of autonomy, and control over the situation.

- Encourage the child to engage in activities in which he or she can be successful and thus promote positive self-esteem.

Contact Healthcare Provider if:

- Joint pain and inflammation worsen despite current medication regimen
- Child's temperature increases to more than 103.1° F (39.5 °C) and is not reduced by such

measures as medication, tepid baths, and cool clothes

- Child appears to be dehydrated (lips dry and cracked, no tearing present, urine output low)
- Child has signs of drug toxicity
- Child's vision appears to be impaired

stiffness help the child to participate in normal day-to-day activities. Some of the more commonly prescribed medications in this group include naproxen (Naprosyn), tolmetin sodium (Tolectin), indomethacin (Indocin), and ibuprofen (Advil or Motrin). Aspirin is no longer a first choice in treatment of JA because of its side effects.

Alert! The use of aspirin has been strongly associated with Reye syndrome in children who have had chickenpox or the flu. Because aspirin may be an ongoing part of the regimen of the arthritic child, warn parents of the relationship between viral illnesses, aspirin, and Reye syndrome, and teach them to identify the symptoms of Reye syndrome.

It may be necessary to try several NSAIDs to determine which one works best. The most common side effect of this class of drugs is stomach upset, which can frequently be avoided by taking the medication with food. Indomethacin is contraindicated in children younger than 12 years of age.

Disease-Modifying Antirheumatic Drugs

For children with prolonged arthritis in several joints that may lead to permanent damage, second-line drugs are often prescribed called *disease-modifying antirheumatic drugs*. This is a category of unrelated drugs defined by their ability to slow the progression of the disease. Drugs in this group include methotrexate (Rheumatrex), sulfasalazine (Salazopyrin), etanercept (Enbrel), gold salts, and antimalarials (e.g., penicillamine, hydroxychloroquine). Disease-modifying antirheumatic drugs operate by different mechanisms, yet are used alone or in combination to decrease the disease progression and reduce the signs and symptoms of moderately to severely active rheumatoid arthritis in patients who have had an inadequate response to other disease modifying agents. The disease-modifying antirheumatic drugs can take up to 6 months to take effect. Each drug has its own side effects that require careful monitoring by regular examination and laboratory tests.

Glucocorticoids

The use of glucocorticoids is not generally considered unless severe, systemic complications of JA are present and are not responding to other drug therapies. These agents suppress the symptoms of JA but do not induce

remission or prevent joint damage. In addition, the side effects of steroid use may lead to even more physical complications for the child. If steroids such as prednisone are used, the dosage of the medication should be reduced and then gradually discontinued as soon as symptoms have been suppressed. With persistent arthritis, injections of steroids directly into the joint can be helpful.

Physical Therapy

Goals of physical therapy and rehabilitation include controlling pain, preventing limitation, restoring ROM in affected joints, maintaining and improving muscle strength, increasing and maintaining endurance for activities of daily living, minimizing effects of inflammation, and ensuring normal growth and development. Methods used include heat-cold application, massage, electrical stimulation, and ultrasound. These therapies are aimed at reducing pain and stiffness so the child will be able to participate in an exercise program to reduce contractures and develop specific muscle groups.

In children in whom permanent contractures develop in the joints, a stabilizer splint must be used as an orthosis (to stabilize flexion contractures by stretching). Gradual casting is also used for this purpose. Ideally, the cast is removed at 24- to 48-hour intervals to enable aggressive stretching before the next cast is reapplied (see [thePoint](#) for Procedures: Cast Care). During an illness flare-up, an inflamed joint can be continually maintained in a neutral position by using an immobilization device. When the flare-up is under control and inflammation has diminished, the splint or brace may be worn only at night.

Passive, active, and resistive exercises are carried out daily by the child to preserve ROM, muscle strength, and gross motor activity. Exercises can be completed at home, at school, in an acute care setting, or at a local health club. Age-appropriate activities are encouraged and modified as needed based on the severity of the child's symptoms.

Children with JA can participate in normal school and family activities. Gymnastics and high-impact contact sports are to be avoided. However, swimming is an excellent exercise for children with JA. Other therapeutic exercises include playing with clay, bicycling, playing the piano, and softball. Extreme stress and fatigue may trigger exacerbations of JA. Encourage rest, relaxation,

leisure activities, and relief from emotional distress to reduce the risk of exacerbations.

For children with progressive debilitation caused by their disorder, occupational therapy can be beneficial. Measures are taken to adapt the child's environment and to train the child to use assistive devices to continue to perform independent daily tasks and activities. Assistive devices may include comb handle extenders, thicker handles on eating utensils, and shoehorns to put on shoes. Clothes with easy Velcro openings can facilitate putting on and removing clothing.

Heat therapy to alleviate pain and stiffness is important for the child with JA. Other treatments include warm baths, moist warm packs, and paraffin (wax) baths for the small joints of the hands once a day (see Treatment Modalities). A warm morning bath can help the child overcome early morning stiffness, but it may be impractical for busy families. An alternative is to have the child use a sleeping bag at night to stay warm. Another alternative is to have an electric blanket with a timer that turns on 1 hour before the child awakens. Use of a waterbed is another option for easing stiffness. Teach children and families about different measures to promote comfort and reduce generalized body stiffness.

Surgical Interventions

Surgery to treat JA is rare. Arthroscopic synovectomy may be performed to decrease pain. Occasionally, some patients require or request a total joint replacement. This procedure should be performed only on older children, because joint replacements wear out in about 20 years.

Nutritional Support

Children with JA are at risk for nutritional problems. Stiffness decreases activity and increases the tendency to gain weight, thus exacerbating the problems associated with mobility. Arthritis of the temporomandibular joint can affect the child's ability to chew, causing pain and limited jaw movement. Undernutrition and wasting can contribute to poor linear growth and low lean-body and muscle mass. Anorexia can lead to acute or chronic undernutrition as a result of an inadequate intake of both calories and protein. Many of the medications taken by the child with JA have potential adverse effects on nutritional status, including anorexia, constipation, nausea, fatigue, diarrhea, and gastrointestinal distress. Additionally, parents of children with JA may select unconventional dietary remedies to "treat" their child. These therapies can interfere with the child's medical therapy and may be a source of malnutrition.

Several measures can be instituted to enhance the child's growth and development by addressing dietary concerns (Nursing Interventions 20–3). Frequent assessment of the child's nutritional status should be an integral part of the contacts between the child and the healthcare team. Obtain height and weight measurements on a regular basis. Ask the child and family about side effects of any medications, appetite and appetite changes, frequency of meals and snacks, types of foods eaten on a

NURSING INTERVENTIONS 20–3

Measures to Promote Adequate Dietary Intake for the Child with Juvenile Arthritis

- Encourage children with poor appetites to eat higher-calorie, nutrient-dense, tasty foods such as nuts, peanut butter, sandwiches, milkshakes and cheese.
- Encourage children with small appetites to eat small frequent meals throughout the day.
- Make meal time a pleasant event. Nagging and food battles only serve to decrease the child's appetite.
- Provide calcium and vitamin D supplementation under the guidance of a dietitian.
- Choose iron-fortified cereals and other products.
- Follow the standard of the Food Guide Pyramid to plan meals with serving sizes appropriate to the child's age.
- If mechanical feeding difficulties are present, provide the child with a soft diet and teach him or her to take small bites. If eating difficulties persist, referral to an occupational therapist may be necessary.
- Assist the child to select activities that will keep him or her mobile and active without causing undue pain and joint problems.
- Assess and treat the side effect of drug/food interactions (e.g., constipation, diarrhea, nausea)
- Discourage children and their parents from using unconventional remedies to treat their child's condition.
- Refer the child to a registered dietitian if dietary issues continue to be an ongoing threat to the child's growth and development.

day-to-day basis, and the presence of discomfort or any mechanical difficulties when chewing.

Promotion of Normal Development

Chronic illness has a great effect on a child's psychosocial well-being (see Chapter 12). Normal developmental milestones such as starting school, socialization, and achieving independence in activities of daily living may be delayed. The family may "overprotect" the child and restrict play activities for fear of injury. To promote growth and development, the child should be encouraged to interact with peers in school and social settings by participating in age-appropriate activities as much as the child's physical condition allows. Assist parents and the child in modifying the child's environment and schedule to account for the child's physical limitations and to decrease the likelihood of fatigue.

The child may be at risk for self-esteem or body image disturbances because of the limitations imposed by illness and any physical manifestations. Encourage the child and family members to speak openly about the child's condition and to feel comfortable asking others for assistance when needed. Support organizations can provide educational materials, specialized services, and financial aid for qualified children and their families (see [thePoint](#) for organizations). Important measures that promote adaptation to the disease and enhance development include encouraging the child's natural skills and characteristics to develop. Provide opportunities for the child to reach their maximum potential while ensuring personal safety and management of their condition.

Community Care

The child with JA can be managed primarily in the home. Clinic, home health, and school nurses are primarily responsible for collaborating with the healthcare team to monitor and manage the needs of the child with this condition. Issues of impaired physical mobility, altered nutrition, risk for impaired skin integrity, and chronic pain must be managed on a daily basis. The child also faces challenges related to altered growth and development, and the potential for body image disturbances caused by the debilitating nature and sometimes disfiguring outcomes of the child's arthritic condition (see TIP 20–3).

Systemic Lupus Erythematosus (SLE)

SLE is a systemic inflammatory disease that affects many organs in the body. *Lupus*, the Latin term for wolf, was combined with erythema to name this disease—lupus erythematosus—because one of the presenting symptoms is a facial rash that looks like the face of a wolf. Lupus is an autoimmune disorder that may involve any organ system but most commonly involves skin, joints, and kidneys. The onset may be sudden, affecting one or more major organ systems, or it may be insidious in nature, with nonspecific symptoms such as fever, fatigue, or joint and muscle pain. When the onset is insidious, diagnosis is often delayed for weeks or months.

Childhood SLE accounts for 15% of all cases, affecting approximately 5,000 to 6,000 U.S. children annually. The incidence is highest among African American, Hispanic, and Asian girls. When males are affected they manifest symptoms at an earlier age and have more severe disease (Adams, MacDermott & Lehman, 2006; Croker & Kimberly, 2005). The mortality rate has decreased with the evolution of newer treatment options. Infection is currently the leading cause of death.

Pathophysiology

The cause of SLE is unknown, but genetic, hormonal, environmental, and immunologic factors are believed to interact and lead to disease expression. Studies indicate there is a genetic predisposition to lupus. Genome studies have indicated a gene on chromosome 1 that is associated

with lupus in certain families. In addition, genes on chromosome 6 called *immune-response genes* were also associated with the disease.

SLE is a multisystem autoimmune disease involving both the humoral and cellular aspects of the innate and acquired immune systems. The autoimmune reactions are directed against the cell nucleus, especially the DNA. Autoantibodies are produced against the nuclear antigens, cytoplasmic antigens, and blood cell surface antigens. When the autoantibodies bind to their specific antigens, complement activation occurs, and immune complexes accumulate within the blood vessel walls, causing ischemia. Ischemia within the blood vessels leads to thickening of the internal lining, fibrinoid degeneration, and thrombus formation. At this point, manifestations of SLE appear.

Assessment

The manifestations of SLE vary, depending on the organs affected and degree of their involvement. The American College of Rheumatology has established criteria of 11 manifestations to distinguish SLE from other connective tissue diseases (Chart 20–1). Evidence of four manifestations in the absence of other definable disease entities is sufficient for the diagnosis of SLE. Generally, nonspecific findings that may be assessed at the time of disease onset include fever, malaise, weight loss, recurrent abdominal pain, anorexia, and fatigue. Headaches are present in more than 10% of children at the time of diagnosis. Conjunctivitis also is a common early manifestation.

Arthritis and arthralgia are the most common presenting symptoms of SLE. The child may complain of morning stiffness and joint pain or swelling. The arthritis of SLE is usually symmetric and affects both small and large joints. Commonly affected joints are hands, wrists, and knees. Joint deformities or erosions are rare. Rheumatoid nodules may appear during periods of disease exacerbations and may disappear as the disease activity diminishes.

Dermatologic findings are the second most common manifestations. These may include maculopapular and vasculitic rashes, livedo reticularis (reddish blue mottling of skin, exacerbated by exposure to cold), and periungual erythema or other nail bed changes. Many acutely affected individuals may have a butterfly rash across the bridge of the nose and on the cheeks that may spread to the scalp, neck, chest, and extremities. The rash may become bullous, possibly leading to a secondary infection. Photosensitivity is a classic dermatologic sign of SLE, especially if it occurs in the presence of arthritis.

Other skin eruptions may include vasculitic lesions with ulceration; purpuric lesions; and subcutaneous nodules on the palms, fingertips, soles, extremities, or trunk. Macular and painless ulcerative lesions in the mouth and nose may be present. Alopecia, resulting from inflammation around the hair follicles, may lead to patchy or generalized loss of hair. Hair may be coarse, dry, and brittle.

Polyserositis, inflammation of several mucous membranes, is another clinical manifestation of SLE. Pericarditis, peritonitis, or pleuritis may be present. Cardiovascular

CHART 20-1 AMERICAN COLLEGE OF RHEUMATOLOGY CLASSIFICATION CRITERIA FOR SYSTEMIC LUPUS ERYTHEMATOSUS

The diagnosis of systemic lupus erythematosus requires the presence of four or more of the following 11 criteria, serially or simultaneously, during any period of observation.

1. Malar rash: fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
2. Discoid rash: erythematous, raised patches with adherent keratotic scaling and follicular plugging; possibly atrophic scarring in older lesions
3. Photosensitivity: skin rash as a result of unusual reaction to sunlight, as determined by patient history or physician observation
4. Oral ulcers: oral or nasopharyngeal ulceration, usually painless, observed by physician
5. Arthritis: nonerosive arthritis involving two or more peripheral joints, characterized by swelling, tenderness, or effusion
6. Serositis: pleuritis, by convincing history of pleuritic pain, rub heard by physician, or evidence of pleural effusion; or pericarditis documented by electrocardiography, rub heard by physician, or evidence of pericardial effusion
7. Renal disorder: persistent proteinuria, > 500 mg per 24 hour (0.5 g per day) or >3+ if quantitation is not performed; or cellular casts (may be red blood cell, hemoglobin, granular, tubular, or mixed cellular casts)
8. Neurologic disorder: seizures or psychosis occurring in the absence of offending drugs or known metabolic derangement (e.g., uremia, ketoacidosis, electrolyte imbalance)
9. Hematologic disorder: hemolytic anemia with reticulocytosis; or leukopenia, < 4,000 per mm³ (4.0×10^3 per L) on two or more occasions; or lymphopenia, < 1,500 per mm³ (1.5×10^3 per L) on two or more occasions; or thrombocytopenia, < 100×10^3 per mm³ (100×10^3 per L) in the absence of offending drugs
10. Immunologic disorder: antibody to double stranded DNA antigen (anti-dsDNA) in abnormal titer; or presence of antibody to Sm nuclear antigen (anti-Sm); or positive finding of antiphospholipid antibody based on an abnormal serum level of IgG or IgM anticardiolipin antibodies, a positive test result for lupus anticoagulant using a standard method, of a false-positive serologic test for syphilis that is known to be positive for at least 6 months and is confirmed by negative *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test
11. Antinuclear antibodies: an abnormal antinuclear antibody titer by immunofluorescence or equivalent assay at any time and in the absence of drugs known to be associated with drug induced lupus

Adapted with permission from Tan EM, Cohen AS, Fries JF, Mast AT, McShane DJ, Rothfield NF, et al. The 1982 revised criteria for the classification of systemic lupus erythematosus. Arthritis Rheum 1982;25:1274, and Hochberg MC. Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus [Letter]. Arthritis Rheum 1997;40:1725.

symptoms that may develop over time include pericarditis, substernal or precordial pain, murmurs, persistent tachycardia, transient dysrhythmias, and pleural and pericardial effusions. Raynaud's phenomenon, in which vasoconstriction causes blanching, cyanosis, and erythema in the toes and fingers in response to cold or stress, may be noted.

Renal involvement is common in children. Nephrotic syndrome and acute glomerulonephritis may develop and are considered life-threatening occurrences. Renal insufficiency is manifested by weight gain, hypertension, edema, increased serum creatinine levels, and decreased creatinine clearance. Additionally, urinalysis reveals hematuria, proteinuria, and increased urinary sediment.

Almost all children with SLE have one or more hematologic abnormalities, including anemia, leukopenia, and thrombocytopenia. Lymphoid involvement may be noted in the form of generalized lymphadenopathy and hepatomegaly.

Central nervous system symptoms may arise as indications of the central nervous system vasculitis, as toxic symptoms resulting from the medication regimen, or as behavioral outcomes of this chronic illness. Central nervous system vasculitis can lead to irritability, depression,

headache, lethargy, dizziness, seizures, ataxia, and hallucinations. Ongoing use of corticosteroids lowers the threshold for seizure activity and may cause personality changes such as depression or euphoria. Depression can also occur as a result of learning that one has SLE or from coping with the issues associated with acute disease activity that limit the child's activities.

With SLE, exacerbations and remissions that vary in severity, depending on the particular organ system involved, occur. After the first 2 years, the disease only rarely involves previously unaffected organ systems. Distinguishing the symptoms of disease exacerbation from those of infectious complications may be difficult. Suspect infection if fever, coughing, shortness of breath, chest pain, and changes in behavior and visual acuity occur until proved otherwise.

Diagnostic Tests

Initial screening for SLE includes the following tests: a complete blood count with differential, ESR, C-reactive protein measurement, antinuclear antibody count, and a test to detect RF. Additional laboratory values may be

determined to rule out other disease processes. The anti-nuclear antibody test identifies the presence of antinuclear antibodies in the blood. The presence of antinuclear antibodies is a marker of an autoimmune process and is most commonly seen in SLE.

Interdisciplinary Interventions

No one treatment for SLE exists; management depends on the manifestations and severity of the disease. Medical management is tailored to meet the individual child's needs, based on organ system involvement and on the severity of inflammation at the time of evaluation. The goal of therapy is to control both the acute exacerbations of the illness and the ongoing chronic disease manifestations to enable optimal functioning, to prevent scarring in any organ system, and to prevent intolerable side effects of the therapy. Collaboration among healthcare professionals is necessary. Child life specialists in the hospital setting and a variety of allied health professionals in outpatient settings, including social workers and psychologists, may help the family and child to cope with issues (e.g., body image concerns related to disease and medications) in a positive manner.

Interventions for Joint Involvement

Joint involvement, specifically, arthralgias, are usually controlled with NSAIDs and antimalarial medications such as hydroxychloroquine. Aspirin is not recommended, because the large doses needed may cause liver toxicity.

Alert! Ibuprofen has been associated with an aseptic meningitis syndrome in SLE; therefore, it should not be administered to children with SLE (Nguyen, Gal, Ransom, & Carolos, 2004).

Medications must be taken daily to maintain adequate blood levels. NSAID therapy requires careful monitoring of renal function, because these agents decrease glomerular blood flow and can precipitate acute renal failure in children with SLE.

A physical therapy program can be implemented to help the child manage joint pain, enhance ROM, and prevent injury and contractures. Periods of rest should be incorporated into the child's daily routine, especially during periods of exacerbation.

Interventions for Skin Involvement

The rash of SLE is generally treated with an antimalarial drug, preferably hydroxychloroquine. Topical steroids may also be used, if cutaneous involvement is limited. Because hydroxychloroquine carries a risk of retinal damage, an eye examination should be performed every 6 months in patients receiving this drug.

Rashes and lesions require careful monitoring for signs of infection. In addition, assess the toes and fingers for vascular compromise. Urge the child and parents to keep the extremities warm during cold weather by using socks,

gloves, and layered clothes. Also instruct them to avoid tight clothing.

Photosensitivity can be well controlled by using sunscreens, avoiding sun exposure, and using steroid therapy. When the child must be exposed to the sun, emphasize the importance of using sunscreens that block both ultraviolet A and B rays (SPF 15 or higher); avoiding long-term exposure; and wearing long-sleeved clothing, pants, large-brimmed hats, and sunglasses. Not only can sun exposure exacerbate the skin rash, but it may also precipitate systemic exacerbations.

Interventions for Systemic Involvement

Major organ system involvement in SLE usually necessitates the use of corticosteroids. Symptoms such as fever, skin manifestations, pleuropericarditis, and lymphadenopathy usually can be effectively treated with low-dose prednisone or hydroxychloroquine. Alternate-day steroid therapy is currently being used to minimize the linear growth and sexual maturation problems associated with steroid use.

KidKare ■ A child with SLE should wear a MedicAlert bracelet to alert emergency personnel to his or her dependence on steroids.

High-dose oral prednisone for a period of 4 to 6 weeks may be indicated for the child with central nervous system and renal involvement. Long-term use of high-dose prednisone is avoided whenever possible because of the serious complications (e.g., cataracts, fractures, hypertension, and metabolic disturbances) that may occur. The aim of therapy is to control activity of the disease with the lowest possible dose of prednisone. To aid in this process, steroid-sparing agents such as azathioprine, methotrexate, and hydroxychloroquine may be used. When the child's condition has been stabilized, the high-dose steroids are tapered to prevent the negative effects of sudden medication withdrawal.

Instruct parents regarding the need for an ophthalmic evaluation for retinal damage within the first 30 to 60 days after initiating drug therapy and every 6 months thereafter. These evaluations aid in detecting and preventing macular inflammatory problems.

Periodic blood work for evaluating drug toxicity and disease activity must also be discussed with the patients and parents.

Sexually active adolescent females need counseling about birth control and pregnancy. Inform them that SLE can become more active with the use of certain oral contraceptives and during pregnancy. It is usually recommended that a diaphragm and spermicide be used for birth control because they do not have adverse side effects that affect the child's SLE. However, low-dose oral contraceptives may be used if the patient is carefully monitored, especially if compliance with barrier contraception is poor. The fetus is at risk for injury both by the mother's disease and by the side effects of the drugs required to treat the mother's disease.

Nutritional Support

The child receiving steroid therapy needs to be monitored for weight gain and fluid retention. If renal involvement is a concern, a low-sodium, low-protein diet may be instituted. Adolescent females on steroid therapy should ingest increased amounts of calcium.

Interventions to Enhance Growth and Development

The child common needs help to deal with any problems that he or she may have related to self-image and self-

esteem. The undesirable effects of medication therapy, such as weight gain and “moon face,” the restrictions related to photosensitivity, and the increased risk for depression are among the factors that can affect the child’s self-concept. The child may refuse to follow preventive measures, thereby precipitating an acute episode of the condition (Developmental Considerations 20–2).

The healthcare team and family members should strive to help the child achieve as normal a lifestyle as possible within the constraints of the illness. Encourage independence in decision making while still monitoring for safety and wellness. Social workers or psychologists trained to deal with chronic illness in children may be helpful in assisting

DEVELOPMENTAL CONSIDERATIONS 20–2

Management Issues for Children With Systemic Lupus Erythematosus

Concerns of the Child	Actions Demonstrated by Child	Healthcare Provider and Family Interventions
“I don’t want to be different than other children.”	Refuses to take medications while at school	Arrange medication schedule to eliminate or minimize need to take medications during school and social activities.
“I don’t like the effects of medications on how I look.”	Avoids taking medication	Have parent unobtrusively monitor child taking medication.
“I want to participate in summer activities in the sun.”	Refuses to avoid the sun	Help child select hats, clothing, lotions, and other protective gear that can be used to protect against overexposure to the sun.
“Applying sunscreen is messy and not cool.”	Does not use sunscreen consistently each day when out in the sun	Review with the child the importance of using sunscreen. Have the child select a favorite type of sunscreen to use. Have the child apply sunscreen at home before meeting friends.
“Rashes make me look funny.”	Does not want to socialize with others or go out in public	Encourage the child to use hypoallergenic cosmetics to cover rashes.
“I can’t do anything. I can’t be like my other friends.”	Feels depressed or different	Assist parents to emphasize child’s positive attributes and accomplishments. Encourage participation in counseling or support group.
“I look fat.”	Feels depressed; cries	Help the child select clothes that camouflage weight gain.
“I am too tired to play with other kids.”	Wants to be excused from school activities and extracurricular activities because of fatigue	Assist the child to pace activities and periods of rest to minimize fatigue. Assist the child to select activities that are not as physically demanding, such as piano playing, art work, and computer activities.

them to learn to cope with their frustrations. Support groups that enable children to meet others with SLE and to discuss common concerns are useful for some children. Several organizations offer written information about SLE and can direct families to local support groups and activities in their community (see [thePoint](#) for organizations).

MUSCULOSKELETAL TRAUMA

QUESTION: The radiograph in the emergency department shows that Chase has an oblique fracture of the fifth metacarpal. It is a closed fracture and the bone is not out of alignment. He has a fiberglass cast applied to his right hand. What are the developmental principles of working with adolescents that you will use to develop an individual teaching plan for Chase, who now has a cast?

Childhood trauma has been the leading cause of death among children for nearly 50 years, and it has been the second leading cause of morbidity. The most common childhood musculoskeletal trauma includes sprains, followed by lacerations, fractures (excluding the skull), intracranial injuries, and internal injuries. The most serious injuries tend to be fractures and intracranial injuries.

Sports Injuries

During the past 20 years, participation in organized athletics by children and adolescents between ages 6 and 21 years has grown considerably. An estimated 3 million injuries are incurred annually during sports participation by children in the United States. Approximately 25% to 30% of sports injuries occur during organized sports, and another 40% occur during unorganized sports (Bautista & Flynn, 2006). More than 200,000 injuries per year are related to use of playground equipment, with 88% of these injuries occurring on monkey bars, jungle gyms, swings, and slides. The highest injury rate among high school athletes is in baseball, followed by soccer, basketball, and football. Gymnastics, tennis, track and field, and cross-country events have lower rates (Bautista & Flynn, 2006).

In recent years, injury rates have been dramatically reduced because of changes in safety requirements for children involved in sports. Preseason examinations, medical coverage at sports events, proper coaching, adequate hydration, proper officiating, proper equipment, and improved field and surface playing conditions have the potential to reduce sports injuries. Chapters 6 and 7 discuss safety concerns and sports activities in more detail. Table 7-1 discusses the ergogenic aids, such as steroids, that young athletes are using or considering in attempts to enhance their athletic performance. Use of these aids may have severe health outcomes for the youth and may contribute to sports injuries.

This section describes the care of children with fractures, overuse injuries, sprains and strains, and dislocations.

Fractures

A fracture occurs when the bone receives more stress than it can absorb. The most common reasons for fractures in children are falls, motor vehicle accidents, bicycle accidents, and accidents that occurred while at school. The incidence of sports-related fractures is increasing (Rewers et al., 2005).

Fractures in children vary in several important ways from fractures in adults, and these variables affect care. First, a child's bone heals faster than an adult's bone. The younger the child, the faster the bone heals, because younger children have a proportionately higher metabolic rate. Children's bones are also softer than an adult's bones, and their bones may bend or buckle rather than break. Another crucial difference between managing adult and pediatric fractures is that children's bones have an open growth plate (epiphysis). Any damage to the growth plate can result in limb length discrepancy, joint incongruity, and progressive angular deformity of the limb.

During the birthing process, fractures may occur in the newborn. However, fractures generally are rare during the first year of life, because the child has limited mobility. Multiple, severe fractures in an infant may be an indication of a metabolic bone disease, such as osteogenesis imperfecta. During the first 2 years of life, many fractures in children may be the result of physical abuse.

Alert! In a nonambulatory child, the accidental occurrence of a spiral fracture is rare. Thus, spiral fractures in young children are most often the result of twisting of the extremity by an abusive adult.

When the child starts to walk, the clavicle and radius are the most commonly fractured bones. Fractures can occur from trauma, such as sudden twisting of a limb or a force applied to the limb, such as a kick. Pathologic fractures occur when preexisting diseases weaken a bone, as happens with bone tumors.

In general, fractures in children heal without complications. Possible complications such as limping, decreased ROM, and nerve deficits rarely occur.

Pathophysiology

The amount of force required to fracture a bone depends on the strength of the bone, the size of the bone, and other extrinsic factors, such as the direction of the force. After the fracture occurs, inflammation develops at the site. Osteoblasts (bone-forming cells) activate within 24 hours to begin making new bone. During the ensuing few weeks, callus forms and knits together into compact bone. This process takes 4 to 12 weeks in children, depending on their skeletal age. Remodeling, a process that rounds off angles and fills in hollows, continues for up to 1 year after the fracture. Because the ability of bone to remodel is enhanced in children, the ends of the fracture do not have to be aligned perfectly, as they do in adults.

A fracture is either closed or open. A closed fracture involves no break in the skin. An open fracture occurs when a portion of the bone protrudes through the skin or when an external wound connects to the fracture site. Open fractures are classified as type I, II, or III, depending on the degree and severity of the soft-tissue damage or loss, the size of the wound, and the amount of wound contamination. For example, with a type I open fracture, the wound size is less than 1 cm and there is minimal contamination and soft-tissue damage. For a type II fracture, the wound size is larger than 1 cm and there is moderate contamination and tissue damage. For a type III fracture, the wound is large, with a high degree of contamination and extensive tissue damage. One fracture type is not more complicated than the other, but the potential for infection is greater with an open fracture.

Classification of fractures also involves identifying the location and describing the nature of the fracture. The location refers to where the fracture occurs along the shaft of the bone (Fig. 20–19). Fractures can also be described in terms of the type of injury that has occurred (Table 20–5).

In general, fractures in children heal without complications. Possible complications such as limping, decreased ROM, and nerve deficits rarely occur. The prognosis varies according to the type of fracture and its location. If the injury involves the growth plate in an immature bone, growth disturbance may follow. The growth plates of the lower extremities are primarily responsible for determining the height of the child. Disturbance of their function may result in slow growth, overgrowth, or cessation of growth. Table 20–6 illustrates a classification system that describes the injury and the potential for growth disturbance.

Assessment

Assessment for fractures is part of the emergency trauma care of a patient after initial stabilization. Obtaining a history of the accident helps determine the nature and extent of the injuries. Motor vehicle accidents and falls have a high index of suspicion for fractures, especially if the child was unrestrained in the vehicle.

KidKare ■ Ask the child to tell how the fracture occurred in his or her own words. If possible, ask this question without the parents present if abuse is suspected and an honest response is desired from the child.

The child may complain of pain, numbness, or tingling in an extremity. Remove all clothing to facilitate assessment. Open fractures may be obvious; a closed fracture can make the limb grossly distorted. However, some fractures, such as of the spine or pelvis, are not as evident. The cervical spine in all trauma patients must be protected by a cervical collar until radiographs rule out a fracture.

Other abnormal physical findings with a fracture include shortening of the limb, swelling, muscle spasm,

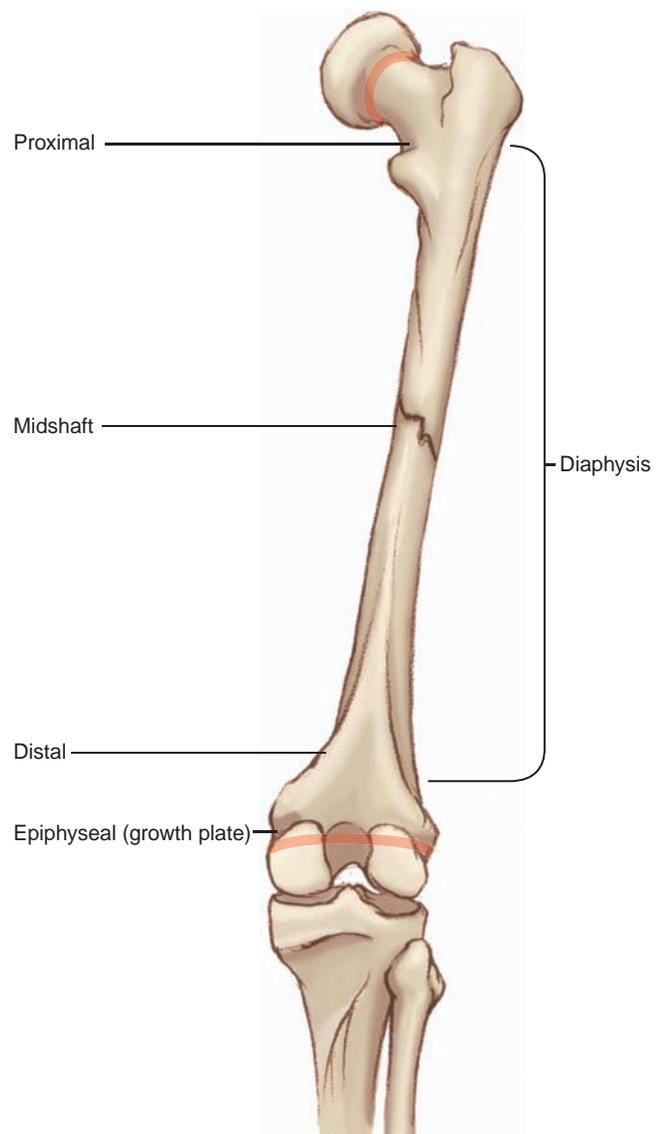

FIGURE 20–19. Classification of fracture by location.

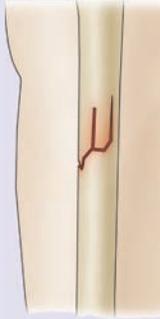

crepitus, and discoloration of the limb. The child may refuse to move the limb, or a change in neurovascular status may be apparent. A fracture always causes pain, although the intensity and severity of the pain vary among children. Ask the parents about the child's normal response to pain or previous experience with pain to help define the pain associated with a possible fracture. In nonverbal children, facial grimacing, whimpering, or crying may be elicited when the child is repositioned or when articles of clothing are removed.

Diagnostic Tests

Radiographs are the primary method used to evaluate fractures. Both anteroposterior and lateral views are recommended. The joints above and below the suspected fracture also must be included to evaluate potential associated injuries. If child abuse is suspected, radiographs are

TABLE 20-5

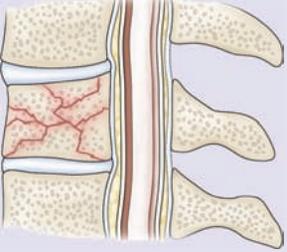

Classification of Fractures by Description of the Type of Break

TABLE 20-5

Classification of Fractures by Description of the Type of Break (*Continued*)

Type	Illustration	Description
Comminuted	 <p>Comminuted A fracture in which bone has splintered into several fragments</p>	Three or more fracture fragments
Compression	 <p>Compression A fracture in which bone has been compressed (seen in vertebral fractures)</p>	Bone becomes wider and more flat; usually seen in the spine

used to detect the presence of old fractures and to determine the extent of healing that has taken place at other fracture sites. In certain cases, other tests can be ordered to evaluate a suspected fracture. These tests include computed tomographic scans, MRI, fluoroscopy, and myelograms.

Interdisciplinary Interventions

Treatment for fractures involves reduction of the fracture, wound care for open fractures, pain management, monitoring for complications, providing nutritional support, and ensuring psychosocial needs are being met. The goal is to restore function.

Interventions to Reduce the Fracture

The choice of treatment for a fracture depends on the type, the location, and other associated injuries. For the bone to heal, the edges of the fracture must be close together or aligned, and relatively immobile. A general treatment principle is to allow the child to mobilize as quickly as possible while the fracture is reduced and the bone is immobilized. Although bone healing is impor-

tant, restoring the use and appearance of the extremity is also crucial. Fracture reduction involves one of two main methods: closed reduction or open reduction.

Closed Reduction

Closed reduction aligns the fracture fragments by manually manipulating the extremity or applying traction. Procedural sedation (see Chapter 10) or general anesthesia may be used before attempting a closed reduction. It is the most humane way to reduce a fracture and has become more common during the past 10 to 15 years. Ideally, the fracture is reduced as soon as possible. However, certain situations, such as when a large amount of swelling is present at the site or when the child's life is in danger, make immediate reduction impossible. In those cases, the physician may have to delay reducing the fracture for a few days. If fractures are not displaced, they do not need to be reduced.

Open Reduction An orthopedist uses open reduction when a fracture cannot be reduced by closed methods or when torn muscles or ligaments must be repaired. Usually, some type of internal fixation stabilizes the

TABLE 20-6**Salter-Harris Classification of Epiphyseal Fractures**

Classification	Description
Type I 	Separation of the epiphysis May be mistaken for a sprain Does not usually affect growth
Type II 	Fracture separation of the epiphysis Circulation remains intact; growth usually not affected
Type III 	Fracture through the epiphysis into the joint Does not usually affect growth if reduced properly
Type IV 	Fracture of the epiphysis extending into the joint and the metaphysis Open reduction and internal fixation usually necessary to prevent growth disturbance
Type V 	Crush injury to the epiphyseal plate Results in premature closure of the epiphyseal plate and growth arrest (occurrence is rare)

fracture until it is healed. A variety of pins, screws, plates, and rods are available for fixation, depending on the type of fracture and the age of the child (see Treatment Modalities earlier in this chapter). Internal fixation with screws, plates, or rods is standard treatment with older children. Intramedullary fixation places a rod in the shaft of the femur to provide stabilization. After the bone has healed, the rods are removed. Telescoping rods are ideal for children who have a chronic bone disease such as OI, but they are not indicated for the treatment of femur fractures in otherwise healthy children.

Immobilization After Reduction

After reduction, the fracture is immobilized by one of a variety of different methods including splints, braces, casts, external fixators, or traction (see Treatment Modalities). Immobilization is used to prevent rotation and shearing of the fracture site, to maintain the position of the fracture after reduction, and to permit active muscle contraction. Also, keeping the site in good alignment relieves pain and allows more ease in movement of the adjacent, unaffected areas of the body.

Wound Care for Open Fractures

The treatment of open fractures differs from that of closed fractures. Either external or internal fixation can be used to treat open fractures. The potential for infection from wound contamination is great. Typically the wound is irrigated and debrided and the fracture is stabilized. The size of the wound determines whether the wound is closed after the initial procedure (primary closure) or is left open for further irrigation and debridement. The child receives antibiotics before the procedure. If the child has a draining wound and the wound culture is positive, antibiotic therapy continues for a few weeks.

Pin site care (see Tradition or Science 20–2) for child in skeletal traction is essential. Anticipate administering analgesics about an hour before pin care if the child experiences discomfort with the treatment. Encourage older children to assist with pin care, even if they simply open the packages of cotton applicators. Participation gives them some feeling of control over a frightening situation.

Pain Management

Pain management for a fracture is essential. Intravenous opioids such as morphine provide relief for the first 24 hours. After the fracture is reduced and immobilized, administer oral narcotics such as acetaminophen with codeine to control discomfort. Muscle spasms, especially with a femur fracture, can be extremely painful. Diazepam, which relaxes the muscle, is highly effective. Muscle spasms generally subside after the first week.

Prevention of Complications

Early complications from a fracture can occur despite prompt treatment and careful observation. These compli-

cations can include shock, fat emboli, **compartment syndrome**, deep vein thrombosis, pulmonary embolism, and infection. Late complications, such as nonunion or delayed union, refracture, joint stiffness, posttraumatic arthritis, or pseudoarthritis, often can be prevented or their effects minimized by aggressive treatment and proper evaluation.

Compartment syndrome is one of the most feared complications associated with musculoskeletal surgery and trauma. This syndrome occurs when the nonelastic fascia that covers bone, muscle, nerves, blood vessels, and soft tissue cannot expand adequately to compensate for the bleeding or swelling from trauma or the pressure from splints or casts. As the pressure increases, circulation slows, and, if the pressure is unchecked, the tissues and nerves may die. The compartments of the lower leg and forearm are most commonly affected.

Alert! The color and pulses of a limb with compartment syndrome remain intact at first. The classic sign of compartment syndrome is unrelenting pain that is not relieved by narcotics. Notify the physician immediately.

If the child in a cast develops compartment syndrome, initially the cast is split or bivalved on one side. If that measure does not relieve the symptoms, a fasciotomy, a surgical incision made through the fascia to release the pressure, is performed. The incision remains open, but is wrapped with a sterile dressing for a few days. At that point, either the physician closes the fasciotomy site or allows it to heal by itself. The best treatment for this complication is to prevent excessive swelling and to detect neurovascular compromise as quickly as possible. Always assess neurovascular status frequently and notify the physician of any change. In addition, elevate the extremity above the level of the heart to decrease swelling, and apply cold packs to the injured site for the first 24 hours.

Nutritional Support

Typically, children with fractures do not have extra nutritional needs if they eat a well-balanced diet containing sufficient amounts of protein, calcium, and iron to promote the healing process. However, a child in a body cast should eat small, frequent meals to avoid abdominal distention. The diet should have increased amounts of fluid and fiber to prevent constipation. A laxative or stool softener is helpful for some children who are in traction or a body cast. Appetite may decrease because of the inactivity.

Supportive Interventions

The child who enters the acute care setting for treatment of a fracture probably has not had any preparation for the experience and has most likely undergone some sort of trauma. The family may also be in a state of shock. Crisis intervention for both the child and family is essential. If

FIGURE 20–20. Children should be introduced at a young age to wearing protective gear to prevent physical injury. Parents can be role models for their children by also wearing bike helmets.

the family was part of a motor vehicle accident or community disaster, multiple family members or friends may be hospitalized. Siblings are encouraged to visit, especially if they witnessed the accident or causal event. A visit helps to reassure siblings that their brother or sister is alive. See Chapter 11 for a more complete discussion of care of the hospitalized child, including managing regressive behaviors, child life interventions, and social service support.

Community Care

Teaching is an important component of the care of a child with a fracture. Instructions on the treatment plan, basic principles of bone healing, neurovascular assessments, and cast care by the nurse can help parents feel more confident about caring for their child in the home (see [thePoint](#) for Procedures: Cast Care and Supplemental Information: Teaching Information for the Child With a Cast).

Depending on the type of fracture, the child's physical mobility may be limited after he or she returns home. Adaptations to the home environment may be needed to accommodate the child in a cast or in traction. Specialized devices such as a rolling wheelchair may be needed. Crutches and walkers are other aids used to restore mobility (see Fig. 20–4). Wagons for small children are fun and useful. A physical therapist can help the family to learn methods of transfer and use of assistive devices. Demonstrate good body mechanics and safety practices to the child to prevent further injury.

A primary role of the healthcare team is to promote public awareness of measures that can prevent accidental injury and trauma to children. Safety fairs held at malls

and other public places educate parents and children about ways to prevent accidents, childproof the home, and develop a family escape plan for fires. Safety programs, often ones that involve the use of puppets or interactive displays, can be used by schools for education. These programs commonly focus on street safety, fire safety, and emergency routines, as well as seat belt and helmet use. In recent years, legislation has been passed in many states that requires certain safety precautions for children, such as the mandatory use of helmets when bike riding (Fig. 20–20) and of car safety restraint devices. The National Safe Kids Campaign is one example of a nationwide program that has local coalitions in every state to focus on community education about accident prevention (see [thePoint](#) for organizations).

ANSWER: Chase will prefer to care for the cast and his hand himself. Direct your teaching to Chase, but have his mother to listen to the care instructions:

- The cast must be kept dry. To shower, place the casted hand in a plastic bag and secure it with a rubber band.
- Keep the hand clean. You can use “baby wipes” or alcohol on paper towels to clean your hand.
- Do not put anything in the cast. Do not scratch inside the cast.
- Your fingers should stay pink, warm, and dry. Call your doctor if you have any severe pain, numbness, or tingling in your hand.

Overuse Injuries

Overuse injuries occur from the repetitive application of stresses to otherwise healthy tissue. This type of injury is common in organized sports (Table 20–7). Most overuse injuries have a good prognosis.

Pathophysiology

The process starts when repetitive activity fatigues a specific structure, such as tendon or bone. Without adequate recovery, microtrauma develops and stimulates the body's inflammatory response, causing the release of vasoactive substances, inflammatory cells, and enzymes that damage local tissue. Cumulative microtrauma can cause degenerative changes, leading to weakness, loss of flexibility, and chronic pain. Children are particularly susceptible to overuse injuries in tissues associated with growth cartilage in the articular surfaces, physes, and apophyses.

- Articular injuries are associated with articular cartilages, secondary areas of ossification found where major tendons attach to bone. These growth centers are the weakest link in the musculoskeletal chain.
- Physeal injuries can be caused by repetitive loading of the physes (primary ossification centers located at the

TABLE 20-7

Common Overuse Injuries

Type	Cause	Physical Findings
Jumper's knee (patellar tendonitis)	Repetitive pulling action on the distal pole of the patellar tendon	Point tenderness at proximal aspect of tibia associated with tendonitis
Little Leaguer's elbow	Repetitive valgus stress Common in adolescent pitchers	Osteochondral injuries Damage to proximal radial epiphysis and growth plate
Little Leaguer's shoulder	Repetitive overhead throwing	Stress fracture of proximal humeral growth plate
Osgood-Schlatter disease	Irritation of tibial tubercle from excessive running or jumping exercises	Point tenderness to proximal tibia Inflammation Possible avulsion injury
Osteochondritis dissecans	Cause unknown May be familial or result of metabolic bone problem	Knee pain Inflammation Swelling Portion of articular cartilage separates
Sever's disease	Activities that include vigorous running or jumping resulting in heel pain	Limp Apophysitis of the calcaneus Point tender heel pain Tight Achilles tendon
Shin splints	Excessive running Improper shoes Running on hard surfaces	Pain Inflammation in anterior aspect of the tibia
Sinding-Larsen-Johansson disease	Excessive extension action on the patellar tendon associated with jumping activities	Knee pain Diagnosed with radiographs Avulsion fracture of the lower pole of patella
Spondylolysis	Excessive flexion and extension activities; commonly seen in gymnasts, skaters, and football linemen	Back pain Diagnosed with radiographs anterior displacement of L5 on S1
Spondylolisthesis	Excessive flexion and extension activities	Back pain Diagnosed with radiographs

ends of the long bones). Ischemia to these areas can disrupt or even arrest growth.

- Shin splints are an inflammation of tendons and muscles of the shin. The shin bone (tibia) is covered by the periosteum, a band of soft tissue that has both nerve tissue and a blood supply. Just above the ankle and below the knee, tendons help attach muscles to the periosteum. When the shin is overstressed by impact forces of exercise, these structures can become inflamed.

Assessment

Overuse injuries are generally diagnosed based on history and physical examination. Focus the history on recent

growth spurts, changes in training, and playing surfaces. Radiographs may be needed to rule out other diagnoses. With overuse injuries, the pain generally worsens with activity and improves with rest.

The child may complain of pain across the lower back and muscle spasm resulting in changes in posture and gait if a stress fracture (spondylolysis and spondylolisthesis) occurs. Radiographs will show the position of the vertebrae.

Interdisciplinary Interventions

Treatment aims to restore as much function as possible in the shortest time and to enable the athlete to return to preinjury performance. Children experience pressure

from coaches, peers, and even parents when they are absent from a sport. Emphasis must be placed on the player's personal capabilities, because serious injuries result when the child returns prematurely.

Conservative treatment methods for the child with an overuse injury include avoiding the causative activity for 6 to 8 weeks. Applying ice to the injured area will help to reduce the inflammation and irritation. NSAIDs (ibuprofen) are used for inflammation and pain control. The physical therapist institutes a stretching and strengthening program for the appropriate muscle groups.

The goals for a child's return to play are determined by the healthcare team. The physician and the nurse should discuss realistic expectations for the treatment plan with the patient and the family.

caREminder

Parents and coaches may not understand that the level of activity that causes overuse symptoms varies from child to child. Notes or telephone conversations from the physician or nurse to the child's coach can clarify any misconceptions about what is expected during the recovery and recuperative periods.

The physical therapist also plays an important role here. Vital facts regarding the athlete's rehabilitative progress and potential can determine outcome. Nurses can link the chain of communication in this interdisciplinary approach.

Sprains and Strains

A *sprain* is a tear or a stretch in a ligament resulting from a pulling or twisting injury to a joint. A *strain* is a tear to the musculotendinous unit. Sprains and strains are uncommon in younger children and are usually seen in the adolescent age group. The growth plate (physis), which is an area of new bone formation, is weaker than the ligaments in younger children; as a result, it is prone to fracture. When children reach puberty, skeletal growth declines and the growth plates begin to close. Thus, the growth plate is less susceptible to injury, and the ligaments and tendons are more vulnerable to sprains and strains. Ankle and wrist sprains are most common.

Sprains are classified according to severity. *First-degree*, or mild, sprains result when the ligament is stretched and the affected joint is stable. *Second-degree*, or moderate, sprains occur when the ligament is partially torn and joint laxity is noted on examination. *Third-degree*, or severe, sprains are produced when the ligament is completely torn and the injured joint is unstable. The prognosis is favorable for first- and second-degree sprains. However, severe sprains carry an increased risk of recurrent injury, persistent instability, and traumatic arthritis, particularly if the athlete does not adhere to the rehabilitation regimen.

Pathophysiology

Ankle sprains and strains are usually the product of an inversion injury, in which the lateral aspect of the ankle joint is thrust outward and the foot is turned inward as if stepping on its side. This mechanism of injury causes insult to the anterior talofibular ligament and, in severe cases, involves the posterior talofibular ligament (Fig. 20–21).

Wrist sprains often occur as a result of repetitive motion injuries. Sprain occurs when the ligaments of the wrist are stretched beyond their normal limits or, in severe cases, completely torn, thus leading to instability of the joint. Wrist sprain may also lead to carpal tunnel syndrome.

Assessment

Obtain a history of the event that caused the injury to help determine the extent of the injury. Information about the mechanism of the injury is important. The timing of swelling and local hemorrhage at the injury site indicates the amount of joint injury sustained. The presence of an audible sound at the time of injury may also indicate the severity of the problem.

Palpate the affected area and the surrounding structures to determine the site of injury and the ligaments injured. Palpate the most painful areas last. A first-degree sprain is characterized by minimal pain, swelling, and ecchymosis. Full ROM of the joint and weight bearing are possible. The joint is stable, with mild tenderness noted over the point of injury. The child with a second-degree sprain has moderate pain, swelling, and ecchymosis. Motion of the extremity is slightly limited and painful. Mild joint laxity is present, with tenderness noted over the joint. The child may be unable to bear weight or perform daily activities with the extremity. When a third-degree sprain has occurred, substantial swelling and severe ecchymosis occur rapidly, usually within the first

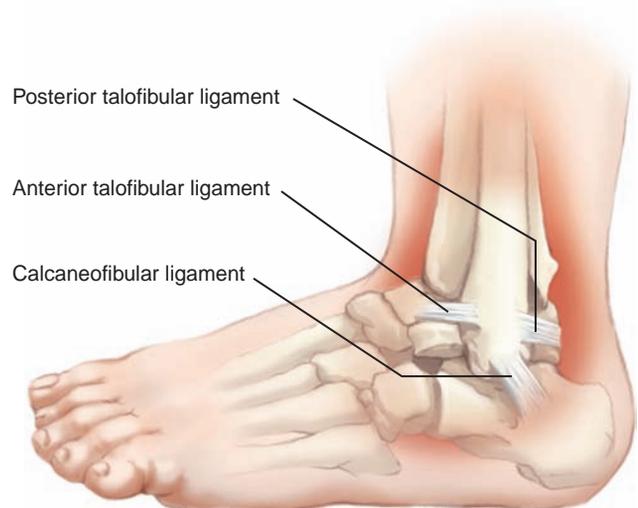

FIGURE 20–21. Ankle sprains occur when the foot is suddenly turned inward, causing tearing of the outside ligaments.

Rest

Ice

Compression

Elevation

FIGURE 20–22. The RICE protocol: rest, ice, compression, and elevation.

30 minutes after the injury. Severe pain over the joint may make it difficult to examine the injury and evaluate the extent of immobility. The child cannot bear weight on or otherwise use the extremity.

Diagnostic Tests

A radiograph of the injured extremity is done if there is evidence of an obvious fracture or misalignment, or if physical examination reveals a third-degree sprain. Fractures may not be easy to identify because of the cartilaginous nature of the young child's bones. The child who does not show improvement within 4 days of therapy should be reevaluated for a potential fracture at the site.

Nursing Diagnoses and Outcomes

The nursing diagnoses for a child with a musculoskeletal condition are presented in Nursing Plan of Care 20–1. In addition, because a sprain or strain can severely limit the mobility of an active youth, the following diagnosis may be applicable:

Noncompliance related to degree of mobility restrictions over an extended period

Outcomes: Child will adhere to treatment regimen, as demonstrated by use of elastic wraps, slings, braces, crutches, or other orthopedic supportive devices.

Child will refrain from weight bearing and sports activities as prescribed.

Interdisciplinary Interventions

Initially, all sprains and strains are treated with a period of rest, ice packs, compression, and elevation (RICE), and early motion of the limb is also encouraged (Fig. 20–22). RICE can be done immediately at the location in which the child was injured. Do not apply heat during the acute phase, because it may cause increase swelling and inflammation through hyperemia.

caREminder

In an injury to the foot or ankle, be sure to keep the player's shoe in place to help control swelling. The possibility of any fractures are ruled out using radiographs.

The severity and location of injury guide further management decisions. External support can be provided with an elastic bandage, brace, sling, or ankle lacer in mild sprains (Fig. 20–23). In grades I and II ankle sprains, rehabilitation can begin immediately. Prolonged immobilization is not recommended. In grade III sprains, in which a ligament is completely torn, the limb is usually

**FIGURE 20–23.** For the child with a sprain, the nurse is responsible for teaching the child how to put on and adjust the device.

immobilized in a cast or brace. Surgery may be needed to relieve pain and restore function.

Early motion after acute injury of the soft tissue will help the child make a more rapid recovery. A stretching and strengthening program is instrumental in returning the child to full function. Physical therapists instruct the patient in quadriceps and hamstring exercises for knee sprains and strains. For ankle and wrist injuries, an ROM program is implemented. The nurse or physical therapist can teach crutch walking. When crutch walking, the child should bear weight on the hands and not the underarms, to avoid nerve damage (see Fig. 20–4).

Community Care

Home care instructions vary, based on the injury and on the treatment indicated. To decrease the potential for swelling, teach the patient and the family the proper technique for wrapping the injured extremity. The wrap should be started distal from the affected area. If the joint is located below the level of the heart, swelling is alleviated by elevating the limb. If anti-inflammatory medicines are used, advise the patient and family of the proper route, action, dosage, and side effects of the agent.

Notes to the physical education teacher or coach by the healthcare prescriber provide an explanation of the extent of the injury and list any restrictions the child may have. The note can also state what the child is permitted to do. For example, if the child sustained a knee strain and is walking with the assistance of crutches, upper body strengthening exercises can continue. The child with a first-degree injury can return to sport activities within 2 to 3 weeks if the affected joint has proper support. The child with a second-degree sprain can do partial weight-bearing activities using crutches. The child should return to full weight bearing and sport activities gradually. When a ligament has torn completely, the return to sport activities should not occur for 4 to 8 weeks after the injury.

Dislocations

A dislocation occurs when extreme force is placed on a ligament, causing two bone ends to become partially or completely displaced, or the head of a bone to be dislodged from its socket. The shoulder and proximal interphalangeal joint of the hand are the joints most often dislocated in sports. A dislocation of the knee or hip is rare, but must be treated as an emergency. Massive force is needed to dislocate the knee, and with dislocation, the peroneal nerve and popliteal artery may be involved.

Dislocations can occur alone or can be accompanied by an avulsion or growth plate fracture. As in sprain and strain injuries, dislocations are not as common in younger children, because the epiphysis is less susceptible to stress and more likely to fracture. However, dislocations are common in children with ligamentous laxity, as is seen in patients with trisomy 21, who are prone to subluxation (partial displacement) or dislocation of the hips. Nursemaid's elbow (subluxation of the proximal radial head) is commonly seen in 1- to 4-year-olds. This dislocation occurs when the

child is lifted, jerked, or swung with the arm extended and the forearm pronated. The subluxation occurs because the head of the radius has not matured and the pulling pulls the head partially out of the encircling ligament.

Pathophysiology

Most dislocations result from one acute incident that ruptures the surrounding soft tissues and ligaments around a joint. Insult to vascular and neurovascular structures is possible. Although simple dislocations can be reduced quickly, manipulation may be more difficult for unreduced joints because of the swelling and possible interposed tissue.

Assessment

With a dislocation, the child experiences pain immediately after the injury, accompanied by swelling and bruising. Movement of the extremity is decreased, and obvious deformity may be seen. The opposite joint is assessed first so that a baseline comparison can be made with the affected joint. Radiographs are acquired to rule out any fractures.

Interdisciplinary Interventions

Dislocations are treated conservatively. The area of dislocation is reduced usually with the child receiving procedural sedation and analgesia or general anesthesia. After reduction, acute dislocations are treated with RICE and immobilization. Slings, splints, or casts are used for 3 weeks after reduction for patient comfort and to allow healing of the capsular structures. Recurrent dislocations require possible surgical intervention.

Frequently assess neurovascular status to detect any variations secondary to the injury or swelling. Also instruct parents on normal and abnormal neurovascular findings. Review any medication information such as dosage, route, action, and side effects, and provide cast care instructions as appropriate (see [thePoint](#) for Supplemental Information: Teaching Information for the Child With a Cast).

Community Care

Mobilization of the joint begins approximately 3 weeks after the injury has occurred, to prevent joint stiffness. The physical therapist instructs the patient and parents on a home exercise program to aid the patient in returning to full ROM with joint stability. As previously discussed, written notes to coaches and teachers should detail permitted and nonpermitted activities.

See [thePoint](#) for a summary of Key Concepts.

The Child With Altered Neurologic Status

Case History

Joey Curricio is 11 years old. He is the most athletic of the Curricio children and also the greatest risk taker. Since he was a young child, Joey finds the extreme in any activity; he climbs higher and jumps further. He loves most sports, but especially soccer.

On a beautiful spring day, Joey's team has a soccer game against their most evenly matched rival. His parents and siblings are all there to watch. The ball is kicked high in the air and Joey and a boy from the opposing team both jump to head the ball. With an audible thud, their heads collide, and both boys fall down. The referee reaches them first, then their coaches, and then the parents. Both boys are conscious but Joey has a laceration at his hairline that is bleeding profusely. Supported by

his father, he walks to the sidelines. Joey sits next to his father talking as his father applies pressure to the cut and his brother returns with a sandwich bag of crushed ice. Then Joey's speech slows, his eyes roll, and he loses consciousness.

Upon arrival at the hospital emergency room, Joey is still unconscious. The nurse's assessment determines his pupils are bilaterally sluggish; he does withdraw from painful stimuli and will open his eyes in response to painful stimuli as well. Within 30 minutes, Joey is opening his eyes to verbal command; he is mumbling incomprehensibly and will purposefully withdraw from painful stimuli. His parents estimate that he was unconscious at the soccer field and en route to the hospital for about 20 minutes.

CHAPTER OBJECTIVES

1. Identify components of the neurologic assessment.
2. Examine the effect of embryonic development on the child's neurologic functioning.
3. Explain the purposes of diagnostic tests used in the assessment of the child with altered neurologic status.
4. Discuss the treatment modalities that can be selected to therapeutically manage the needs of the child with altered neurologic status.
5. Identify common neurologic conditions that children may experience, and their causes and defining characteristics.

See [thePoint](#) for a list of Key Terms.

The child with altered neurologic status presents a variety of complex healthcare concerns. This chapter highlights some common disorders and offers guidelines for developmentally appropriate interventions that address the child's physiologic, emotional, and social needs. Include the family as an integral component of care for the child.

Nurses are often in the best position to coordinate the interdisciplinary teams that manage children with neurologic problems. Depending on the facility, personnel available to the child and family may include physicians, advanced practice nurses, nurses, psychologists, social workers, child life specialists, physical therapists, occupational therapists, pastoral care staff, recreation specialists, nutritionists, and speech therapists. In addition, support groups and national organizations can provide assistance, education, and networking for specifically affected populations. When these services are unavailable to a family whose child has a complex neurologic problem, referral to a regional medical center for evaluation is indicated.

DEVELOPMENTAL AND BIOLOGIC VARIANCES

The fetal nervous system begins to develop as a thickened area of embryonic ectoderm called the *neural plate*. By the 22nd day of gestation, this plate folds, becoming the neural tube and ultimately forming the spinal cord and the ventricular system of the brain.

Neuronal proliferation is complete by birth, and most full-term infants are born with a full complement of neurons. However, neuronal development and proliferation during the second to fourth months of gestation can be influenced by exogenous (nutrition, infection, toxic exposure, ischemia) or endogenous (genetic) factors, leading to brain malformation.

After birth, the nervous system continues to mature through the processes of myelination and synaptogenesis. Myelination is the process of formation and deposition of myelin (a phospholipid protein) on nerve fibers, which insulates the fibers and enhances the efficiency of

impulse conduction. Myelination begins at about 30 weeks' gestation and continues for several years after birth. Synaptogenesis is the process by which nerve cells develop connections with each other. Proliferation and overproduction of synaptic connection start prenatally and continue after birth. In a process that is highly dependent on experience and exposure, synaptic connections are gradually eliminated for some time after birth. Synapses that are used frequently are maintained, so early experiences are vital to developing and maintaining synapses, and are therefore vital to brain development and maturation. The development of increasingly complex behavioral, sensory, and motor functioning depends on this process. Early life neglect characterized by decreased sensory input alters growth and organization of the brain and causes neurologic dysfunction (Taylor & Rogers, 2005).

Skull Bones

Most of the bones of the infant skull are ossified at birth. However, the individual bones are joined by connective tissues, called **sutures**, and they move in relation to each other. This flexibility is essential to allow the head to pass through the birth canal. However, the pressures of vaginal birth can cause **molding**, an abnormal skull shape that may be evident for several days after prolonged labor or after deliveries requiring forceps or vacuum-assisted extraction. Molding may indicate a difficult delivery, but does not indicate neurologic problems. In most cases, the head becomes normocephalic within 1 to 2 days. **Fontanels** (wider areas of unossified membranous tissue) occur at the intersections of sutures. Ossification of the bones of the skull is not fully complete until approximately 12 years of age.

Brain Growth

During the first year of life, the brain grows to 50% of its adult size (Fig. 21-1). The skull grows and takes shape in response to pressure from the growing brain and cerebrospinal fluid (CSF) spaces. The size and shape of a child's head should follow proportional dimensions and grow proportionately with the rest of the child's body. If intracranial pressure (ICP) is increased, as with hydrocephalus, head growth will occur out of proportion to height and weight. Conversely, in the presence of certain genetic conditions, malnourishment, or neglect, brain and head growth will be less than expected. Premature closure of one or more sutures causes craniosynostosis (abnormal head shape), which can occur as an isolated defect or as part of a syndrome.

Children have proportionately large and heavy heads, which makes them prime candidates for cerebrospinal trauma secondary to inadequate head control. For example, young children learning to walk are clumsy and top heavy; when they fall, the head usually leads. Before the fontanels and sutures are completely fused, toddlers are at higher risk than older children and adults for serious consequences of head injury.

The child's brain is constantly undergoing organization of function and myelination; thus, the full implications of a neurologic insult or injury may not be immediately apparent and may take up to several years to manifest.

A child may exhibit focal or generalized electrical discharges on an EEG that would be considered abnormal in an adult.

Increased intracranial pressure (ICP) may separate the sutures, especially the sagittal suture, until age 10–12 years.

A neonate's neurodevelopmental age is calculated to be the neonate's chronologic age minus the number of weeks born before term.

In the neonate, the spinal cord terminates at L3, compared with an adult, where it terminates at the L1–L2. This affects the site of needle insertion for the lumbar puncture.

Accurate and complete neurologic assessment of infants and young children is limited by their developmental level.

Open sutures and fontanels in infancy and early childhood help compensate for increases in ICP.

At birth, the brain is about 25% of adult size; at age 1 year, 50% of adult size; and at age 5 years, 90% of adult size.

Cerebrospinal fluid volume is 50 mL in the neonate, compared with 150 mL in the adult.

Premature development of handedness before age 1 year is not usual and may point to a focal neurologic lesion.

Myelination begins in the third fetal month and usually is complete by puberty.

Many developmental reflexes are present at birth and disappear by age 1 year. Persistence or asymmetry of the reflexes may indicate an abnormality.

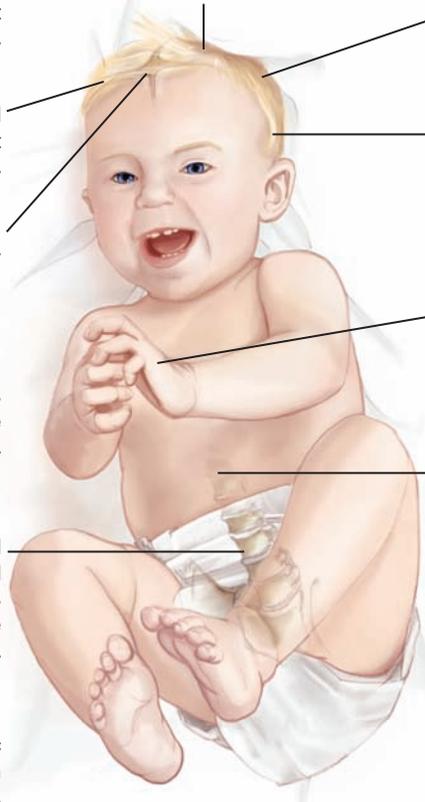

FIGURE 21–1. Developmental and biologic variances: neurologic system.

Ventricular System and Cerebrospinal Fluid

The ventricular system plays an important part in the overall function of the central nervous system (CNS). The ventricles are interconnected cavities in the brain where 90% of the body's CSF is produced. CSF bathes the brain and acts as a liquid shock absorber, decreasing the force of impact to the head on the brain. It also carries away waste products from tissues in and around the brain. Normally, the rate of CSF production, approximately 0.35 mL/minute, equals the rate of absorption. The circulating volume of CSF in children is approximately 65 to 140 mL and for adults is 90 to 150 mL (Aicardi, 1998).

Cerebral Blood Flow

Cerebral blood flow (CBF) in various age groups is estimated and averaged. In adults, it is thought to be 50 mL/100 g brain tissue/minute. The rate in newborns is similar to that in adults, with normal CBF estimated at 40 mL/100 g brain tissue/minute. These values are different from those in young children, in whom CBF is estimated at 70 to 80 mL/100 g brain tissue/minute (Lancon, Haines, & Bruce, 2001). Such differences may be attributable to variations in brain metabolism as the brain matures.

ASSESSMENT OF THE CHILD WITH ALTERED NEUROLOGIC STATUS

Assessing a child with altered neurologic status requires both a comprehensive health history and a physical assessment focused on the child's neurologic systems and appropriate to the specific situation.

Focused Health History

QUESTION: To evaluate Joey's current neurologic status, what is the information in the case study that is an important part of Joey's health history and that establishes his baseline?

The most important factor in evaluating a child with altered neurologic status is the history. Gather the health history by interviewing the child and parents, and by reviewing medical records. The urgency of the child's problem, age of the child, and availability of reliable historians guide the health history (Focused Health History 21–1).

Obtain a description of the presenting problem. In emergency or critical care areas, this history may be given by emergency or transport personnel. Although the health

Environmental history	<ul style="list-style-type: none"> Exposure to radiation Lead exposure
Growth and development	<ul style="list-style-type: none"> Sleep patterns Ability to meet developmental milestones

*This history is focused on the neurologic system. See Chapter 8 for a comprehensive format.

interview should focus on the child's presenting neurologic signs, evaluating nonneurologic signs and symptoms can also provide useful information. For example, neurologic disorders may initially present as nonspecific viral illnesses, failure to thrive, or developmental delay or regression, or they may occur at the same time as other systemic diseases.

Consider aspects of the past medical history to place the current problem in perspective. For example, prema-

ture infants may have a history of intracranial bleeding, seizure activity, or episodes of apnea that can substantially affect current neurologic functioning. Likewise, the child with a history of bacterial meningitis is at increased risk for hydrocephalus and hearing impairment.

Nutritional status, both past and current, is an important aspect of the history. Poor nutritional intake can affect the child's attention span and ability to concentrate.

A history of failure to thrive may indicate a metabolic disorder that affects neurologic functioning. Ingestion of nonfood substances (pica) can cause harmful toxicities that may affect neurologic function.

For a complete assessment, use developmental and biologic milestones to determine whether the child's patterns of development are normal, delayed, or demonstrate regression. Developmental milestones include activities such as when the infant or child first rolled over, sat unsupported, took steps, and rode a tricycle. The ages at which babbling and first words began are also important cognitive milestones to evaluate. History of school achievement and current school placement offer insight into current cognitive functioning.

ANSWER: It is important that the healthcare team knows that Joey is a well-nourished, athletic 11-year-old boy with no neurologic deficits and no obvious risk factors.

Focused Physical Assessment

Neurologic assessment of the infant and young child can be challenging. The child's emotional state and cognitive ability affect the examination. Document the presence of any factors, such as anxiety, pain, limited mobility, or the influence of medication, which may alter optimal responses. Also, consider development when interpreting the results of the examination. For example, the presence of a startle reflex is normal until about 4 months of age, but if this reflex persists past 4 months, it is evidence of neurologic dysfunction.

Much information can be obtained by observing the child carefully during the history taking. Continue observation as the child remains in a comfortable position, perhaps playing or sitting on the parent's lap. This approach gives the child an opportunity to become comfortable with the examiner and increases the chance that the child will cooperate with the examination. Observe how the child interacts with both his or her parents and the examiner. At about 8 or 9 months of age, the child should begin to demonstrate stranger anxiety; absence of this response may indicate neurologic dysfunction. As the child plays, note symmetry and smoothness of muscle movements as well as any abnormal postures. Assess muscle strength by watching the child crawl, pull up to a standing position, squat and resume standing, and walk. Evaluate the child's intellectual and language skills while watching him or her play. Assess behavior; note impulsivity, distractibility, hyperactivity, or unusual patterns of social interaction. Observe how the parent deals with the child's behavior to gain insight into the quality of parent-child interactions.

caREminder

Follow a systematic approach while examining the level of consciousness, cranial nerves, motor skills, sensory responses, and cerebellar function (Focused Physical Assessment 21–1).

Perform the most intrusive or distressing portions of the examination last to keep the child calm and cooperative for as long as possible during the examination.

Incorporate developmentally appropriate toys or games as part of the assessment. Examples of familiar and inexpensive items that may be helpful in assessing the child include the following:

- Blocks, crayons and paper, and clay to assess dexterity, handedness, and grip strength
- Pull toys, a jump rope, and a ball to assess cerebellar functions such as gait, balance, and functions dependent on cranial nerve (CN) VIII
- Brightly colored picture books and beanbag toss toys to assess visual acuity and eye movement served by CNs III, IV, and VI
- Salty snacks, lemon juice, sugar, and tonic water to assess CN I function and sensory portions of CNs VII and IX
- Books, magazines, and flash cards to assess language skills

Inspect the child's head for disproportionate growth and unusual shape. The best way to evaluate cranial growth patterns is to obtain serial head circumference measurements, plot them on a standardized growth chart for head circumference, and compare them with weight and length at each well-child visit (see Chapter 8).

Consider the child's status when performing the physical assessment. Typically, assessments of children's neurologic systems can be divided into three common forms:

1. The brief screening examination
2. The acute neurologic check
3. The comprehensive neurologic examination

Most often, portions of these examination forms are combined, depending on the child's status and on the nature of the problem.

The Brief Screening Examination

Brief screening examinations are usually performed in emergency situations to triage neurologic deficits, to establish baseline data for later evaluation, and to develop an initial plan of care. When cardiac and respiratory status are deemed stable, perform a limited neurologic assessment, which includes

- Cerebral function, vital signs, level of consciousness, mental status, and verbal response
- Cranial nerves, usually CNs II, III, IV, and VI for pupil reactivity; cardinal fields of gaze; and eye movement
- Motor system: Strength, movement, and symmetry
- Sensory system: Tactile and pain sensation in extremities
- Reflexes: Deep tendon reflexes and superficial reflexes

Alert! Immobilize the neck in a trauma patient until radiograph and clinical evaluation determine that cervical injury is absent.

FOCUSED PHYSICAL ASSESSMENT 21–1

The Child With Altered Neurologic Status

Assessment Parameter	Alterations/Clinical Significance
General appearance	Head nodding, lip tremors, eye blinking, and staring may be evidence of epilepsy or motor tics. Dysmorphic features may be present with certain genetic syndromes. Stuttering, dysarthria, nasal speech, or dysphonia may indicate cranial nerve or cerebral abnormalities.
Integumentary system	Café-au-lait spots, port-wine stain, or abnormal areas of pigmentation may be indicative of a neurocutaneous syndrome. Presence of a sacral dimple or tuft of hair may indicate spina bifida occulta.
Head and neck	Bulging fontanels may indicate increased ICP; sunken fontanels may indicate dehydration. Asymmetry of head shape may indicate plagiocephaly or craniosynostosis. Changes from child's growth trajectory may indicate hydrocephalus (if increasing) or malnutrition and decelerating brain growth (if decreasing). Head circumference less than the fifth percentile indicates microcephaly.
Eyes	Asymmetry of eye movements, ptosis, or inability to follow an object through the cardinal fields may indicate cranial nerve abnormality. Asymmetry of pupillary response may indicate increased ICP, an intracranial mass, or brain stem herniation. Vertical nystagmus indicates brain stem dysfunction.
Ears	Failure to respond to voice or sounds may indicate cranial nerve impairment or conductive hearing impairment. Nausea, ataxia, and vertigo suggest vestibular pathology.
Face, nose, and oral cavity	Absent or asymmetric gag reflex, stridor, hoarseness, or dysphonia suggests cranial nerve abnormality. Asymmetry of facial expression suggests cranial nerve abnormality. Fasciculations of the tongue suggests neuromuscular disease.
Musculoskeletal	Spasticity with increased deep tendon reflexes suggests upper motor neuron disease. Flaccidity with decreased deep tendon reflexes suggests lower motor neuron disease, peripheral neuropathy, or myopathy. Hypertrophy of the calf muscles and positive Gowers' sign suggests a muscular dystrophy. Generalized hypotonia with decreased deep tendon reflexes suggests neuromuscular disease.
Neurologic	<i>Consciousness:</i> Irritability, restlessness, and inability to be consoled by the parent are early signs of increased ICP. Lethargy and diminished or no response are late signs of increased ICP, or may be the effect of drugs. <i>Mentation:</i> Impulsivity, short attention span, and distractibility may indicate attention deficit hyperactivity disorder or other behavior disorder. Impaired verbal and nonverbal communication, short- and long-term memory, and inability to perform age-appropriate activities of daily living may indicate cognitive impairment. <i>Motor skills:</i> Inability to perform rapid alternating hand movements or finger-to-nose movement, ataxia, or positive Romberg sign may indicate cerebellar dysfunction. <i>Reflexes:</i> Absence, asymmetry, or persistence of developmental reflexes may indicate cerebral abnormalities.

Immediately report **decorticate** and **decerebrate posturing**, which are characteristic body positions that indicate brain dysfunction (Fig. 21–2).

The Acute Neurologic Check

QUESTION: What is Joey's initial score on the modified pediatric Glasgow Coma Scale (GCS)? What is his score after 30 minutes in the emergency department? What are the implications of these scores?

Acute neurologic checks are performed to monitor at-risk patients closely, because subtle changes in neurologic function may precede rapid deterioration. Perform the acute examination repeatedly and frequently (Chart 21–1) and document each examination. Compare sequential assessments with the child's baseline state and note acute changes as well as trends to determine deterioration or improvement and document. Vital signs, which are sensitive to changes in neurologic function, require prompt intervention to avoid potential life-threatening situations. For example, ICP initially slows heart rate and elevates

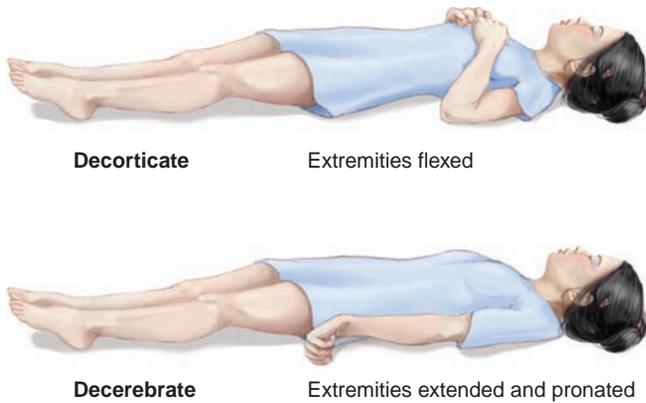

FIGURE 21-2. Decorticate and decerebrate posturing.

blood pressure. Base the frequency of assessments on the child's acuity level, the type of injury, illness, or surgery, and nursing judgment.

In addition to acute neurologic checks to evaluate the child with a depressed level of consciousness, a modified pediatric GCS can be used (Table 21-1). The GCS uses eye opening, motor and verbal response to quantify level of consciousness, allowing objective comparisons over time.

ANSWER: Using the modified pediatric coma scale, Joey's initial score is a 7 out of 15 possible points. He will open his eyes to painful stimuli (2 points), he withdraws from painful stimuli (4 points), and he is making no verbal responses (1 point). After 30 minutes, Joey's coma score has improved to 9 points. He is opening his eyes to verbal command (3 points), withdraws from painful stimuli (4 points), and is making sounds (2 points). The nurse will continue to assess Joey to determine whether there are changes in his assessment. If Joey's score decreases, the medical intervention will become more aggressive. If his score continues to improve, the response will be more conservative.

The Comprehensive Neurologic Assessment

The comprehensive neurologic assessment, used in nonacute situations or after the child's status has been stabilized, is described in Chapter 8. This examination includes a health history and evaluation of mental status, behavior, achievement of developmental milestones, motor and sensory functions, infant reflexes (see Table 8-10),

CHART 21-1 ACUTE NEUROLOGIC CHECK: ASSESSMENT PARAMETERS

Vital Signs

- Blood pressure
- Pulse
- Respiratory pattern

Level of Consciousness

- Stimulus needed to achieve a response (voice, light touch, deep pain?)
- Quality of response (arousal with ability to answer questions appropriately, arousal with momentary eye opening and no meaningful verbalizations, no response?)
- Duration of response (e.g., awake and conversant for 15–20 minutes after arousal, awake and able to maintain alertness for only 1–2 minutes?)

Verbal Responses

- Spontaneous?
- Appropriate?

Pupil Size and Reactivity

- Observe first via indirect light, then via bright-light stimulus; pupils should constrict promptly and briskly
- Record description of pupillary response: nonreactive, sluggish, absent, or unequal (anisocoria)

NOTE: Extremely small pupils may be a side effect of narcotic medications used during anesthesia or used postoperatively for pain control.

Eye Movements

- Assess eye movements as indicated in Table 8-11
- If child comatose, assess the **oculocephalic reflex** by moving the child's head left to right or up and down; when the reflex is present, the eyes look left when the head is moved right, and vice versa; absence indicates brain stem injury

Motor Function

- Note movement of all extremities and whether movement is
 - Symmetric
 - Spontaneous
 - Elicited only by stimulus (note type of stimuli required and the response elicited)
- Note abnormal motor responses to noxious (painful) stimulation: decorticate and decerebrate posturing
- Assess tone by feeling the resistance of the child's extremities to passive movement
- Assess strength by testing the child's ability to move against resistance
- Describe muscle tone and strength as
 - Flaccid (hypotonic)
 - Normal
 - Spastic (hypertonic)
 - Clonus: hypertonic response indicating motor pathway abnormalities; ankle clonus seen as repetitive movements elicited by quick flexion of the foot

TABLE 21-1
Pediatric Coma Scale*

Assessment component	Score	>1 Year	<1 Year
Eyes opening	4	Spontaneously	Spontaneously
	3	To verbal command	To shout
	2	To pain	To pain
	1	No response	No response
Best motor response	6	Obeys	Localizes pain
	5	Localizes pain	Flexion withdrawal
	4	Flexion withdrawal (decorticate rigidity)	Flexion abnormal (decorticate rigidity)
	2	Extension (decerebrate rigidity)	Extension (decerebrate rigidity)
	1	No response	No response
Best verbal response		>5 Years	2-5 Years
	5	Oriented and converses	Appropriate word and phrases
	4	Disoriented and talks	Inappropriate words
	3	Inappropriate words	Cries and/or screams
	2	Incomprehensible sounds	Grunts
	1	No response	No response
Total	3-15		

*Modification of GCS.

cranial nerve function (see Table 8-11), and deep tendon reflexes (see Table 8-12).

Diagnostic Criteria for Evaluating Neurologic Status

 **QUESTION:** Which of the following diagnostic criteria will be most effective for Joey? How can the nurses support Joey and his family during the diagnostic tests?

Numerous diagnostic studies are available to help healthcare practitioners diagnose neurologic dysfunction. Tests and Procedures 21-1 describes various procedures, invasive and noninvasive, for evaluating neurologic status, including specific preparations for each test. The nurse's role in helping children and their families who are undergoing these tests includes teaching and preprocedure preparation.

For children, any diagnostic procedure can be frightening. When preparing the child, consider the child's developmental level, cognitive ability, and physical status, including level of consciousness and pain threshold. In emergency situations, there may be little time to provide

teaching; therefore, offer the child comfort measures during the study and support the family until the child is stabilized. Minimize painful interventions, which may require premedicating the child (if allowed) to reduce anxiety.

Many nonpainful diagnostic procedures may be considered uncomfortable to the child because he or she must remain still or be awkwardly positioned. Use measures to help the child relax during procedures such as computed tomography (CT) or magnetic resonance imaging (MRI). Effective interventions include use of guided imagery, music therapy, and audiotapes to tell stories to the child during the procedure. Such methods help to minimize the use of sedatives to assist the child in remaining calm (Stouffer, Shirk, & Polomano, 2007; Train et al., 2006).

caREminder

In some cases, hair ornaments (e.g., beads) may cause an artifact on a CT scan or MR image. Inform the family about the specific requirements of the radiology department for their child's diagnostic tests. Treat children with head lice or tinea capitis before they undergo electroencephalogram (EEG).

Tests and Procedures 21–1 Evaluating Neurologic Status

Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
Lumbar puncture	A hollow needle with a stylet is introduced into the lumbar subarachnoid space of spinal canal to withdraw CSF.	<p>Diagnostic: Measures CSF pressure, collects CSF sample for laboratory tests for blood or microorganisms, contrast dye injected for radiographic studies, and evaluates CSF flow dynamics.</p> <p>Therapeutic: Injection site for spinal anesthesia or intrathecal medications. Presence of blood may be the result of trauma during needle insertion or may signal CNS hemorrhage.</p>	<p>Assist as necessary with positioning, securing, and calming child (see thePoint for Lumbar Puncture Procedure: Procedures/Interventions).</p> <p>Encourage fluids before and after lumbar puncture.</p> <p>Have child empty bladder before lumbar puncture, because child must remain supine for 4 to 6 hours after procedure.</p> <p>Premedicate for pain, and monitor for signs and symptoms of headache related to decreased amount of CSF.</p> <p>Maintain strict asepsis.</p> <p>Be aware test is contraindicated in patients with substantially increased ICP because brain stem may herniate downward, causing tissue compression, which may lead to death.</p>
Plain Radiographs	Detects of structural abnormalities. Common views are posteroanterior, lateral, Towne's (semiaxial, half axial), and any portion of spinal column.	Identifies the presence of fractures, widened skull sutures, calcifications, bone erosion, or skeletal anomalies.	<p>Remind child to be still during procedure.</p> <p>Ensure that support person wears protective apron.</p>
Ultrasound (sometimes called an <i>echoencephalogram</i>)	Pulsed ultrasonic beam (Doppler) is used to locate midline brain structures. Probe is placed at a vertical angle, reflecting sound waves off structures. Images are created on a screen and produce measurable pictures.	<p>Diagnoses intracranial abnormalities such as mass lesions and enlarged ventricles.</p> <p>Measures two tables of the skull and the third ventricle.</p> <p>May be used in prenatal testing for fetal anomalies such as spina bifida.</p>	<p>Be aware child must have open fontanel and remain still for the study.</p> <p>Teach child and family that ultrasound is a painless procedure and usually takes 15 minutes.</p>
Computed tomography (CT)	Views the brain in three dimensions. Radiographic beam scans cranium in successive layers (cuts), and computer digitizes image. Differentiates density of bone (lighter) and air (darker). Test becomes invasive if radioisotope dye is injected to enhance views of blood vessels, vascular lesions, and localized changes in blood–brain barrier.	Used for effective visualization of tumors, ventricles, brain tissue, CSF, hematomas, and cysts.	<p>Inform child that noncontrast study is painless. If CT is enhanced, prepare child for intravenous (IV) access.</p> <p>Anticipate sedation; motion destroys clarity of scan.</p> <p>Tell child test takes about 20 to 30 minutes.</p>
Magnetic resonance imaging (MRI)	Creates images without radiation using radiofrequency emissions that are converted to computer images. Child is	Provides sharp anatomic detail and information about the chemistry of living tissue. Useful in tumor identifica-	<p>Be aware that contrast MRI requires IV access.</p> <p>Anticipate sedation if child is restless or dislikes confined</p>

Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
	<p>supine and placed in a cylindrical opening that encases a strong magnet. MRI machines make loud humming and intermittent tapping noises. MRI produces images that differentiate between gray and white matter.</p>	<p>tion. T1-weighted images may be done to determine hydrogen–tissue density. T2-weighted images detect changes in tissue biochemistry, indicating early disease.</p>	<p>spaces. Avoidance of motion is critical. Most children younger than 6 years of age require sedation. Remove all metal/magnetic items. Surgical implants such as pacemakers, bone pins, or cerebral clips are contraindications. Noncontrast study is painless. Suggest ear plugs or headphones to dampen noise. If age appropriate, allow child to see MRI machine before study. Depending on imager, tell child that study takes 45 to 60 minutes.</p>
<p>Positron emission tomographic (PET) scan</p>	<p>Online cyclotron creates positron-emitting radionuclides. Patient is injected with or inhales radioactive tracer, which crosses the blood–brain barrier. The positron reacts to electrons, creating gamma rays. The biochemical and physiologic function of living tissue is studied as gamma rays are measured and coded by a computer.</p>	<p>PET scans can measure cellular processes, cerebral metabolism, CBF, membrane transport, synthesis, and receptor binding. They identify specific areas of the brain that are functioning or malfunctioning.</p>	<p>Obtain consent because of the nature of radioactive tracer substance. Anticipate the need for sedation of child to remain still. Be aware that PET scans are clearer than conventional radionuclide scans.</p>
<p>Myelography</p>	<p>Images produced via radiograph, fluoroscopy, or CT. Water-based contrast media more commonly used than oil-based media. When in the CSF, the media enters nerve tissue by upward diffusion. This eliminates the need to reposition the patient. The rate of uptake is reduced by maintaining the child in a sitting position. If water-based media enter the cranial vault, seizures are likely to occur. There is no need to remove contrast fluid when the myelogram is completed because it is absorbed and excreted in the urine. Metrizamide can cause extreme diuresis.</p>	<p>Visualizes any or all of the spinal axis for diagnosis of tumor, congenital lesions, or bony changes. Significant risk factors include allergic reaction to iodine, headache, aseptic meningitis/infection, and seizures.</p>	<p>Obtain history of iodine allergy. Child must be NPO 4 hours before myelogram. Obtain frequent neurologic assessment and vital signs. Maintain seizure precautions. Minimize activity. Strictly monitor intake and output. Water-based medium: Discontinue all neuroleptic drugs, monoamine oxidase inhibitors, and psychostimulants 48 hours before myelogram. After study: Avoid administration of phenothiazines, maintain a quiet environment, and keep child supine with head of bed elevated 30 to 45 degrees for 12 to 24 hours. Oil-based medium: Premedicate as ordered, such as with meperidine (Demerol) or atropine. After study, keep child flat in bed for 6 to 24 hours per physician’s order.</p>

(Continued)

Tests and Procedures 21-1 Evaluating Neurologic Status (Continued)

Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
Electroencephalogram (EEG)	<p>Graphic recording of electrical activity of the brain via 17 to 21 electrodes glued to the scalp. Differences in electrical activity between electrodes create brain wave patterns, which are classified based on the number of cycles per second (cps). Four frequency bands are identified: (1) delta (1–4 cps), (2), theta (4–8 cps), (3) alpha (8–13 cps), and (4) beta (13–35 cps).</p> <p>Brain waves are usually recorded at rest, after hyperventilation, during photic (flashing light) stimulation, and during sleep.</p>	<p>Detects and locates abnormal electrical discharges produced in the brain. It is used to detect seizure activity; monitor patients with head injury, stroke, metabolic coma, and some psychological illness; and to assist with brain death determination. EEG may also be used during intracranial surgery for intractable seizures. EEG strips “map” electrical activity on the surface and guide the extent of cortical resection. Abnormal findings are epileptiform activity, slowing of normal waves, abnormal amplitude, or disorders of age-specific patterns.</p>	<p>Withhold medications or foods known to alter brain wave activity, per physician’s order, such as stimulants, depressants, antiepileptics, tranquilizers, chocolate, colas, and tea.</p> <p>Ensure that child’s hair is clean, without oils, sprays, or lotion.</p> <p>Alleviate common fears such as that the EEG will cause electrical shock and reads minds.</p> <p>Inform child that EEGs are painless procedures and usually take 45 to 60 minutes.</p> <p>After the EEG, clean hair of glue and gel, and resume medication.</p>
Evoked potential studies (EVPs)	<p>Small electrodes attached to a wire and placed over the skull and a visual or auditory stimulus is given (visual auditory). Electrodes are placed on either arm or leg and stimulus is given (somatosensory).</p>	<p><i>Visual EVP:</i> Determines that visual pathway is intact. In infants, light-emitting diode goggles are used.</p> <p><i>Auditory EVP:</i> Determines that auditory pathway is intact. Earphones are used.</p> <p><i>Somatosensory EVP:</i> Determines both spinal cord and critical appreciation of electrical stimulus. These can be obtained in the upper extremities by stimulation of mid-arm nerve and in lower extremities by stimulation of popliteal nerve.</p>	<p>Keep in mind that complete cooperation and immobility are required.</p> <p>In young or uncooperative children, maintain NPO status for 4 hours, and anticipate the need for sedation.</p>
Electromyography (EMG) and nerve conduction velocity (NCV)	<p>Small Teflon-coated needles attached to a wire are inserted into muscle, and the brief electrical discharge is recorded. Patient contracts muscle, causing electrical activity, and motor unit action potential is studied. Electrodes are placed over a peripheral nerve in two locations, reclining and sending. An electrical impulse is sent from sending to receiving with the speed and amplitude of the response measured.</p>	<p>Analyzes electrical events associated with skeletal muscle fiber contraction. EMG and NCV are usually ordered together to diagnose and differentiate between peripheral nerve and muscle disorders.</p>	<p>Be aware that NCV can slow if child is hypothermic.</p>

ANSWER: CT is ordered to determine whether any subdural bleeding is present. The CT scan will produce an image that shows both bone and soft tissue. To obtain the best image possible, Joey must keep still for the procedure. It is not possible to predict when he will regain consciousness, and sedation would mask neurologic changes, so use of immobilizers is preferable. Supporting Joey's physical status includes positioning Joey so that his head is in alignment and, if possible, slightly elevated, which may prevent an increase in ICP during the procedure. Supporting Joey's family includes assuring them that Joey is not uncomfortable and keeping them informed throughout the procedure.

TREATMENT MODALITIES

QUESTION: Considering Joey's improving neurologic assessment, which of the following treatment modalities do you think is most applicable?

Management of the child with a neurologic disorder varies based on the condition. General measures, medication, surgery, and supportive care are discussed in this section; more tailored management is discussed in the section on specific conditions.

Pharmacotherapy

Pharmacologic agents are used to treat a variety of neurologic conditions. Antibiotics or antivirals are used to treat infectious disease processes. Broad-spectrum antibiotic or antiviral therapy is typically initiated until CSF, blood, and wound cultures indicate that no infection exists or that the type of agent used must be changed because the child has a sensitivity to the current agent. Start antibiotic or antiviral therapy after CSF, blood, and wound samples are obtained. Acetaminophen is given concurrently to reduce fever associated with the infectious process.

Antiepileptics are used to treat and prevent seizures. Glucocorticoids and diuretics are used to reduce cerebral edema. Paralytic agents may be used if the child is receiving mechanical ventilation to control restlessness and agitation in the child at risk for increased ICP. Pain medications may be necessary, as may sedatives to relieve anxiety and agitation. Sedatives should be administered in an intensive care setting where close monitoring of neurologic status is available.

Cranial Surgery

Treating many neurosurgical injuries or problems requires direct access to the brain through the bony structures of the skull. The following discussion addresses the general care given to children having cranial surgery involving craniotomy and craniectomy.

A **craniotomy** refers to a “flap” opening of the skull in which the bone is removed and then replaced at the completion of surgery. If part of the cranium (skull) is excised and not replaced, the procedure is termed a **craniectomy**. When large portions of bone are not replaced, a **cranioplasty** may be done to repair the cranial defect and to protect the brain by placing a molded piece of synthetic material, usually Silastic, or autologous or donor bone, over the opening.

Anatomically, the brain can be divided into two regions for surgical access. The tentorium cerebelli is a double fold of the dura mater that forms a separation between the **supratentorial** region (the upper brain structure, or the cerebrum) and the **infratentorial** region (the lower area of the cerebellum and brain stem, which includes the midbrain, pons, and medulla). Most surgical procedures in the supratentorial region of the brain are indicated for

- Resection or biopsy of tumors or cysts
- Resection of epileptogenic cortex (seizure foci)
- Placement of ventricular catheters to drain CSF
- Draining collected blood after head injury
- Placement of ICP monitors

Surgical procedures in the infratentorial region are usually indicated for tumor or cyst resection. Care of the child with a tumor is discussed in Chapter 22.

Preoperative Care

Preparing children and families for intracranial surgery is not always possible. If the child is admitted following trauma or in another emergency situation, little time is available for teaching. In these cases, the physician's priority is to obtain informed consent from the parents by discussing the purpose of the surgery, the possibility of alternative treatment or lack of treatment, the potential risks, and the expected outcomes. Ideally, the nurse should be present during the physician's discussion with the family, to reinforce and clarify the information presented.

If the admission is planned, begin education before surgery. Assess the family's ability to comprehend the diagnosis and planned treatment. Parents are often overwhelmed with fear and anxiety; therefore, incorporate the family's coping mechanisms into the teaching plan and review information as needed. Emotional support is essential from the first contact with the family and throughout the child's recovery period. Provide education and emotional support for the child according to the child's developmental stage and ability to understand. Specific topics important to discuss with the child and family prior to a neurosurgical procedure are outlined in Teaching Intervention Plan (TIP) 21-1. Because neurosurgical procedures often involve the head and face, some of the child's and parent's preoperative anxiety and fears may be related to shaving the hair and worrying about visible scars (Tradition or Science 21-1).

Neurologic surgery that involves the frontal or temporal bones often results in marked periorbital edema for several days after surgery. Prepare the family for this

TIP 2 1–1 A Teaching Intervention for the Child Undergoing Cranial Surgery

Nursing diagnoses and outcomes

Risk for infection related to presence of surgical incision

Outcome:

- Child's incision site remains free from infection.

Disturbed body image related to physical appearance after cranial surgery

Outcomes:

- Child and family will discuss feelings about altered appearance.
- Child will express positive feelings about self.
- Child and family will implement positive coping skills to deal with altered appearance.

Deficient knowledge: Child's condition, treatment plan, and home care requirements

Outcomes:

- Child and family will express interest in learning about child's condition.
- Child and family will demonstrate healthcare behaviors needed to manage child's care at home.
- Child and family will express understanding of postoperative plan, routines, and expectations.

Teach child/family

Postoperative Plan

- Expected length of surgery and recovery
- ICU routines and policies
- Necessity of assessments and their frequency
- Necessity for and types of monitors, access lines, catheters, and so forth
- Necessity for and types of tests and medications

- Progression of diet and activity orders
- Plan for pain management
- Expectations for family involvement in postoperative care

Postoperative Appearance

- Complete or partial head shave possible
- Location of incision and type of dressing
- Potential for facial edema
- Potential for postoperative motor/sensory deficits

Community Care Postoperatively

- Care of incision and dressings (staple or stitch removal)
- Signs and symptoms of potential short- and long-term complications
- Plan for medical/surgical follow-up: clinic appointments, diagnostic tests
- Medications
- Diet and feeding
- Plan for rehabilitation if needed (physical, occupational, speech therapies)
- Anticipatory guidance about potential neurologic deficits, safety measures, and adaptations
- Referrals to appropriate community agencies if indicated (home healthcare, social services, public health)
- Plan for resumption of usual activities, return to school

Contact Healthcare Provider if:

- Redness or drainage is noted from surgical incision site
- Child has a fever
- Child displays changes in neurologic status as demonstrated by changes in level of consciousness, lethargy, irritability, vomiting, and fontanel fullness

postoperative event. Often, the child and the family understand the reasons for the postoperative effects of surgery, and they simply need the nurse's presence for support, reassurance, and as a sounding board to express their feelings or to begin an anticipatory grief process.

An accurate, well-documented preoperative neurologic baseline assessment is essential in monitoring the child's postoperative functioning for potential complications. Carefully document problems with vision, hearing, communication, and any other preexisting neurologic deficits or developmental delays.

If the child has seizures preoperatively, document the description of the events in detail and implement seizure

precautions, such as padding the side rails of the bed to prevent injuries. If the child has been taking antiepileptic medications, they are usually given before surgery, so that serum levels remain constant. Medications can be given with a sip of water or in parenteral forms while the child is NPO.

Postoperative Care

The type and location of surgery will affect the postoperative nursing assessments. Surgery in the supratentorial area is most likely to be associated with postoperative seizures, focal motor deficits, or confusion. Infratentorial

TRADITION OR SCIENCE 21–1

Is hair removal necessary for cranial surgery?

EVIDENCE-BASED PRACTICE

Studies demonstrate that cranial surgery without hair removal is safe and not associated with increased risk of wound infection (Gil et al., 2003; Miller et al., 2001; Tang et al., 2001). Not removing the hair also may prevent additional psychological stress for the child and family.

surgery may involve entry to the area from a midline incision at the back of the skull. This procedure carries a risk of respiratory compromise, because midline entry into the cranial vault is close to the medulla oblongata, which contains the major respiratory center of the brain. The child may remain intubated for a longer time, especially if surgery was done to remove a tumor of the spinal cord, cerebellum, or brain stem.

WORLDVIEW: If hair is shaved, do not discard it during the surgery. Return it to the postoperative unit where the child is managed, in case the family requests it. In some cultures, loss of the hair is considered to be a serious loss to the child's spiritual well-being.

The nursing role after cranial surgery involves frequent acute neurologic monitoring and assessment of vital signs, intake and output, dressing, drainage, and pain to monitor the child for any potential complications. Complications may include increased ICP, seizure, hemorrhage, leakage of CSF, local tissue hypoxia, hyperthermia, hydrocephalus, hypovolemic shock, syndrome of inappropriate antidiuretic hormone (SIADH), infection, and respiratory compromise resulting from edema in the respiratory center. In addition, the child is at risk for complications associated with immobility.

As soon as the child is in the postoperative setting, frequently assess vital signs and neurologic status to identify subtle changes and trends. Measure intake, output, and urine specific gravity to monitor for signs that the child is developing SIADH (see Chapter 26). Identify any complications of postoperative immobility including pneumonia, deep vein thrombosis, constipation, and skin breakdown. Do not overlook these possibilities, even during the acute monitoring phase.

Note and report any substantial drainage on the dressing. It is a common practice to gently outline the border of the fluid with a surgical marker, indicating the time and change in amount of drainage. Follow strict infection control measures, because the child with a healing surgical wound is very vulnerable to infection.

Alert! Closely monitor drainage from the dressing, incision, nose, or ears after neurosurgery for any similarity to CSF. If the dura mater tears during surgery, CSF can leak into the ear or nose.

The possibility of CSF drainage is greater when the surgery is done after a traumatic injury in which a skull fracture may have occurred or after infratentorial surgery for a tumor. Collect suspected drainage in a sterile test tube for CSF glucose determination. To minimize sources of infection, do not pack, suction, or disturb these areas until the drainage is identified. Discourage the child from touching the drainage or the dressing and instruct him or her not to blow the nose. Encourage the child to remain quiet.

Implement both pharmacologic and biobehavioral comfort measures to keep the child comfortable during the postoperative period. Carefully titrate analgesics to provide comfort for the child while enabling adequate neurologic assessment.

Nursing Interventions 21–1 summarizes the guidelines for immediate postoperative nursing management of the child after intracranial surgery. A drain may be used for the first 24 hours postoperatively. Sutures or staples are usually removed in 7 to 10 days.

Supportive Care

The child who experiences an alteration in neurologic status is at high risk for experiencing altered responsiveness during the course of his or her condition. **Responsiveness** is the child's ability to interact with the environment. It includes the ability to receive and prioritize sensory stimuli (input); process, analyze, and integrate the input (throughput); and produce a response (output). Responsiveness is expressed by thoughts, verbalizations, movement, behavior, and mood. Responsiveness is affected by developmental age and by the current level of maturity of the nervous system.

Altered responsiveness involves the impairment of input, throughput, or output. For example, input may be altered in a child with congenital blindness or deafness. Throughput may be altered in a child with a perceptual problem, such as a visual motor deficit, or a child who experiences delays in processing time after a severe head injury. Output is altered in a child who experiences paralysis, sensory motor deficits, or speech impairment.

Altered responsiveness may appear as an acute, self-limiting process (e.g., after cranial surgery) or may be a long-term condition (e.g., after a traumatic brain injury). Additional hazards may result if the child is immobilized or at risk of physical injury resulting from sensory and perceptual deficits.

Managing Altered Responsiveness

Nursing care for the child with altered neurologic functioning varies according to the nature of altered responsiveness. In general, goals for nursing care are to continue assessment for alterations in health status, protect the child from additional injury, and assist the family in adapting to the child's needs.

Physical safety is a concern for the child with altered responsiveness. To prevent falls from the bed, keep the side rails up at all times. Use adaptive supports as necessary to prevent falls when the child is out of bed (e.g.,

NURSING INTERVENTIONS 21–1

Assessments and Interventions After Cranial Surgery

System	Assessment	Interdisciplinary Interventions
Neurologic	Level of consciousness Pupillary reaction Corneal reflex Ocular movement Gag reflex Motor function Sensory function Vital signs including ICP Reflexes Monitor for seizures	Monitor frequently. Test cranial nerve function. Note medications that may affect pupillary response. Maintain ICP less than 20 mm Hg. Note widening pulse pressure, bradycardia, and altered respirations (Cushing's triad) and report immediately. Maintain neutral position of head and neck. Elevate head of bed 30 degrees. Palpate infant fontanel. Provide safe environment with side rails up. Minimize activity. Consult neurology and ophthalmology as needed.
Respiratory	Breath sounds Oxygen saturation Cyanosis Respiratory rate Airway patency Blood gases	Turn child every 2 hours to promote postural drainage. Adjust ventilator settings per physician's order. Gently suction secretions. Provide humidified oxygen per physician's order. Encourage deep breathing exercises. Consult respiratory therapy.
Elimination	Urine output, 0.7 mL/kg/hour Indwelling urinary (Foley) catheter intact Constipation Monitor blood urea nitrogen, creatinine, specific gravity	Strictly monitor input and output. Provide catheter care to prevent infection. Give daily stool softener to reduce hard stools or straining (Valsalva maneuver), which increases ICP. Consult nutritionist.
Fluid and electrolytes	Mucous membranes and eyes for dryness	Restrict fluids per prescriber's orders. Provide hydration/medication. Use intravenous pump to avoid fluid bolus. Use artificial tears in eyes. Provide oral care.
Musculoskeletal	Pressure ulcers Flexibility of joints	Provide range-of-motion exercises daily. Provide skin care/sheepskin pad on bed. Consult physical therapy.
Psychosocial	Level of pain Level of fear or anxiety	Administer pain medication. Provide emotional support. Encourage parental participation in care. Explain all interventions before touching child. Anticipate and answer questions. Consult child life specialist.

when the child is positioned in a chair, use safety belts as necessary to maintain the child comfortably in an upright position and ensure support so the child will not slip from the chair to the floor or become entangled in the belt). The mobile child may be prone to falls because of altered

spatial perception, altered motor ability, or altered mental processing, which can lead to impulsive behavior. Protective helmets can be used to protect the mobile child's head from further injury. However, restraints and protective equipment do not replace close monitoring and

supervision. Preventing the hazards of immobility is also important.

ANSWER: Supportive care and careful monitoring are critical for Joey. Be aware of the potential rapidity for change. Should Joey's ICP increase, he could decompensate very quickly. By the same token, if he should regain consciousness, he may be disoriented, confused, and potentially angry, and requires careful monitoring.

Minimizing Disuse Syndrome

Complications from altered responsiveness and immobility can include respiratory complications, musculoskeletal problems, gastrointestinal problems, urinary tract problems, and altered skin integrity. These complications place the child at risk for *disuse syndrome*, a state in which the child is at risk for deterioration of a body system as a result of musculoskeletal inactivity or immobility.

The immobile child also has decreased lung capacity because the inspiratory muscles are not aided by gravitational pull, chest expansion is limited by the weight of the body against one aspect of the chest, and, when the child is in a horizontal position, the abdominal contents push against the diaphragm. Furthermore, stimulus for fully expanding the lungs is minimal when little or no muscular activity occurs. Pooling of secretions within the lungs and exposure to microorganisms may lead to serious respiratory infection.

Although chest physiotherapy for the unresponsive child cannot include voluntary deep breathing and coughing, turning the child from side to side at least every 2 hours helps to expand different areas of the lungs and reduces pooling of secretions in the lungs. Elevate the head of the child's bed periodically, if the child can tolerate it, and position the child in a sitting posture for short periods, if the physician's orders permit. Healthcare personnel in contact with the unresponsive child must wash their hands carefully and avoid persons with active respiratory infections.

Airway management also helps to prevent infection in the child. Gently suction nasal and oral secretions, and maintain good hygiene of oral and nasal mucous membranes, keeping them free of dried secretions; lubricate regularly to prevent breaks in membrane integrity. Oral health maintenance is often complicated by the bite reflex in children with neurologic damage.

caREminder

Never insert your fingers in the child's mouth, and do not insert anything in the child's mouth that could damage the teeth or gums in case the child's jaws close unexpectedly.

Muscles that are not used regularly lose strength, tone, and mass rapidly. Also, contractures may form at unused joints, permanently limiting the child's musculoskeletal functions. Exercise therapy, including passive range-of-

motion exercises (unless contraindicated by volatile ICP), and attention to body alignment when positioning the child can prevent these complications. The heavier the child, the more care is needed in positioning, because the weight of the limbs may strain major joints, muscles, ligaments, and tendons. Place pillows under the arms and between the legs to minimize this stress. Shoulder supports can help to prevent dislocation. Washcloths, small gauze rolls, or hand splints can help keep the fingers in functional alignment. High-top tennis shoes or ankle-foot orthoses can help prevent foot drop.

When the child begins to recover, reinstitute weight bearing as soon as it can be tolerated. Physical therapy regimens include range-of-motion exercises and use of a tilt table, a standing frame, and parallel bars to help gradually restore weight bearing and active range of motion.

Altered oral-motor function, chaliasia of the cardiac sphincter, and delayed gastric emptying put the child with altered consciousness at risk for regurgitation and aspiration of gastric contents. If the child requires enteral feeding, elevate the child's head during feeding to help prevent aspiration of food particles. Give infants who retain a sucking reflex a pacifier during enteral feedings to help prevent the development of oral-motor defensiveness and to help retain the suck reflex for future oral feeding.

caREminder

Do not attempt oral feedings until oral-motor function is evaluated, and gag and swallow reflexes are known to be intact.

Nutritional monitoring, including careful calculation of caloric needs, is important to prevent muscle wasting. Because metabolism decreases with inactivity, also take care not to overfeed the child.

If possible, hold infants and small children for feedings, to preserve the social contact and caring interactions they have previously associated with feeding. Holding, rocking, and other caring interactions with the family and with the nursing staff are equally important for older children. If the child's condition contraindicates being held, techniques such as massage (tactile stimulus), singing to the child (auditory stimulus), and frequent contact that keeps the caregiver's face in the child's line of vision may be appropriate substitutions.

Assess bowel function by auscultating bowel sounds in all abdominal quadrants and by maintaining a record of the child's bowel movements. Diarrhea may accompany a change in the feeding regimen and may be a sign that the feeding is not being tolerated. Adjustments may be required to enteral volume, rate, or formulation.

Constipation may be a sign of inadequate fluid intake or sluggish peristalsis related to the child's immobility. Lack of bowel movements, passage of hard balls of stool, or abdominal palpation for firm, full intestines can help to confirm suspicions that bowel evacuation is inadequate. Assess and intervene promptly to manage constipation and avoid impaction.

Bladder tone and bladder emptying may also be affected by altered motor and sensory function. Neurogenic bladder is a common sequela of spinal cord injury (SCI) and myelodysplasia. With neurogenic bladder, clean intermittent catheterization may be required to provide urinary continence, to prevent overdistention of the bladder, and to protect the upper urinary tract from damage (see Chapter 19).

Immobility is a major assault to the integumentary system. Constant rubbing on bed linens, body pressure against wrinkled garments, pressure of body weight on delicate tissues, reduced blood flow in pressure areas, mechanical irritation from tubing, and chemical irritation from wet and soiled diapers all contribute to the risk for altered skin integrity. Use pressure-relieving mattresses, keep linen wrinkles to a minimum, and ensure that no small objects (e.g., plastic sheaths from disposable needles) are left in the child's bed. Protect opposing skin surfaces and pressure points with pillows and foam supports. Inspect the skin thoroughly during regular care for any areas of redness. Reposition nonred, bony prominences and massage them to increase circulation, but do not further irritate reddened areas of the child's skin with massage.

Promoting Health Maintenance

For some children, altered neurologic functioning may be a lifelong condition. Involving the family members who will help care for the child at home as early as possible in discharge planning and teaching helps to ensure that they develop the skills needed to care for the child. Include the child in planning, teaching, and self-care to the extent possible.

Explain how the illness or disorder affects the child, including the anatomy and physiology of the neurologic processes involved. Give the family written material on symptoms that indicate the need for medical intervention, so they know when to call the healthcare provider. Teach care techniques by demonstrating and having the parents, and child as appropriate, perform the technique. Such techniques may involve feeding the child through a nasogastric tube, tracheostomy care, eye care, oral care, positioning, use of various equipment, passive range-of-motion exercises, skin care, and safety precautions (see Chapter 11). Provide information about medications, including purpose, administration, and side effects. Emphasize the need for medical follow-up, including laboratory studies to monitor therapeutic drug levels.

Family members need time to accept alterations in the child's level of responsiveness and may need help in modifying their expectations. Help them recognize the child's capabilities and strengths by pointing out those skills and abilities that have been preserved; point out events that indicate progress. Some families find it helpful to keep a journal or video log; looking back helps them see the progress that their child is making. At the same time, the family may need help accepting the child's new limitations. For example, the family may need help distinguishing reflex movements from voluntary movements, so that movements such as posturing are not mistaken for purposeful responses.

The incidence of behavioral problems in children with developmental delay and cognitive disabilities is higher than in typically developing children (Fox et al., 2007). Provide information about techniques for behavior management and discipline, and about community resources for ongoing support after hospital discharge. Some families may benefit from professional counseling.

The family also needs information about the availability of physical and financial support for the child's care after discharge. In most states, supplemental insurance plans are in place to assist in meeting the healthcare expenses of caring for a child with a disability. Community agencies are available to assist families in identifying financial resources. Arrange for referral to a social worker.

Caring for a child with altered neurologic functioning has a tremendous effect on the entire family. Counsel parents about the physical and emotional hazards associated with full-time care of the child with a disability. Encourage them to take advantage of respite care offered by friends, relatives, and community resources. As the family adapts to the child's condition, roles and responsibilities may shift. Parents gain added responsibilities that place increased demands and restrictions on the entire family. Even though parents may adapt to their child's disability, they may never fully accept it, and sorrow never completely subsides. Chronic sorrow often develops and periodically waxes and wanes. Times of transition, or life changes, are especially difficult (Coffey, 2006). Sensitivity, presence, availability, communication skills, and knowledge help the nurse provide support to the family.

Family members often have questions about the child's prognosis and whether to seek additional opinions from other healthcare professionals. Such discussions call for sensitivity on the part of the nurse. It takes time for the family to understand and to accept the reality of a neurologic deficit, whether temporary or permanent. The nurse can help the family obtain needed information and ensure that their questions are adequately addressed. In many cases, arranging a meeting for the family with the multidisciplinary team will address parent's concerns while all the care providers are present. Often, the presence of a social worker who has been involved with the family is very helpful.

NURSING PLAN OF CARE FOR THE CHILD WITH ALTERED NEUROLOGIC STATUS

QUESTION: Which of the nursing diagnoses, interventions, and outcomes in Nursing Plan of Care 21-1 are most pertinent to Joey?

Conditions affecting the child's neurologic status are of special concern to the healthcare team, because such conditions create the potential for long-term sequelae that can affect the child's cognitive and motor functioning. In addition, the child's social and personal development

may become impaired. Therefore, the goals of health-care management are to intervene immediately to prevent progression of neurologic insult while, if possible, simultaneously treating the underlying condition. During these early critical stages of the child's care, monitor and maintain physiologic functioning of all body systems, because the brain and its functions are vitally linked to other systemic body functions. Support the family as the child is stabilized, a diagnosis is reached, and treatment interventions are initiated. As the child responds to the interdisciplinary interventions, the goals of the healthcare team become directed toward optimizing the child's outcomes through rehabilitation activities. Nurses in the home, the school, and the rehabilitation center help the family evaluate the child's capabilities and help the child reach his or her highest level of growth and development. Nursing Plan of Care 21-1 summarizes the nursing diagnoses that can be applied to children experiencing a neurologic disorder. These diagnoses reflect the broad scope of problems that confront the child and family as they deal with both the emergent and long-term issues surrounding the child's condition.

ANSWER: A potential nursing diagnosis for Joey would be ineffective tissue perfusion related to injury. Except for the intervention regarding assessing fontanels, all the interventions are appropriate and all the expected outcomes apply to Joey.

ALTERATIONS IN NEUROLOGIC STATUS

Alterations in neurologic status may stem from adverse outcomes of neurologic conditions, congenital disorders, craniofacial abnormalities, infectious and parainfectious processes, neuromuscular disorders, neurocutaneous syndromes, or neurologic trauma. Neurologic events that can affect neurologic function include increased ICP, seizures, epilepsy, breath-holding spells, and headaches.

QUESTION: What adverse outcomes could result from a head injury like Joey sustained?

Increased Intracranial Pressure (ICP)

ICP is determined by the space occupied by the three intracranial components: brain, blood, and CSF. The incidence of increased ICP cannot be determined, because its etiologies vary widely.

Pathophysiology

ICP is governed by CBF and cerebral perfusion pressure (CPP). If initial compensatory mechanisms and autoregulation

cannot maintain optimal ICP, brain tissue can herniate into other brain structures.

For ICP to remain constant if the volume of one of the components increases, the volume of the other components must decrease. These components—brain, blood, and CSF—can alter their volume to maintain normal ICP, a mechanism known as **compensation**. When an increase in volume occurs, the brain begins a complex series of activities aimed at decreasing the overall ICP and maximizing perfusion of sensitive brain tissue. These compensatory mechanisms enable a normal volume–pressure relationship to be maintained for as long as possible. If these mechanisms become exhausted, an imbalance occurs, volume increases, and increased ICP results. This explanation of cerebral volume dynamics is known as the **Monro-Kellie doctrine**.

Cerebral Blood Flow (CBF)

CBF provides oxygen to the brain and transports metabolic components to and from its cells. Carbon dioxide causes vasodilation in cerebral blood vessels, which increases blood volume and, therefore, increases ICP. Oxygen content can also affect ICP, although to a much lesser degree. Profound hypoxia ($\text{PaO}_2 < 50$ mm Hg) can lead to cerebral vasodilation as the body tries to send more oxygen to the brain tissue. For these reasons, airway management for the child at risk for, or experiencing, increased ICP is paramount.

Cerebral Perfusion Pressure (CPP)

CPP, a major factor affecting CBF, is the pressure gradient that determines blood flow and oxygenation to the brain tissue. It is calculated by subtracting the ICP value (determined by using an ICP monitor) from the mean arterial blood pressure. CPP is affected by changes in arterial blood pressure as well as by changes in ICP. A normal CPP is approximately 80 mm Hg, with values more than 60 mm Hg considered acceptable in children with acutely increased ICP secondary to trauma.

Mechanisms That Increase Intracranial Pressure

Several mechanisms are known to increase ICP, including increased brain mass, increased cerebral blood volume, increased CSF volume, and obstructed CSF flow. Increased brain mass can result from brain tissue edema secondary to cell anoxia after head injury, brain surgery, infections, and inflammatory diseases such as encephalitis. Lesions within the brain also increase brain mass.

Vasodilation, which occurs for numerous reasons, including oxygen deprivation and increased systemic blood pressure, increases cerebral blood volume. Cerebral blood volume is also increased by decreased venous outflow and increased intrathoracic pressure.

Increased CSF volume can result from increased production of CSF by the choroid plexus, obstructed flow of

NURSING PLAN OF CARE 21–1: CHILD WITH ALTERED NEUROLOGIC STATUS

Nursing Diagnosis: Ineffective breathing pattern related to effects of seizures, neurotrauma, and CNS damage

Interventions/Rationale

- Assess child's respiratory status.
Provides baseline data from which to evaluate changes in the child's status.
- Maintain a patent airway; use airway adjuncts as needed.
Promotes oxygenation and helps avoid increases in carbon dioxide, which can cause vasodilation and increase intracranial blood volume. Anoxic events can increase brain size; both anoxic events and increased brain size can decrease cerebral perfusion.
- Monitor respiratory rate, rhythm, and depth; auscultate breath sounds.
As ICP increases, vital centers located in the brain stem are affected, causing abnormal respiratory patterns. Monitoring status allows for early detection of problems and implementing interventions.
- Assess color, amount, and consistency of pulmonary secretions.
A change in consciousness or responsiveness may impair the child's ability to clear pulmonary secretions. Accumulated secretions provide a good medium for bacterial growth and may result in increased PCO₂, which may cause increased ICP.
- Assess circulatory status (e.g., pulse, blood pressure, and skin color).
Assists in detecting hypoxia.
- Monitor arterial blood gas values.
Enables early detection of acid–base abnormalities and decreases in oxygen saturation, allowing for early intervention.
- Administer oxygen as ordered; assess effectiveness.
A change in consciousness or responsiveness may impair the child's ability to clear pulmonary secretions or aerate adequately, causing hypoxemia and acid–base disturbances.
- Encourage deep breathing and limit coughing.
Deep breathing aids in aeration and preventing stasis. Coughing increases ICP.

Expected Outcomes

- Child's respiratory rate will remain within age-appropriate parameters.
- Child will exhibit arterial blood gases within normal range.
- Child will maintain respirations without ventilatory support.

Nursing Diagnosis: Risk for ineffective cerebral tissue perfusion related to effects of brain injury or seizure activity

Interventions/Rationale

- Assess neurovascular status and vital signs every 1 to 2 hours as needed (see Nursing Interventions 20-1).
If deviations from normal are noted promptly, interventions can be implemented in a timely manner. An alteration in either arterial pressure or ICP alters cerebral perfusion.
- Assess fontanels in children younger than 2 years of age.
In children younger than 2 years of age, a bulging fontanel may indicate increasing ICP.
- Elevate the head of the bed 30 degrees, and align the head and neck.
Head elevation up to 30 degrees may reduce ICP without affecting cerebral perfusion pressure. Head alignment facilitates venous outflow from the brain, maintaining balance in intracranial volume (i.e., brain tissue, blood, and CSF).
- Describe and record behavior carefully.
Changes in behavior may be some of the earliest signs of alteration in neurovascular status.
- Administer fluids within fluid restrictions to prevent cerebral edema.
Overhydration expands intravascular volume, potentially increasing ICP.

Expected Outcomes

- Child will maintain or improve current level of consciousness.
- Child will exhibit ICP within normal range.
- Risk factors for altered cerebral perfusion and complications will be reduced as much as possible.
- Child will achieve adequate oxygenation and nutrition at the cellular level.

Nursing Diagnosis: Ineffective thermoregulation related to neurologic trauma or illness

Interventions/Rationale

- Assess child's vital signs and monitor routinely.
Provides baseline data from which to evaluate changes in the child's status. Hypothalamic injury or disease can alter the child's ability to thermoregulate. Monitoring enables early detection of deviations from normal, allowing for early intervention.
- Administer antipyretics as ordered.
Hyperthermia increases metabolic rate, stressing homeostasis and increasing insensible water loss, disrupting fluid balance. Antipyretic therapy is a central cooling intervention.

- Implement cooling or warming measures, as indicated.

Physical cooling or warming methods also help the child maintain normothermia in the presence of thermoregulatory dysfunction.

Expected Outcome

- Child's body temperature will be maintained within normal limits.

Nursing Diagnosis: Risk for acute confusion related to effects of neurologic injury or illness

Interventions/Rationale

- Assess child's thought processes and level of orientation, and monitor routinely.

Provides baseline data to evaluate changes in child's status and facilitates early detection of changes.

- Orient child to name, time, place, and surroundings at every contact. Teach family to reorient a conscious child periodically to surroundings.

Neurologic injuries may result in an alteration in consciousness that may be short or long term. Including familiar persons may decrease confusion and anxiety for the child.

- Remain with the child who is not fully conscious and oriented until the child is stable.

Impaired consciousness may place the child at risk for injury to self or others.

Expected Outcomes

- Child will receive treatment for physiologic causes, resulting in restoration of thought processes.
- Child will demonstrate improvement in sensorium via care activities that help to restore thought processes.
- Child will remain safe and free of injury.

Nursing Diagnosis: Risk for infection related to presence of surgical incision, head trauma, or bacteria infecting the neurologic system

Interventions/Rationale

- Assess for signs of infection (e.g., increase in temperature, erythema) and behavior indicating neurologic infection (e.g., irritability, decreased level of consciousness).

Facilitates early detection of infection.

- Implement interventions such as wound care to reduce risk of infection. Maintain a closed drainage system for external venous drainage.

Surgical intervention, the use of external drains, and head trauma result in a break in skin integrity. The use of shunts introduces a foreign object into the head that is a potential source for infection.

- Report any changes in vital signs or behavior (e.g., irritability, decreased level of consciousness) immediately.

Prompt detection of deviations from normal allows timely, intervention.

- Monitor operative sites, shunt sites, and sites of injury for signs of redness and swelling.

Prompt detection of deviations from normal allows timely intervention.

Expected Outcomes

- Child will remain free of infection.
- Child will receive prompt treatment for infectious process, if present.
- Child will demonstrate resolution of infectious process without complications to neurologic integrity.

Nursing Diagnosis: Risk for injury related to effects of sensory and motor deficits

Interventions/Rationale

- Assess the child's level of consciousness to determine changes and to determine ability to participate in self-care activities.

Physical injury may occur during periods of altered consciousness and seizure activity.

- Monitor for seizure activity.

Children with a history of epilepsy are at increased risk for additional seizures. Cerebral edema may alter neuronal functioning, leading to the development of seizures. Metabolic imbalances such as hypoxia, hypoglycemia, and electrolyte imbalances secondary to neurosurgery or neurologic insult can also contribute to the development of seizures.

- Protect from potential injury related to seizures (e.g., keep bed in low position, keep side rails up and padded).

Changes in cognitive functioning and sensorimotor impairments place the child at risk for injury.

Expected Outcomes

- Child and family will identify factors that increase potential for injury.
- Family members will assist in identifying and implementing safety measures to prevent injury.
- Child will increase self-care activities within parameters posed by sensorimotor limitations.
- Child will remain safe in the environment.

Nursing Diagnosis: Delayed growth and development related to physical or neurologic impairment

Interventions/Rationale

- Assist parents to individualize growth and development expectations for child. Help develop methods to promote achievement of milestones.

NURSING PLAN OF CARE 21–1: CHILD WITH ALTERED NEUROLOGIC STATUS (CONTINUED)

Parents may not have realistic expectations regarding growth and development of their child, especially if the neurologic condition was sudden in onset and the child lost previously achieved developmental milestones.

Expected Outcomes

- Child will demonstrate age-appropriate skills as able, given sensorimotor limitations.
- Parents will express understanding of their child's growth and developmental potential as defined by the child's condition.
- Child and parents will participate in activities to enhance child's achievement of developmental milestones.

Nursing Diagnosis: Disturbed body image related to altered physical capabilities, lifestyle changes, or physical appearance following neurologic injury or illness

Interventions/Rationale

- Assess child's perception of body image.
Provides baseline data from which to evaluate changes in the child's perception of self.
- Encourage discussion concerning misconceptions, fears, the reality of public discrimination, and social stigma.
Children with neurologic disorders and their families must cope with social stigma and rejection because of the public's misconceptions and prejudices about these conditions (e.g., epilepsy, myelomeningocele). The child may be embarrassed and may feel insecure and resentful about the condition and about his or her inability to participate in typical activities for age. Expressing and discussing feelings may help child to cope.
- Inform parents of the importance of treating their child as any other child.
Helps the child to feel normal and may avoid behavioral problems from lack of limits.
- Assist the parents to plan age-appropriate developmental activities for the child, based on the child's capabilities.
Will help the child master skills to achieve developmental potential.
- Prepare the child to assume self-care responsibilities.
Will help the child achieve developmental potential.

Expected Outcomes

- Child will discuss feelings about change in body image.
- Child will express positive feelings about self.
- Child will implement positive coping skills to deal with change in body image.

Nursing Diagnosis: Deficient knowledge: Child's condition, treatment plan, and home care requirements

Interventions/Rationale

- Assess family's knowledge of child's condition and care needs.
Assists in focusing teaching to family's needs.
- Explain all treatments and procedures, and be present when information is given by other healthcare team members. Reinforce and clarify information.
Helps the child and parents to understand condition and treatments, and to make informed decisions.
- Demonstrate required care. Provide opportunity for return demonstration.
Helps the child and parents master care needs.
- Teach and counsel family regarding child's condition and need for adhering to current interdisciplinary regimen.
Child and parents cannot manage treatment program if deficient knowledge exists. Misconceptions and poor care are fostered when the family lacks understanding or knowledge.
- Teach child and family to identify and report symptoms that indicate a change in the child's condition or a deleterious side effect of medications or other treatments.
Enables prevention or early detection of problems and early intervention.

Expected Outcomes

- Child and family will express interest in learning about child's condition.
- Child and family will participate in teaching sessions to learn about child's condition.
- Child and family will demonstrate healthcare behaviors needed to manage child's care at home.
- Family will verbalize confidence in caring for child's ongoing health needs.
- Family will manage child's healthcare in the home.

Nursing Diagnosis: Disabled family coping related to response to severity of child's condition and potential or actual long-term disability

Interventions/Rationale

- Assess family's coping and identify needs regarding child's care related to condition.
Allows identification of family strengths and areas where support is needed.
- Encourage family expression of fears and feelings of helplessness, guilt, anger, and despair outside the child's hearing range. Arrange for spiritual and counseling support as needed.

Family may find it difficult to maintain open communication under stress. They often need validation that their feelings are normal.

- Enlist other personnel (e.g., child life specialist, social worker, clergy) to assist child and family in coping with child's condition.

Recognition of individual perceptions and previously successful methods of coping can help families in coping with their child's condition.

- Provide a list of community resources and support for emotional and spiritual needs.

Ongoing support can help with coping and meeting emotional needs.

Expected Outcomes

- Family will express their concerns about coping with child's illness.
- Family will be able to identify their needs.
- Family will seek resources and sources of emotional and spiritual support.
- Family will be able to meet their needs as well as the child's to their mutual satisfaction.
- Family will obtain financial and physical resources to manage child's care in the home.

CSF through the ventricular system, or decreased absorption of CSF in the subarachnoid space. Increased CSF volume secondary to hydrocephalus or meningitis is common in children. The mechanisms of increased ICP are interrelated, and more than one process can occur at one time.

Compensatory Mechanisms

Several compensatory mechanisms serve to maintain ICP in response to increasing volume within the skull. These mechanisms include (1) a displacement of CSF from within the cranial cavity to the distensible subarachnoid space around the spinal cord, (2) an increase in the rate of CSF absorption into the venous system, and (3) a reduction in cerebral blood volume resulting from compression of the low pressure venous system.

Cerebral blood vessels alter their diameter to maintain a constant blood supply to brain tissue despite fluctuation in the arterial blood pressure, via a mechanism termed *autoregulation*. When arterial pressure increases, vasoconstriction occurs; when arterial pressure decreases, vasodilation occurs. However, dramatic changes in arterial blood pressure (to <50 mm Hg or >150 mm Hg) impair cerebral autoregulation. When the systemic blood pressure declines to less than 50 mm Hg, cerebral ischemia occurs and cell function is impaired. When severe hypertension occurs, the blood-brain barrier breaks down, and cerebral edema results. When autoregulation is impaired, CBF and CPP become passively dependent on systemic arterial pressure.

Herniation of Brain Tissue

Herniation can be described as a physical displacement of a portion of the brain through and into other brain structures, usually because of an increase in the volume of brain, blood, or CSF. When pressure in one area is excessive, the brain may displace to an area of less resistance, causing serious and potentially life-threatening consequences. The best treatment is prevention of increased ICP through early management.

The most common type of supratentorial herniation is uncal herniation, which can be unilateral or bilateral. As the uncus of the temporal lobe pushes into midline structures, it puts pressure on the oculomotor nerve, causing pupil dilation and sluggish or absent response to light. Other signs and symptoms of uncal herniation include declining consciousness, decerebrate posturing, increased blood pressure, slow pulse, and respiratory irregularity.

Infratentorial herniation is less common and can involve herniation of the cerebellar tonsils up through the tentorium or down through the foramen magnum. The brain stem can also herniate down through the foramen magnum. Signs of infratentorial herniation include decerebrate or decorticate posturing, declining consciousness, impaired upward gaze, irregular respiration, pupillary constriction or dilation, and lower cranial nerve palsies. Medullary compression can result in death from cardiac or respiratory arrest.

ANSWER: Intracranial swelling or bleeding resulting from a head trauma such as Joey sustained could result in increased ICP, necessitating placement of an ICP monitor.

Assessment

Signs of increased ICP vary depending on the age of the child (Developmental Considerations 21–1). In infants and young children, open sutures allow the cranial bones to spread apart to accommodate increased cranial volume during the initial phases of increased ICP, especially when the buildup of pressure is slow or chronic. In instances of acute increased ICP, however, the skull may not change as readily to compensate for the added volume. Because of this phenomenon, the signs and symptoms of acute and chronic increased ICP in infants and young children vary. The skulls of older children are less accommodating.

Differences in the signs and symptoms are also related to whether the underlying process is acute or chronic,

DEVELOPMENTAL CONSIDERATIONS 21–1

Clinical Manifestations of Increased Intracranial Pressure

Headache in the morning that decreases with vomiting or lessens throughout day
Cranial enlargement secondary to hydrocephalus
Vomiting
Diplopia
Papilledema
Lethargy and somnolence (late signs)

Child Younger Than 3 Years

Marked irritability
Bulging fontanel
Disrupted sleep patterns
Resistance to being held or comforted
Decreased appetite
Developmental delays or loss of acquired milestones
Increased head circumference
Delayed closure of anterior fontanel (usually between 8 and 18 months of age)

and to the child's developmental level and ability to communicate subjective symptoms. A complete assessment of factors in the child's history, including changes in behavior, attainment of developmental milestones, or level of alertness or responsiveness, is vital.

Ask about headache, a common symptom of increased ICP at all ages. Headache is generalized and is worse in the morning on awakening or on rising to a standing position. The pain is usually constant but varies in intensity. Vomiting, especially on arising in the morning, is often present. Visual disturbances, including diplopia and strabismus, may also occur. Pertinent physical assessment findings include impairment of upward gaze and papilledema (passive swelling of the optic disk).

Palpate the anterior fontanel of a quiet infant to assess ICP. Bulging of the fontanel above the level of the bone edges, and an inability to palpate the bone edge, indicate increased ICP.

After establishing a baseline, monitor neurologic status and vital signs as necessary in accordance with the child's condition and the prescriber's orders. Monitoring may be required as frequently as every 15 minutes for a child whose condition is unstable and changing rapidly, or it may be several times daily for a more stable patient.

Diagnostic Tests

Diagnostic tests are obtained to identify the specific cause of increased ICP. These tests may include skull radio-

graphs, CT scans and MR images, CBF studies, EEG, and evoked potentials.

Nursing Diagnoses and Outcomes

Nursing Plan of Care 21–1 presents a variety of nursing diagnoses that may be applicable to the child with a neurologic condition. The following diagnosis applies specifically to the child with increased ICP:

Decreased intracranial adaptive capacity related to changes in intracranial components

Outcome: Child's ICP will remain in normal range.

Interdisciplinary Interventions

QUESTION: Should Joey's parents be allowed to stay with him during his assessment in the emergency department?

The treatment of increased ICP is complex and specific to the causative factors. Prevention programs to prevent head and brain injury focus on the use of helmets, seat belts, and barriers to water access. Recent programs have also focused on preventing high-risk behaviors and violence.

Increased ICP may require medical and surgical methods of treatment. Generally, medical measures are instituted while the need for surgery is assessed. In many instances, surgical and medical management occur simultaneously.

Monitoring Intracranial Pressure (ICP)

Continuous monitoring of ICP is used to assess the effects of treatment in maintaining adequate CPP. ICP is measured in millimeters of mercury or in centimeters of water. Monitoring devices range from a noninvasive transducer that may be placed over a fontanel to more commonly used invasive devices, such as an epidural transducer, a subarachnoid bolt or screw, and an intraventricular catheter transducer. An ICP monitor is placed by a neurosurgeon, either at the bedside or in the operating room. The nurse assists in gathering supplies, ensuring strict asepsis during the procedure, and supporting the family with information.

Normal ICP ranges from 0 to 15 mm Hg, although temporary elevations to as high as 100 mm Hg can occur with activities such as coughing and the Valsalva maneuver. Increased ICP may be moderate (20–40 mm Hg) or severe (>40 mm Hg). The placement of an ICP monitor enables calculation of CPP, which is a more accurate predictor of long-term outcome for children with increased ICP.

When the child's ICP is being monitored, the goal is to keep the ICP at less than 20 mm Hg and the CPP at more than 40 mm Hg (Stiefel et al., 2006). To attain this goal, mean arterial blood pressure must be 70 mm Hg or more.

A sudden increase in ICP can occur as a result of a change in head and neck position, a partially obstructed

airway, hyperthermia, and increased patient agitation caused by noxious external stimuli. Stroke, intracranial hemorrhage, and impending herniation are also potential causes of a change in ICP. If ICP suddenly increases, quickly assess the child to note any change in vital signs or in neurologic parameters (NIC 21–1).

Assess for hypercapnia (elevated PaCO₂) and hypoxia (decreased PaO₂) by means of blood gas analysis and pulse oximetry. If suctioning is necessary to maintain the airway, do this in short intervals to prevent suction-induced hypoxia. When mechanical ventilation is necessary, maintain PaCO₂ between 35 and 38 mm Hg and PaO₂ more than 85 mm Hg (Orliaguet, Meyer, & Baugnon, 2008). In the presence of refractory increased ICP, PaCO₂ less than 35 mm Hg may be used (Orliaguet et al., 2008). When positive end-expiratory pressure is used for pulmonary hypoxia, avoid excessive intrathoracic pressure, which may also contribute to elevated ICP. Reducing the PaCO₂ by controlled hyperventilation causes vasoconstriction of cerebral blood vessels, which in turn decreases ICP. Because of this unique phenom-

enon, manual hyperventilation to decrease PaCO₂ may be used in the critical care setting.

Closed Ventricular Drainage/Ventriculostomy

In cases of increased ICP in which ventricular access is obtained to measure ICP, controlled drainage of CSF may be used during the acute phase of treatment. Sterile closed-drainage systems enable close monitoring of CSF drainage and easy access to inline ports for drawing CSF specimens to monitor infection and other parameters.

The ventricular drainage catheter is usually inserted through a burr hole in the skull into the lateral ventricle. The catheter is tunneled under the subcutaneous tissue and exits the scalp some distance from the burr hole, an approach that decreases the risk of intraventricular infection. The catheter is connected to a drainage system, which works by gravity, so the amount of CSF drainage depends on the position of the drip chamber in relation to the lateral ventricle. The physician may order continual drainage or intermittent drainage when the ICP reaches a specific level.

NIC 21–1 Nursing Interventions Classification: Cerebral Edema Management

Definition: Limitation of secondary cerebral injury resulting from swelling of brain tissue

Activities:

- Monitor for confusion, changes in mentation, complaints of dizziness, syncope
- Monitor neurologic status closely and compare with baseline
- Monitor vital signs
- Monitor CSF drainage characteristics: color, clarity, consistency
- Record CSF drainage
- Monitor CVP, PAWP, and PAP, as appropriate
- Monitor ICP and CPP
- Analyze ICP waveform
- Monitor respiratory status: rate, rhythm, depth of respirations; PaO₂, pCO₂, pH, bicarbonate
- Allow ICP to return to baseline between nursing activities
- Monitor patient's ICP and neurologic response to care activities
- Decrease stimuli in patient's environment
- Plan nursing care to provide rest periods
- Give sedation, as needed
- Note patient's change in response to stimuli
- Screen conversation within patient's hearing
- Administer anticonvulsants, as appropriate
- Avoid neck flexion or extreme hip/knee flexion

- Avoid Valsalva maneuvers
- Administer stool softeners
- Position with head of bed up 30 degrees or greater
- Avoid use of PEEP
- Administer paralyzing agent, as appropriate
- Encourage family/significant other to talk to patient
- Restrict fluids
- Avoid use of hypotonic intravenous fluids
- Adjust ventilator settings to keep PaCO₂ at prescribed level
- Limit suction passes to less than 15 seconds
- Monitor laboratory values: serum and urine osmolality, sodium, potassium
- Monitor volume pressure indices
- Perform passive range-of-motion exercises
- Monitor intake and output
- Maintain normothermia
- Administer loop-active or osmotic diuretics
- Implement seizure precautions
- Titrates barbiturate to achieve suppression or burst suppression of EEG as ordered
- Establish means of communication: ask yes-or-no questions; provide magic slate, paper and pencil, picture board, flash cards, VOCAID device

From Bulechek, G. M., Butcher, H. K., & Dochterman, J. M. (2008). *Nursing interventions classification (NIC)* (5th ed.). St. Louis, MO: Mosby. Reprinted with permission.

Nursing care for the child with a ventricular drainage system includes carefully recording the color, amount, and rate of drainage. Ensure that the system is at the proper level with the correct settings. Keep in mind the effects of positioning on ICP. Use strict aseptic technique and maintain a closed system. Monitor electrolytes closely and anticipate that fluid lost with CSF may have to be replaced with intravenous fluids.

Positioning

Neck flexion and head rotation appear to increase ICP. Keep the head and neck in a neutral position in relation to the shoulders and upper trunk and elevate it 15 to 30 degrees (Fan, 2004). Use pillows to prevent the child from sliding down in bed and to support the head in a neutral position when the child lies on his or her side. Support the child's head in a neutral position during turning and lifting. Increases in ICP have also been seen in response to lateral and prone positioning, which should be avoided.

Temperature Regulation

Fever causes vasodilation and increased CBF. Fever treatment can decrease the vasodilation and reduce systemic and cerebral metabolic requirements. Administering antipyretics and using tepid water sponge baths and cooling blankets are recommended to maintain body temperature at 97.7 to 100.4 °F (36.5–38.0 °C). Lower the body temperature slowly to prevent shivering, which increases ICP.

Pharmacologic Interventions

A common treatment for ICP is the use of the hyperosmolar therapy with agents such as mannitol or hypertonic saline. These agents increase the osmotic pressure in the cerebral blood vessels, thereby causing water to move from the brain tissue to the vascular space. Hyperosmolar therapy may be most effective during the first 48 hours of administration. Frequently monitor neurologic status, urinary output, and fluid and electrolyte balance. Assess for potential hypovolemia.

Sedation (e.g., midazolam) reduces the stress response and lowers ICP. Analgesics such as fentanyl provide pain relief and help depress airway reflexes in the intubated patient; antianxiety agents should never be used in place of appropriate analgesics. If initial medical management is not successful, a barbiturate coma may be induced.

Pancuronium (Pavulon), a paralyzing agent, may be used during the initial phases of management to decrease muscle responses to voluntary, central, and environmental stimuli. Although a child treated with pancuronium cannot move or respond to stimuli, sensory functions are not altered, so the child may still be able to hear and feel. Nursing care includes meticulous skin care, the application of artificial tears and eye lubricant, and frequent neurologic assessments.

Antiepileptics such as phenobarbital or phenytoin (Dilantin) may be ordered if the child has a history of seizures. Monitor drug levels frequently to avoid toxicity. Giving a patient with brain injury an antiepileptic on a

prophylactic basis is controversial if a seizure has not occurred (Liu & Bhardwaj, 2007).

If an ICP monitor is in place, the child will receive prophylactic antibiotics. Monitor peak and trough drug levels to prevent toxicity and to optimize the drug's effect.

Steroids such as dexamethasone are used primarily to reduce edema surrounding mass lesions. Antacids must be given concurrently to minimize side effects, including gastritis and stress ulcer.

Surgical Interventions

Surgery to relieve rapidly increasing ICP may be acutely needed in cases of severe head injury resulting in large hemorrhages. A decompressive craniectomy is performed to relieve ICP in children with severe traumatic brain injury, diffuse cerebral swelling, and intracranial hypertension (Sahuquillo & Arikan, 2006). Chronic clinical conditions also may present as a surgical emergency, especially if they are undiagnosed for a long time. Examples include brain tumors and subdural hematomas secondary to nonaccidental trauma in shaken baby syndrome. In these latter cases in particular, medical management is necessary to lessen the substantial risk of morbidity or mortality during surgery on a highly pressurized brain. In some cases, this risk cannot be avoided. In most cases, an ICP monitor is inserted during surgery to assist in postoperative management of ICP.

Comfort and Support Interventions

In addition to assessing and monitoring, nursing care of the child with increased ICP focuses on reducing the child's pain, crying, and agitation with comfort measures including the timely use of analgesics and sedatives as necessary. Also, enlist the parents' help to provide comfort measures (see Chapter 10). Encourage the presence of family members at the child's bedside. In some cases, parental presence will lead to more agitation and increased ICP, and the parents will need frequent explanations and support through the acute phase of treatment. Suggest that parents bring security objects from home to comfort the child. Plan care activities so that the child has uninterrupted periods of rest and sleep, and reduce the number of care activities at any one time. Support for the family during this crisis is vital.

ANSWER: Yes, an important component of family-centered care is to keep parents with their child. An important aspect of nursing management of a child with increased ICP is to prevent distress and agitation that can elevate ICP.

Seizures

Seizures can be categorized as epileptic or nonepileptic. An epileptic seizure is a transient clinical event that results from abnormal and excessive activity of cerebral neurons. The abnormal activity, which can be seen on an EEG, results in paroxysmal disorganization of one or

more brain functions. The resulting effects may be excitatory (motor, sensory, or psychic), inhibitory (loss of awareness or muscle tone), or a combination of the two. Nonepileptic seizures, such as a psychogenic seizure or a brief convulsion as the result of a syncopal event, are not associated with an epileptic discharge in the brain. Seizure episodes may affect the child in any one or combination of the following ways: altered responsiveness; altered sensation, perception, or both; or altered movements, mobility, or muscle tone.

The clinical features of an epileptic seizure depend on the characteristics of the abnormal electrical discharge and the area of the brain involved. Children may have occasional seizures as the result of a specific event, such as a febrile illness, hypoglycemia, or CNS infection. Some children may have recurrent seizures without a specific provoking event. This pattern is considered epilepsy. Epilepsy may be idiopathic (without an identified cause) or symptomatic (resulting from an acquired cause). This section covers care of the child experiencing a seizure of any kind, regardless of circumstances, cause, and seizure type, and also reviews status epilepticus. Febrile seizures, mentioned briefly in this section, are described in detail in Chapter 31. Epilepsy is covered in the following section.

Pathophysiology

About 5% of children in the United States will have a seizure before age 20. About 25% of these children will develop epilepsy, a condition characterized by recurrent, unprovoked seizures (MacAllister & Schaffer, 2007).

Seizure susceptibility changes with age and developmental stage (Developmental Considerations 21–2). Several factors may contribute to the immature brain's propensity to have seizures. Many of these factors relate to the normal developmental process of synapse formation in infants and children:

- Excitatory process developing before inhibitory process
- Differences in the ionic microenvironment
- Immaturity of circuits that modify expression of seizures
- Reduced threshold for activating seizures

In normal brain activity, certain groups of neurons are active during the processes of thinking, hearing, moving, or other activities. Other groups of neurons are less active, and still others are inactive at any given moment. During a seizure, groups of neurons all activate at the same time, causing a sudden burst of electrical activity in the brain and disrupting normal function. Two factors account for neuronal tissue's potential to produce an epileptic seizure. First, disruptions of cellular depolarization and repolarization mechanisms result in abnormal excitability, causing cells to fire randomly. Second, abnormal synchronization of a group of neurons may occur, which initiates the electrical burst of an epileptic seizure.

Many nonepileptic paroxysmal events occur in childhood that can be mistaken for seizure activity. These events can range from the benign (e.g., breath-holding

DEVELOPMENTAL CONSIDERATIONS 21–2

Common Causes of Seizures

Neonate

- Hypoxic–ischemic encephalopathy
- Intracranial hemorrhage
- Blood chemistry imbalance such as hypoglycemia, electrolyte imbalances
- Intracranial infection
- Cerebral malformations
- Genetic factors such as genetic syndromes, benign familial neonatal seizures (autosomal dominant inheritance), familial congenital cerebral malformation, inborn errors of metabolism, neurocutaneous syndromes
- Neonatal abstinence syndrome
- Head trauma

Beyond Neonatal Period

- Seizure onset after neonatal period may result from causes listed earlier
- Intracranial infection
- Head trauma
- Exposure to drugs of abuse or other toxins
- Tumor or malignancy
- Idiopathic
- Hypoxia

spells, hyperventilation, night terrors, gastroesophageal reflux) to life threatening (e.g., cardiogenic syncope, hypoglycemia). Tourette's syndrome and other related tic disorders are not seizures and require different medical management.

Classification of Seizures

A system to classify epileptic seizures was developed by the International League Against Epilepsy (1989). Epileptic seizures are first classified as partial or generalized, based on the origin of the event, and are then further classified based on the clinical symptoms present. Seizures are termed *unclassified* if the available information is not enough to classify them as partial or generalized.

Partial Seizures

In partial seizures, the abnormal neuronal firing is initially localized to one or more groups of neurons or areas within the same hemisphere of the brain. The effect on brain function is limited, or focal. The abnormal activity may spread to involve the entire brain, an event called *secondary generalization*. Partial seizures are further classified as simple or complex, according to whether consciousness is lost during the event.

Simple Partial Seizures

Simple partial seizures are usually brief events, often lasting less than 1 minute, during which consciousness is preserved. Simple partial seizures may consist of motor, sensory, autonomic, and/or psychic signs or symptoms. Motor involvement, the most common, involves rhythmic movement, alternating contraction and relaxation (clonic) typically limited to one muscle group (such as the fingers) or to a contiguous group of muscles (as in an arm or a leg). Involvement may spread from this initial site to involve all the muscles on one side of the body. **Todd's paralysis**, a transient paralysis of the involved muscle groups, may follow a simple partial seizure and may last as long as 24 hours.

Simple partial seizures beginning in the parietal lobe are associated with somatosensory symptoms, such as a “pins and needles” sensation or a feeling of numbness. Involvement of the occipital lobe may cause visual symptoms consisting of flashes of light or color, or loss of vision in a specific area (scotoma or hemianopia). Autonomic symptoms may include vomiting, pallor, flushing, sweating, dizziness, erection of body hairs, pupillary dilation, tachycardia, incontinence, and other autonomic functions. Psychic symptoms may include cognitive symptoms, affective symptoms, illusions, or hallucinations.

Complex Partial Seizures

Complex partial seizures, the most common type of seizures in children, often originate in the temporal lobe, an area concerned with memory and emotion. Symptoms may be variable and may include a wide range of behaviors.

Some children with complex partial seizures experience a *prodrome*—that is, they are aware of an impending seizure days or hours before it occurs. Others experience an *aura*. A prodrome differs from an aura in that the prodrome is not part of the actual **ictal** (seizure) event. An aura is an ictal phenomenon; it is part of the actual seizure activity. It is the portion of the seizure that occurs before consciousness is lost and for which memory is retained when consciousness is regained. Auras vary considerably among individuals; children may experience sensory (e.g., visual, auditory, olfactory, gustatory) symptoms, visceral sensations, or complex subjective experiences such as fear, embarrassment, or dizziness.

Following the loss of consciousness, various types of automatic behavior (automatisms) may occur, such as chewing, gagging, choking, lip smacking, spitting, waving, clapping, scratching, masturbating, walking, skipping, running, screaming, crying, or laughing. On regaining consciousness (the **postictal** period), the child often feels tired and falls asleep.

Generalized Seizures

In a generalized seizure, the abnormal electrical activity occurs throughout the brain, and cortical functions are disrupted. Generalized seizures can be primary—that is, both hemispheres are involved from the outset—or secondarily generalized from a partial seizure. Consciousness is impaired in a generalized seizure.

Generalized Tonic–Clonic seizures

Generalized tonic–clonic seizures may be preceded by both a prodromal phase and an aura. An aura indicates that the seizure began focally (as a partial seizure) and then spread throughout the brain. Typically, generalized tonic–clonic seizures involve five recognizable phases: flexion, extension, tremor, clonic, and postictal. During the brief (5-second) flexion phase, consciousness is lost. Seizure activity usually begins in the face with the eyes rolling upward and the mouth opening with jaw muscles rigid. Flexion of the extremities follows. The extension (tonic) phase (which lasts 10–30 seconds) begins with extension of the back and the neck, and includes extension of the legs. The jaws clamp together tightly, and tongue biting can occur. Apnea may begin during the tonic phase, with rigid extension of the thoracic and abdominal muscles, and may persist through the clonic phase. The tremor phase (5–10 seconds) marks the transition between the tonic and clonic phases. Fine tremors usually begin in the extremities and spread proximally. The clonic phase may last 30 to 50 seconds. A characteristic rhythmic jerking is produced by the rapid contraction and relaxation of opposing muscle groups. The jerking decreases in frequency as this phase nears completion. Apnea frequently lasts through the clonic phase, causing increasing cyanosis. Secretions pool in the mouth and throat, leading to noisy respirations. This stage can be difficult for observers, because the child appears to be in great distress, yet nothing can interrupt the seizure. After the last clonic jerk, the bladder sphincter relaxes, and incontinence may occur. During the immediate postictal phase, the child is still unconscious, but relaxation of muscles results in a flaccid posture. Cyanosis resolves as breathing returns to normal, but pallor often lingers. The child may either gradually awaken or progress directly into a sleeping state.

Clonic Seizures

Clonic seizures consist of episodes involving loss of awareness followed by rhythmic jerking movements of the arms and legs. The length of the seizure varies, and the jerking can be unilateral or bilateral. These seizures are relatively rare, but they can occur in all ages, including neonates.

Myoclonic Seizures

Myoclonic seizures are characterized by sudden, brief jerks of muscle groups. Flexor muscles are often involved on both sides of the body, resulting in sudden falls for older children or spasms for infants. Loss of consciousness may be momentary and unobserved. Myoclonic seizures may occur several times in a row.

Tonic and Atonic Seizures

Tonic seizures consist of a brief, sudden onset of increased tone of the extensor muscle. If the child is standing, he or she typically falls to the floor. Atonic seizures involve a sudden loss of muscle tone and loss of consciousness. During a brief attack, the seizure may be confined to a particular group of muscles and, although the child's head may drop suddenly, the child may not fall. Seizures of larger

muscle groups may initiate falls and are often referred to as *drop attacks*. More prolonged attacks may begin with a fall, but then continue with the child lying limp and unresponsive for seconds or for minutes. Longer attacks are usually followed by drowsiness.

Absence Seizures

Absence seizures consist of a sudden, brief (usually no longer than 30 seconds) arrest of the child's motor activity accompanied by a blank stare and loss of awareness. The child maintains posture. At the end of the seizure, the child returns to the activity that was in progress as though nothing has happened. Interruption of mental activity may be incomplete, allowing the child to continue simple or automatic behavior during the lapse of full mental function. The child retains no memory of the seizure but may be aware of a "time loss." Postictal confusion and sleepiness do not occur.

Febrile Seizures

Febrile seizures are defined as seizures that occur in association with a febrile illness in the absence of CNS infection, electrolyte imbalance, or previous afebrile seizure. It is not necessary for the child to have a fever at the time of the seizure for the seizure to be considered a febrile seizure. Higher fevers are associated with a greater risk of febrile seizure. These seizures most frequently occur in children from 6 months to 3 years of age, and the peak incidence is at 18 months (Leung & Robson, 2007).

Simple febrile seizures are less than 15 minutes in length, are generalized, and occur as a single event during a single febrile illness. Complex febrile seizures are longer than 15 minutes, have a focal component, and occur repeatedly during the same illness.

The prognosis for febrile seizures is generally good, and children rarely have any short- or long-term deficits. Recurrent febrile seizures are associated with younger age of onset, family history, low peak temperature at time of first febrile seizure, and a complex first seizure. Less than 1% of children who have a simple febrile seizure will develop epilepsy (Leung & Robson, 2007).

Diagnostic evaluation of a child who presents with a seizure associated with fever is aimed at determining whether the child had a febrile seizure or if a more serious underlying condition is present. The presence of CNS infection is determined by lumbar puncture and is indicated in a child younger than 18 months and in older children if there are clinical signs of meningitis. Except for blood glucose documentation, additional diagnostic studies are not indicated unless signs and symptoms other than fever and seizures are present.

For the child who has a history of febrile seizures, using daily antiepileptic medication to prevent further seizure is not recommended, because the medication causes substantial adverse effects (Leung & Robson, 2007). Rectal diazepam is often recommended for emergency treatment of febrile seizures and is indicated for children with a history of prolonged or multiple febrile seizures and for those who live long distances from medical care. Although parents must be trained in its use, the

drug is easy to administer and provides the family with a sense of control. Counsel the family of a child with a febrile seizure that the seizure is not life threatening and does not cause permanent injury.

Neonatal Seizures

Neonatal seizures do not resemble the seizures of infants or older children. Myelination of the CNS is incomplete during the neonatal period, and epileptic discharges are not transmitted well in the neonate's brain. As a result, partial or fragmentary motor events or subtle behavioral changes such as apnea may be manifestations of seizures. Types of seizures that are recognizable in the infant include

- Focal clonic seizures: Repeated, irregular jerking affecting one or both limbs on one side
- Multifocal clonic seizures: Migratory jerking movements noted first on one limb then another, and on one side then the other; facial muscles may be involved
- Focal tonic seizures: Rigid posturing of the extremities and trunk, fixed deviation of eyes may be present; may be associated with apnea
- Myoclonic seizures: Brief repeated extension and flexion movements of arms, legs, or all limbs
- Subtle seizures: Chewing motions, excessive salivation, apnea, blinking nystagmus, bicycling or pedaling movements, and changes in skin color

Common causes of neonatal seizures were listed in Developmental Considerations 21–2. Pyridoxine dependency, a rare metabolic disorder, may also precipitate seizures in the neonate. Seizure activity in neonates may be difficult to distinguish from nonepileptic activity (Chart 21–2). Observation is crucial for appropriate diagnosis.

In neonatal seizures, interictal EEG patterns (activity in between seizures) are helpful in predicting outcome. Normal interictal patterns are associated with a good prognosis, with no seizures beyond the neonatal period, and normal developmental progress. Abnormal patterns are associated with a poor prognosis, generally continued seizures, and abnormal or delayed development.

CHART 21–2 DISTINGUISHING NEONATAL SEIZURE ACTIVITY FROM NONEPILEPTIC MOVEMENTS

Seizure Activity	Nonepileptic Movements
Tachycardia and increased blood pressure	No changes in vital signs
Movement not suppressed by general restraint	Movement suppressed easily with gentle restraint
Seizure activity unchanged by sensory stimuli	Enhanced nonepileptic movements with sensory stimuli

Treatment of neonatal seizures is aimed at identifying and treating the cause. Care involves maintaining a patent airway and supporting cardiovascular function. A trial of pyridoxine is usually given to treat potentially pyridoxine-dependent seizures. Antiepileptic therapy includes lorazepam, phenobarbital, or phenytoin. Therapy is usually very short term and may be discontinued after 2 weeks of complete seizure control.

Status Epilepticus

Status epilepticus occurs when seizures last longer than 30 minutes or recur without return of consciousness between seizures. It is a common neurologic emergency in children and can be life threatening. Children younger than 3 years of age are most likely to develop status epilepticus, and most who present with status epilepticus do not have a prior history of seizure. The most common cause of status epilepticus in children is febrile seizure (Shinnar, 2007). For a child with a history of epilepsy, the most likely cause of status epilepticus is poor adherence to taking medications or acute antiepileptic drug withdrawal.

The clinical outcome of status epilepticus depends on the etiology and is worse for children with status epilepticus precipitated by serious intracranial insults. Death is usually the result of the underlying cause rather than the seizure itself. Sequelae include epilepsy and motor or cognitive deficits. Outcome is greatly improved by rapid intervention and cessation of the seizure activity.

Assessment

Some seizures are more easily recognized than others because the signs and symptoms are so variable. For example, generalized tonic-clonic seizures are easily recognized, whereas simple or complex partial seizures may be more difficult to recognize, possibly occurring repeatedly before being recognized. Absence of a preexisting history of seizures also makes recognition more difficult.

A seizure has three distinct parts. The ictal phase, the postictal phase, and the interictal phase, which describes the period between seizures and is considered the child's baseline. Clinical manifestations depend on the area of the brain that is involved. Observe the seizure or obtain an accurate description of the seizure from the parents or caregiver to assist in accurate diagnosis and treatment. Simultaneously, intervene as appropriate (Nursing Interventions 21–2).

In the event of a first-time seizure or status epilepticus, assess to determine causative factors. Conduct a thorough physical examination, and evaluate urine, blood, and CSF (e.g., serum glucose, electrolytes, and drug levels) as indicated for infectious, metabolic, or toxic cause of seizure. Urgent brain imaging with CT can determine whether there is a traumatic or neoplastic cause. EEG and MRI are conducted when the child is stable.

Interdisciplinary Interventions

Caring for a child with a seizure involves providing initial management, pharmacologic therapy, and simultaneous investigation of the cause. Also, institute safety measures

to reduce the potential for injury to the child if another seizure occurs.

Initial Management

Initial management of the child with a seizure involves basic first aid and is similar regardless of the seizure type:

- Remain calm and stay with the child.
- Protect the child from any additional injury; use common sense.
- Provide time for the child to recover after the seizure stops.
- Reassure and provide support to the child and to others (see Nursing Interventions 21–2).

caREminder

Do not insert a tongue blade or similar object into the child's mouth, because it may cause injuries. Do not give the child anything to eat or drink until he or she has clearly recovered from the seizure.

Protecting the child from injury depends on what happens during the seizure. Individuals experiencing only staring or altered responsiveness may require no initial intervention other than someone standing by to make sure that the child does not fall or lose balance. Speak softly, if at all, to the child with altered responsiveness to avoid agitating or confusing the child.

If the child is having altered sensations or perceptions, acknowledge these states. Reassure the child that he or she is safe and that the experience will soon be over.

Recovery time after a seizure varies. Some children can immediately return to activities. Other children may be confused or may fall deeply asleep for several hours.

KidKare ■ After recovery, reassure the child in a manner similar to this: "You just had a seizure and it is over now; everything is OK."

The child's questions determine whether he or she needs more information to understand the experience. Young children witnessing a seizure may think that the child is dying, having a tantrum, choking, or misbehaving. Adults often think the same thing. Again, simple explanations are helpful. Statements, such as, "It's OK; he's having a seizure and it will be over soon," can be tremendously reassuring if delivered in a calm, confident manner by the nurse.

It may not be necessary to call for emergency help during a seizure because the event is self-limiting and, by itself, does not injure the child. However, seek emergency help if

- The child does not start breathing after the seizure, in which case initiate artificial ventilation
- The seizure activity continues for longer than 5 minutes

NURSING INTERVENTIONS 21–2

Seizure Assessment and Management

Assessment

Seizure Onset

- Note activities and potential precipitating factors prior to onset.
- Did the child indicate an aura or knowledge of impending seizure?
- Did the child alter activities? If so, how?
- Observe the sequence of events.

Level of Awareness

- Note level of responsiveness to self, others, and environment.
- Observe whether responses were rote or more complex and how much they were affected (e.g., partially, totally).
- Assess response to stimuli: tactile (e.g., touch lightly, gently shake or move arm or leg), auditory (e.g., state child's name, give a command), and visual (e.g., make sudden movement toward child, wave hands in front of child's face).
- Is the child performing inappropriate activities (verbalization: strange words, mumbling, cursing; combative, agitated; wandering, performing activities without awareness)?

Muscle Movement/Tone

- Note general postural change or specific muscle movements; observe location and specific activity. If bilateral, note whether it was symmetric.
- Observe for purposeful movements and automatisms (repetitive, purposeless movements).
- Assess muscle tone. Is it normal, increased (tonic, spastic, rigid), or decreased (limp, flaccid)?

Physiologic Responses

- Assess for autonomic symptoms (color change, perspiration, skin temperature change, drooling, increased heart rate, blood pressure, bladder and sphincter tone).
- Check pupil reactivity.
- Note apnea.

Postictal

- Assess for possible incontinence resulting from muscle relaxation.
- Describe child's behavior.
- Ask child what he or she remembers before, during, and after seizure.

- Note length of time until child resumes normal behavior and activities.
- If confusion or disorientation is present, describe and note duration.
- Note presence of any temporary deficits (memory loss, aphasia, paresis).

Interventions

- Remain with child; provide privacy as possible.
- Direct movements during seizure to prevent injury:
 - Do not restrain or restrict the child's movements.
 - Move any harmful objects away from the child.
 - If the child is walking and headed for a dangerous situation (e.g., open stairs), attempt to steer the child in a safe direction.
 - Assist or move child into a lying position on the floor, if necessary and possible.
- Monitor neurologic status, behavior, and vital signs.
- Administer medication, as ordered, and monitor for side effects.
- Reassure and provide psychosocial support to child and bystanders.
- When the event is finished
 - Turn the child to a side-lying position.
 - Position to maintain airway.
 - Turn head toward the side to prevent choking and aspiration.
 - If the child is lying on the floor, place something soft under the head.
 - Monitor until child returns to baseline status.

Documentation

- When and where the seizure began (date, time of day, pre-seizure activity of child)
- Whether the onset and entirety of seizure were observed
- Duration
- Any warning signs that the seizure was about to happen (aura)
- Clinical characteristics (specific description of movements and behaviors, including description of progression)
- Level of consciousness
- Signs and symptoms after the seizure stopped (post-ictal events)
- Child's memory of events

- The child has one seizure after another without regaining consciousness between the seizures
- The child has sustained serious injuries

If this is the child's first seizure, or if the child is experiencing status epilepticus, emergency care is warranted to treat, monitor, and stabilize the child's condition.

Treatment of the child with status epilepticus includes rapidly treating the seizure itself, treating the underlying cause, and providing supportive care. Almost simultaneously in an emergency setting, an airway is secured, cardiac status is evaluated, vital signs are measured, an intravenous line is established, blood is drawn, antiepileptic drugs are given, and diagnostic tests are completed. Blood is usually drawn to obtain glucose level, complete blood count, electrolytes, calcium, magnesium, phosphorus, and antiepileptic drug levels (if appropriate), and for blood culture. Intravenous glucose is administered, using a 2-mL/kg dose of 25% glucose in children and a 5-mL/kg dose of 10% glucose in infants younger than 6 months.

Pharmacologic Interventions

In treating status epilepticus, the most common mistake is failing to give a sufficient amount of drug early enough. In the acute care setting, first-line therapy is a benzodiazepine (lorazepam as first choice) given intravenously, followed by phenytoin or fosphenytoin, then phenobarbital, valproate, or levetiracetam. If intravenous access cannot be established, diazepam rectal gel may be used. If the seizures persist, an infusion of midazolam, pentobarbital, or propofol may be started (Costello & Cole, 2007). Monitor electrocardiogram and blood pressure closely while administering medications. Immediately treat any identified abnormalities. After early aggressive treatment has brought status epilepticus under control, maintenance therapy is initiated. Antiepileptic drugs are always tapered in dosage to the point of complete withdrawal; the drug should not be stopped suddenly. Further information on maintenance antiepileptic drug therapy can be found in the discussion of epilepsy.

The dosages of antiepileptic drugs used to treat status epilepticus cause decreased responsiveness, with the potential for ineffective breathing patterns and ineffective airway clearance. Less common but more serious reactions may include allergic and other idiosyncratic responses. Nursing care involves monitoring serum drug levels and seizure activity; laboratory testing; monitoring oxygenation, vital signs, and lung sounds; assessing the adequacy of breathing patterns; and airway clearance. To minimize aspiration and airway problems, position the child in a side-lying position and turn every 2 hours.

Safety Measures

Protect a child undergoing a seizure from falls and injuries, aspiration pneumonia, hyperthermia, and drug side effects. Children with seizure-related falls and injuries may have fractures, dislocations, lacerations, or hematomas. Risk also exists for injury secondary to continued seizure activity. Nursing care includes continuous observation of

the child. Institute seizure precautions as indicated, including padding the side rails, keeping the bed in the lowest position with raised side rails, removing harmful objects from the child's environment, and having bag-valve-mask ventilation and suction readily available. In addition, administer medications as ordered, monitoring the child for possible side effects and checking drug levels as ordered. Teaching the child and parents about precipitating factors, medications, use of a MedicAlert identification, and basic seizure management are also important to maintain the child's safety (Community Care 21-1).

Aspiration pneumonia can occur from choking on food or other objects in the child's mouth, or from aspiration of vomitus. Nursing care may include suctioning, positioning of the child in a semiprone or side-lying position, monitoring vital signs and lung sounds, inserting a nasogastric tube, and ensuring that the child is NPO until he or she has recovered from the seizure and from the depressant side effects of antiepileptic drugs, and gag and swallow reflexes are adequate.

Hyperthermia may occur as a symptom of CNS infection, or it may occur as a result of continued status epilepticus, especially when motor symptoms are involved. Nursing care may include keeping the child in minimal, light clothing; giving tepid sponge baths; monitoring temperature; and using cooling devices.

Supportive Care

The level of self-care deficit depends on the type of seizure and how consciousness and responsiveness are affected. If the child is unconscious, nursing care includes providing adequate fluids and nutrition, starting with NPO status, intravenous fluids, and enteric feeding until the child recovers, then progressing to oral food and fluids as tolerated. Assess skin integrity, turn and position at least every 2 hours, provide hygiene related to urine and bowel incontinence, eye care if the eyelids do not shut, and oral hygiene.

Epilepsy

Epilepsy is a chronic condition characterized by recurrent seizures, but the terms *seizure* and *epilepsy* are not synonymous. Many types of seizures do not fall under the classification of epilepsy. Epilepsy has numerous causes and is not a single disease entity; rather, it is an indication of brain dysfunction.

Epilepsy may be the only evidence of an underlying brain abnormality, or it may be one of many symptoms. The younger the child at the onset of symptoms, the greater the likelihood that the cause of the disorder will be identified. A familial predisposition to epilepsy appears to exist. Evidence from sibling, offspring, and twin studies points to a genetic component, although it is poorly defined. In most cases, epilepsy is idiopathic (without an identifiable cause).

Epilepsy syndromes are defined as clusters of signs and symptoms that tend to occur together. They are classified as focal or generalized, and as idiopathic or symptomatic (associated with a known disorder). Identifying a specific

COMMUNITY CARE 21-1

Safety for the Child With Poorly Controlled Seizures

General

- Have the child wear a MedicAlert bracelet.
- Keep emergency treatment medication readily available, if prescribed.
- Teach care providers outside of family about child's condition and treatments.

Falls and Injury Prevention

Increase safety of child's environment:

- Remove potentially harmful objects from child's environment (sharp corners, objects).
- Use carpeting and padding.
- Place barriers at open stairways.
- Use chairs with arms.
- Have child wear a protective helmet.
- Have child avoid stairs or use with supervision.
- Allow child to participate in age-appropriate activities with appropriate safety equipment (e.g., bike

helmets, elbow and knee pads); do not allow participation in antigravitational activities (e.g., wall/rope climbing, monkey bars).

Water Safety

- Have the child bathe with supervision, using minimal water levels, and pad the fixtures.
- Allow older children to shower if preferred when a responsible other can routinely check on their safety. Leave the door unlocked.
- Ensure that the child swims under lifeguard supervision with a buddy.

Sleep Safety

- Use low bed, away from furniture.
- Use thin pillow and minimal padding in sleep area (pillows, stuffed animals, comforters).
- Use infant monitor.

epilepsy syndrome is helpful in making treatment decisions and determining prognosis. Some epileptic syndromes include the following:

- **Benign rolandic epilepsy:** One of the most common syndromes; usually occurs between 4 and 11 years of age, typically in boys. Characterized by partial seizures at night (described as tingling sensations on the side of the face), inability to talk without loss of consciousness; possible secondary generalization; normal neurologic examination, typically with normal development and intelligence in child. There often is a positive family history. An EEG demonstrates a distinctive diagnostic pattern. Antiepileptic agents (carbamazepine) are given only if seizures occurring frequently or during the day.
- **Infantile spasms:** Age-dependent epilepsy syndrome, usually between 3 to 12 months of age. Characterized by clusters of myoclonic seizures. Cause is known (symptomatic, such as neurocutaneous disorders, brain malformations, metabolic and degenerative diseases) or unknown (cryptogenic). Seizures consist of sudden flexor or extensor movements of the neck, trunk, and extremities, and occur in clusters of up to 100 spasms. It is possibly difficult to differentiate from colic or a startle reflex. An EEG will demonstrate a distinctive pattern called *hypsarhythmia*. Is associated with developmental delay, although early treatment may lead to improved development. Spasms are resistant to conventional antiepileptic medications, and treatment usually consists of daily intramuscular injection of adrenocorticotropic hormone with potential side effects (hypertension, hyperglycemia, and gastrointestinal bleeding).

West syndrome is a subtype of infantile spasms with a triad of symptoms: infantile spasms, mental retardation, or developmental delay and hypsarhythmia on EEG.

- **Lennox-Gastaut syndrome:** Is characterized by multiple seizure types including tonic, atonic, atypical absences, and episodes of tonic and nonconvulsive status epilepticus with an onset usually between ages 1 to 7 years. Multiple causes are associated with this syndrome, but most children have a brain lesion. EEG demonstrates a typical pattern of slow spike and wave. Most children have cognitive deficits. Seizures are highly resistant to treatment and require multiple medications.

Assessment

A diagnosis of epilepsy is made on the basis of clinical data and historical information. A specific history obtained from someone who witnessed the seizure is extremely helpful in establishing the diagnosis. An EEG can provide supportive evidence and can aid in classification and treatment of the disorder. Indications for further workup may include failure of medications or specific findings on the neurologic examination that indicate an underlying brain abnormality.

Interdisciplinary Interventions

The child with epilepsy requires intervention from an interdisciplinary health team. From acute to chronic care, nurses are often the best resource for organizing, planning,

CLINICAL JUDGMENT 21-1

The Child Who Presents With Seizures

Four-year-old Dwayne is brought to the clinic by his mother because he had a seizure earlier in the morning. His mother describes the seizure as jerking movements of the arms and legs with drooling from the mouth. Dwayne was very tired after the seizure and fell asleep. Dwayne has had three similar episodes in the past, so his mother decided to wait until he awoke to come to the clinic. His previous seizures occurred when he was 1 year, 2½ years, and 3½ years old. All these seizures were associated with a fever and illness. Dwayne has had a cold for the past 4 days. His mother has not taken his temperature, but has been giving him acetaminophen because he felt warm.

Questions

1. What other information would you collect from the mother at this time?
2. What type of seizure might Dwayne be exhibiting?
3. Dwayne has an EEG that reveals consistent findings for the diagnosis of epilepsy. He will be placed on an antiepileptic medication. What nursing diagnosis would you select to reflect the family's teaching needs at this time?
4. When Dwayne returns to the clinic 1 month later, what data should be reviewed with the family?
5. What information would help you determine that Dwayne and his family are responding well to his treatment plan?

Answers

1. More information regarding diagnostic tests and treatment measures that occurred when Dwayne had other seizures; family history of seizures; Dwayne's ability to meet age-appropriate developmental milestones; history of recent ear infections, other illnesses, or immunizations; medications he is taking. Ask mother to provide more details of when the seizure occurred, how long it lasted, the child's responsiveness during and after the seizure, and behaviors seen during the seizure.
2. Simple febrile seizure, complex febrile seizure, exposure to medications or toxins, or epilepsy
3. Deficient knowledge: Management of epilepsy, or health-seeking behaviors: Management of epilepsy
4. Review parent and child's perception and understanding of diagnosis, treatment plan, and future course of illness; discuss the importance of monitoring the child's development. Review medication schedule, dosage, and side effects. Review parental interventions if Dwayne has another seizure. Determine whether other child care providers are prepared to assist Dwayne if he has a seizure when in their care.
5. Family reports medications are given as scheduled with no difficulty encountered in refilling the prescription as needed, family attends all scheduled clinic visits, Dwayne has no seizure activity, drug levels are within therapeutic ranges, and Dwayne continues to progress well developmentally

and evaluating the complexities of epilepsy management. The manifestations of this condition are frightening, yet most pediatric epilepsies can be successfully controlled.

Management of the child with epilepsy includes managing seizures, educating the family and the child, and addressing associated emotional or learning disabilities (Clinical Judgment 21-1). Treatment with medications is the mainstay of epilepsy management. Alternative therapies, including surgery, ketogenic diet, or vagal nerve stimulation may be options for the child with seizures that are unresponsive to drug therapy. Supportive care is discussed in the section on seizures.

Pharmacologic Interventions

The goal of drug therapy is optimal seizure control with minimal side effects (see [thePoint](#) for Medications and Administration: Antiepileptic Medications). Drug treatment typically begins with one antiepileptic agent, and the dosage is increased gradually until seizures are

controlled, clinically important toxicity is experienced, or serum drug levels reach the high end of the therapeutic range without controlling the seizures. If the first drug is ineffective, a second is added, or another drug is tried. Pay careful attention to the potential for drug interactions when the child is being treated with more than one medication. During this process, ensure that the child and family are aware of the need to report changes in sensation and behavior that may signal a toxic reaction, and that they understand the importance of close follow-up care. Assess serum blood levels frequently until it is determined how the child metabolizes a particular drug.

Antiepileptic therapy is usually continued until the child has been seizure-free for 2 or 3 years and the EEG is normal. Antiepileptic medications must be tapered and not stopped abruptly.

Surgical Interventions

Epilepsy surgery may be indicated for children with intractable or uncontrolled seizures who have not gained

seizure control after therapeutic trials with the most appropriate antiepileptic drugs. In the absence of a tumor causing the epilepsy, the epileptic focus is removed. Such children should be referred to a medical center for a comprehensive epilepsy evaluation. Prolonged EEG monitoring with surgically implanted depth electrodes or an electrode grid may be required to more clearly define the epileptogenic focus. Potential candidates for lobectomy may also undergo an intracarotid amobarbital test (WADA) angiogram to localize the speech center. Neuropsychological testing as well as evaluations with psychologists and speech, physical, and occupational therapists are usually completed. Appropriate medical selection of the children who may benefit from this procedure is essential. Seizures must be focal, intractable to medical management, and must arise from an area of the brain that could be removed without significant neurologic deficit.

Alternative Therapies

Alternative therapies such as the ketogenic diet have been used to treat refractory epilepsy. This diet has been found to be especially effective for myoclonic epilepsies, but it is effective for other types of epilepsy as well. It is often tried for seizures associated with Lennox-Gastaut syndrome, with varying results. Because the ketogenic diet is high in fat and low in carbohydrates, monitoring the child carefully for hypoglycemia and ketonuria is essential. The diet requires commitment by the family, because it is very restrictive. Use of less restrictive diets such as modified Atkins or low-glycemic index diets show promise as effective in managing epilepsy (Kang & Kim, 2006; Kossoff, McGrogan, Bluml et al., 2006).

Electrical Therapies

Vagus nerve stimulator therapy controls seizures by delivering an intermittent electrical impulse to the brain. A pacemakerlike device, implanted under the skin in the left chest, sends mild, intermittent electrical impulses through a lead to the left vagus nerve, which then sends signals to the brain.

Community Care

Family members must make a commitment to maintain close medical follow-up through outpatient clinic visits, to consent to periodic diagnostic evaluations, and to comply with recommended drug therapy. Education should be an ongoing, individually tailored process. Because of the chronic nature of epilepsy, the plan of care must allow for changes based on physical growth and emotional maturation. Siblings and extended family may provide valuable support if they are included in the overall treatment regimen.

Educating children and their parents is crucial to seizure control. Children want to know as much as their parents and to have information presented at their level (McNelis, Buelow, Myers et al., 2007). Parents want to know about all aspects of the conditions. In one study, parents felt that they were not given enough information

about the condition, treatment plans, or medications; and felt that information should be given over time (McNelis, et al.). Provide parents with information about the child's seizure type, events that can trigger seizures, seizure recognition, initial seizure management, medications, and the potential effect of seizures and medication on early development and behavior (TIP 21–2). Also include teaching about status epilepticus and need for emergency care.

The Epilepsy Foundation of America (see [thePoint](#) for Organizations) offers a comprehensive teaching and support program, and can provide information appropriate for children, parents, and teachers in both English and Spanish.

Although most children with epilepsy have normal intelligence, comorbid conditions such as attention deficit hyperactivity disorder, depression, and anxiety may occur. These may result from the epilepsy itself, or they may be side effects from antiepileptic drugs. These conditions affect the child both at home and at school, and can influence academic success considerably. Upon parental request, facilitate a conference with school staff to identify the child's specific needs and treatment plan, and to alert the school staff of any potential side effects of medications. The child may qualify for special education services under the Individuals with Disabilities Education Act. Adaptations may have to be made in the educational plan so that the child can succeed (see Chapters 2 and 12).

Encourage the family to provide a MedicAlert bracelet for the child to wear at all times. A helmet may be necessary for children with kinetic, or “drop,” seizures or for those children with substantial delays in motor development. Encourage parents to focus attention on well siblings who may have unexpressed fears about the disease or may harbor guilt or anger toward the affected sibling.

Breath-Holding Spells

Breath-holding spells are the voluntary cessation of breathing in response to a painful, noxious, or frustrating stimulus. This nonepileptic paroxysmal event may resemble seizures. Breath-holding spells, although dramatic, are considered to be benign. If prolonged, however, they can lead to unconsciousness or convulsion. These spells are most common in children 1 to 3 years of age. In the child older than 6 years of age, breath-holding spells are unusual and require further investigation.

Pathophysiology

Two types of breath-holding spells occur: pallid and cyanotic. Pallid breath-holding spells are vagally mediated events that follow a trivial, unpleasant stimulus such as a bump on the leg or a mild injury to the head. A sudden collapse, pallid color, diaphoresis, and rigid posture with a few extremity jerks are typical. After the precipitating event, the child may lose consciousness. The hypersensitive vagal response also results in bradycardia and, sometimes, asystole. Crying is usually not noted. Sleep may follow the episode.

TIP 21–2 A Teaching Intervention Plan for the Child With Epilepsy

Nursing diagnoses and outcomes

Risk for injury related to hypoxia, aspiration, and loss of or impaired consciousness

Outcomes:

- Child will remain free from injury, aspiration, or respiratory distress during a seizure.

Deficient knowledge: Medications, diet, and management of child during a seizure

Outcomes:

- Family administers medications safely to the child.
- Family verbalizes side effects of medications.
- Family identifies when treatment plan is not controlling child's seizures.

Teach the child/family

Management of the Child During a Seizure

- Refer to Interventions section in Nursing Interventions 21–2.
- Remove sharp objects and hazards from area around the child.
- Loosen tight clothing.
- Do not put anything into the child's mouth.
- Remove the child's eyeglasses to prevent injury to face.
- Allow seizure to end without interference.
- After the seizure, position the child in side-lying position with head in a midline position. Do not hyperextend the neck. If child vomits, carefully turn the child to the right side to prevent aspiration.
- Observe and document details of the child's seizure, including activity before, during, and after; date, time, and length of episode; and child's physical status during seizure (e.g., incontinence, difficulty breathing, paralysis, loss of consciousness).
- Observe the child's respiratory status during seizure. If breathing becomes impaired, call for emergency medical assistance.

Preventing Seizures

- Give medications as ordered. Consistent drug therapy is critical.
- Avoid events, activities, or stimuli that trigger seizure activity.
- Inform teachers or daycare providers about child's condition and how to intervene if a seizure occurs.

Medications

- Ensure that family knows names of drugs, amount, time to be administered, why they must be given consistently, why antiepileptics cannot be stopped abruptly, and possible side effects.
- Monitor for side effects such as drowsiness, lethargy, ataxia, nystagmus, and gastrointestinal upset.
- Take the child to the healthcare provider for scheduled evaluations of therapeutic drug levels and blood counts.

Nutrition

- Provide instructions regarding ketogenic diet if used for seizure control.
- Encourage adequate intake of vitamin D and folic acid if child is taking phenytoin or phenobarbital.

Activity

- Be aware of the need for possible activity restrictions depending on frequency of seizures and degree of seizure control that is maintained.
- Provide supervision during activities such as swimming or bicycle riding.
- Avoid having the child become overtired.

Contact Healthcare Provider if:

- Child experiences an increase in seizure activity
- Child is lethargic or listless
- Child has a high fever
- Child is experiencing depression or negative feelings about self because of seizure disorder
- Child experiences breathing difficulties during a seizure

Cyanotic breath-holding spells are more complex events, precipitated by anger or frustration. In the midst of crying, the child stops breathing during expiration, to the point of cyanosis. Cerebral oxygenation decreases, and loss of consciousness follows. There may be associated clonic movements of the extremities.

Pallid and cyanotic breath-holding spells are differentiated from seizures by the events that trigger the spell, time of occurrence (never during sleep), and the progression of events (Table 21–2). EEG is normal between attacks. During an episode, the EEG may show diffuse slowing with rhythmic slowing during the tonic-clonic

activity. In both types, cardiac evaluation may be warranted because prolonged QT syndrome or other cardiac events may be the cause (Akalin, Turan, Guran, et al., 2004). Iron-deficiency anemia and autonomic dysregulation may also contribute to breath-holding spells (Kolkiran, Tutar, Atalay, et al., 2005). Breath-holding spells usually resolve spontaneously, without sequelae.

Interdisciplinary Interventions

Treatment for breath-holding spells is not usually necessary. The child may be treated with iron, which has been

TABLE 21-2

Differentiating Breath-Holding Spells From Seizures

Characteristic	Breath-Holding Spell	Seizure
Age at onset	6–18 months	Variable depending on cause
Precipitating event	Cyanotic spell: frustration, anger Pallid spell: minor injury, fear	Rarely noted
Crying at onset	Typically present	Not typically noted
Cyanosis	Typically present at onset	Rare at onset of seizure, may occur if seizure is prolonged
Convulsive activity	Occasionally seen	Typically noted
Incontinence	Never	Sometimes occurs
Level of consciousness	Unconscious	Unconscious
Postictal confusion	Uncommon	Common, lethargic, sleepy
Physical examination	Typically normal Bradycardia	Variable Tachycardia
EEG	Typically normal	Typically abnormal

demonstrated to decrease the number of spells (Boon, 2002).

If unconsciousness occurs during either type of breath-holding spell, carefully place the child on the floor on his or her side to prevent aspiration. These events may be very frightening, and parents require explanation and support. Focus family interventions on behavior modification and assisting the child to express anger and frustration in other ways. Advise parents of normal developmental parameters and suggest they not give undue attention to the child after the breath-holding event, because attention may unintentionally reinforce continued demonstration of these behaviors.

Headaches

Headaches are a common neurologic symptom in childhood; about 75% of children have a significant headache by age 15 years (Hershey, Winner, Kabbouche, et al., 2007). Children experience a variety of different headache types, including tension headache, migraine headache, and chronic daily headache.

In general, the term *headache* is used to describe pain or discomfort in the skull or facial structures, because the brain has no pain receptors. The pain is referred from dura, from blood vessels (traction), from dilation of blood vessels, or from sustained contraction of muscles.

Headaches are broadly classified as primarily neuronal (migraine or tension type) or secondary to another process (brain tumor, increased ICP, infection) (Table 21-3). Headaches are described as acute, resulting from an acute illness such as meningitis or subarachnoid hemorrhage; acute recurrent, caused by migraine; chronic progressive,

caused by intracranial hypertension or tumor; and chronic nonprogressive, possibly caused by muscle contraction (tension). The acute or chronic progressive headaches are of the most concern as potential indicators of underlying neurologic problems. In children, documentation of a specific cause, such as tumor or stroke, is uncommon.

Assessment

Conduct a complete clinical history and examination. Characterizing a headache helps to define the cause (e.g., tumor, tension, migraine). Headaches associated with meningitis or subarachnoid hemorrhage are often described as bursting, with a rapid progression of pain that radiates down the neck and spine. The chronic progressive headache of intracranial hypertension usually presents as aching and throbbing, which is increased by coughing or straining and is present on arising in the morning. Both acute headaches and those associated with intracranial hypertension are associated with other neurologic symptoms, such as papilledema or alterations of consciousness. Muscle contraction (tension-type) headaches are described as bilateral, manifesting diffuse tightness or pressure in a bandlike distribution.

Assessment of the child begins with a detailed history of the child's condition (Focused Health History 21-2) to evaluate the characteristics of the headaches and to distinguish any findings that may indicate pathologic abnormality. Indicators such as a recent onset or recent increase in frequency or severity; an occipital or consistently localized headache; head trauma accompanying the headache; behavioral, personality, or gait changes accompanying the headache; or complaints that the headache interrupts sleep, is exacerbated by changes in position, or

Headaches in Children

Primary Headaches		Secondary Headaches				
	Migraine	Tension Type	Traumatic	Rebound	Infectious	Structural Disorder
Etiology	Primarily a neuronal process, trigeminal activation, hyperexcitable cerebral cortex Likely genetic basis Production of norepinephrine and serotonin resulting from stimulation of brain structures leading to inflammation of pial and dural blood vessels, and stimulation of the trigeminal nerve, and pain	Pathophysiology poorly understood Probably a combination of muscular and central emotional factors	Head or neck trauma; hemorrhage	Substance use/withdrawal: alcohol, drugs, carbon monoxide exposure Medication overuse (e.g., analgesics)	Intracranial infection; occasionally systemic infection	Increased ICP, neoplasm, arteritis, teeth, sinus or vision disorders
Epidemiology	Occurs at any age, but frequency increases with age. Before puberty, boys more than girls; after puberty, more frequent in girls Atypical migraine variants more common in younger children	Older children	Any age	Older children	Younger children	Any age
Characteristics	Without aura more common in children; unilateral, pulsating, intense pain aggravated by routine physical activity, associated with anorexia, nausea, vomiting, photophobia, phonophobia, overall feeling of exhaustion; relieved by sleep Abdominal symptoms more frequent in children than adults	Bilateral, nonpulsatile, pressing/tight quality, intensity mild or moderate	May be present without obvious sign of trauma Neurologic signs: altered mental status, abnormal eye movement, optic disk distortion	No typical qualities	Diffuse continuous pain, aggravated by straining, nausea, or focal neurologic signs	Diffuse pain, with increased ICP is often worse in morning with associated vomiting (no nausea); symptom onset may be gradual Head circumference may increase if fontanelles not fused
Management	Prophylaxis: regular schedule for sleep, meals, exercise Avoidance of caffeine and trigger foods Biobehavioral: biofeedback, relaxation, cognitive control of stress, acupuncture Acute treatment: analgesics, triptans, biobehavioral methods as noted earlier, sleep	Over-the-counter analgesics, sleep, biobehavioral interventions, as under Migraine	Manage trauma	Eliminate exposure to toxin (or offending agent) Decrease frequency of analgesic use	Treat infection: antibiotics for bacterial	Manage structural disorder

FOCUSED HEALTH HISTORY 21–2

The Child With Headaches*

Acute History

- Recent illness
- Injury
- Change in sensory perception or mobility
- Diet or weight change
- New medication or oral contraceptive use
- Level of activity
- Onset of puberty or menses

Chronic History

Pertinent past history of

- Illness, infection, surgery
- Developmental abnormalities
- Dental problems
- Alcohol or drug use
- Allergies
- Visual disturbances or corrections
- Diet, include caffeine and sugar intake
- Sleep patterns
- Family history of migraine or other disorders

Psychosocial Factors

- Perceived stressors
- Scholastic ability
- Feelings of depression or sadness
- Changes in lifestyle
- Concept of self
- Affect
- Appearance
- Relationship with family and friends
- Social activities and hobbies
- Nonverbal cues
- Family history of headache and effect on patient
- Patient's perception of significance of headache (e.g., fear of cause, outcome, diagnosis)

- Past experience with hospitals or healthcare providers
- Identification of other person in the patient's confidence

Headache Data

- Location
- Duration
- Frequency
- Quality
- Time of occurrence
- Severity
- Accompanying symptoms
- Treatment attempts
- Outcome of treatment
- Documentation of headache pattern
- Presence or lack of prodromal warning (aura)

Pain Assessment

- Type of pain
- Pattern of progression or intensity
- Identification of factors that make pain worse or better
- Specific causes related to headache pain (e.g., bright lights, foods)
- Biobehavioral therapy and effectiveness
- Medication and effectiveness
- Patient's experience with other types of pain

Identification of Headache Triggers

- What factors seem to start headache? Activity, foods, medication, menses, specific stressors, change in environment or seasons, work or school atmosphere?

*This history is focused on headaches. See Chapter 8 for a comprehensive format.

occurs on arising and is accompanied by vomiting and then fades; or headache in a child younger than 3 years of age warrant immediate evaluation.

When examining the child with headaches, include a neurologic assessment, percussion of the sinuses, and notation of blood pressure. Evaluate visual acuity and listen for cranial bruits. The presence of a bruit warrants further investigation. Children with tension or migraine headaches usually have a normal physical examination.

Diagnostic Tests

Extensive diagnostic investigation is required in acute and chronic progressive headaches to rule out brain

tumors or meningitis. This investigation would include neuroimaging and possibly CSF examination.

Nursing Diagnoses and Outcomes

Nursing Plan of Care 21–1 presents a variety of nursing diagnoses that can be applied to the child with a neurologic condition. The following diagnosis also applies specifically to the child with headaches:

Acute pain related to effects of pathology

Outcomes: Child will not experience pain from headaches. Child and family will use measures to reduce factors that precipitate onset of headaches.

Child and family will implement pain control measures to reduce child's discomfort.

Interdisciplinary Interventions

The goal of therapy is to stop the headaches (see Table 21–3). Treatment for acute or chronic progressive headaches focuses on treating the underlying organic cause and most likely requires hospitalization to provide healthcare interventions such as surgery, ICP management, or intravenous antibiotic therapy. Management of chronic, nonprogressive headaches usually includes administering mild analgesics and teaching stress management techniques. Treatment of migraines involves using medications and behavioral management, as well as teaching patients to avoid headache triggers.

Pharmacologic Interventions

Symptomatic medications (analgesics) to manage pain are available in both over-the-counter and prescription forms. They are most effective if taken at the first sign of a headache. Exercise caution if giving acetaminophen or aspirin to children. Excessive doses of acetaminophen have been linked to hepatic toxicity. Salicylates, such as aspirin, contribute to Reye syndrome. Acetaminophen, ibuprofen, and aspirin are contained in many combination over-the-counter medications. Teach parents that they must read medication labels and not exceed the recommended dose. Acetaminophen and ibuprofen should not be taken more than two to three times a week, because of the risk of rebound headache (see Table 21–3) and the development of chronic daily headache.

Pharmacologic therapy for migraine consists of three basic approaches: symptomatic (as noted earlier), abortive, and preventive. *Abortive* medications modify migrainous changes in blood vessels and are usually ergot alkaloid preparations. Cafergot is an ergotamine tartrate medication. The most common side effect is nausea and vomiting, which can be treated with antiemetics. Triptans are serotonin agonists that are available in multiple types of preparations (nasal spray, disintegrating tablets, tablets, or injectable). As with many medications, the U.S. Food and Drug Administration has not approved either class for use in children, but they are often used off label (see Chapter 9).

Alert! Teach families that triptans and ergot preparations should not be used within 24 hours of each other, because their vasoconstrictive effects are additive and may result in prolonged vasospasm, which could cause brain infarct.

As with symptomatic medications, it is important that abortive medications be taken as soon as the aura or the headache starts. If the medication is not taken until the headache is well established, it is less likely to relieve the pain.

Preventive therapy is instituted if the frequency of headache has a significant effect on the child's daily life.

Preventive therapy includes use of daily doses of tricyclic antidepressants, calcium channel blockers, beta blockers, alpha-agonists, or antiepileptics. Preventive medications gradually decrease the frequency and intensity of the headaches and may take 4 to 6 weeks to be fully effective. Ensure that the family understands that such medication must be taken every day, not just when the child is experiencing headache. Preventive medications are gradually discontinued several months after the headaches stop.

Biobehavior Management

Headache pain can be incapacitating and may cause children to lose valuable time in school and social activities. A wide variety of foods and other substances are known to be migraine triggers (see [thePoint+](#) for Supplemental Information: Foods and Products Associated with the Onset of Migraine). Use a headache calendar or diary to assist the family in identifying which substances and activities may be acting as triggers. Avoiding these substances may prevent recurring headaches. If stress is a major factor in triggering headaches, suggest supportive counseling through hospital, school, community, or religious resources. School attendance should be mandatory. Encourage parents to arrange for medication to be available at school and, with parental permission, provide information for school personnel so they understand the importance of providing the medication as soon as the headache starts. Enlist the support and observation of school counselors. If the child needs to remain at home, encourage bed rest, with a return to school the same day if the headache recedes. Teach the family to give minimal attention to the headache, to avoid creating a situation in which the child uses headaches to draw unnecessary attention or as a means to avoid school.

Other interventions include providing a dark, quiet environment. Therapeutic touch or massage therapy may help. The use of biofeedback mechanisms is also useful and may help avoid heavy use of pharmaceuticals.

Provide education to the child and parents regarding types of headaches, preventive measures, and judicious use of medication. If the child requires acute pain management, pharmacologic interventions must precede implementation of the longer term strategies. Teach the child to maintain a regular schedule of sleep, intake (do not skip meals), and physical activity; and to limit caffeine consumption and avoid smoke (both active and secondhand).

Neural Tube Defects (NTDs)

Most CNS anomalies present at birth result from abnormalities in the formation of the neural tube or disordered development of neurons in the fetal brain. Others result from abnormal formation of the bony covering of the nervous system. Many of these anomalies are genetic. The most serious defects involve large portions of the spinal column and brain. Smaller defects may be limited to specific areas. Severity of the anomaly is related to its location, size, and degree to which the nerve tissue is

TABLE 21-4

Common Neural Tube Defects

Type	Description	Outcomes
Anencephaly	Failure of anterior neural tube closure, resulting in only rudimentary development of the brain stem and basal ganglia with no bony covering of the dorsal skull area	Sustained extrauterine life is virtually impossible; most stillborn; remainder die during neonatal period.
Encephalocele	An external sac or mass that may occur at any point over the vertex or base of the skull May be covered with either scalp or a transparent membrane	Dependent on presence of hydrocephalus, infection, actual rupture of the encephalocele, and amount of neural tissue in sac.
Spina bifida cystica	Incomplete fusion of one or more vertebral laminae, resulting in an external protrusion of the spinal tissue; occurs most commonly in lumbosacral area Myelomeningocele: protruding saclike structure contains meninges, spinal fluid, and neural tissue Meningocele: protruding sac contains meninges and CSF	Spinal roots may terminate in sac, which significantly affects motor and sensory function below that point. Neurologic complications are less severe than in myelomeningocele.
Spina bifida occulta	Incomplete fusion of vertebra at one level that may be signaled only by an overlying dimple or tuft of hair	Usually there is no evidence of dermatologic, neurologic, or musculoskeletal disorders. It may present with some of these problems in late childhood.

involved. Neural tube defects (NTDs), hydrocephalus, Chiari malformation, microcephaly, and craniosynostosis are examples of congenital disorders discussed in this chapter.

Defects in the formation of the neural tube (neurulation defects) result in **dysraphic defects**: structural malformations of the brain and spinal cord arising from an interplay among genetic and environmental factors. Anencephaly, encephalocele, and spina bifida are examples of dysraphic defects resulting from incomplete closure of the neural tube. Thus they are termed *neural tube defects* (Table 21-4).

Since the introduction of folic acid supplementation, the overall prevalence of NTDs has decreased during the past three decades. In addition, antenatal testing procedures can be used to detect NTDs early, permitting termination of the pregnancy if desired.

The cause of NTDs is multifactorial. NTDs may occur as a result of various chromosomal aberrations or after fetal exposure to teratogenic drugs, but exact reasons for abnormal closure of the neural tube remain unclear. Factors associated with NTDs include

- Poor nutrition: Folic acid deficiency; in addition, zinc and generalized vitamin deficiencies are thought to be contributing factors, as is maternal obesity
- Maternal age: Adolescents and women older than 35 years are at greater risk for newborns with NTDs
- Pregnancy history: Women who miscarry during the pregnancy immediately preceding the current pregnancy are thought to be at higher risk

- Birth order: Firstborn children are at highest risk
- Socioeconomic status: The prevalence of NTDs is higher in groups with low socioeconomic status, possibly because of poor nutrition

The increased incidence of NTDs in siblings underscores the importance of genetic counseling and proper periconceptual nutrition. Dietary sources of supplemental folic acid seem imperative, particularly in genetically vulnerable families.

Pathophysiology

Malformations of the neural tube usually involve malformations of the laminae and pedicles of the vertebral column. The formation of the bony vertebral column occurs simultaneously with the formation of the neural tube, except that the vertebral column originates from mesodermal, rather than ectodermal, cells. If the neural tube either fails to close properly on either end or becomes overdistended and ruptures after initial normal closure, then the NTD occurs.

Anencephaly is one of the most severe congenital neurologic anomalies. There is no treatment.

Spina bifida, or myelodysplasia, refers to incomplete closure of the primary neural tube. Of the defects collectively termed spina bifida, 95% are myelomeningoceles, the most severe form of spina bifida. The remaining 5% are meningoceles, and because they do not involve the spinal cord, they may be easier to repair and are often asymptomatic. The most common site of involvement in

the spine is the lower thoracic, lumbar, or sacral area (Fig. 21–3).

Although the pathologic abnormalities observed at the site of the open spinal defect are the most obvious, other abnormalities are often found throughout the brain, spinal canal, and other body systems, such as the genitourinary and cardiovascular systems. The degree of functional impairment associated with the various types of spina bifida depends on the level and the extent of the associated defects. The neurologic findings usually correlate with the particular muscle groups (myotomes) that are innervated by affected spinal cord segments.

Assessment

An infant with anencephaly presents with portions of the forebrain and parts of the brain stem that appear to have little definable structure. The exposed neural tissue resembles a mass of hemorrhagic, fibrotic, degenerated neural tissue, and the frontal, parietal, and parts of the occipital bone structure are usually absent. The physical appearance of the infant is grossly abnormal.

Immediately after delivery of an infant with spina bifida, a team of specialists complete a comprehensive evaluation.

caREminder

In addition to the appropriate delivery room routines, take care to protect the child's spinal or cranial lesion from injury and infection.

As soon as possible, take the infant from the delivery room to the specialty care nursery for close monitoring and examination. A complete physical examination with

attention to the neural tube defect itself, the presence or absence of hydrocephalus, degree of nerve involvement, and motor and sensory functional capacities is needed. The possibility of associated cardiac, renal, or gastrointestinal conditions that might interfere with early surgery must also be ruled out. This evaluation is best accomplished in medical centers with spina bifida teams and may require transporting the infant to a tertiary care hospital.

The defect is examined in regard to size, level, and nature of tissue covering. Any leakage of CSF is noted. The cranial sutures and fontanels are palpated, and head circumference is measured. Development and movement of upper and lower extremities are assessed. An initial evaluation of bowel and bladder function is also carried out.

Assess the degree of neurologic dysfunction. The dysfunction secondary to spina bifida can range from complete paralysis to minimal involvement; most often, it is somewhere in between. A lesion at the middle thoracic level causes total paralysis of the lower extremities. The more common lumbosacral lesions generally leave children with some degree of hip, knee, or ankle flexion, enabling them to walk with either braces and crutches or with minimal assistive devices, depending on the functional level of the lesion. Closed or nonvisible lesions (spina bifida occulta) often go undiagnosed until later in childhood and are frequently not associated with any impairment.

In most lumbosacral lesions, the muscles of the legs are affected, and the electrical responses of these muscles may vary. Sensory disturbances are usually symmetric but patchy. Determine sensory level with a dermatome chart, which is used to delineate areas of skin innervated by each sensory spinal nerve.

Club feet, scoliosis, contractures, and dislocated hips are common in children born with lesions of the lumbosacral area. Bowel and bladder dysfunction such as constipation,

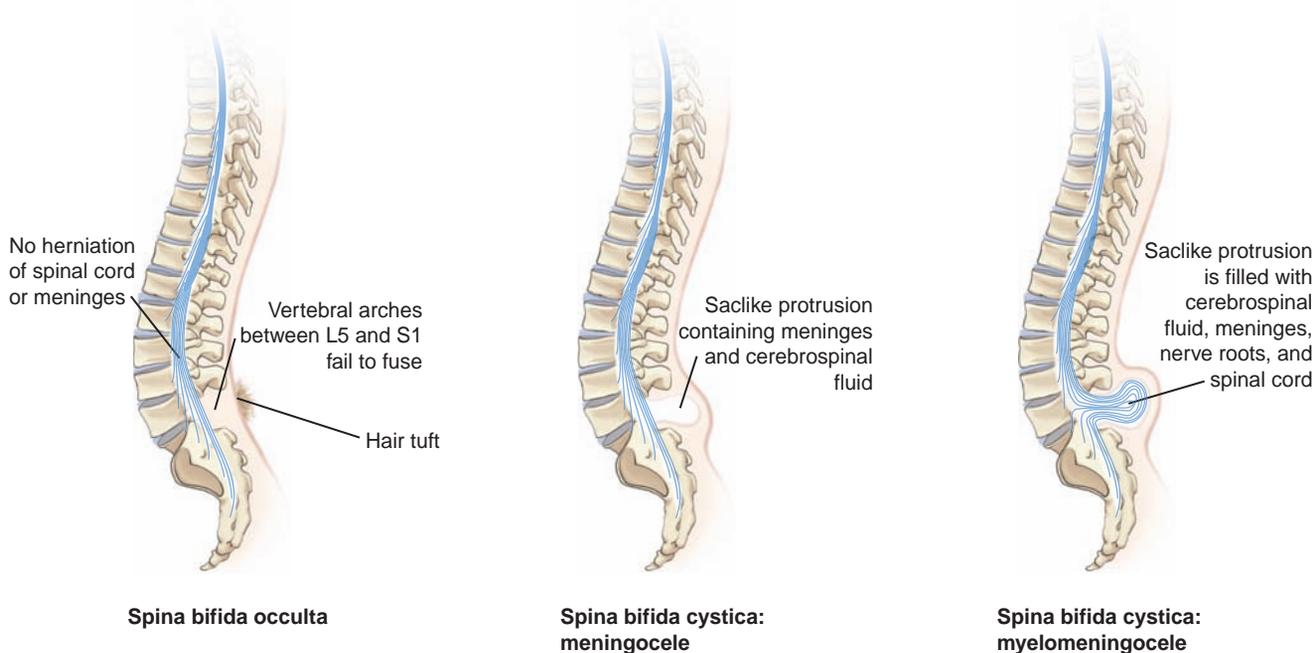

FIGURE 21–3. Malformations of the spine.

incontinence, or urinary tract infections are almost always apparent, because the nerves that supply these organs are located in the sacral area. The clinical manifestations associated with all the lesions of spina bifida are only as clear as the diagnostic assessment of functional capacity.

Diagnostic Tests

As with many NTDs, prenatal diagnosis is possible using assays of fetal amniotic fluid, ultrasonography, or maternal serum to determine elevated maternal serum alpha-fetoprotein concentrations. However, false-positive results may occur with maternal serum alpha-fetoprotein assays, resulting in unnecessary prenatal anxiety for parents.

Measurement of maternal serum alpha-fetoprotein between 16 and 18 weeks' gestation aids in determining NTDs. This level is typically elevated in open NTDs. Level II ultrasonography can determine specific structural defects and is typically performed after detection of high levels of maternal serum alpha-fetoprotein. Three- or four-dimensional ultrasound provides additional clarity. Ultrasonography is also useful in prenatal detection of closed NTDs, in which alpha-fetoprotein levels are not elevated. Amniotic alpha-fetoprotein, which detects a majority of all open NTDs, can be obtained; however, amniocentesis increases the risk of pregnancy loss.

CT or MRI will be performed to delineate the anatomy of the herniated mass. Ultrasound or CT studies of the head are done to determine the degree of hydrocephalus present. Diagnostic studies to monitor urinary tract and renal function may be obtained.

Nursing Diagnoses and Outcomes

Nursing Plan of Care 21-1 identifies a variety of nursing diagnoses that can be applied to the child with a neurologic condition. The following diagnoses also apply specifically to the child with spina bifida:

Risk for infection related to inadequate primary defenses (broken skin), sequelae of invasive procedures (shunt placement)

Outcomes: Child's lesion or incision will remain protected to prevent infection (e.g., meningitis, urinary tract infection, decubitus).

Child will be free from urinary stasis.

Child will be free from breaks in skin integrity.

Bowel incontinence related to effects of decreased innervation of lower intestinal tract

Outcomes: Child will not be constipated.

Child will learn measures to control bowel function.

When appropriate for age, child will participate in bowel-training program.

Impaired urinary elimination related to urinary retention associated with decreased innervation of bladder and sphincter

Outcomes: Child will remain free from urinary tract infection.

Child's bladder will be emptied at regular intervals.

When appropriate for age, child will participate in bladder-training program.

Risk for injury related to exposure to latex

Outcomes: Child and family will be able to identify and avoid substances containing latex.

Child will remain free of exposure to latex and will take latex precautions during all healthcare encounters.

Interdisciplinary Interventions

In light of the physical defects, be particularly sensitive in handling the postpartum experience with involved family members. Supportive care is given to the infant with anencephaly until all body functions cease. Social work and pastoral care may provide the most beneficial interventions. Parents will likely require medical and nursing services to answer genetic and physiologic questions. Each family responds to the situation in different ways; assess their needs individually.

Surgical Interventions

Fetal surgery for NTDs, specifically for myelomeningocele, covers the defect with skin to protect it from further damage from contact with amniotic fluid, which may lessen the resulting neurologic deficit. Early results of this approach suggest a lower incidence of hydrocephalus and hindbrain herniation in infants who underwent prenatal closure of the NTD (Sutton, 2008). However, further long-term study and development of fetal surgical techniques are needed before fetal surgery can be considered a treatment option for NTDs.

After birth, early neurosurgical treatment for the child is aimed at preventing infection such as meningitis by surgical reduction and closure of the open lesion. The infant undergoes ultrasound or CT studies of the head to determine the degree of hydrocephalus present. In most cases, a ventriculoperitoneal shunt is placed to aid CSF drainage and to reduce ICP.

Surgical repair of symptomatic spina bifida occulta (see Table 21-4), regardless of the specific anomaly, is undertaken relatively soon after diagnosis, although it need not be an emergency procedure. The primary surgical aim in these cases is to free up the spinal cord, which may be tethered or tied by the defect, so that progressive deterioration of function is arrested.

In cases of encephalocele, the timing of surgical intervention may vary, depending on the size, location, and extent of nervous tissue involvement. Early death is common in severe cases, usually related to complications of hydrocephalus, infection, or actual rupture of the encephalocele. In any of the aforementioned cases, meticulous postoperative care is essential to maintain wound integrity, prevent infection and CSF leaks, and promote timely healing of the repair.

Early operative care for spina bifida cystica (see Table 21-4) focuses on preserving all neural tissue, providing a normal anatomic barrier, and controlling early progressive hydrocephalus. Maintain a sterile, constantly moistened saline dressing on the sac until the surgery is performed, so that it will not dry out. The surgical procedure involves dissecting the exposed sac and closing the dura mater and skin over the preserved neural tissue. Skin

grafting may be performed over the lesion. If hydrocephalus is present at birth, a ventriculoperitoneal shunting device may be inserted at the time of initial closure. If the clinical features of hydrocephalus are not apparent initially, the child should be evaluated for this condition frequently, because hydrocephalus eventually develops in 86% of children with myelomeningocele (Olsson, Dahl, Mattsson et al., 2007).

General Postoperative Management

After surgery, ensure adequate cardiopulmonary function and nutrition, which are essential to wound healing. The child must lie prone for several days postoperatively to avoid pressure on the wound and infection. When the infant is less restricted in positioning and is allowed to be supine, obtain orthopedic, rehabilitative, and urologic consultations to better understand the child's functional capacity. Hip and spine radiographs, renal ultrasound, electrical muscle testing, and auditory testing are commonly done before discharge from the hospital. Close follow-up of fontanel size and head circumference is also important. As for any child, perform normal well-child care routines and monitor infant development; do not let these measures be overshadowed by the special care requirements of these children.

Assist with determining the child's functional abilities, including motor performance and sensory deficits. Perform skin assessment, including observation of incisions from surgical closure or shunt placement and any pressure points or areas of breakdown. Also evaluate bowel and bladder function, monitoring for symptoms of urinary tract infection or bowel obstruction. Assess nutrition, mobility, and psychosocial adjustment of the child and the family to the defect and to its associated problems.

Assess shunt function and monitor for increased ICP. Monitoring for increased ICP includes obtaining serial daily head circumference measurements, checking for bulging fontanels, and noting changes in the child's level of consciousness.

Infection Prevention

During the neonatal period, care of the protruding sac is extremely important. For an encephalocele covered with skin, position the infant to avoid pressure on the lesion. If the encephalocele is in the occipital area, a foam "half donut" may be useful in positioning. The more common lumbosacral spinal myelomeningoceles are usually protected only by a thin membrane. Apply a sterile, saline-soaked dressing after the sac is examined for gross tears or leakage. Rather than being changed frequently, keep the dressing moist with a sterile saline solution at regular intervals. The infant may be placed on a prophylactic broad-spectrum antibiotic if the defect appears to be infected. Take meticulous care to avoid any contamination of the sac by the child's stool and urine. Monitor for signs and symptoms of meningitis, which may include irritability, fever, feeding intolerance, and seizures. Alert the physician if any of these symptoms become apparent.

After surgery, treat the wound aseptically and maintain the child in the prone position for several days to avoid both pressure on the incision and CSF leak. Use a protective barrier drape to prevent contamination by stool or urine and change it when necessary. Frequently change the diaper if the child has continuous urine and stool leakage. Notify the neurosurgeon of any potential wound contamination.

Urinary tract infections are prevented by a bladder program that includes intermittent catheterization or, in more severe cases, surgical diversion techniques to protect the kidneys from infection. Teach the child (when old enough) and parents how to perform intermittent catheterization and how to recognize urinary tract infections. Odorous or cloudy urine, pain on urination, increased irritability, and hematuria are common symptoms. Educate the family to alert the urologic specialist about changes in bladder function throughout the child's developing years.

Skin Care Measures

Prevent pressure ulcers by optimizing skin integrity and avoiding pressure on any at-risk area. Areas that require special attention include the spinal defect area, perianal area, sacrum, knees, elbows, ankles, and any area with diminished sensation. The use of a skin barrier (Duo-Derm or Stomahesive wafer) cut and applied in two parallel strips or a windowpane fashion prevents skin breakdown from continual tape removal when frequent dressing changes are needed after initial closure. After the dressing is changed, pull a barrier drape over the dressing to prevent contamination from stool below the closure. Often the best nursing care for skin breakdown in the anal area is to leave the child's buttocks exposed to air or to use a heat lamp safely to promote drying of the area. Ensure adequate nutrition for the child.

As children grow, teach them to inspect their skin routinely and to avoid skin contact with potentially abrasive or thermal sources to prevent unnoticed skin breakdown secondary to decreased sensation.

Prevention of Latex Allergy

Sensitivity to latex products such as gloves and urinary catheters poses a life-threatening health risk for patients with myelomeningocele. Although only 15% of patients with spina bifida demonstrate a clinical allergy, about 50% are latex sensitive and at high risk of anaphylaxis when exposed to latex (Rendeli, Nucera, Ausili et al., 2006).

caREminder

Carefully screen for latex and rubber allergies in the patient and family.

The incidence of allergic reactions increases with age, because the older child is exposed repeatedly over time to latex products. Consider all children with NTDs as latex sensitive and place them on latex precautions.

The child with latex sensitivity should be premedicated with steroids or diphenhydramine before surgery or diagnostic testing. Have nonlatex products available in operating rooms, emergency departments, and all other settings where care is likely to be given to latex-sensitive children. Help the family understand this risk and supply them with educational materials and latex-free equipment. Chapter 11 discusses the management of latex allergies.

Prevention of Neurologic Injury

Rupture of the fluid-filled sac could lead to immediate death as a result of sudden decompression of CSF from the cranial cavity. Correctly position children with spinal lesions in either the prone or side-lying positions, depending on the function of the child's lower extremities. A flat position is also favored. A cloth roll under the infant's hips in the prone position helps to enable proper alignment of the lower extremities and promotes downward flow of stool and urine away from the open lesion.

Most children with spina bifida manifest hydrocephalus. Many children require the insertion of a shunt during the time of the back closure, whereas others are followed with serial ultrasound examinations and then have a shunt placed, if needed, at a later date. Most children require shunting within the first few months of life.

Assess the appearance and nature of the fontanel, the sutures, and the child's head circumference. Use cardiopulmonary monitoring for infants who do not have shunts in place to evaluate for signs of apnea and bradycardia secondary to increased ICP. Lethargy, feeding intolerance, and seizures are also evidence of increasing ICP and of the need for shunt placement.

Prevention of Orthopedic Injury

Neuromuscular and sensory deficits can lead to orthopedic problems, including scoliosis, kyphosis, hip dislocation, and ankle deformities. Joint stability may be affected by contractures, muscle control, and altered sensation. Teach parents and children which activities are safe and which are potentially risky. As children with this condition become more mobile, teach parents to monitor the child's use of or function of his or her limbs. Hip dislocation and limb fractures may go unnoticed for long periods because of decreased sensation. Encourage routine orthopedic follow-up.

Promotion of Elimination

More than 90% of children with spina bifida have a neurogenic colon. Fecal incontinence and constipation, the two most common problems, are related to the loss of parasympathetic innervation of the colon and the pelvic floor, to the loss of sensation in the rectum, and to the loss of motor innervation of the external anal sphincter. Encourage parents to institute a bowel program in early childhood, incorporating the five elements of timing, diet, exercise, posture, and rectal stimulation. Teach the parents and the child to plan bowel evacuation after a meal and encourage the child to eat a well-balanced diet

that is high in fiber and low in carbohydrates. Exercising the lower portion of the body after the meal and adopting a knee-chest position to put pressure on the abdomen can aid in bowel evacuation. Finally, encourage rectal stimulation with a suppository or by digital stimulation to initiate or to sustain the defecation reflex.

Clean intermittent catheterization for bladder elimination has generally replaced the use of the Credé maneuver (manual pressure applied from the umbilicus toward the symphysis pubis to express urine). Drug therapy with anticholinergic drugs and surgical procedures, including bladder augmentation and placement of an artificial sphincter, are also common. Nursing care includes maintaining bladder programs, teaching parents signs of urinary tract infection, and addressing psychosocial issues related to bladder elimination.

Supportive Interventions

The initial crisis after the birth of the child with an NTD must be effectively resolved if the family is to function well as a unit. This is a time of major crisis for parents as they deal with an unexpected outcome of the pregnancy. Their expectations of a perfect baby are shattered by the reality of the birth defect, by separation from the infant if the infant is transported, and by the critical need for medical intervention. When assessment of the infant is completed, the child's long-term prognosis should be discussed with the family. Emphasize to the parents that surgery does not restore normal neurologic function; it merely preserves existing function.

Allow the parents to grieve by being with them and listening to them. An example of a phrase that might be helpful in eliciting some of their feelings is, "This isn't really what you expected, is it?" or "This whole event must be so overwhelming to you." Give the family honest information about the most immediate aspects of medical care.

As the child heals from the surgery and discharge is planned, assess the family's coping skills and available resources to ensure a successful transition to home. It is normal for parents to continue grieving the birth of a child with a congenital malformation even as they feel relief that their child has recovered from surgery.

The nurse is often the one person who has the knowledge, the skill, and the time to clarify any misconceptions, to repeat any information as necessary, and to assess the family's values and perceptions about NTDs. Assess the family's support system and available resources as well, providing contacts and assistance as needed.

Community Care

Caring for the child with an NTD such as spina bifida is a lifelong commitment for families. The affect of medical costs as well as social and emotional concerns can be overwhelming. Direct care toward maximizing the child's abilities rather than focusing on disabilities (Developmental Considerations 21-3, TIP 21-3).

Although children with spina bifida tend to score in the low average range of intellectual function, they have

DEVELOPMENTAL CONSIDERATIONS 21–3

Teaching Needs of the Child With Spina Bifida

Infancy

Focus teaching toward parents, siblings, and relatives:

- Teach skin care.
- Teach bowel and bladder function.
- Discuss nutrition.
- Discuss signs of increased ICP.
- Discuss activity and mobility.
- Demonstrate methods to promote achievement of developmental milestones.
- Select methods to promote family coping.

Early Childhood

Continue teaching with family, begin including child:

- Continue bowel- and bladder-training program.
- Teach diet and weight management.
- Discuss child's concept of spina bifida.
- Discuss behavior management.
- Teach activities to promote independence and autonomy.
- Consult specialists to maximize mobility (braces, wheelchair).
- Obtain "Handicapped" tags for family cars.
- Discuss availability of preschool or daycare.
- Encourage socialization and age-appropriate activities.
- Encourage use of developmental toys and games.
- Teach skills to adapt home environment for child safety and mobility.
- Perform baseline intellectual function testing.

Middle Childhood

Teach more advanced concepts to child and parents:

- Discuss body image.
- Begin to use more medically correct terminology.

- Encourage discussion of emotions and social supports.
- Encourage peer interaction via summer camp and school groups.
- Plan activities to promote sense of achievement.
- Discuss accomplishments as well as failures.
- Provide teaching and consults to school staff.
- Begin teaching intermittent bladder catheterization.

Parental involvement:

- Outline self-care activities within the child's ability level.
- Assist parents with the child's psychosocial changes.
- Discuss parent's concept of child's progress and needs.

Adolescence

Focus teaching on the adolescent:

- Discuss issues of body image, sexuality, and social interactions.
- Teach self-care regarding bladder emptying, hygiene, and skin care.
- Encourage peer interaction to develop group identity.
- Refer to nutritionist for diet and weight management.
- Discuss theory of personal identity within family structure.
- Suggest patient begin a journal for questions and concerns.

Parental involvement:

- Stress importance of the child's need to be included in decisions.
- Discuss methods to promote independence at home and school.
- Begin transition to adult healthcare facility.

problems in socialization, academic function, and vocational accomplishment, and demonstrate impaired attention and executive function, which may contribute to their social difficulties (Rose & Holmbeck, 2007). Many children with spina bifida are able to attend regular schools and, with proper evaluation, are able to maintain attendance in age-appropriate classes.

Many factors affect the self-esteem of a child with spina bifida, including mobility, physical appearance and weight, family support, and experiences within the health-care system. Obesity is a common problem, particularly in adolescents. Promote healthy eating habits at an early age

in accordance with the child's activity level. Encourage involvement in wheelchair sports activities. Self-esteem may have a direct effect on the child's desire to maintain a normal weight. Involving the whole family in self-esteem-building activities is paramount.

Because children with spina bifida may have many surgical procedures throughout their lives, providing for a successful operative experience is essential. Provide pre-operative preparation such as age-appropriate play activities, and honest, but not scary, developmentally appropriate explanations about the procedure. Many of the orthopedic procedures required for these children

TIP 21–3 Teaching Intervention Plan for the Child With a Repaired Neural Tube Defect

Nursing diagnoses and outcomes

Risk for infection related to consequences of surgical incision, presence of shunt, urinary retention, and immobility

Outcomes:

- Child's incision site remains free from infection.
- Child remains free from urinary tract infections.
- Child's skin remains intact.

Urinary retention related to effects of lack of innervation of bladder and sphincter

Outcomes:

- Child remains free of urinary tract infection.
- Child remains free of constipation.
- Child participates in bowel- and bladder-training program when age appropriate.

Risk for injury related to effects of neuromuscular and sensory deficits

Outcome:

- Child remains free of contracture, alterations in skin integrity, and trauma to extremities with altered sensation.

Delayed growth and development related to sensorimotor limitations

Outcomes:

- Parents participate in activities to promote child's developmental outcomes.
- Child achieves developmental milestones to highest level of ability given the sensorimotor limitations.

Teach the child/family

Skin Care

- Examine skin daily for areas of redness or a break in the skin integrity.
- Provide wound care and dressing changes (if necessary).
- Reposition child every 2 hours.
- Use sheepskin or air mattresses on areas of bony prominence.
- When removing splints and braces, assess skin for reddened areas.

Bowel and Bladder Function

- Establish routine and regular bowel program with suppository and stimulations.
- Effect clean intermittent catheterization.
- Institute bowel- and bladder-training program when age appropriate.

Nutrition

- Maintain good fluid intake and high-fiber diet to prevent constipation.
- Encourage intake of fluids such as cranberry, grape, and prune juices or those high in vitamin C to prevent urinary tract infections.
- Monitor child's weight; a low-calorie diet may be necessary.

Activity and Mobility

- Observe the child's movements for signs of loss of sensation of lower extremities.
- Consult a specialist to maximize mobility as child grows (braces, wheelchair).
- Perform passive range-of-motion exercises.
- Use proper positioning with pillows, pads, and rolls, as needed.
- Have child ambulate or sit in wheelchair whenever possible.
- Periodically evaluate adaptive equipment for damage, loose screws, alignment, or similar faults.

Growth and Development

- Modify home environment as child grows to ensure child's safety.
- Encourage stimulation with age-appropriate activities.
- Encourage child to be as independent as possible.
- Teach alternative methods for personal hygiene and mobility.
- Praise child's independent behaviors.
- Allow child to ventilate feelings about self and interactions with peers.

Monitoring for Complications

- Monitor for signs of increased ICP (changed level of consciousness, changes in behavior, headache, vomiting, fever) that may be signs of shunt malformation.

Health Maintenance

- Organize and maintain child's medical records.
- Access community resources and support groups.
- Seek financial assistance as needed.
- Discuss baby-sitting and child care options.

Contact Healthcare Provider if:

- Redness or discharge is noted from site of surgical incisions
- Areas of the child's skin become reddened or there is a break in the skin surface
- Urine becomes cloudy or foul smelling
- Child displays changes in neurologic status as demonstrated by changes in level of consciousness, lethargy, irritability, vomiting, fontanel seeming to be full
- Child has fever

involve long periods of rehabilitation to achieve the best results. Continual support and positive reinforcement from the nursing staff are important to the child's optimal recovery and function.

Teachers and other school personnel are an important part of the team caring for the child with spina bifida. Prolonged absences affect the child's success at school. Help the parents make a plan for the child to continue his or her schoolwork while in the hospital or at home recovering from hospitalizations. Adaptations may be necessary to account for cognitive impairments. School also provides an important social outlet for the child, so make every effort to keep the child involved in a school program, even if involvement is less than full time. School success has a positive effect on self-esteem and on future life success.

Hydrocephalus

Hydrocephalus is defined as a dilation of the ventricles inside the brain caused by an imbalance in the rate at which CSF is produced and absorbed. The two primary causes, whether congenital or acquired, are (1) blocked flow of CSF and (2) impaired venous absorption of CSF in the subarachnoid space. A third, but rare, cause is overproduction of CSF caused by a tumor, called a *choroid plexus papilloma*. The clinical manifestations of hydrocephalus vary with its precise cause and duration, with the age of the child, and with the ability of the skull to expand.

Congenital hydrocephalus occurs in approximately 4 per 1,000 live births and may be diagnosed prenatally by ultrasound or may be overt at birth (Rudy, 2005). Congenital etiologies include spina bifida, Chiari malformations, congenital arachnoid cysts, congenital stenosis of the aqueduct of Sylvius, Dandy-Walker cyst, and other intracranial masses, including congenital tumors.

Acquired hydrocephalus occurs secondary to mass lesions. Acquired lesions in infancy are most commonly a result of intracranial bleeding, meningitis, or both, resulting in fibrosis of the meninges, which prevents

reabsorption of CSF by the arachnoid villi. Infants born prematurely are at increased risk of intraventricular hemorrhage.

Pathophysiology

CSF is primarily manufactured in, and secreted by, the choroid plexus. This structure lines the base of the paired lateral ventricles and the roof of the third and fourth ventricles (Fig. 21–4). CSF is produced and then propelled in a pulsatile fashion from the choroid plexus through a small passageway called the *intraventricular foramina of Monro* to the third ventricle. From there it travels through the aqueduct of Sylvius to the fourth ventricle. From the fourth ventricle, the CSF flows through the foramen of Magendie and the paired foramina of Luschka into the subarachnoid space up over the surface of the brain and downward around the spinal cord. The CSF is then reabsorbed by the arachnoid villi located in the dural sinuses, which are the large blood vessels that drain the venous blood from the head, and through the walls of capillaries of the CNS and pia mater. Small amounts of CSF are absorbed in the cells lining the ventricles and through the lymphatic system of the spinal cord.

The terminology used to describe hydrocephalus has been confusing, because the terms used were coined before the era of modern diagnostic testing, when the site of the blockage may have been implied rather than precisely identified. The terms *communicating* and *noncommunicating* hydrocephalus are still used occasionally to describe the status of the ventricles in this disease. Communicating hydrocephalus describes a blockage “outside” the ventricular system (e.g., meninges). The implication is that the ventricles can still communicate, despite the blockage. Noncommunicating hydrocephalus implies a blockage somewhere in the ventricular system that prevents CSF from reaching the subarachnoid space for reabsorption. Another way to classify hydrocephalus is to categorize the disorder as either *congenital* or *acquired*, as described earlier. Most believe it best to classify hydrocephalus by the site of the blockage, by the cause, and by

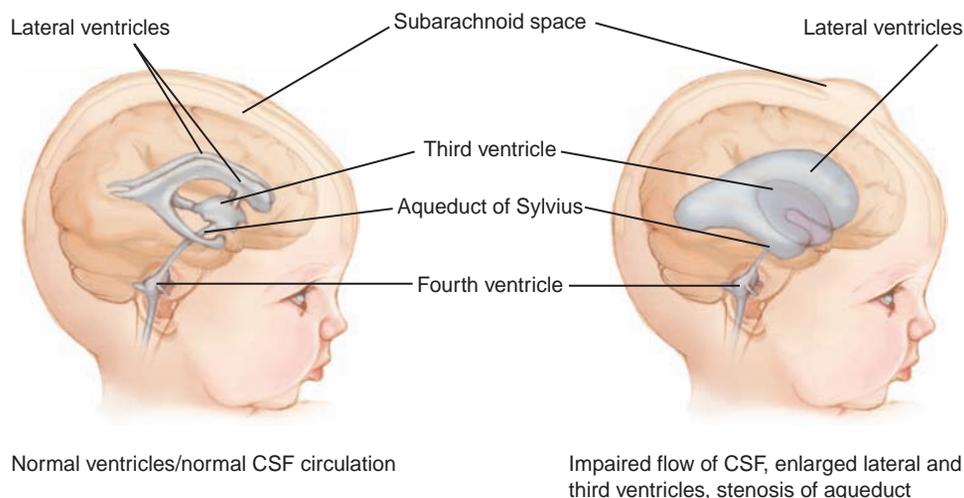

FIGURE 21–4. Normal CSF circulation and alterations caused by hydrocephalus.

the state of progression. Prognosis for the child with hydrocephalus depends on these and other factors.

Assessment

Ask about any history of trauma, CNS infection, familial megalencephaly, birth injury, or prematurity, and note the onset and duration of symptoms. Measure head circumference. An abnormal increase above the established growth curve, a circumference above the 95th percentile at birth, or a rapidly increasing head circumference should raise suspicion of hydrocephalus. Note spilt sutures, or a full or bulging fontanel, especially one that is nonpulsatile, indicating high pressure. Other clinical signs and symptoms become apparent as hydrocephalus progresses. Cranial nerve palsies result in the classic “sunset” appearance of the eyes, in which the sclera are visible above the iris and the infant is unable to look upward with the head facing forward. Collier’s sign (upper eyelid retraction) may also be present and may occur with third ventricle lesions. Scalp veins are prominent, and the infant may demonstrate lethargy, irritability, high-pitched cry, poor feeding habits, and projectile vomiting. Increased motor tone, spasticity, or opisthotonic posturing (arched back) may be present. Developmental delays are also common in children younger than 2 years of age.

In the older child with a fused cranium, signs and symptoms of hydrocephalus may develop either slowly or rapidly. Rapid development leads to acute neurologic deterioration. Signs of increased ICP in these children include frontal headache, nausea, and vomiting that may be projectile. If these symptoms occur on awakening, suspect increased ICP. Carbon dioxide retained during sleep and decreased venous drainage while the child is lying flat may contribute to morning symptoms. Other signs and symptoms include poor school performance, restlessness, changes in personality or activity level, double vision, papilledema, spasticity, hyperreflexia, ataxia, and new onset or change in seizure pattern. In later stages, bradycardia or altered respirations and seizures are life threatening if not treated.

Diagnostic Tests

Level II ultrasonography of the fetus can confirm a prenatal diagnosis of hydrocephalus. This condition is not always detected by a screening ultrasound. Transuterine placement of ventriculoamniotic shunts during late pregnancy is being developed, but the technique involves risk to the fetus and mother, and remains controversial (Bruner, Davis, & Tulipan, 2006).

In infants and children, evidence of hydrocephalus is most frequently obtained with a CT scan. In infants with an open fontanel, ultrasound may be used. When a complex lesion is suspected, MRI may be used initially. Skull radiographs may show widened or split sutures, and the skull may have a “beaten silver” appearance, characteristic of chronically increased ICP.

Interdisciplinary Interventions

After hydrocephalus is identified, treatment is directed toward resolving the cause of obstruction. Doing so may

not be possible in congenital hydrocephalus. When acquired hydrocephalus occurs in an older child, the lesion causing the obstruction (most frequently neoplasm) can be removed to enable CSF flow to return to normal. In some cases, however, even complete resection of a tumor fails to reestablish normal CSF pathways.

Cerebrospinal Fluid Removal

Medical management of hydrocephalus is limited to withdrawal of CSF by lumbar puncture or by ventricular tap. This procedure is usually performed on a short-term basis in infants with inflammatory processes or intracranial hemorrhage. In some cases, acetazolamide (Diamox) is prescribed, which may decrease CSF production. However, this drug has not been shown to be very effective (Garton and Piatt, 2004).

Surgical Interventions

Advances in neuroendoscopy have led to the development of smaller scopes and powerful light sources, allowing the neurosurgeon to gain access to the ventricular space in the brain through a small burr hole. Once there, the surgeon can visualize the ventricles, fenestrate cysts, and place indwelling catheters.

The most common treatment for hydrocephalus is to reduce the ICP by surgically shunting the CSF from the ventricles to another body cavity, such as the peritoneal cavity, where it is absorbed.

The three main components of mechanical shunting devices are (1) ventricular catheter, (2) reservoir and valve to regulate flow of CSF (and thus ICP), and (3) distal tubing. The CSF is drained by the ventricular catheter to the distal cavity, where the CSF is resorbed into the body’s fluids. The soft shunt tubing is placed directly under the scalp on the skull bones and is palpable under the skin of the scalp; it then travels along the neck, after which it is placed into the distal site.

The *ventriculoperitoneal* location is chosen for most mechanical shunts (Fig. 21–5). After insertion of the ventricular tube through a cranial burr hole, the length of the shunt is tunneled subcutaneously to the upper quadrant of the abdomen. A small incision is made and the shunt is guided into the peritoneal cavity with plenty of extra tubing to enable the child to grow without having to undergo further surgery to lengthen the shunt. Specific risks of this procedure include bowel perforation and ascites if the CSF is poorly absorbed.

The *ventriculoatrial* shunt is placed only if a concurrent abdominal problem exists that precludes insertion of a ventriculoperitoneal shunt. This shunt can be inserted into the right atrium of the heart by passing it through the jugular vein, or, in more extensive cases, directly into the heart. Risks include catheter movement, dysrhythmias, operative risks associated with more extensive surgery, endocarditis, septicemia, and congestive heart failure.

The *ventriculopleural* shunt, used very infrequently, is placed only if both peritoneal and cardiac access are unobtainable. Children younger than the age of 10 are not candidates because the volume of CSF that drains into the pleural space may compromise respiratory

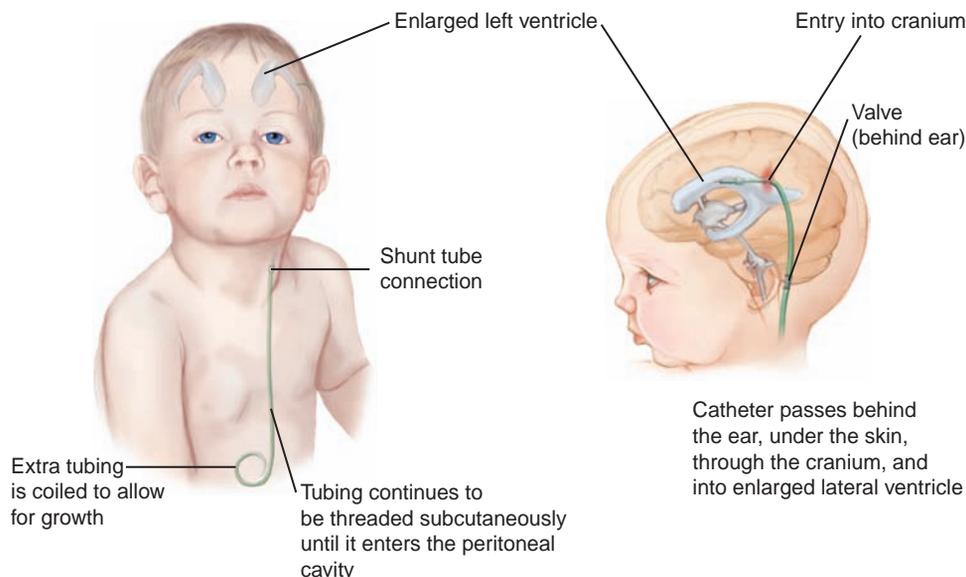

FIGURE 21–5. Placement of ventriculoperitoneal shunt.

function. Because the absorptive properties of the pleura vary, ventriculopleural shunts may not be as effective as ventriculoperitoneal shunts. Risks include respiratory compromise or infection, or both, from stasis of respiratory secretions. A child with this kind of shunt will require frequent chest radiographs to monitor expected pleural effusion.

A third ventriculostomy is an endoscopic procedure to treat hydrocephalus without the need to place a shunt. Criteria for candidacy include large ventricles at baseline, no evidence of abnormal absorption of CSF in the subarachnoid space (i.e., communicating hydrocephalus), and absence of previous infection or bleeding into the brain. Older children with acquired obstructive hydrocephalus are often appropriate candidates. Through a small incision, the scope is placed into the lateral ventricles and moved into the third ventricle, where a small hole is punctured to allow CSF to flow into the subarachnoid space. The recovery time is 1 to 2 days. The size of the ventricles on postoperative CT does not change rapidly, as is sometimes the case with a shunt. This procedure fails in some children, for whom placement of a shunt is eventually required (Ray, Jallo, Kim et al., 2007).

Preoperative Interventions

In addition to preparing the child and family for surgery, a key intervention is monitoring for increased ICP and instituting measures to reduce the risk of increasing the pressure. Cardiorespiratory monitoring and frequent monitoring of pupil size, motor movements, and level of consciousness are essential. Immediately report changes in status and administer medications as ordered. Be ready to assist if a ventricular shunt tap is needed. Regularly assess fontanels and note bulging or flatness. If the child is vomiting, intravenous hydration may be necessary. Hydration should be administered at a rate of no more than 75% to 80% of *maintenance* fluid requirements to

prevent fluid overload that may increase ICP. Elevate the head of the bed 30 degrees and decrease external stimuli. Have oxygen and suction ready at the bedside in case the child has a seizure. In some centers, a preoperative dose of intravenous antibiotics may be ordered as prophylaxis against infection. Follow individual surgeon preferences for laboratory work or skin shampoo preparation.

Begin teaching and preparation of the child and family as soon as the decision to place a shunt is made. Provide information about the procedure as well as what to expect after it. Assist families in understanding the terminology and the equipment used. Make written handouts, preprinted booklets, and a structured teaching session a part of the preoperative plan. Provide the child with age-appropriate information. Evaluate family understanding of the shunt, its function, and how to manage follow-up care. Photographs of normal CT scans and scans that show hydrocephalus offer compelling comparisons for parents.

KidKare ■ ■ ■ Allow the older child to handle a demonstration shunt. This exercise can alleviate many fears and often generates additional questions.

Postoperative Interventions

In addition to basic postoperative care following cranial surgery (covered earlier in this chapter), perform postoperative care specific to the child with a shunt:

- Observe for signs of neurologic deterioration after an initial period of recovery or signs of slow and incomplete recovery. Report any of these trends to the physician, so that appropriate radiographs can be ordered. Children who experience a rapid decrease in ventricular size after shunt placement are susceptible to developing subdural fluid collections.

- Avoid applying any cardiac lead patches, temperature probes, or unnecessary tape over the shunt site because of the fragility of the skin. Be particularly careful with the scalp, because it is often stretched and is therefore more susceptible to breakdown. A newborn infant may be placed on a waterbed initially to prevent pressure on the skin around the shunt.
- Monitor for potential complications, especially infection, shunt malfunction, and excessive drainage of CSF.
- Pay close attention to the integrity of surgical incisions and ensure that children keep their hands away from fresh incisions (use a stockinet cap if appropriate), and monitor the child's temperature and administer antibiotics, if ordered. The organisms most commonly isolated from infected shunts are *Staphylococcus epidermidis* and *S. aureus*. If the organism is difficult to eradicate, intraventricular instillation of antibiotics may be useful. In most cases of shunt infection, the distal end of the shunt is externalized to a CSF-collecting system until the bacteria are eradicated and a new shunt is placed. In nearly all cases, the shunt must be completely removed and replaced to achieve a cure.
- Monitor for shunt malfunction that *may* be hardware related or the result of obstruction (often resulting from infection or buildup of fibrin debris and protein substances). Assess for signs of increased ICP.
- Assist with preparing the child for diagnostic tests to evaluate shunt function, including radiographs, brain imaging, shunt tap, radionuclide shuntography, and ICP monitoring.

Alert! Monitor for signs and symptoms of shunt infection or malfunction, which can be acute or chronic, depending on the cause and the child's abnormality and brain compliance. Acute presentation includes rapid onset of vomiting, severe headache, irritability, lethargy, fever, redness along the shunt tract, and fluid around the shunt valve.

Some children with shunt failure from infection or malfunction present with more insidious symptoms, and problems may not be noted until weeks or months after the initial surgery. Occasional changes in school performance, intermittent headaches, and mild behavior changes are noted by those around the child, leading to eventual evaluation and the determination that the shunt is malfunctioning. Because parents are usually aware of their child's day-to-day behavior, they are sensitive to the changes that indicate shunt malfunction. Listen to a parent's intuition, even if a shunt has recently been placed, because shunts may require several revisions (Clinical Judgment 21–2).

Shunt overdrainage is a complication of a functioning shunt. This complication may lead to the **slit ventricle syndrome**, in which overdrainage causes the ventricles to become accustomed to a very small or slitlike configuration. When normally occurring variations in ICP arise, the ability of the ventricles to act as a buffer is limited, leading to symptoms consistent with intermittent catheter occlusion, such as headache, dizziness, and nausea. Children with slit ventricle syndrome present challenging management problems and may require changes in valves to more finely regulate pressure and siphoning.

Community Care

Home care instructions for parents include monitoring for signs and symptoms of shunt malfunction, proper handling of the child with a new shunt, home safety, and indications for calling the physician if problems occur. For example, instruct the parents to place the child on the unoperated side to prevent pressure on the shunt valve (if directed by the physician) and to elevate the head of the bed to enhance gravity flow through the shunt. Educate them to observe the operative site for redness, puffiness, or oozing of fluid. Teach them the signs and symptoms of blockage or infection such as increasing drowsiness, vomiting, headache, irritability, restlessness, swelling around the pump, persistent bulging of fontanel, fever, poor feeding, and seizure activity, and to notify the healthcare provider should any occur. In some cases, the shunt requires pumping. Teach the parents, if ordered by the physician, to depress the valve area firmly and quickly with forefinger, leaving the finger on pump to feel it refilling. Advise them not to force the depression if it is difficult and to call the healthcare provider immediately.

It is imperative that the healthcare team and the family establish trust and good communication. Maintenance of a therapeutic relationship involves ongoing education, mutual decision making, and the creation of a supportive atmosphere for verbalizing questions and concerns. Nurses facilitate this process by teaching, initiating care conferences, and organizing resources to assist families.

Children should be closely monitored with developmental screening either in the school setting or with routine medical checkups. Most parents are concerned about the effect that hydrocephalus may have on their child's intelligence and development. The degree of disability depends on the severity of hydrocephalus, the presence of other brain anomalies, and the presence of conditions such as intraventricular hemorrhage, infection, and hypoxia. Generally, normal intelligence is enhanced if shunts are placed early, proper function is maintained, and infection is avoided.

Chiari Malformation

Chiari malformations are congenital anomalies of the structures at the junction of the brain and the spinal cord. This anatomic area is often referred to as the *cervicomedullary junction*.

Two other diagnoses associated with Chiari malformations are **syringomyelia**, or *syrinx*, and **hydromyelia**. Syringomyelia is a cavity lying outside the central canal area of the spinal cord that is not lined by ependymal cells, and hydromyelia is a cavity within the spinal cord that is partially or completely lined with ependyma. These two diagnoses are frequently discussed in conjunction with Chiari malformation because of their similar clinical presentations and their probable common pathophysiologic development. Chiari malformation is associated with several cranial and vertebral abnormalities as well as genetic syndromes and is felt to have a genetic basis.

CLINICAL JUDGMENT 21–2

The Child With a Ventriculoperitoneal Shunt

Three-month-old Shila had a ventriculoperitoneal shunt placed 2 weeks ago following a diagnosis of congenital hydrocephalus. The family has returned to the clinic for a follow-up appointment.

Questions

1. How could the diagnosis of hydrocephalus be assessed in one so young?
2. What concerns might parents have at this time?
3. Shila has a temperature of 101 °F (38.3 °C) and it is noted that the shunt incision site is reddened and not healing well. What nursing diagnosis would be appropriate for the child with a shunt infection?
4. What healthcare interventions are appropriate to treat Shila's ventriculitis?
5. Family teaching is given regarding management of Shila's shunt. What information should the family be able to relate back to the nurse to indicate that effective teaching has taken place?

Answers

1. During well-child visits at 1 and 2 months of age, an abnormal increase in head circumference may be noted. Other findings that are suspicious

include a full or bulging fontanel, increased motor tone, developmental delays, irritability, high-pitched cry, poor feeding, projectile vomiting, and cranial nerve palsies resulting in the classic “sunset” appearance of the eyes.

2. Is the shunt working? How can they tell if it is working? Will their child be normal?
3. Risk for infection related to placement of ventriculoperitoneal shunt
4. First the shunt is tapped to look for suspected bacteria. Antibiotics are given correctly and in a timely manner. Vancomycin in conjunction with gentamicin or a broad-spectrum cephalosporin is initially given. Antibiotics are readjusted based on the determination of the cultures and susceptibility outcomes. Acetaminophen is given for fever. Monitor for signs of improvement or worsening. Provide comfort measures.
5. Family can state signs and symptoms of increased ICP and shunt malfunction, demonstrate proper handling of child with new shunt and home safety measures, and identify indications for calling the healthcare provider if problems occur.

Pathophysiology

Chiari malformation is characterized by abnormalities of anatomy and physiology (Fig. 21–6), which in turn produce mechanical deformities. Four variations of the Chiari malformation exist. Each type is defined by associated structural anomalies and by the symptoms they produce. Chiari type I presents most often in adolescents and adults. The condition is characterized by a displacement of the cerebellar tonsils into the cervical canal. The clinical features include malformation of the base of the skull and upper cervical spine. Hydromyelia, syringomyelia, and diastematomyelia (longitudinal splitting of the spinal cord) are frequently present. Because symptoms often progress slowly, Chiari type I malformation may go undetected for many years.

Chiari type II, which is uniquely associated with myelomeningocele, is found in infants and is the most common of these malformations. Chiari type II is characterized by downward displacement of the cerebellar tonsils and medulla through the foramen magnum. As the cerebellar tonsils at the base of the spine protrude downward into the foramen magnum of the cervical spine, normal CSF pathways are blocked, and the fourth ventricle becomes dilated with CSF. Signs and symptoms of hydrocephalus occur. Nearly every case of thoracolumbar, lumbar, and

lumbosacral myelomeningocele is accompanied by the Chiari type II malformation. Hydrocephalus is also associated with the Chiari type II malformation in 80% to 90% of cases (Rath, Bithal, & Chaturvedi, 2006). In addition to the complications of the myelomeningocele lesion, other common problems include apnea, laryngeal stridor, and feeding disturbances such as reflux and aspiration. Functional compromise of lower cranial nerves may occur. Ataxia and nystagmus indicate cerebellar impairment, and there may be increased deep tendon reflexes, loss of vibration and position sense, and recurrent occipital and frontal headaches. About half of deaths that occur among infants with myelomeningocele can be attributed to hindbrain anomalies that affect vital physiologic processes. The age at which symptoms of Chiari type II appear has implications for prognosis: the earlier the symptoms appear, the more likely it is that brain stem nuclei are hypoplastic, and the poorer the prognosis.

Type III Chiari malformation is essentially an occipital encephalocele, consisting of an opening of the skull and cervical area, through which the cerebellum protrudes. Type IV consists of a single abnormality, failure of the cerebellum to develop, and may be a variation of the Dandy-Walker syndrome (a congenital malformation of the cerebellum and fourth ventricle).

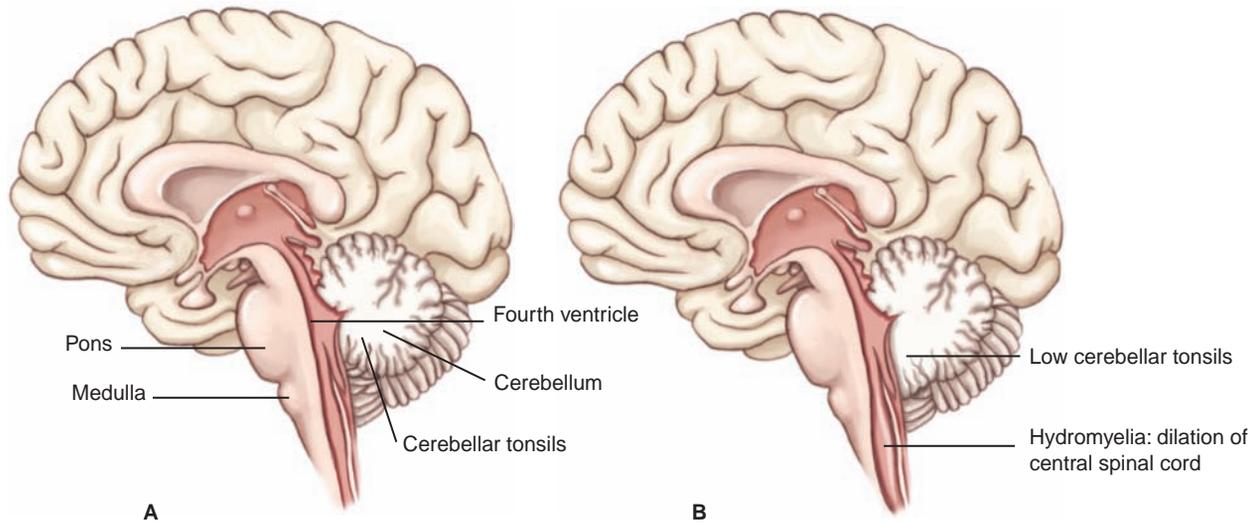

FIGURE 21-6. (A, B) Normal posterior fossa (A) and Chiari malformation with hydromyelia (B).

Assessment

The clinical examination focuses on the most common signs and symptoms of the Chiari type II malformation. These signs and symptoms include nystagmus, nuchal rigidity, poor suck reflex, drooling, difficulty swallowing, vomiting, weak or absent cry, and inspiratory stridor during agitation. In more severe cases, episodes of apnea may be reported. Be alert for these signs and symptoms in a child with myelomeningocele, because they can progress very rapidly and may require immediate surgical intervention. In older children, decreased strength in upper extremities, with increased tone and exaggerated deep tendon reflexes, may also be present.

A type I malformation may not be detected for years, possibly until adolescence. The adolescent with Chiari type I malformation is likely to have a more chronic presentation that includes occipital headaches, neck pain, urinary infrequency, progressive lower limb spasticity, and scoliosis.

Radiographic techniques are used to demonstrate the type and extent of the lesion, including the presence of hydromyelia or hydrocephalus. MRI is particularly useful in identifying the anatomy to provide accurate diagnosis.

Interdisciplinary Interventions

Children with a Chiari malformation require careful monitoring and MRI to determine the extent of neurologic involvement associated with the condition. If symptoms are not life threatening, a conservative approach is undertaken in the hope that the child will stabilize and outgrow the symptoms. Surgery may be recommended to decompress the suboccipital and cervical areas.

Surgical decompression involves removing the posterior aspect of the foramen magnum and excising the upper cervical vertebral arches. This decompression alleviates the pressure on the fourth ventricle and the affected cranial nerves, arresting symptom progression. Besides performing bony decompression of the area, many surgeons incise the

dura and place a graft to allow further decompression of the anatomic structures. Postoperatively, some of these children who have received grafts develop symptoms of meningeal irritation, which require close monitoring to rule out infection. Some children show little objective improvement, and deficits that existed preoperatively may be permanent. The goal of the surgery is to prevent further symptoms, rather than to relieve existing ones, although existing symptoms are usually relieved to some degree. Ventriculoperitoneal shunts are placed to treat hydrocephalus, and because they are usually permanent, patients are monitored throughout life by a neurosurgery team.

Postoperative care is the same as that described for cranial surgery. Give special attention to avoiding respiratory distress and respiratory infection. Airway function and protection may be altered as a result of preexisting symptoms and respiratory compromise during surgery. Ensure that oxygen and suction are readily available at the child's bedside if needed. Feed children with poor gag and swallow reflexes slowly, and place them in an upright position after feeding to avoid aspiration and pneumonia.

Ensure adequate pain control. Neurologic assessments help to determine whether overmedication or postoperative complications have occurred. Teach parents to assess for changes in their child's neurologic status, to recognize impending signs of respiratory problems, and to report any signs of incisional redness or irritation. Before discharge, address any need for occupational therapy to adapt feeding, or for stimulation programs to meet the child's functional capacity, if the child will later require a referral.

Cerebral Palsy (CP)

Cerebral palsy (CP), the most common cause of physical disabilities in developed countries, is defined as a movement disorder of posture and movement. It is often associated with epilepsy and abnormalities of speech, vision, and intellect. As gestational age decreases, the incidence of CP increases (Petrini, Dia, McCormick, et al., 2009).

The incidence of CP in preterm infants has increased as a result of neonatal intensive care and multiple births. The rates of CP in term infants have remained steady.

Pathophysiology

The precise pathophysiology of CP is not known. Typically, CP results from a defect or lesion of the developing brain. However, in some cases, no specific lesion or area of infarct can be found. Although the encephalopathy itself does not progress, it produces a permanent disorder of posture and movement that results in progressive musculoskeletal pathology in most affected children. The brain injury may occur before, during, or after birth, usually before age 5 years. Risk factors associated with CP may include perinatal factors such as exposure to teratogens, intrauterine infection, fetal/placental dysfunction, maternal preeclampsia, complications of labor and birth, prematurity, asphyxia, and sepsis; and childhood factors such as traumatic brain injury, carbon monoxide poisoning, respiratory distress syndrome, meningitis/encephalitis or brain abscess, respiratory obstruction, hemorrhage, and embolus or thrombus. Increased use of brain imaging has demonstrated that perinatal influences may be stronger than previously thought.

The patterns of dysfunction seen in the child are related to whether damage is limited to one area of the brain, is scattered in multiple areas, or is unilateral or

bilateral. Dysfunction is also related to the cause of the damage and the stage of brain development at the time of injury. In all cases, the lesion cannot be repaired, although it does not worsen.

The essential motor problem in CP is lack of muscle control. This lack of control usually stems from failure to inhibit specific reflexes of the CNS. The reflexes involving muscle movement are stretch, crossed extension, long spinal, symmetric tonic neck, asymmetric tonic neck, vestibular, and startle. Each of these reflexes is normally present in infancy. Normally, these reflexes fade or are inhibited as development progresses. Injury to the brain may cause these reflexes to persist, barring control of muscle movement. Without control of these movements, functional ability is lost or cannot be attained. As the child grows, motor and nonmotor manifestations, such as scoliosis and muscle contractures, may become more disabling. Scoliosis can cause lung compression, loss of ambulation, or inability to sit; muscle pull imbalances can cause a subluxated or dislocated hip, leading to pain and problems with sitting.

Children with CP are classified by the area (extremity) most affected and by the degree of involvement (Table 21-5). Children with CP often have other physical abnormalities such as seizures; vision, hearing, or speech deficits; difficulty with feeding; and learning difficulties (Chart 21-3). Intelligence may be average or below

TABLE 21-5

Types of Cerebral Palsy

Type and Incidence	Characteristics
Spastic type (65%)	Increased muscle tone with clasp knife character Increased deep tendon reflexes Pathologic reflexes Spastic weakness Difficulty with fine and gross motor skills Muscle contractures common Scoliosis
Hemiplegia (30%)	Primary unilateral involvement, often with the arm more involved than the leg
Quadriplegia (5%)	Four-limb involvement, with legs more involved than arms, although legs still show substantial involvement
Diplegia (30%)	Four-limb involvement, with legs more involved than arms; arms may have only minimal impairment and no functional handicaps
Athetoid type (20%)	Purposeless, involuntary, uncontrollable movements of face and extremities Fluctuating muscle tone Deep tendon reflexes and movements increase with stress and voluntary movements; deep tendon reflexes absent during sleep Symmetric four-limb involvement
Ataxic type (5%)	Disturbed coordination Unsteady gait Hypotonic muscles Slurred speech In general, good motor prognosis
Mixed type (10%)	Usually a mixture of spastic athetoid types

CHART 21–3 DEFICITS ASSOCIATED WITH CEREBRAL PALSY

Musculoskeletal and Reflexive Deficits

Hypotonia

Spastic hypertonia

Hypertonus: lead pipe rigidity that can be “shaken out” by rapid movements of the extremities

Persistent primitive reflexes

Contractures

Osteoporosis

Scoliosis

Neurologic Deficits

Mental retardation (30%–77%)

Language disorder (approximately 40%)

Learning disability (approximately 40%)

Range of neurobehavioral disorders (up to 50%), attention deficit hyperactivity, autism, hyperkinetic or distractible behavior

Visual disorders (50%–90%)

Hearing disorders (10%)

Somatosensation (up to 50% of hemiplegia)

Seizures (30%–40%)

Gastrointestinal and Nutritional Problems

Drooling

Malnutrition

Bowel and bladder incontinence

Constipation

Other Systemic Complications

Growth failure

Genitourinary complaints

Respiratory infections

Fatigue

average. These associated deficits reflect the fact that motor areas of the brain work together, and rarely a specific area is affected in isolation.

Assessment

Developmental surveillance is a key part of assessing a child with CP. Abnormal patterns emerge as the damaged nervous system matures. Observe for suspicious signs such as excessive docility or irritability. Poor feeding during the neonatal period combined with irritability, poor sleep patterns, and difficulty in cuddling with poor

visual attention merit additional screening or referral. Note evidence of early motor signs including poor head control, asymmetric fisting, and increased tone in limbs. Often, CP cannot be diagnosed until the child is 6 to 12 months old, a time when the child’s inability to achieve a developmental milestone becomes more evident. An infant identified with any of the previous findings requires referral for further evaluation.

caREminder

Presentation of reflexes that persist beyond the expected age of disappearance (e.g., tonic neck reflex) or the absence of expected reflexes is highly suggestive of CP.

Neuroimaging tests can be performed on the child with CP to determine the site of the brain impairment and to provide clues regarding the potential cause. The results of these tests do not affect the child’s treatment. Other diagnostic tests may be performed to rule out other potential causes of the child’s current condition. These tests include cytogenetic studies (genetic evaluation of the child and other family members) and metabolic studies.

Nursing Diagnoses and Outcomes

Nursing Plan of Care 21–1 and Nursing Plan of Care 20–1 outline the plan of care for the child with altered neurologic and musculoskeletal status, respectively. The physical disabilities and impaired neuromuscular status of the child with CP are addressed with nursing diagnoses that focus on impaired physical mobility, skin integrity, and neurovascular function. In addition, the child with CP experiences difficulty in self-care activities as a result of physical and cognitive limitations. The nursing plan of care should reflect the stress on family members as they relate to a child with a lifelong disability. In addition to these considerations, the following diagnoses could apply to the child with CP:

Impaired verbal communication related to effects of condition

Outcomes: Child will communicate and express his or her needs as much as possible.

Child will communicate needs and desires without undue frustration.

Child will use alternative means of communicating, including the use of adaptive equipment, as needed and as able.

Imbalanced nutrition: Less than body requirements related to inability to ingest food or retain food in the presence of gastroesophageal reflux

Outcomes: Child will receive optimal nutrition to maintain ideal body weight.

Child will tolerate gastrostomy tube feedings if needed to maintain ideal body weight.

Interdisciplinary Interventions

CP is a disorder that cannot be corrected. Therefore, interventions focus on preventing or minimizing deformities

and maximizing the child's functioning in the home, school, and community via an integrated healthcare plan using the expertise of a variety of professionals. The healthcare team works to maximize the child's potential, considering neurologic and other impairments. The child is encouraged to learn to function independently.

Children younger than 3 years old can benefit from early intervention services. Early intervention is a system of services to support infants and young children (see Chapter 30). For older children, special education and related services are available through the public school system to help each child achieve and learn.

Medical and Surgical Interventions

Management of the child with CP is challenging. The musculoskeletal pathology is much more complex than simple contractures. Torsion of the long bones, joint instability, and degenerative changes in the weight-bearing joints are common and debilitating. The primary management goal is to prevent development of fixed contractures.

Managing spasticity has been shown to delay the onset of orthopedic problems; treatments are classified as focal or generalized. One of the most commonly used agents is BTX-A, a potent neurotoxin produced by the bacterium *Clostridium botulinum* under anaerobic conditions. It binds to cholinergic nerve endings and inhibits release of the neurotransmitter acetylcholine. It decreases a spastic muscle's ability to generate forceful contraction, therefore decreasing the spastic response. BTX-A is injected by the healthcare provider into the affected muscles and can be used in combination with serial casting. Its safety has been established in a number of open-ended studies.

Conservative measures such as bracing may be used to provide support for ambulation and to discourage contractures. If contractures do develop, orthopedic surgery may be indicated. Various muscle releases and tendon transfers can be done to correct or to relieve contracture. For example, to correct a subluxated or dislocated hip, a hip osteotomy and release of soft tissues and tight tendons may be performed to hold the hip in place. Spinal stabilization with instrumentation can greatly improve or stop the progression of scoliosis.

Neurosurgical Interventions

Selective dorsal rhizotomy is a neurosurgical procedure performed to reduce muscle stiffness and spasticity in children with CP. For some children, the procedure reduces spasticity, resulting in improved walking; it enables others to sit more comfortably in a wheelchair. Selective dorsal rhizotomy may also improve respiratory function, improve arm and head control, and decrease leg spasticity. The procedure takes about 4 hours and involves making a 4- to 6-in incision in the lower back to uncover and test small nerve rootlets that make up the sensory nerve fibers in the spinal cord. Using a surgical microscope, the surgeon locates, divides, and tests the rootlets of each nerve and cuts rootlets with abnormal responses. Ideal candidates for rhizotomy are children between the ages of 3 to 10 years.

This procedure is most beneficial for child with spastic diplegia who have some form of forward movement and can take steps by themselves without falling. Here, the goals of surgery are better gait and improved leg function. It is also helpful for children with severe spastic quadriplegia, or spasticity in all extremities with very limited movement. The goal of surgery is to increase their independence by enabling them to sit for longer periods of time, use a potty seat, and power a wheelchair on their own. Selective dorsal rhizotomy involves intensive follow-up, so the family's ability to cooperate is essential.

Pain Management

Pain management in children with CP is complex. Although opioids are useful for incisional pain after surgery, they do not ease muscle spasms. Because of positioning and immobilization in casts, children with CP have more problems with muscle spasms than other children. Muscle relaxants, such as diazepam or other benzodiazepines (e.g., clonazepam), can be administered along with narcotics to relieve discomfort. Muscle relaxants and seizure medications may be needed on a long-term basis, depending on symptoms.

caREminder

Undermedication of children with CP is common because of their communication difficulties. Assess nonverbal pain cues carefully (see Chapter 10). Epidural analgesia is a good option for pain management in children with CP who have had lower extremity surgery, particularly if they are nonverbal. Administering a constant infusion maintains a steady level of analgesia.

Community Care

Acute care of the child with CP is usually necessary only during initial evaluation, to perform surgical procedures to deal with mobility or nutritional issues, or to provide supportive care during serious illnesses such as pneumonia, dehydration, or systemic infection. To optimize the child's level of functioning and provide for the child's basic healthcare needs, orthopedic and neurosurgical services collaborate with a variety of other professionals in outpatient and community settings. These services continue throughout the child's life, with modifications in the treatment goals as the child grows and matures.

Physical and Occupational Therapies

The interventions provided by the physical and occupational therapist are essential in helping to reduce the risk of contractures and to promote the optimal use of motor function. The child's ambulation is likely to be difficult or inefficient. Formal gait analysis and ongoing therapy can assist the child to ambulate. Abnormalities of tone and reflexes can interfere with the child's abilities to perform daily functions. The therapist can introduce techniques or adaptive equipment to help the child achieve activities of daily living that he or she is cognitively capa-

ble of completing. The therapist ensures continuity of the plan of care by providing teaching to both the nurse and parents regarding the specific measures that will enhance the child's motor functions. Activities such as swimming or horseback riding can help strengthen weaker muscles and relax the tighter ones.

Nutritional Therapy

The nutritional status of children with CP must be addressed. Oral–motor dysfunction leads to limited food intake, which can lead to growth failure, especially in children with severe CP. Severe feeding dysfunction is associated with lower weight, height, and muscle mass. Food must be easy to swallow (chopped or mashed), and jaw support must be given to help the child chew. Gavage or gastrostomy feedings may be needed to meet the child's caloric requirements or if risk of aspiration is severe. A nutritionist can provide the family with suggestions to increase caloric intake, including high-calorie milkshakes and formulas. Reinforce the nutritional information provided to the family and ensure that menu selections reflect guidelines established by the dietitian. Evaluating and documenting the child's intake will provide further evidence of compliance with the dietary plan.

Speech and Language Therapies

Twenty percent of children with CP display hearing or language problems, because CP affects the muscles used to produce speech, resulting in slow and slurred speech with a nasal quality. The child's facial features may also seem distorted when he or she is speaking. The child should be evaluated by a speech therapist to determine the best method to help the child communicate most effectively. For the child with good receptive language skills who has difficulty speaking, alternative forms of expressive communication (e.g., computer, “touch-talker,” communication board, sign language, or facial gestures) can be used. Parents are usually adept at interpreting their child's needs and can help decrease the child's frustration with his or her inability to communicate.

Vision Support

Up to 75% of children with CP have some sort of visual problem or impairment. They may have acuity loss, field loss, oculomotor problems, or processing problems. These conditions may impair eye–hand coordination. Referring these children to an eye care specialist for treatment such as glasses, eye patching, or surgery is important.

Hearing Support

Children with CP are prone to hearing loss, which is often not detected because of their communication difficulties. Failure to follow directions or be attentive to sounds can be wrongly associated with the child's level of cognitive ability. Thus, all children with CP should be referred to an audiologist to ensure accurate and sensitive assessment of their hearing. In most cases, an amplification device (hearing aid) is recommended (see Chapter 28 for more information on

hearing loss and treatment). Treating hearing loss early can substantially improve the child's overall outcomes.

Psychosocial Support

The family of a child with CP may experience emotional, physical, and financial challenges because of the ongoing demands of the child's condition. Social services can help the family to find support groups, respite care, and other community resources for needed equipment (see Chapters 2 and 12 for more information on community care, chronic conditions, and rehabilitation). Ramps, vans, electric wheelchairs, computers, and mechanical feeders are just a few of the devices that can make the child more independent. The United Cerebral Palsy Association can help parents dealing with the problems of children with CP (see [thePoint](#) for Organizations).

Special Education

Problems that may affect learning for some children with CP include learning disabilities, cognitive challenge, and seizures. The interdisciplinary healthcare team collaborates with the school to ensure that these issues are addressed by developing and implementing an individualized educational plan and providing the necessary adaptations, modifications, and services the child needs to succeed (refer to Chapters 2 and 12 for detailed information on developing an individualized educational plan). Depending on the child's mental capacity and physical disabilities, additional interventions such as physical therapy, occupational therapy, or speech therapy may be needed. In addition to therapy services and special equipment, children with CP may need assistive technology. Examples of assistive technology include communication devices, such as communication boards and voice synthesizers, and computer-based assistive technology. Computers range from electronic toys with special switches to sophisticated computer programs operated by simple switch pads or keyboard adaptations. The health team's goal is to integrate the child into normal school activities as much as possible, and to provide a learning environment that is structured to meet the child's unique learning and developmental needs. Every effort should be made to allow the child the intellectual and social stimulation that school provides (see Chapter 12 for more detailed descriptions of the rehabilitative and home care measures that can be provided for the child with CP).

Craniofacial Abnormalities

Craniofacial malformations may occur as a result of genetic influences, multifactorial prenatal influences, acute craniofacial trauma, and disfigurement associated with cranial or facial tumor resection. Advances in imaging techniques and three-dimensional reconstructive surgery techniques have resulted in improved methods to enhance the physical appearance of affected children. Developments in fetal surgery offer the potential of treating selected anomalies in utero. The most common craniofacial malformations seen in children that occur as a

result of alterations in normal development are microcephaly and craniosynostosis (Fig. 21–7). Table 21–6 provides a summary of these abnormalities.

Bacterial Meningitis

Infectious processes can affect the brain and spinal cord. *Meningitis* refers to inflammation of the membranes of the brain, spinal cord, or both. The three meningeal layers that can be affected include (1) the dura mater (pachymeningitis), (2) the subarachnoid mater, and (3) the pia mater (leptomeningitis). The etiologic agents involved in meningitis include bacterial, viral, and fungal organisms. Chemical toxins such as lead and arsenic, contrast media used in myelography, and metastatic malignant cells can also trigger an inflammatory process that, although not infectious, is similar in clinical appearance.

Bacterial meningitis is a pyogenic (purulent) infection that involves the pia mater and arachnoid mater layers of the meninges and the subdural space, including the CSF. It occurs most frequently among children between 1 month and 5 years of age (Theodoridou, Vasilopoulou, Atsali, et al., 2007). Because of infant immunizations, the incidence of some types of bacterial meningitis has decreased (Table 21–7). Outbreaks of *Haemophilus influenzae* meningitis can occur, however, in unvaccinated populations and immunocompromised children.

Bacterial meningitis can be a devastating illness because of the systemic involvement and severity of its clinical course. Rapid diagnosis and early treatment contribute to the most favorable recovery.

Pathophysiology

The pathogens responsible for meningitis usually disseminate from a distant site of infection and then spread into the meninges. Bacterial colonization and infiltration of the meninges most commonly occur after an upper respiratory infection or bacteremia accompanying otitis media, sinusitis, or mastoiditis. Pathogens can also enter through penetrating wounds, or through the skin in the presence of a structural defect, such as a meningomyelocele. In the neonate, additional risk factors include maternal infection, premature rupture of amniotic membranes, premature birth, low birth weight, prolonged labor, and the immaturity of the neonatal immune system. After the pathogen is implanted, it proliferates and spreads into the CSF and through perivascular channels and meningeal folds to the brain parenchyma. Later, clumps of purulent exudate collect around the base of the brain, obstructing CSF and potentially causing hydrocephalus and cranial nerve palsies. Blood vessel walls and endothelium become involved, and cerebral perfusion may be compromised, leading to cerebral edema. Vasculitis associated with thrombosis can cause infarctions (strokes), seizures, and focal deficits. Continued necrosis of cells in the brain cortex and hydrocephalus can lead to permanent damage, increased ICP, and death.

Assessment

In neonates, the symptoms of infection and meningeal irritation may be minimal or absent. Consider bacterial meningitis in any newborn who fails to thrive and who

exhibits irritability, apnea, seizures, a tendency to **opisthotonos** (a form of spasm in which the head and heels are bent backward and the body is bowed forward), poor feeding, emesis, hypothermia, hyperthermia, hypotonia, hypertonia, grayish skin, jaundice, or other evidence of sepsis. Bulging fontanels are present as ICP rises.

The infant may have few striking symptoms. The parents may notice only that the infant is resistant to being cuddled or diapered, displays irritability, and has a mild fever. The infant may have a high-pitched cry, a transient vacant stare, and anorexia. A bulging, tense fontanel is a common symptom and may indicate increased ICP. Older children may have nonspecific complaints, such as high fever, vomiting, and fatigue. Severe headache, altered consciousness, stiff neck (nuchal rigidity), and convulsions are often present and suggest neurologic involvement.

Ask the child to try to touch the chin to the chest. If pain prevents the child from doing so, nuchal rigidity, caused by inflamed meninges, may be present.

The Kernig sign (inability to extend the legs fully when lying supine) and the Brudzinski sign (flexion of the hips when the neck is flexed from a supine position) are frequently present.

Document any rash. Both *H. influenzae* meningitis and meningococcal meningitis can cause a petechial rash. As the rash rapidly progresses, darker purpuric eruptions occur. These eruptions are associated with meningococemia septic shock, known as Waterhouse-Friderichsen syndrome (Fig. 21–8).

Alert! Advise any parent inquiring about a “purple rash,” especially one associated with other symptoms such as fatigue, fever, and vomiting, to have the child seen by a healthcare provider immediately.

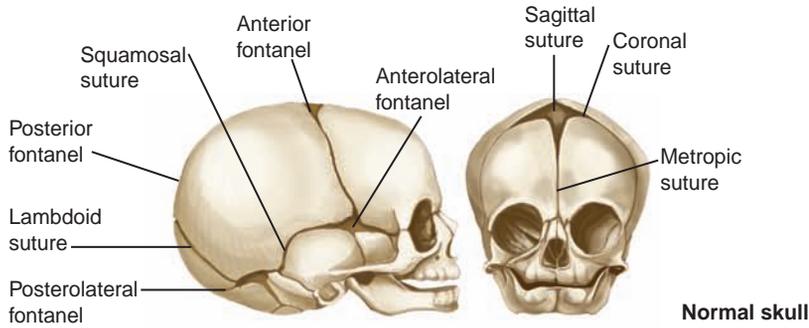

Meningococemia, an overwhelming septic infection, may develop in 5% to 20% of patients with *Neisseria meningitidis* meningitis (Manchanda, Gupta, & Bhalla, 2006). Its high fevers, purpuric lesions, and circulatory collapse from adrenal insufficiency constitute a medical emergency. The accompanying inflammatory response is marked by disseminated intravascular coagulation, encephalitis, lung abscess, and organ hemorrhage leading to tissue necrosis. This collection of symptoms may result in death only hours after the onset of fever. Rapid diagnosis and antibiotic therapy can be lifesaving.

Diagnostic Tests

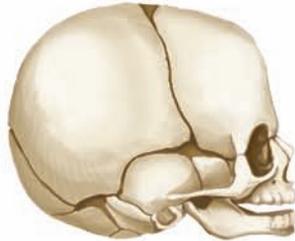

Bacterial meningitis can be diagnosed through signs and symptoms, plus a CSF culture. The fluid is examined for cloudiness, blood cell counts, white blood cell differential, and protein and glucose levels (Table 21–8).

caREminder

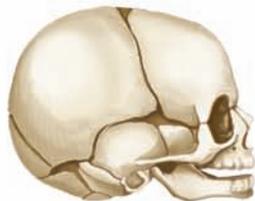

The glucose and protein content of the CSF provide clues to the etiology of meningitis. A low glucose level and high protein count in spinal fluid indicate bacterial meningitis. A normal to high glucose level and a normal to low protein count typically indicate viral meningitis.

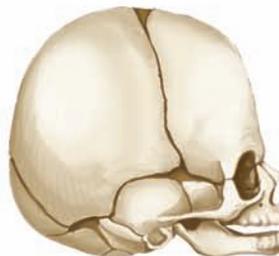

Microcephaly: Head circumference more than 2 standard deviations below the mean for age, gender, and race.

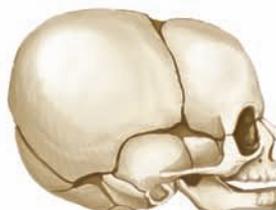

Scaphocephaly or dolichocephaly: Premature closure of the sagittal suture results in restricted lateral skull growth.

Brachycephaly: Premature closure of the coronal suture results in excessive lateral skull growth and large head circumference.

Oxycephaly or acrocephaly: Premature closure of all sagittal and coronal sutures results in excessive upward skull growth and small head circumference.

Plagiocephaly: Unilateral premature closure of the coronal suture results in asymmetrical skull growth.

FIGURE 21-7. Normal skull and variations that result from premature closure of cranial sutures.

TABLE 21-6

Craniofacial Abnormalities

Description	Assessment	Interdisciplinary Interventions
Microcephaly		
<p>HC that measures 2 SD below the mean for the child's age and gender.</p> <p><i>Primary</i> (genetic) microcephaly caused by a genetic inheritance pattern or syndrome (e.g., trisomy 21, trisomy 18, cri-du-chat, Cornelia de Lange).</p> <p><i>Secondary</i> (nongenetic) microcephaly can result from exposure to noxious agents in utero or during times of rapid brain growth (e.g., radiation, congenital infections, maternal ingestion of drugs or alcohol, meningitis or encephalitis, malnutrition, maternal diabetes, hyperthermia, hypoxic ischemic encephalopathy).</p>	<p>Measurement of HC (at birth or over time) and visual inspection may reveal a very small head. Record HC of parents and siblings to evaluate for familial tendencies.</p> <p>Assessment for other physical and congenital abnormalities (e.g., abnormal facies, short stature, deformities of the hands, congenital heart disease).</p> <p>Karyotypes are obtained if chromosomal syndrome is suspected.</p> <p>CT or MRI used to assess structural abnormalities of the brain or intracerebral calcifications.</p> <p>Blood or urine analyses are done to determine specific causative agents (e.g., cytomegalovirus, rubella, or herpes simplex infection).</p>	<p>No treatment to alter or reverse the child's small HC.</p> <p>Treat causative agent (if known) to minimize involvement of further body systems.</p> <p>Work in collaboration with the family to optimize the child's development (see Chapter 30 for care of the child with a developmental disability). Most children with microcephaly experience some degree of cognitive deficit.</p>
Craniosynostosis		
<p>Absence of, or premature fusion of, one or more cranial sutures; the process of early suture closure. <i>Craniosynostosis</i> (often used synonymously with <i>craniosynostosis</i>) describes the deformity that results from early fusion of sutures.</p> <p><i>Primary, simple synostosis</i>: involvement of one suture; <i>primary, compound synostosis</i>, absence or early fusion of two or more sutures.</p> <p>Most cases present as an isolated problem not associated with other syndromes or anomalies.</p> <p><i>Secondary</i> occurs as a result of a known disorder causing failure of brain growth and expansion or early fusion of sutures.</p> <p><i>Syndromic</i> involves closure of multiple sutures and occurs in conjunction with other morphologic syndromes or developmental anomalies, (e.g., Crouzon and Apert syndromes; see thePoint, for Supplemental Information: Genetic Disorders Associated With Craniosynostosis). In these cases, development of facial bones is also affected, and increased ICP can be a serious secondary complication.</p> <p>The number of sutures involved and the rate and degree of fusion determine cranial asymmetry. Growth is inhibited at right angles to the fused suture, whereas compensatory expansion</p>	<p>Parents are often the first to notice abnormalities in the infant's head shape.</p> <p>Palpate the head for suture location and mobility; note bony ridges along suture lines and any facial or cranial asymmetry.</p> <p>Evaluate asymmetry by comparing the location of the external ear canals and the outer canthi of the eyes from right to left; best made with the examiner looking down on the infant or child from a superior position. Move the child's hair away from the forehead during examination, especially when synostosis of the metopic or either coronal suture is suspected.</p> <p>Plot serial measurements of HC on growth chart to provide an early indication of the development of craniosynostosis.</p> <p>Measure height, weight, and HC simultaneously to ensure that the child is not failing to grow on all parameters for other reasons.</p> <p>Perform a complete neurologic examination; evaluate sensory and motor function, cranial nerves, and for signs indicative of chronic increased ICP (progressive papilledema, impairment of vision, and changes in mental status such as increased irritability or lethargy), which may occur if the cranial</p>	<p>Assess the family's goals. It is hard for a parent of an otherwise healthy-appearing child to consent to surgery of this magnitude, even in the presence of obvious deformity. Elicit concerns and provide positive reinforcement.</p> <p>Surgical intervention to prevent increased ICP and correct cosmetic deformity is usually done between 3 to 12 months of age, when the child's bone is still pliable.</p> <p>Preoperatively, make parents aware of the potential for blood loss in the child; the family may wish to donate blood. Educate family members about skull anatomy and how surgery will change it. Show before-and-after photographs of children who have undergone similar corrective surgery. Prepare parents for the postsurgical appearance of their child with a turban-style head dressing, orbital edema that may cause the child's eyelids to swell shut, and irritability for the first few days.</p> <p>Postoperatively, monitor the child's neurologic status, including level of consciousness, pupillary responses (not done if eyes are swollen shut), and signs of increased ICP. Monitor vital signs for changes indicating infection or changes in ICP. Assess surgical dressings and drains, and</p>

Craniofacial Abnormalities (Continued)

Description	Assessment	Interdisciplinary Interventions
<p>occurs at the sutures that are functional. The earlier in fetal or infant life that synostosis occurs, the greater the effect in cranial growth and appearance.</p>	<p>bones are not able to expand with brain growth. Conduct a full developmental evaluation. Check the family history for indications of genetic findings in other family members, living or dead. Radiographic studies and a CT scan assist in detailing the bony structure and associated intracranial abnormalities.</p>	<p>monitor fluid and electrolyte balances, because children undergoing this surgery often have mild to moderate cerebral edema. Facial swelling and severe eye and periorbital swelling require skin surveillance to prevent further trauma, skin breakdown, or infection. Elevate the head of the head at least 20 to 30 degrees per surgeon preference. Increased intrathoracic pressure, which results from elevating the torso, has been known to increase ICP. For this reason, children recovering from surgery are maintained on moderate fluid restrictions. Prophylactic antibiotics may be administered for a few days. Monitor the child for CSF leak. Prevent the child from touching the incision after removal of the head dressing; this may require use of elbow splints. Administer prophylactic eye drops or ointments as ordered if prolonged eye swelling increases risk of conjunctival infection or ulcer. Provide pharmacologic pain management, implement biobehavioral methods as adjuncts (see Chapter 10); considerable postoperative pain is typical. Be aware that easing the fear and anxiety of a young child who cannot see is a challenge, but sedatives are rarely ordered, because they mask true neurologic status and make assessment difficult. Ask parents what biobehavioral measures help their child to cope. Maximize use of the senses of touch, taste, smell, and hearing to assure a child that his or her familiar and comforting world has not disappeared. Ensure adequate rest periods, even as the child appears to get back to normal activity.</p>
<i>Positional plagiocephaly</i>		
<p>A nonsynostotic disorder resulting from molding caused by repeat positioning on the same side of the head</p>	<p>Assess as with craniosynostosis.</p>	<p>To prevent or minimize positional plagiocephaly, teach parents to alternate the sleep position of the child (e.g., put the child's feet at one end of the bed for a week, then at the other end</p>

(Continued)

TABLE 21-6

Craniofacial Abnormalities (Continued)

Description	Assessment	Interdisciplinary Interventions
		<p>the next week), alternate feeding positions, hang decorations or move crib to encourage child to look to both sides, and put the child prone daily while awake.</p> <p><i>Dynamic orthotic cranioplasty</i> incorporates the use of special hard-shell helmets, designed by orthotic technicians or physical therapists, that have internal inserts that place gentle pressure on the skull, aligned opposite to the affected area. The helmet is worn 24 hours a day, generally for 3 to 6 months. Controversy exists over whether the helmets are necessary, because many children outgrow this deformity without them (de Ribaupierre, Vernet, Rilliet et al., 2007). Teach the parents to assess the scalp daily for redness or abrasions, and to provide good hygiene to the scalp. As the child adjusts to the helmet, acetaminophen may be needed to decrease irritability and to promote comfort. Teach the family the importance of follow-up evaluations for assessment of the child and to adjust the helmet based on the progression of the therapy.</p>
<p>HC, head circumference; SD, standard deviation.</p>		

Common microbiologic tests for bacterial meningitis also include a Gram stain and a blood culture. These tests are positive in 80% to 90% of infected patients for spinal fluid and 30% to 60% for blood specimens. Counterimmunoelectrophoresis and latex agglutination tests can detect bacterial antigen in spinal fluid, urine, or blood in less than 1 hour. These rapid tests are helpful when children have been pretreated with antibiotics before the lumbar puncture or blood culture. Although these rapid diagnostic tests are available, they cannot be used as the sole basis of diagnosis, because false results can occur.

Other laboratory tests may include cultures of blood, urine, nasopharynx, and CSF leaks to identify the source of septicemia. Complete blood cell counts may show an increased total white blood cell level with elevated numbers of immature granulocytes. Serum C-reactive protein levels increase acutely with bacterial infection. CT or MRI may be used to monitor the course of the illness and to determine the need for specific interventions.

Nursing Diagnoses and Outcomes

Nursing Plan of Care 21-1 presents a variety of nursing diagnoses that can be applied to the child with a neurologic condition (see [thePoint](#) for Care Path: The Child With Uncomplicated Bacterial Meningitis).

Interdisciplinary Interventions

Treating bacterial meningitis requires prompt, intensive medical management and nursing care; it also frequently requires pain management.

Pharmacologic Interventions

Treatment for bacterial meningitis calls for aggressive intervention with appropriate intravenous antibiotics, given for 7 to 14 days. Broad-spectrum antibiotic therapy is initiated before the results of CSF cultures are obtained. After organism sensitivities are known, antibiotic therapy is refined based on sensitivities identified by

TABLE 21-7
Bacterial Meningitis

Pathogen	Predisposing Factors	Considerations	Prevention
Pneumococcus (<i>Streptococcus pneumoniae</i>)	Otitis media, mastoiditis, basilar skull fracture, sickle cell disease, asplenia	Accounts for 25% of all cases and has a 25% mortality rate with treatment	Pneumococcal conjugate vaccine recommended for all children 2 to 23 months Pneumococcal polysaccharide vaccine recommended for high-risk children 2 years old or older
Meningococcus (<i>Neisseria meningitidis</i>)	Close contact with a previous case at daycare center, nursery school, or college dorm	Accounts for 25% of all cases Has a 5% to 10% mortality rate with treatment	Rifampin, ceftriaxone or ciprofloxacin for all close contacts Meningococcal polysaccharide diphtheria toxoid conjugate vaccine for high-risk children 11 years or older Meningococcal polysaccharide vaccine for high-risk children 2 to 10 years
<i>Haemophilus influenzae</i>	Otitis media, pharyngitis, sickle cell anemia, asplenia	Accounts for 10% to 15% of cases Has a 5% mortality rate with treatment	Rifampin for all household contacts <i>H. influenzae</i> type B conjugated vaccine recommended for all children beginning at 2 months
Gram-negative enteric bacteria	Maternal vaginal or perineal colonization, congenital dural defects (meningomyelocele)	Accounts for 10% of cases Has a 50% to 75% mortality rate with treatment	No chemoprophylaxis or vaccine available.
Group B streptococcus	Maternal vaginal or perineal colonization	In twin delivery, requires treatment of both twins even if only one is symptomatic.	No chemoprophylaxis or vaccination is required. Intrapartum administration of ampicillin by mother may prevent infection of newborn.
<i>Listeria monocytogenes</i>	Maternal vaginal or perineal colonization. Maternal infection from consuming contaminated dairy products.	Pregnant women should avoid unpasteurized milk and soft cheeses, such as goat cheese.	No chemoprophylaxis or vaccine is available
Shunt-associated meningitis (coagulase-negative or coagulase-positive <i>Staphylococcus</i> , gram-negative rods, enterococci)	Ventriculoatrial or ventriculoperitoneal shunt	Requires scrupulous technique Requires adequate skin asepsis when accessing shunt	Based on causative pathogen

the culture, and dosages are adjusted to maintain therapeutic serum antibiotic levels, when appropriate. Intravenous corticosteroids, such as dexamethasone, may be used as an adjunct to antibiotic therapy to decrease meningeal inflammation and prevent hearing loss (van de Beek, de Gans, McIntyre, et al., 2007).

Infection Control Interventions

Droplet precautions are recommended until at least 24 hours of effective antibiotic therapy have elapsed. Generally, continuing isolation beyond 24 hours is not recommended for any of the forms of bacterial meningitis except those caused by *H. influenzae* and *N. meningitidis*.

FIGURE 21–8. This child's legs exhibit the characteristic purpuric lesions of meningococcal disease.

Surgical Interventions

Surgical treatment may be necessary for infants or children with severe seizures, increased ICP, ventriculomegaly, hydrocephalus, subdural effusion, or empyema. Treatment may include ventriculostomy to drain infected or obstructed fluid. A shunt may be necessary. Some organisms may require careful intraventricular administration of antibiotics. Subdural effusions may be treated with subdural antibiotic irrigation and drainage performed by a physician or advanced practice nurse.

Supportive Interventions

Supportive interventions include managing fever and hydration, which entails monitoring response to treatment. Avoid overhydration to prevent the onset of

SIADH that would further exacerbate cerebral edema and lead to life-threatening compromise of cerebral tissues. Fluids are often restricted to a combined oral and intravenous total of one half to two thirds of maintenance fluids (see [thePoint](#) for Care Path: The Child With Uncomplicated Bacterial Meningitis). Supportive care may also include recognition and treatment of increased ICP, seizures, cerebral edema, hydrocephalus, subdural effusion, and empyema.

If seizures have occurred, the child may receive a loading dose of phenobarbital, phenytoin (Dilantin), or fosphenytoin sodium (Cerebyx), followed by maintenance doses. If seizure activity persists beyond 4 days, risk of residual damage and chronic seizure disorders increases.

Additional interventions include acute neurologic monitoring, evaluating vital signs and head circumference, palpating the anterior fontanel, measuring daily weight, measuring intake and output, and assessing the intravenous site (Clinical Judgment 21–3). Assess the child for discomfort, irritability, behavioral problems, seizures, vomiting, appetite, thirst, and other potential complications. The child is at risk for seizure activity, so keep bedside rails up, and ensure that someone stays with the child in the bathroom. If a seizure occurs, provide appropriate immediate care, observe and document seizures, and administer antiepileptic medications as ordered by the prescriber. Teach family members and the child about seizure observation, management, and medications.

Monitor the child for potential hearing loss caused by meningitis or ototoxic side effects of aminoglycoside antibiotics and diuretics by assessing the child's response to auditory stimuli and the ability to localize sounds. If hearing loss is suspected, notify the prescriber to ensure that the child is tested appropriately. An otologist can determine treatment and ongoing follow-up.

Assessment for potential arthritis and stress ulcer is also indicated in the child with meningitis.

TABLE 21–8

Analysis of Cerebrospinal Fluid for Central Nervous System Infections

	Pressure, mm H ₂ O	Appearance	Leukocytes/mm ³	Protein, mg/dL	Sugar, mg/dL
Normal cerebrospinal fluid	60–200 (5–15 mm Hg)	Clear	0–5	10–30	40–80
Bacterial meningitis	Elevated	Turbid, cloudy	Elevated, 100–60,000, polymorphonuclear cells predominate	Elevated, 100–500	Decreased
Aseptic meningitis	Normal or slight elevation	Clear	10–1,000	Not greater than 100	Normal to low, <40
Tuberculosis meningitis	Elevated	Clear	25–100	100–200	<50
Brain abscess	Elevated	Clear	Elevated, 10–200	Elevated, 75–500	>50

CLINICAL JUDGMENT 21–3

The Child With Meningitis

Kara is 9 years old and is brought to the emergency department by her guardian because of severe headaches and a stiff neck for the past 24 hours. Kara did not want to go to school today. Upon arrival in the emergency department, she vomited. She has had no history of a recent cold or other illness. Her temperature is 102 °F (38.9 °C).

Questions

- To determine whether Kara has meningitis, what diagnostic tests and procedures should be completed?
- What clinical finding is classically associated with meningococcal meningitis?
- The CSF fluid is cloudy with an increased white blood count, low glucose level, and elevated protein level. What nursing diagnosis could be selected to reflect Kara's potential for neurologic dysfunction?
- Kara is transferred to the pediatric unit. What nursing measures should be taken to make Kara comfortable and free from pain?
- Twenty-four hours later, Kara demonstrates no improvement. She remains febrile, continues to vomit, and has become very irritable and lethargic. What action should the nurse take?

Answers

- Lumbar puncture; cultures of blood, urine, and nasopharynx; CT or MRI of the head for child with symptoms of increased ICP
- Rapidly spreading purpuric skin lesions
- Risk for injury related to complications of meningitis including increased ICP, seizures, and hearing loss
- Analgesics should be given as ordered. Head of bed should be elevated and the room should be kept quiet, with subdued lighting. Healthcare activities should be arranged to cause the least amount of disturbance to Kara. Comfort objects should be provided.
- Report these findings immediately to the physician. The antibiotics may need to be changed. New lumbar puncture and blood cultures may be performed.

Pain Management

The child with meningitis is likely to experience pain related to meningeal irritation. In addition, some diagnostic tests, such as lumbar punctures, blood draws, administration of intravenous fluids and antibiotics, and immobility associated with bed rest, may cause discomfort. Although completely relieving the child's pain and discomfort may not be possible, use pharmacologic and biobehavioral measures to maximize the success of pain relief interventions (see Chapter 10). Discuss pain with the child honestly, indicating how much a procedure will hurt, how long it will last, and what will help to lessen the pain. Ensure that the child understands that the pain is *not* a punishment.

Community Care

Community care begins with prevention measures for meningitis and control so that existing cases do not cause others. Ongoing home care is crucial.

Prevention and Control

Preventive measures against bacterial meningitis include prompt treatment for upper respiratory infections, otitis media, sinusitis, mastoiditis, and other infections, espe-

cially in younger infants and children. Immunization with *H. influenzae* type B, 7-valent pneumococcal conjugate vaccine, 23-valent pneumococcal polysaccharide vaccine, meningococcal (groups A, C, Y, and W-135) polysaccharide diphtheria toxoid conjugate vaccine, or meningococcal polysaccharide vaccine primes the child's immune system and facilitates effective response to subsequent exposure, thus preventing meningitis. See Chapter 8 for a discussion of immunizations.

For family members and exposed staff, chemoprophylaxis is only necessary in cases of exposure to meningococcus or *H. influenzae*. Family members who share the same household with the infected child should receive rifampin prophylaxis; adults can receive a single dose of ciprofloxacin. Any daycare or school contacts should also receive prophylaxis, because the duration and extent of contact with the infected child may be difficult to determine. Generally, if close, intimate mouth-to-mouth contact has occurred, then prophylaxis is necessary. However, many parents of children in the same classroom or school demand prophylaxis because meningitis is so devastating. Rifampin is relatively inexpensive and causes few side effects. Thus, most health departments give prophylaxis generously. Ciprofloxacin is an attractive alternative to rifampin for persons older than 18 years, because it is given as a single dose.

caREminder

Unless a healthcare worker has unprotected, intimate contact with the patient, prophylaxis is not indicated. Intimate contact involves face-to-face encounters, such as intubating the child, assisting with a lumbar puncture, or giving mouth-to-mouth resuscitation without using a mask.

Many employee health and infection control programs offer prophylaxis to healthcare workers regardless of the extent of the exposure. However, the American Academy of Pediatrics and the Centers for Disease Control recommend prophylaxis for healthcare workers based on actual exposure, rather than heightened concern (American Academy of Pediatrics, 2006a).

Home Care and Rehabilitation Interventions

Home care and rehabilitation are based on the residual effects of the disease and vary for each child. The child may be discharged while still on intravenous antibiotic therapy if the child is stable, afebrile, has no complications, and the family is able to manage care at home. Make arrangements with the home health nurse before discharge to ensure a smooth transition of care from acute to home care settings. Instruct parents how to assess neurologic status and to evaluate changes in vital signs, and encourage collaboration with the healthcare team. Compare developmental findings with previously recorded assessments to evaluate developmental delays. In addition, the healthcare team works with the family to provide rehabilitation as needed to address problems with other systems that arise during the course of the illness. Before discharge, brain stem auditory-evoked potentials or audiometry for older children is usually done. If hearing loss occurs, early intervention is possible. Careful follow-up is advisable, with developmental testing and information about appropriate infant stimulation.

Tuberculous Meningitis

Tuberculous meningitis, a complication stemming from primary lung infection with tuberculosis (see Chapter 24), is most prevalent in children younger than age 3 years (Saitoh, Pong, Waecker, et al., 2005) and is rarely seen in infants younger than 3 months old (van den Bos, Terken, Ypma, et al., 2004); congenital cases are rare. Occasionally, tuberculous meningitis may occur many years after the primary infection, resulting from the rupture of one or more tubercles, which discharge bacilli into the subarachnoid space.

Outcomes are favorable with early diagnosis and treatment. However, if untreated, death is likely. Complications are related to the effectiveness of treatment and the stage of infection at which the child is diagnosed. Long-term sequelae can include hearing loss, communicating hydrocephalus, intellectual and emotional disturbances, seizures, and muscle spasticity.

Pathophysiology

Mycobacterium tuberculosis is the organism responsible for tuberculosis infections. In children younger than 20 years of age, the lungs are the predominant site for *primary* tuberculosis infections, followed by the lymph nodes, pleural space, and meningeal covers of the brain. *Secondary* infection occurs as *M. tuberculosis* bacteria enter the lungs and rapidly spread throughout the body via the lymphatic system and bloodstream. When organisms reach the highly vascular meningeal covering of the brain, the child becomes at risk for tuberculous meningitis; therefore, the infection may be classified as either primary or secondary.

Assessment

The onset of tuberculous meningitis may be rapid or gradual. Rapid onset is more common in infants and younger children, with acute hydrocephalus, seizures, and cerebral edema developing after only a few days of symptoms. More common, onset is gradual, with signs and symptoms developing over weeks. Initial symptoms are nonspecific and include fever, lethargy, headache, and malaise. Within 10 to 14 days, positive meningeal signs (nuchal rigidity, Kernig sign, severe headache) develop.

Diagnostic Tests

Analysis of CSF fluid may show little abnormality because the fluid is obtained from a site proximal to the inflammation and obstruction. CT scans or MR images are usually normal during the early stages of the illness. Diagnosis is typically based on clinical suspicion because laboratory, radiographs and clinical findings are often nonspecific.

Interdisciplinary Interventions

The child requires treatment for tuberculosis (see Chapter 24). In addition to long-term treatment with isoniazid, rifampin, and pyrazinamide, steroids have been shown to improve survival in adults (Thwaites, Macmullen-Price, Chau, et al., 2007) and their use is advocated in children (Padayatchi, Bamber Dawood, et al., 2006).

If neurologic sequelae are present, other therapy (e.g., physical or occupational therapy) may be warranted. Provide emotional support to the family; ongoing disease sequelae and long-term medication regimes are stressors. Teach and reinforce with children and their families the importance of adhering to the medication regime.

Aseptic Meningitis

Aseptic meningitis is one of the most common causes of infection of the meninges. It occurs at all ages, but is more common in children. Meningitis with negative bacterial cultures from CSF is termed *aseptic*. It can be caused by many agents, such as fungi, rickettsiae, drugs, or postinfection, but enteroviruses are the most common cause (Lee & Davies, 2007). Common enteroviruses include echoviruses, coxsackievirus, and polio. Herpes

simplex types I and II may cause aseptic meningitis in adolescents and life-threatening encephalitis in neonates and children.

Pathophysiology

Viruses gain access to the CNS through systemic circulation. They enter cells in the meninges, causing inflammation and edema. Incidence of infection by enteroviruses is highest during the summer months.

Assessment

The clinical manifestations are similar to those of bacterial meningitis; however, they do not progress as rapidly and are usually less severe. Assess the child for fever, headache, vomiting, and stiff neck. Seizures are seen less frequently in aseptic meningitis than in bacterial meningitis. Irritability, drowsiness, and lethargy may occur but are milder than in patients with encephalitis. The child's history usually reveals the presence of a recent or concurrent viral illness.

Document the presence of any rash or other physical signs. When aseptic meningitis occurs with or follows a discrete, red, maculopapular rash, enterovirus or coxsackievirus infection is likely. When coxsackievirus is the offending pathogen, symptoms may also include the appearance of vesicles and ulcers on the soft palate, paroxysmal pain in the intercostal muscles caused by irritation of pleural surfaces, and symptoms of pericarditis. If aseptic meningitis is caused by mumps virus, parotiditis may also occur.

Diagnostic Tests

Lumbar puncture is completed to obtain CSF for examination and potentially differentiate aseptic meningitis from bacterial meningitis (Fig. 21–9 and see [thePoint](#) for Procedures: Lumbar Puncture). The CSF in aseptic meningitis usually contains a greater amount of white blood cells than normal, but fewer than in bacterial disease. CSF glucose may be normal, and protein may be only mildly elevated. Virus or virus antibodies may be

FIGURE 21–9. Positions for lumbar puncture. (A) Knee–chest position. (B) Recumbent position. (C) Sitting position.

isolated from CSF, blood, sputum, stool, or other specimens. The lumbar puncture may also help to alleviate symptoms of increased ICP.

Interdisciplinary Interventions

Healthcare interventions for aseptic meningitis are primarily supportive and are aimed at ameliorating symptoms. The child may be hospitalized to monitor and manage neurologic status, to monitor fluid and electrolyte balance, to control hyperthermia, to provide supportive care, to control pain, to maintain adequate nutrition, and to treat seizures, if they occur.

Young infants are routinely hospitalized because of the risk of meningitis caused by bacterial infection. Because bacterial meningitis can be so devastating, young infants receive broad-spectrum antibiotics (ampicillin and cefotaxime) until CSF bacterial cultures are negative and thus bacterial meningitis is ruled out. Older and less severely affected children may be managed on an outpatient basis, with analgesics and antipyretics administered as needed.

Encephalitis

Encephalitis is defined as an inflammation of the brain. When the meninges are also involved, the term *meningoencephalitis* is used. If the spinal cord is involved, the term *myelitis* or *encephalomyelitis* is used. Although encephalitis closely resembles meningitis in origin and presentation, the clinical course may be more severe, because the infection affects actual brain tissue.

A wide variety of infectious agents may cause encephalitis. Viral encephalitis is most commonly seen in children. The viruses most frequently identified as causative agents are enteroviruses, arboviruses, and herpes simplex virus. Viral encephalitis is particularly common in children who are immunosuppressed. The advent and widespread use of measles, mumps, rubella, and chickenpox vaccines has substantially decreased the incidence of viral encephalitis.

Nonviral causes of encephalitis include bacteria, spirochetal infections, cat-scratch disease, parasites, fungi, rickettsial infections, protozoa, and helminths. These organisms may be inadvertently introduced into the body during administration of certain chemotherapeutic agents, diagnostic imaging dyes, detergents, or alcohol into the CSF.

The prognosis of encephalitis depends on the degree and duration of cerebral and CNS involvement, and the ability to successfully manage secondary complications. Neurologic sequelae are present at discharge in 60% of children who recover from acute infection (Fowler, Stodberg, Eriksson, et al., 2008).

Pathophysiology

CNS involvement is believed to be secondary to an infectious process occurring elsewhere in the body. The CNS may be severely affected, with associated dysfunctions as seen in Guillain-Barré syndrome (GBS) and Reye syndrome. As the brain tissue becomes inflamed, fever, head-

ache, seizure, agitation, and altered states of awareness result from increasing cerebral or cerebellar dysfunction.

Assessment

The onset of symptoms may be acute or gradual, with complaints of general muscle pain, fever, gastrointestinal distress, and mild respiratory symptoms. Clinically, the neurologic presentation is similar to that in meningitis, including headache, changes in arousal and consciousness, and possible persistent seizures. Complete a thorough history to evaluate any recent viral illnesses or exposures that may identify the causative organism. Assess for signs of increased ICP and for meningeal irritation, including headache, fever, and stiff neck.

Diagnostic Tests

Laboratory evaluation includes examination of CSF, blood, stool, and sputum to help establish the cause of the disease. In many cases, CSF values are unspecific. Lymphocyte count may be increased, glucose is usually normal, and protein levels are often mildly elevated. If localized CNS hemorrhage has occurred, red blood cells and hemoglobin may be present in the CSF. CSF should also be examined for acid-fast organisms, parasites, and bacteria. Fourteen to 21 days after the onset of encephalitis, the CSF should again be evaluated and tested.

CT and MRI may show cerebral edema, hydrocephalus, or lesions. An EEG may show abnormalities consistent with seizure activity.

Interdisciplinary Intervention

The care of the child with encephalitis is directed toward managing and preventing secondary complications such as seizures, increased ICP, and respiratory involvement. Severely affected children may receive mechanical ventilation, ICP monitoring, and ventriculostomy care as warranted (see the discussion on increased ICP earlier in this chapter).

If a causative organism is identified, appropriate antimicrobial medications are prescribed. Herpes simplex encephalitis should be treated with intravenous acyclovir for 10 days. Until cultures reveal a specific etiologic agent, children with fever and acute encephalic symptoms are generally given acyclovir and an antibacterial agent.

If seizures have occurred, treatment is initiated by administering intravenous diazepam or lorazepam. Characteristically, the seizures associated with encephalitis are difficult to control. If benzodiazepine is ineffective, intravenous phenytoin is administered. Further seizure activity may require the use of phenobarbital. Aggressive and prolonged use of antiepileptic medications creates the need for mechanical ventilation to support the child's respiratory status and cardiac monitoring to assess for cardiac conduction defects. As always, monitor the child for side effects.

The child's precarious condition and the lack of a definitive treatment for the child's illness are likely to cause the family a great deal of stress and fear. Provide frequent

communication to the family regarding the child's status. Arrange support services to help the family through this difficult time. Involve parents in care decisions and in direct care for the child.

Brain Abscess

A brain abscess is a localized infection that extends into the brain parenchyma. Brain abscess can be multiple or single and is most often located in the frontal and temporal lobes.

Brain abscesses are rare, yet serious. They are typically caused by streptococci, staphylococci, enteric bacteria, or mixed flora. Gram-negative enteric pathogens are most common in neonates (Yogev & Bar-Meir, 2004). *S. aureus* is the primary cause of direct infection following head trauma or intracranial procedures. Blood-borne spread of organisms is likely to cause multiple abscess formation, whereas other mechanisms generally result in single lesions. Risk factors for brain abscess in children include sinusitis, otitis, pulmonary infection, cyanotic congenital heart disease, endocarditis, meningitis, bacteremia, and immunodeficiency (Frazier, Ahn, & Jallo, 2008).

Widespread use of antibiotics and development of more precise diagnostic imaging tools have decreased the mortality rate associated with brain abscess to 4% to 12% (Frazier et al., 2008). The likelihood of recovery without substantial neurologic deficit is increased by rapid diagnosis, antimicrobial medications, and diligent monitoring.

Pathophysiology

The origin of brain abscesses can usually be traced to one of three situations:

1. Extension of local infections of the middle ear, mastoid, or sinuses
2. Distal infections in the chest or lungs, or spread through bloodstream in immunocompromised host (metastatic abscess)
3. Direct infection as a result of open head trauma, intracranial surgery, bacterial meningitis, or cranial traction

Within 2 weeks of initial microbial entry, the abscess becomes an encapsulated lesion filled with pus.

Assessment

Symptoms occur in two stages and vary according to the location of abscess. At the onset of infection, the child may complain of earache, fever, or vomiting. Assess for neurologic changes, such as drowsiness and sensory deficits, which may be present but unnoticed because they are mild. Organization and enlargement of the abscess lead to compression of brain tissue, causing signs of increased ICP. Severe headaches, changes in ocular function, seizures, and ataxia may occur, signaling parents to seek medical attention. Elicit any history of recent otitis media, mastoiditis, sinusitis, or dental abscess. If a child presents with these symptoms, alert and collaborate with a physician to complete diagnostic studies.

Diagnostic Tests

Diagnosis is confirmed by CT and MRI. In infants with an open fontanel, cranial ultrasonography may also be used for diagnostic purposes. Radiographs of the chest and skull help to locate the primary source of infection, such as an object aspirated into the lungs.

Alert! Lumbar puncture is contraindicated in patients with brain abscess, because increased ICP creates a risk of cerebral herniation.

Blood analysis is usually inconclusive regarding the causative organism. The white blood cell count may be normal, but an elevated erythrocyte sedimentation rate is not consistently present.

Interdisciplinary Interventions

Managing brain abscess involves both intravenous antibiotic therapy and surgical draining of the lesion. The type of antibiotic used depends on the causative organism, the site of the abscess, and the child's state of health. Antibiotic therapy is adjusted after the abscess drainage is cultured and organism sensitivities are obtained. Antibiotic therapy continues for 4 to 8 weeks.

Surgical excision and drainage of the abscess remains the definitive treatment for brain abscess. The child and the parents will require reassurance regarding surgery. Monitor children postoperatively for increased ICP and drainage or bleeding from the incision site.

Community Care

When fever is reduced and aspiration or excision of the abscess has reduced ICP, parents can be taught to administer intravenous antibiotics at home and to assess the child for changes in neurologic status. A central venous access is usually inserted before discharge to avoid repeat punctures of the child's skin. If the family feels uncomfortable administering the medications, a home care nurse can be employed to complete the task and to monitor the child's progress.

In some cases, if the child is medically stable, conservative treatment with antibiotics only, administered in the home or outpatient setting, may be scheduled. The child's progress is monitored by follow-up CT and by careful clinical examinations.

Tetanus

Tetanus is an acute infectious process caused by the exotoxin *Clostridium tetani*, a gram-positive anaerobic rod. The infectious process leads to a spastic, paralytic illness. The illness has been reported to occur after penetrating or crushing wounds, burn injury, pregnancy, and general surgery, and in neonates with umbilical stump infections. The disease is preventable with proper healthcare and a series of vaccinations.

The paralysis of tetanus rapidly becomes severe during the first week of onset, stabilizes during the second week, and gradually recedes over an ensuing 1- to 4-week period. Long-term sequelae may include CP, hypoxic brain injury, diminished mental capabilities, and behavioral problems. Shorter incubation and onset periods are associated with a poorer prognosis (Roper et al., 2007).

Pathophysiology

C. tetani spores are found in soil, house dust, animal intestines, and human feces. The spores are harmless until they enter a susceptible host. Any inadequately immunized patient who has been exposed to high levels of bacterial contamination from an injury is at high risk for tetanus.

After injury, local production of exotoxins occurs in the wound, and these toxins are then carried centrally via neural pathways. The primary sites affected are the spinal cord and brain stem. Tetanus toxin blocks normal inhibition of antagonist muscles, causing affected muscles to sustain maximal contraction. The autonomic nervous system also becomes unstable as a result of the infectious process. Airway obstruction and asphyxiation can occur as a result of laryngeal and respiratory muscle spasms.

WORLDVIEW: Tetanus neonatorum is more common in developing countries where women are not immunized against it, where contaminated instruments are used to cut the umbilical cord, or where native poultices such as cow dung or fermented milk are used for umbilical cord care.

Assessment

Ask about recent injuries. The incubation period from time of injury to onset of symptoms is usually between 7 and 14 days. Early signs of tetanus vary but may include low back pain, stiffness in the jaw and lower limbs, and dysphagia. As the disease progresses, the classic “lockjaw” or trismus is seen, which is spasm of the masticatory (chewing) muscles. As the facial muscles become more rigid, the corners of the mouth are drawn up and outward, resulting in what appears to be a fixed smile, a condition referred to as *risus sardonicus*, which is caused by intractable spasm of facial and buccal muscles. Paralysis extending into the abdomen, lumbar spine, hip, and thigh muscles can cause the child to assume an arched posture (opisthotonos) in which only the back of the head and the heels touch the ground.

The seizures associated with tetanus appear suddenly and are characterized by tonic contractions of muscles with clenched fists, flexion and abduction of the arms, and hyperextension of the legs. Seizures last a few seconds to a few minutes, with intervening periods of rest. As the illness progresses, the seizures become sustained and exhausting. Seizure activity may be triggered by sight, sound, or touch.

Ask about output; dysuria and urinary retention occur from bladder sphincter spasm. Bowel incontinence may occur during seizures. Temperature as high as 104 °F (40 °C) is generally present as a result of the sustained metabolic energy generated by spastic muscles. Tachycardia, arrhythmias, labile hypertension, diaphoresis, and cuta-

neous vasoconstriction occur as the autonomic nervous system becomes involved. The child does not lose consciousness and experiences extreme pain.

Neonatal tetanus is characterized by poor sucking, irritability, and fever occurring 3 to 12 days after birth. As the infection progresses, the infant develops facial grimaces, muscle rigidity, and opisthotonos. If the child is untreated, death occurs secondary to asphyxia. Diagnosis of tetanus is based on the clinical presentation because wound cultures often fail to detect *C. tetani*.

Interdisciplinary Interventions

The most critical goals of interdisciplinary management of tetanus are to maintain a patent airway, control seizures, neutralize the circulating toxin, and eradicate the *C. tetani* organisms.

Airway Maintenance

Endotracheal intubation may be required to prevent aspiration and respiratory arrest resulting from laryngospasm. In many cases, oxygen therapy and suctioning to manage oral secretions are sufficient. Approach suctioning cautiously, because manipulation of the airway can provoke muscle spasm and seizures. In severe cases, a tracheostomy may be performed.

Seizure Control

Diazepam is considered to be the most effective sedative for control of tetanic activity. The medication is given by continuous intravenous infusion and is titrated as needed to control spasms. The dosage is slowly reduced as the child’s symptoms recede. Phenobarbital also may be used to control seizures. Apnea can occur as a result of high doses of these medications; thus, mechanical respiratory support may be needed.

Control of Infection

The bacteria must be killed to halt continuation of the infectious process, and the neurotoxin within the child’s system must be neutralized. Penicillin G, given intravenously for 10 to 14 days, remains the antibiotic of choice. Erythromycin and tetracycline can be given if the child is allergic to penicillin.

To neutralize toxin that is diffusing from the wound, human tetanus immune globulin (TIG) is administered as a single intramuscular dose. If TIG is not available, human intravenous immune globulin or equine tetanus antitoxin can be administered. In addition, after the child is actively recovering from the disease, immunization with DT (diphtheria-tetanus) or DTaP (diphtheria-tetanus-acellular pertussis) can be given if

- Five years have lapsed since the child’s last tetanus shot
- The child is younger than 6 years of age
- The child has never been immunized for tetanus

Wound debridement is essential to the healing process. Meticulous care of the umbilical cord site or wound site is needed to ensure no further growth of spores.

Supportive Interventions

Provide care to minimize stimulation. A quiet, darkened setting is preferred. The child must be sedated to manage pain and prevent seizure activity. Monitor cardiorespiratory status and initiate suctioning as needed.

Monitor fluid and electrolyte status, and bowel and bladder function. Seizure, sustained rigid paralysis of the muscles, and instability of the autonomic nervous system predispose the child to many complications. The child is likely to be hemodynamically unstable, and thermoregulation may be difficult to manage. When the child's condition becomes more stabilized, consult physical therapy personnel to begin rehabilitation of affected muscle groups.

Community Care

Tetanus is preventable through active immunization. Chapter 8 discusses and Appendix E provides links to pediatric immunization schedules. Immunizing pregnant women with tetanus toxoid can prevent neonatal tetanus.

Tetanus prophylaxis should be followed as a part of wound management. Tetanus toxoid should always be given after a dog or other animal bite. Treatment of all wounds, except those experienced by fully immunized patients, should include administration of human TIG. If the immunization status of the child is unclear or if the child receives a tetanus-prone wound (e.g., crush or projectile wound, contaminated wound), TIG should be administered intramuscularly. Immediately clean and debride the wound itself. A tetanus toxoid booster is given to all persons with a wound if

- Their immunization status is unknown
- Their immunization status is incomplete
- The wound is clean but more than 10 years have passed since the last booster
- The wound is serious and more than 5 years have passed since the last booster (American Academy of Pediatrics, 2006b)

Work to ensure that a child's immunization status is up to date. Providing education to high-risk communities with limited healthcare resources is a valuable activity. Encourage parents to keep organized immunization records that are easily accessed by family members if the child is injured.

Reye Syndrome

Reye syndrome is an acute, noninflammatory encephalopathy with fatty degenerative changes in the liver, brain, and kidneys, first described in 1963 by Reye and colleagues.

The syndrome, which peaked in the 1980s, is now relatively rare. Although identification of potential causes enables avoidance of some agents, the potential for epidemic recurrence still remains (Johnsen & Bird, 2006).

Evidence supports the hypothesis that Reye syndrome is associated with aspirin (salicylate) use during the febrile prodrome of viral infections such as influenza A or B, or

varicella; some argue a causal linkage exists (Glasgow, 2006). Reye-like illness has been linked with agents such as valproic acid, aflatoxin, and chemical toxins, but research has not supported this association (Glasgow, 2006). Strong warnings were issued from the Centers for Disease Control and the American Academy of Pediatrics in the early 1980s when studies confirmed a relationship between aspirin administration during viral illnesses and the onset of Reye syndrome. Warning labels continue to be placed on containers of salicylate, which is believed to have reduced the incidence of this disease.

Early diagnosis and implementation of supportive care can prevent progression of the syndrome. Prompt intervention is crucial, because the disease can have a rapid onset, leading to coma or death within hours. Full neurologic recovery is usually achieved if cerebral edema does not progress.

Pathophysiology

The pathophysiology of Reye syndrome is complex and appears to involve a defect in mitochondrial function. Chemical metabolic imbalances are a hallmark feature. Examples include hyperammonemia from decreased levels of the enzymes that convert ammonia to urea, hypoglycemia and lactic acidosis from prolonged vomiting, and increased amounts of short-chain fatty acids. Any combination of these metabolic dysfunctions can generate cerebral edema and increased ICP.

Assessment

Evaluate the child's history generally for recent mild respiratory or gastric illness. Clinical signs and symptoms include persistent vomiting and diarrhea during the recovery phase of a viral illness and altered levels of consciousness such as lethargy, agitation, combativeness, or seizures. Also question the parents and child about the use of aspirin or aspirinlike products during the illness.

Diagnostic Tests

Abnormalities in hepatic function are demonstrated by elevated aspartate transaminase, activated clotting time, lactate dehydrogenase, and ammonia levels. A liver biopsy, completed only if the diagnosis is unclear, reveals microvascular fat and mitochondrial alterations. A staging system is used to describe the clinical course and the severity of the syndrome (Table 21-9).

Interdisciplinary Interventions

Children with Reye syndrome are cared for in an intensive care setting because of the high risk for increased ICP and liver dysfunction. No specific treatment exists. Supportive care is directed toward monitoring and managing cerebral edema (see earlier discussion on increased ICP). Interventions include nasotracheal intubation with ventilatory control to maintain low PCO₂ levels and to decrease CPP. Mannitol is administered to decrease elevated serum osmolarity. A barbiturate-induced coma

TABLE 21-9

Stages of Reye Syndrome

Stage	Symptoms
Stage I	Vomiting, lethargy, sleepiness, mild confusion, elevated serum liver enzymes, normal blood ammonia level, grade I EEG
Stage II	Disorientation, delirium, combativeness, hyperventilation, hyperreflexia, appropriate response to noxious stimuli, elevation in blood ammonia and serum liver enzymes, grade II or III EEG
Stage III	Coma, decorticate posturing, preservation of pupillary light reflexes, pupils dilated, persistent elevation in blood ammonia and serum liver enzymes, grade III or IV EEG
Stage IV	Deepening coma, decerebrate rigidity and posturing to painful stimuli, oculocephalic response, fixed pupils, hypoventilation, decreased blood ammonia and serum liver activity, grade III or IV EEG
Stage V	Coma, seizures, absent deep tendon reflexes, respiratory arrest, flaccidity, hypotension, decreased blood ammonia and serum liver enzyme activity, grade IV or electrocerebral silence on EEG

may be used if cerebral edema cannot be controlled. Vitamin K may be administered to correct prolonged prothrombin time. Phenytoin may be given to control seizures.

Ensure frequent and open communications are maintained between the healthcare team and the family. Explain all equipment and treatment measures. Parents may desire social services or clerical support to help them to deal with this unexpected crisis.

To prevent Reye syndrome, teach children and adults not to administer salicylate products to children, especially if the child has respiratory or gastrointestinal symptoms. Salicylate can be found in a number of over-the-counter products.

Guillain-Barré Syndrome (GBS)

GBS is an acute, demyelinating polyneuropathy of primarily peripheral nerves, which occurs as a postinfectious process. This immune-mediated process is triggered by a viral or bacterial illness such as a respiratory or gastrointestinal illness. The incidence of GBS in children birth to 15 years of age is 0.34 to 1.34 per 100,000 (McGrogan, Madle, Seaman, et al., 2008). GBS is a reversible disease with a good prognosis for most children.

Pathophysiology

During the viral illness that precedes GBS, the myelin sheath surrounding the peripheral nerves is altered. The altered myelin is perceived as a foreign protein, and sensitized lymphocytes attack it, leading to edema, destruction, and nerve root compression. Normal nerve conduction is interrupted, resulting in symmetric ascending weakness that progresses over about 2 weeks in most cases (some up to 4 weeks). A plateau of function at maximal weakness (the static phase) occurs over a variable period with proximal, then distal, strength returning over weeks or months (Hughes & Cornblath, 2005).

Assessment

The clinical examination focuses on motor, sensory, cranial nerve, and autonomic functions. Assess for progressive, ascending motor weakness of more than one limb. Note any areflexia or complaints of excruciating pain in the upper legs and back. Rapid progression of symptoms makes prompt diagnosis urgent, because respiratory failure, loss of swallow and gag reflexes, and need for ventilatory support can develop quickly. Respiratory failure may be preceded by progressive involvement of truncal musculature and cranial nerves, as well as sensory impairment. Elicit history of recent viral infection and determine the child's immunization status to eliminate the possibility of poliomyelitis.

Blood and urine cultures are completed to search for a causative agent and underlying systemic or immune-mediated disorders. Analysis of CSF reveals few white blood cells, with elevation of protein. Peripheral nerve conduction time studies and electromyogram demonstrate decreased nerve velocities.

Interdisciplinary Interventions

The treatment of GBS is primarily supportive. Because of the potential for rapid deterioration and respiratory failure, the child must be admitted to a high-observation area with possible rapid transfer to intensive care. During the acute phase of the disease, frequently assess respiratory function, heart rate, and blood pressure so that rapid intervention can be implemented if deterioration occurs.

The immune basis for GBS suggests use of intravenous immune globulins or plasmapheresis to prevent demyelination. Either therapy should be used early during the acute phase. The goal is to prevent respiratory compromise and the need for ventilatory support, thereby promoting a shorter recovery course (Hughes, Raphael, Swan, et al., 2006).

During the acute period, provide supportive measures to sustain life, to prevent complications, and to promote

comfort. Preventing the complications of immobility is of paramount importance, so initiate interventions as early as possible during the acute phase. The child is at risk for mobility problems such as joint contractures, skin breakdown, and deep vein thromboses. Perform passive range-of-motion exercises, frequent repositioning, and meticulous skin care to minimize these complications. Parenteral nutrition is provided if the child is intubated. Solid foods are introduced after extubation, after the child's ability to swallow is established. If severe pain is present during the initial stages of the disease, administer comfort measures. Pain medications should not interfere with the child's respiratory function or ability to cough.

Children with severe respiratory insufficiency may be intubated and placed on a ventilator. The inability to verbalize needs and loss of bodily functions are frightening to the child and the family. Incorporate developmental assessments and psychosocial support measures throughout the acute course.

During the static phase, nerve conduction to the bladder may be poor; therefore, an indwelling or intermittent catheter is indicated to relieve urinary retention. Tachycardia and arrhythmias may occur, and cardiac monitoring should continue. Sleep disturbances are common and are caused by pain, lack of scheduled rest periods, noise, and treatment interventions. Ensure adequate pain management. Organize care and create a schedule to provide quiet time for the child.

During recovery, children slowly regain muscle strength and sensation, and they experience reduced pain. Comprehensive care is still vitally important in the five most commonly affected areas: respiration, mobility, nutrition, autonomic nervous system, and psychological response. The early phases of the recovery program must balance activities with adequate rest. Fatigue or exhaustion can cause symptoms to return, which may be devastating for the child. Provide support and encouragement as progress is made in each area.

Community Care

Encourage parents to accept relatives' and friends' offers of help and respite. Educate parents about exercise, diet, and measures to provide psychosocial support to their child. Ideally, discharge planning begins with the child's admission to the hospital. Provide the family with resources to ease the return to normal life. The family may require home health nursing services. Good communication between the acute care setting and outreach teams facilitates high-quality continuity of care. GBS is an illness that requires a highly skilled, interdisciplinary healthcare team to manage the many facets of patient care. To the team, the nurse contributes clinical skills and expertise as an educator, patient advocate, supportive listener, and coordinator of resources.

The illness creates an abrupt interruption of established routines. If mentally and physically able, some children are able to continue their education using home teaching sessions. Child life specialists may offer suggestions for developmentally appropriate activities to alleviate boredom. The stress of pain, isolation, and dependency

may cause feelings of anger or depression. The child likely will regress to previous developmental stages to meet security needs. When parents are aware of these natural responses, they can provide better support.

Spinal Muscular Atrophy (SMA)

Spinal muscular atrophy (SMA) is a disorder characterized by degeneration of the anterior horn cells of the spinal cord and some cranial nerve nuclei, resulting in weakness and wasting of voluntary muscles. SMA is the most common autosomal recessive neuromuscular disorder and, after cystic fibrosis, the most common recessive condition leading to death in children (Pyatt & Prior, 2006). SMA is linked to an abnormality on chromosome 5 that is consistent across all forms of the disorder. Although the disorder is inherited, a high rate of spontaneous mutation has also been noted.

Pathophysiology

In SMA, anterior horn cells in the spinal cord and motor nuclei of the brain stem are progressively lost. Loss of function in one motor neuron results in abnormalities and loss of function in the muscles supplied by that motor neuron. As deterioration or loss of motor neuron function increases, muscle fiber and function are also lost. There is no cardiac involvement. Intelligence is normal.

Historically, three forms of SMA have been described. Common to all forms is the presence of more proximal, lower extremity weakness. SMA I, also known as Werdnig-Hoffmann disease, is the most severe form and begins in utero or early infancy. These infants can perform few spontaneous movements, are unable to lift the head, have difficulty with sucking and swallowing, and deep tendon reflexes are lost. Initial examination may also document **fasciculations** (continuous, involuntary "wormlike" movements that are best observed in the tongue). They may also be present in the child's deltoid, biceps, and quadriceps muscles. Intercostal muscles are also weakened, resulting in respiratory failure.

SMA II, the late infantile form, has a later onset (6–24 months) than SMA I and causes less initial weakness. These infants may achieve sitting and, with orthotic support, may achieve ambulation. On clinical examination, deep tendon reflexes are absent, and fasciculations may be present.

SMA III, also called Kugelberg-Welander disease, is the juvenile form of SMA, with onset occurring between 3 and 17 years of age. Early symptoms are nonspecific and include delayed developmental milestones and motor clumsiness. Atrophy of proximal muscles may be present.

Assessment

When taking the history, note early infant deaths within the family, family members with similar problems, and any maternal observations of decreased fetal movements, all of which suggest SMA I. Focus the clinical evaluation on assessment of the motor system and cranial nerves. Document any findings of hypotonia, generalized weakness, thin muscle mass, the presence of fasciculations, and altered tendon stretch reflexes. Inability to meet motor

developmental milestones is one of the first diagnostic clues of concern to family members.

Diagnostic Tests

When the diagnosis is suspected, a specific gene deletion study by blood sample should be performed. Documentation of the defect in chromosome 5 eliminates the need for muscle biopsy. However, weakness and hypotonia in infants have many potential causes. Therefore, an EMG is usually performed to document specific muscle responses. The EMG results vary by type of SMA in the quantity and character of fibrillations and fasciculations.

When the blood deletion study is negative, but the EMG suggests SMA, a muscle biopsy is performed. The histologic specimens differentiate SMA from other intrinsic muscle diseases. Specifically, large group muscle atrophy is seen in SMA.

Interdisciplinary Interventions

Treatment of SMA is supportive and involves monitoring respiratory and nutritional status. In SMA I, the most common cause of death is loss of respiratory function as muscle weakness leads to ineffective airway clearance and diminished vital capacity. Involvement of cranial nerve nuclei and swallowing problems lead to inadequate nutrition. Alternative feeding methods may be required.

In SMA types II and III, loss of respiratory function may also occur but is usually not as rapid as that seen in type I. Monitor respiratory status, growth, and development. As the child grows and continues to have weakness, contractures and scoliosis may occur because of immobility. Orthopedic care is instituted to provide support and maintain strength of functional muscles. Monitor and treat skin as immobility increases.

For the family, the rapid deterioration characteristic of SMA I requires many decisions regarding the extent of medical intervention that should be instituted. Measures taken may prolong the child's life without improving its quality. Encourage the child with SMA type II or III to participate in age-appropriate activities to the extent that he or she is able. Monitor nutritional intake and ensure that immobility of a muscle group does not lead to further musculoskeletal alterations. Ensure that the family's psychosocial, emotional, cognitive, and interpersonal needs are being addressed (see Chapter 12 regarding care of the child with a chronic condition).

Juvenile Myasthenia Gravis (MG)

Myasthenia gravis (MG) is a neuromuscular disease caused by immunologic neuromuscular blockade. The disease is characterized by progressive weakness of certain voluntary muscles. The disease most commonly affects the oculomotor, facial, laryngeal, pharyngeal, and respiratory muscles.

Pathophysiology

MG is related to an antibody-mediated autoimmune attack directed against acetylcholine receptors in the

postsynaptic membrane. In affected children, antibodies destroy acetylcholine receptor sites, resulting in diminished muscle response and weakness. The condition may be acquired or congenital. Acquired MG includes *transient neonatal MG* and *juvenile MG*. The genetic forms of MG are rare.

Transient neonatal MG occurs in approximately 7% of infants born to mothers with MG (Cheng, Lin, Lin, et al., 2007). Infants acquire maternal acetylcholine receptor antibodies transplacentally, and symptoms occur shortly after birth. Symptoms of transient neonatal MG disappear without residual neurologic or developmental complications within 2 to 4 weeks of birth. These infants are not at risk for developing MG later in life.

Juvenile MG has a mean onset at 8 years of age; 11% to 29% of patients with MG first present between 1 and 15 years (Ashraf, Taly, Veerendrakumar, et al., 2006). The pathophysiology for juvenile MG involves antibody depletion of acetylcholine receptors. With juvenile MG, patients who experience muscle weakness only in the extraocular and facial muscles generally have a milder course. Permanent, spontaneous remission of symptoms is inversely proportional to the severity of the symptoms. With treatment, prognosis is good, and the child has a normal life expectancy.

Congenital (genetic) MG is a familial abnormality of neuromuscular transmission with a little understood pathophysiology. It differs from the transient form in that

- It is not immunologically mediated
- Mothers do not have MG
- Symptoms first appear from birth to age 12 months
- Extraocular muscles are more severely affected
- Response to medication or surgery (thymectomy) is limited
- Symptoms are present throughout life

Treatment and supportive care for congenital MG improve the outcome overall (Besson, Hantac, Lochmuller, et al., 2005).

Assessment

Low Apgar scores for respiratory effort, muscle tone, and reflex irritability should alert to the possibility of transient neonatal MG. The baby may appear cyanotic, "floppy," expressionless, and too weak to cry. Attempts to feed are marked by poor sucking and rapid fatigue.

Initial symptoms of juvenile MG include unilateral or bilateral ptosis or diplopia in a diurnal pattern (symptoms worsen as the day progresses). For more severely affected children, dysarthria, dysphagia, skeletal muscle weakness, and respiratory problems can occur. The onset of these symptoms may develop over years or as quickly as within 24 hours.

Diagnostic Tests

Diagnosis of MG is confirmed by the edrophonium chloride (Tensilon) test. An injection of Tensilon is given at an age-determined dosage. Initial administration of 20%

of the dose is followed by a full dose after no adverse effects have been noted. The injection should result in immediate, but brief, improvement in muscle tone.

Electrodiagnostic evaluation of muscle response identifies the defect at the myoneural junction, indicating MG. Repeated stimulation of the nerve results in sequential reduction of muscle response (decremental response). A positive decremental response is seen in 80% of children with MG.

Interdisciplinary Interventions

Treatment is based on the type of MG, the child's age, and the severity of symptoms. In all cases of MG, provide supportive care to ensure airway protection and adequate oxygenation.

Supportive Interventions

For the newborn with transient MG, intubation, mechanical ventilation, and enteral feedings may be necessary until the condition resolves naturally. Promote bonding by encouraging parents to hold their infant and assist with daily care activities. If the mother wishes to nurse her infant, and the infant shows no signs of respiratory distress, she can attempt short periods of breastfeeding. She may also express milk and freeze it for later use. Supplemental nutrition should be administered by feeding tube to conserve the infant's energy.

Monitor the infant's respiratory function by assessing breath sounds, rate, and oxygen saturation (especially during feedings). Ensure that suction equipment is available at the bedside if the airway becomes blocked with secretions. Continuous pulse oximetry is a useful tool in ongoing evaluation of the infant's oxygenation status.

Pharmacologic Interventions

Controversy still exists regarding the most effective management of MG. Anticholinesterase drugs, usually pyridostigmine (Mestinon), are the first line of treatment to control symptoms. Short-term use of anticholinesterase drugs is effective in transient neonatal MG. The dosage of medication is closely monitored to detect toxicity.

If symptoms are disabling, steroid therapy (prednisone) is used. When long-term steroid therapy is initiated, potassium supplements, antacids, or H₂-blocking agents, vitamin D, and calcium supplements may be required to promote healthy bone development and healing.

Surgical Interventions

Thymectomy remains a controversial therapy in the pediatric population. The entire thymus and mediastinal fat are removed during the procedure. If removal of the thymus gland is indicated, provide pre- and postoperative care.

Emergency Interventions

Emergency situations (cholinergic crisis) may also arise with elevated levels of acetylcholinesterase drugs, and

may require intubation and ventilatory support. The Tensilon test is used to differentiate between myasthenic and cholinergic crises (Table 21–10).

As with MG diagnosis, if the injection of edrophonium improves muscle strength, the likely diagnosis is myasthenic crisis. More medication is then needed for treatment. If the Tensilon test does not improve symptoms, or they worsen, they are most likely being caused by cholinergic crisis. Anticholinergic medications should be temporarily withheld.

Educational Interventions

Because of the chronic nature of persistent and juvenile MG, teaching is a lifelong part of the treatment plan. Teach the family to reduce factors that may exacerbate the disease to the point of myasthenic crisis, including stress, infection, or prolonged physical activity. Be knowledgeable about drug therapy, side effects, and disease course to develop a teaching plan for the child and family.

Alert! Certain medications can exacerbate weakness in the child with MG. These drugs include aminoglycosides, procainamide, quinidine, curare, succinylcholine, and possibly calcium channel blockers and beta blockers. Teach the child and parents to avoid sedatives, antibiotics, and cold remedies that contain these products by ensuring that healthcare providers are aware of the MG diagnosis and the medications that may exacerbate symptoms.

As children grow older, help the family to adjust roles so the child assumes appropriate responsibility for managing their disease to foster independence through self-care.

Neurocutaneous Syndromes

The most frequently occurring neurocutaneous syndromes are collectively called *phakomatoses*. These diseases are characterized by their tendency toward tumor formation in the CNS, skin, and visceral linings of various organ systems, and by their recognizable cutaneous manifestations. Because of the rarity of these diseases, this chapter covers only the three most common phakomatoses: tuberous sclerosis, neurofibromatosis, and Sturge-Weber disease (Table 21–11).

Assessment

The diagnosis of neurocutaneous diseases is often made by the characteristic findings of each disease. A thorough genetic history is helpful. Focus assessment on developmental, behavioral, and psychosocial issues. Obtain neurologic baseline assessment and examine systems that are known to be affected by tumors, tubers, or other findings associated with these disorders.

Diagnosis is based on clinical features. Specific genes for tuberous sclerosis complex and neurofibromatosis have been identified, and genetic testing may confirm these diagnoses. Because the manifestations of these diseases vary widely, some possible tests include EEG, CT, MRI, positron emission tomography, skin biopsy, ophthalmologic examinations, and various other tests, depending on the organ systems involved.

TABLE 21-10

Myasthenic Versus Cholinergic Crisis

Myasthenic Crisis	Cholinergic Crisis
<p>Etiology</p> <p>Severe weakness with bulbar and respiratory compromise occurring during natural course of disease</p> <p>May be preceded by an infection</p> <p>Symptoms may lead to an overdose of anticholinesterase drugs</p>	<p>Anticholinergic drug (ACED) toxicity</p>
<p>Symptoms</p> <p>Anoxia</p> <p>Cyanosis</p> <p>Bowel and bladder incontinence</p> <p>Decreased urinary output</p> <p>Absence of swallow reflex and cough</p>	<p>Hypotension</p> <p>Nausea</p> <p>Vomiting</p> <p>Diarrhea</p> <p>Abdominal cramps</p> <p>Pallor</p> <p>Blurred vision</p> <p>Facial muscle twitching</p>
<p>Tensilon Test</p> <p>Produces temporary improvement</p>	<p>Produces no improvement or worsening of symptoms</p>
<p>Treatment</p> <p>Early detection</p> <p>Managing respiratory function</p> <p>Medical support of other body functions</p> <p>Plasmapheresis</p> <p>Increase anticholinesterase medications</p>	<p>Discontinue ACEDs and gradually reinstate medications as symptoms improve</p> <p>Manage respiratory function</p>

Interdisciplinary Interventions

No cure exists. Care for children with these disorders is individualized and depends on the specific disease, with the focus of care aimed at alleviating symptoms. When seizures are present, antiepileptic regimens may be tried until control is achieved. Brain lesions such as tumors, tubers, or neurofibromas may be surgically excised, especially if they cause increased ICP or seizures. In some cases of Sturge-Weber disease, the lobes of the brain causing the seizures are surgically removed.

When these children are hospitalized, seizure precautions may be necessary. The child may also display some degree of cognitive disability or behavior that is difficult to control. Guard the child's safety at all times, modifying the plan of care to adapt to the child's behavioral needs.

Help the family to cope with the diagnosis and assist with genetic counseling to assess the probability of abnormalities occurring in future children. Allow the family to express the initial denial and guilt that may manifest shortly after diagnosis.

Families facing these diseases require ongoing support, particularly when the family is faced with many hospitalizations. In some instances, encourage the family to explore long-term resources. A nurse may interact with the same child several times during many hospitalizations. Continuity of nursing care can promote trust and a more positive view of the healthcare system for the child.

Head Injuries

Head injury is the general term for several different types of injury. This section covers scalp injuries, skull fractures, concussions, contusions and lacerations, vascular injuries and hematomas, and cranial nerve and diffuse brain tissue injuries.

QUESTION: Which elements of Joey's experience are typical for a head injury?

Head injury in the pediatric population is one of the most common causes of death and disability (Ducrocq, Meyer, Orliaguet, et al., 2006). The spectrum of injury ranges from minor concussion that requires a few hours of observation to major trauma with dismal long-term consequences for the child. Rates are highest among children age 0 to 4 years (Rutland-Brown, Langlois, Thomas, et al., 2006).

The most common causes of head trauma in infants and children are falls, child abuse, and motor vehicle accidents. Infants may experience head trauma during a difficult delivery with forceps or a prolonged, traumatic labor and delivery. Infants or young children may sustain a head injury because of a fall from a caregiver's arms, out of windows, or down stairs. These children are also at the age when they may be victims of child abuse, particularly

TABLE 21-11

Neurocutaneous Syndromes

Condition/Inheritance	Characteristics
Tuberous sclerosis complex, autosomal dominant	Cognitive deficits, autism, epilepsy, adenoma sebaceum (red, highly vascular papules on the face) Lesions called <i>tubers</i> may invade the brain and the retina; other types of tumors may invade the heart and the kidneys; skin, lungs, and skeleton may be affected
Neurofibromatosis (NF) previously referred to as <i>von Recklinghausen disease</i> , autosomal dominant	Areas of increased skin pigmentation (café-au-lait spots), central and peripheral nervous system tumors (neurofibromas), and other skeletal, endocrine, and vascular findings Initial symptoms are usually cutaneous changes, neurologic symptoms often occur, language disorders and learning disabilities common Difficulty with tasks that require planning, attention, and organization common, leading to higher incidence of attention deficit hyperactivity disorder NF1: Peripheral nerve tumors and a higher incidence of brain tumors; neurofibromas usually develop at 10 to 15 years of age NF2: Much rarer; multiple tumors of the brain, spinal cord, auditory nerves; hearing loss may become evident in adolescence; the vestibular nerve may also be affected, resulting in poor balance
Sturge-Weber syndrome (encephalo-facial angiomatosis), only phakomatosis without a recognizable hereditary pattern	Port-wine stain (facial nevus) usually apparent at birth, often associated with congenital glaucoma; focal or generalized seizures, usually begin before 1 year of age and are difficult to treat; intracranial calcification, hemiparesis, and often cognitive deficits and behavioral problems Abnormalities of the dura mater over the occipital lobe, calcification and necrosis of underlying brain tissue common

shaking injuries. During early and middle childhood, children are susceptible to being injured while playing or climbing. Vehicular accidents and athletic injuries are the most common causes of head trauma in adolescents. Other factors that may predispose a child to head injury are seizure disorders, gait instability, alcohol or drug ingestion, and cognitive delays, including poor judgment.

ANSWER: The fact that Joey is male and injured in an athletic activity are two common elements in a preadolescent head injury.

Pathophysiology

The pathophysiology of head injuries is complex in that the extent of the visible injury may not indicate the extent of actual brain injury. A head injury may involve any or all of the cranial and skull layers, including scalp, skull, dura, brain, and blood vessels, as well as neurons and supportive glial cells. Injuries can be classified as *primary*, meaning they result from the actual traumatic event, or as *secondary*, indicating that the damage is caused by pathologic processes that occurred as a result of the initial injury. Secondary injury may be related to how quickly treatment is initiated after the injury has occurred.

Injury in pediatric head trauma occurs through several mechanisms. Blunt or nonpenetrating injury can distort brain tissue and shear neurons, even without outward evidence of injury or trauma. Penetrating or open injuries

can produce either focal or diffuse damage, depending on the velocity and the type of penetration. Compression injuries are the result of the skull being compressed between two forces, crushing the brain and compromising its integrity. Other commonly used terms are **coup** (pronounced “coo”) and **contrecoup** injuries. These terms are used to describe an injury to brain tissue that results when a blow to the head causes the brain to hit the skull at the location of impact (*coup*), and then rebound to the opposite side of the skull, where injury can also occur (*contrecoup*) (Fig. 21-10).

Scalp Injuries

The scalp is composed of five layers, including connective tissue and vascular structures. Together these layers offer tremendous protection to the skull. Scalp injuries include abrasions and lacerations.

Skull Fractures

QUESTION: Could Joey have a skull fracture? If so, which type is most likely?

The human skull is composed of two layers, the inner and outer tables, separated by a spongy tissue called the *diploic space*. In a head injury, a fracture may occur at the site of impact or in areas of the skull with less tensile strength. There are five types of skull fractures: linear, depressed, comminuted, diastatic, and basilar.

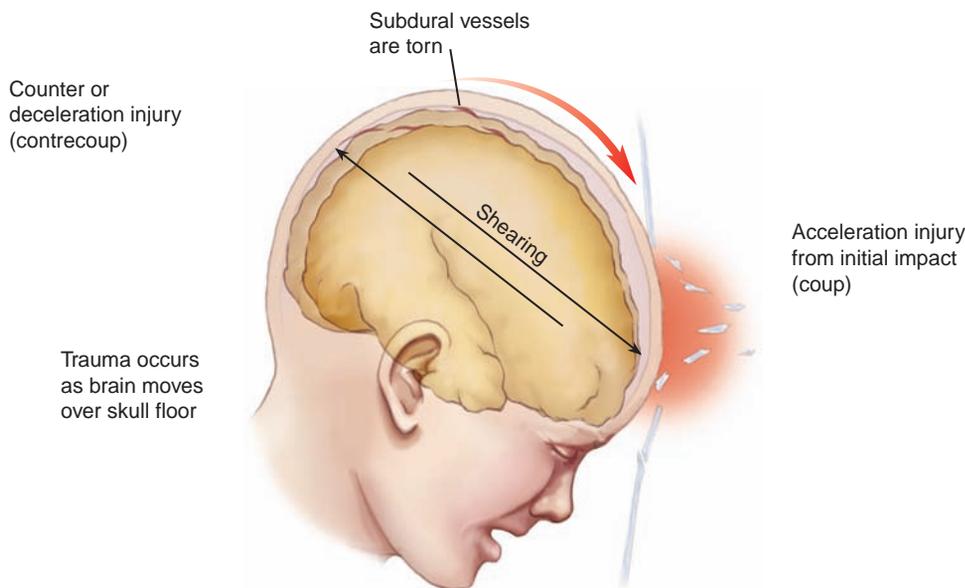

FIGURE 21–10. Mechanisms of coup–contrecoup injury.

Nearly 70% of skull fractures are *linear* and involve the cranial vault. Fracture lines may be simple or complex and follow no predictable pattern. Children with uncomplicated linear fractures are usually admitted to the hospital for a short period of observation and are likely to resume normal activities within a few days. The bone heals on its own, and the fracture is not likely to be evident on skull radiographs 6 months to 1 year after the injury.

There are two concerns with linear fractures. First, an unrecognized tear may occur in a layer of meninges that permits CSF to escape. If the tear is unrepaired, a “growing fracture of childhood” may occur as the CSF collects and begins pulsating outward. The fracture widens, and a small lump develops over the area of the fracture. The second concern is the presence of a linear fracture over the middle meningeal artery in the temporal region. Because the artery adheres closely to bone in this area, a linear fracture can tear the artery, resulting in an epidural hematoma.

Depressed skull fractures are often associated with scalp lacerations. The exception is “ping-pong” fractures or other fractures of the infant skull. A fracture is considered depressed when the inner table is displaced by more than the thickness of the skull. Compound depressed skull fractures (those with lacerations) should be debrided and elevated as soon as possible after the injury. Surgical elevation of the fragments is considered in closed injuries in which fragments are depressed more than 0.5 to 1 cm. Depressed fractures with many fragments are referred to as *comminuted*.

Diastatic skull fractures occur along the suture line. The separation is usually visible on skull radiograph. These fractures often do not occur at the site of impact; they are seen most frequently in newborn babies and infants.

The most serious type of skull fracture is a *basilar skull fracture*. These fractures involve a break in the basal portions of the frontal, ethmoid, sphenoid, temporal, or occipital bones. Two signs of this type of skull fracture are the

Battle sign (bruising or ecchymosis behind the ear, caused by blood leaking into the mastoid sinus) and “raccoon eyes” (blood leaking into the frontal sinuses, causing an edematous and bruised periorbital area). Children with these fractures may also have CSF leakage from the nose (rhinorrhea) or ears (otorrhea) because of tears in the meninges. CSF leaks are rare but can be serious, especially if they do not stop spontaneously. Basilar skull fractures are associated with cranial nerve injuries. Optic, extraocular, and acoustic nerve injuries are the most common.

ANSWER: Although Joey does have a scalp laceration and edema surrounding the laceration, there is no external evidence of a compression fracture. Furthermore, he does not display the Battle sign or raccoon eyes and he does not have any CSF leaking from his ears or nose, so it is unlikely he has a basilar skull fracture. The most likely type of fracture is a linear fracture, and the CT scan will determine this.

Concussions, Contusions, and Lacerations

The most common injury from blunt trauma is a concussion. In minor, reversible head trauma, a concussion may occur. Concussions tend to occur from impact when the head is in motion, rather than in a fixed position. This injury is a transient and reversible neuronal dysfunction that produces instantaneous loss of awareness and responsiveness on the part of the child that may last minutes or hours. The child has amnesia of events immediately surrounding the head trauma. Most concussions are mild and do not require either hospital observation or admission.

Contusions are “bruises” to the brain. They occur either at the site of impact or at a point directly opposite the impact (coup–contrecoup injury). The injury may cause focal edema, or generalized cerebral edema or bleeding at either location; increased ICP may occur. Symptoms may

not peak until 48 to 72 hours after the injury, and complications from the edema last for days.

Lacerations are discontinuity of brain tissue caused by penetrating craniocerebral trauma such as gunshot wounds. Lacerations are considered to be serious because of the substantial intracerebral bleeding that can be caused by this type of injury.

Vascular Injuries and Hematomas

QUESTION: Could Joey have a “bleed?” If so, which type would be most typical and why is this worrisome?

Hematomas occur when the shearing force created by impact tears bridging vessels that supply blood to the various layers of the dura mater. Epidural hematomas are likely to be acute and usually result from a tear in an artery, although 25% have a venous origin. An epidural hematoma occurs between the bone and the dura (Fig. 21–11). The child usually has a short period of unconsciousness followed by a period of lucidity in which he or she is believed to have recovered; within 4 to 8 hours, the child begins to experience a rapid decline in neurologic function that causes severe cerebral shift and even death if left untreated. Common locations for epidural hematomas are the temporal fossa, subfrontal, and occipital areas. Surgical treatment is emergent and arrests the serious symptoms if done rapidly.

Acute subdural hematomas are usually of venous origin and are often associated with an underlying contusion. These hematomas occur under the dura mater. Subdural hemorrhage has also been shown to occur from shaking injury. This type of hematoma occurs more frequently in infants and is usually bilateral, whereas epidural hematomas are unilateral. Common symptoms are increased ICP and seizures.

Chronic subdural hematomas are usually related to trauma, but they may not be identified until long after the injury, usually after skull growth has accelerated

beyond the normal level. The characteristic symptoms are irritability, full nonpulsatile fontanel, failure to thrive, and low hematocrit levels.

ANSWER: Joey might possibly have a “bleed.” A CT scan is ordered primarily to determine whether there is any intracranial bleeding. An epidural bleed would be most likely given his age and injury. This is problematic, because he might seem to recover but could then quickly decompensate and die.

Cranial Nerve and Brain Tissue Injury

Although basilar skull fractures are the most common cause of cranial nerve injury, nerve damage can also be caused by compression, stretching, or severe laceration, most commonly involving CN I (loss of smell), VII (facial paralysis), V and VI (eye movements), II (optic fields), and VIII.

Damage to neurons is called *diffuse axonal injury* (also known as *shearing*). When the head is subjected to impact, the gray matter on the cortical surface is displaced more than the deep white matter. As a result, the axons degenerate, and their ability to transmit impulses effectively diminishes. The course and outcome for the child depend on the extent of the injury.

Assessment

QUESTION: In addition to his GSC score, what parameters would a nurse assess on Joey?

The primary components of the assessment are a thorough history and physical examination, and appropriate imaging studies.

Note the actual mechanism of injury or state of consciousness after the injury, or both, which can be a useful tool in diagnosing the type of trauma. Another major aspect of history taking is to determine whether there has

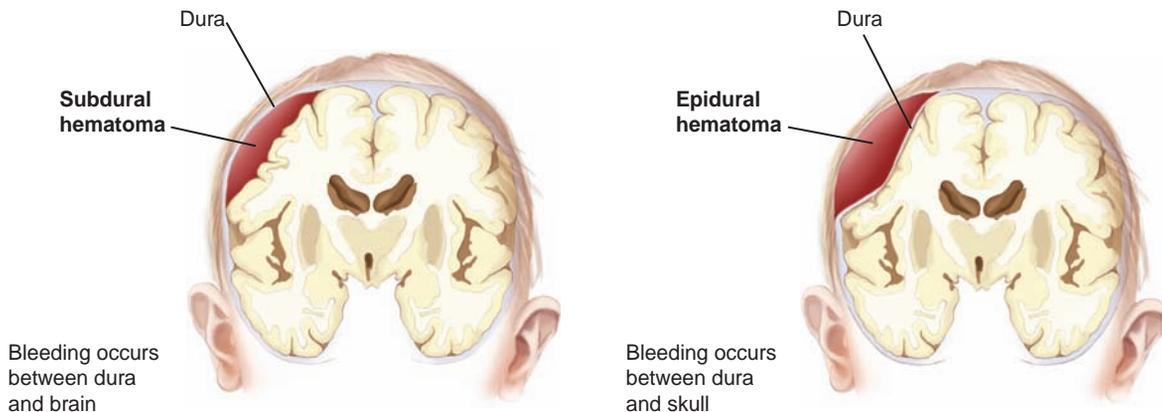

FIGURE 21–11. Epidural hematoma and subdural hematoma.

been posttraumatic amnesia, as in concussion injuries, or a seizure at the time of injury, predisposing the child to injury. Also note a family history of bleeding disorders. If retinal hemorrhages are present in an infant with signs and symptoms of hematoma, be alert for the possibility of shaken baby syndrome (see Chapter 31).

After the family history and the history of the event have been gathered, carry out a complete neurologic assessment. Assess cognitive and mental functions and cranial nerves. Evaluate for signs of increased ICP. If the injured child arrives at the healthcare facility in a state of rapid neurologic decompensation, assessment and interventions are often done simultaneously. If any evidence exists of a pressure buildup great enough to threaten herniation of the cerebral lobes, immediate action must be taken to alleviate the pressure.

Determine and document level of consciousness, ability to follow commands, presence of confusion or irritability, pupil responsiveness, extraocular eye movements, and generalized strength and tone of extremities. In severe cases of neurologic trauma, posturing may be present. Begin each assessment by providing the same degree of stimuli to the child, so that a comparison of responses can be made over time. Observe whether any CSF is leaking from the ear canals or nares and whether changes have occurred in external findings (increased swelling or tenderness over scalp abrasions or wounds). Record any abnormal motor movements or potentially seizure-related activity. Finally, monitor cardiorespiratory and vital sign parameters closely and immediately report evidence of increasing ICP.

ANSWER: The nurse would assess Joey's vital signs, quality of respirations, pupils, and physical symptoms such as the presence of leaking CSF from the ears or nose.

Diagnostic Tests

Radiographic studies for head injury generally include skull and cervical spine films and a CT scan. If the injury is minor, and the child appears to be neurologically intact, a CT scan may not be necessary, although plain skull films are usually obtained to rule out a skull fracture. MR images are being used more frequently, particularly in children with more severe injuries, as a way to follow white and gray matter changes over time.

If seizure activity occurs after the injury, an EEG is necessary. Injuries involving the cranial nerves may be followed with brain stem auditory-evoked responses or with visual-evoked responses, or both. A child with long-term cognitive deficits may require neuropsychological evaluation to assess functional, learning, and, eventually, vocational abilities.

Interdisciplinary Interventions

Care of the child with head trauma varies according to the mechanism of injury, the location, and any association with multisystem injuries (e.g., fracture of ribs, femur, laceration of liver). For scalp injuries, gentle

cleaning followed by hemostasis, conservative debridement of dead tissue, and suturing without tension is the recommended approach to management.

Conservative Interventions

The treatment for mild head injury is generally a conservative observational approach that may involve monitoring the clinical manifestations for several hours before discharging the child. Most nondepressed skull fractures heal over time. A moderate head injury may involve a prolonged hospital stay and the use of methods to decrease ICP. Keeping some children hospitalized may be necessary to follow cranial nerve functions and to ascertain that there is no worsening disease process.

Surgical Interventions

Surgical management of head injury may be necessary, most commonly to elevate a depressed skull fracture or remove an acute epidural or subdural hematoma. Chronic subdural hematomas may require mechanical shunting to the peritoneal space. Severe injuries necessitate a critical care environment with close monitoring of vital functions. The insertion of an ICP measuring device by the neurosurgeon may be necessary to monitor changes in ICP and to initiate medical therapy based on these changes.

Supportive Interventions

The child with head injury is at high risk for altered cerebral perfusion. Carefully monitor oxygen saturation with pulse oximetry and administer oxygen as necessary. When a child's oxygenation status is questionable, administering oxygen is prudent even before a pulse oximetry reading is obtained. Monitor the child's hemoglobin and hematocrit levels closely to ensure adequate oxygen carrying capacity within the blood. To promote optimal cerebral tissue perfusion, closely monitor systemic perfusion parameters, such as blood pressure and other vital signs. Monitor fluid and electrolyte status to avoid fluid overload and resultant cerebral edema. Administer antiepileptics as ordered, implement seizure precautions, and document any seizure activity.

Slightly elevating the head of the child's bed is important in managing increases in ICP, and it is useful in optimizing airway position. Slight hyperextension of the neck can be achieved by placing a towel roll underneath the child's shoulders. Never attempt this measure, however, until cervical spine injury has been ruled out. Oral or deep suction may be necessary every 2 to 4 hours to clear secretions and to stimulate a cough. Have an appropriate-size bag and mask available at the bedside to ventilate the child in an emergency, as needed.

Ongoing Interventions

QUESTION: Joey has now been in the emergency department for 30 minutes. How frequently is the nurse obtaining vital signs and neurologic checks on Joey?

Perform ongoing assessment of the child's neurologic function, including level of awareness or responsiveness and the presence of confusion, every 1 to 2 hours after injury. Document any changes in the child's condition and assess the child more frequently if warranted. Changes in level of consciousness are often the first indication of changes in ICP and cerebral perfusion.

ANSWER: Joey is still unstable and could change rapidly. Assessments should be done at least every 15 minutes and the nurse or an adult should remain with him at all times.

Investigate the possibility of a CSF leak from the nose or ears, or from scalp lacerations, and report to the physician as soon as possible. Suspect a CSF leak if copious, clear fluid is draining from the nose, ears, or scalp lesion. Differentiating CSF from other fluids may be difficult. One method is to measure the glucose of the suspected fluid. If the fluid is CSF, the glucose level will be equivalent to that in CSF obtained by lumbar puncture. Antibiotics will likely be administered prophylactically when the scalp has been lacerated or when an open injury is present. Cleanse wounds as indicated, perform frequent oral care, and monitor for signs of skin and systemic infection.

Community Care

Ongoing involvement after the child leaves the hospital centers on helping the family to cope with the effects of the injury and preventing further injury to the child. After a minor head injury, educate parents to observe the child closely for 24 hours for signs as previously discussed; check the child every few hours when sleeping. If abnormal signs occur, notify the healthcare provider.

If the child is severely brain injured, the biggest task facing the family is the grief of losing the child they once had. Frequently, the personality changes in the child are dramatic and disturbing. The entire structure of the family is likely to change. Initially, when progress seems to occur daily, families have strong hope that their child will recover completely. As the family realizes their loss, depression and related stress can set in. Offer the family realistic expectations and support throughout their grief work. Refer the family for further counseling if needed. Encourage the family to take part in their child's care, but encourage them to breaks for themselves.

Provide the child and family with assistance in making sound judgments in daily activities. Comprehensive rehabilitation programs that involve a component of behavior modification, such as increased helmet use, are usually effective in helping children become aware of their own safety.

For children with long-term sensory deficits (vision, hearing, smell), address the need for adaptations to prevent further injury. Educate family members about seizure precautions, if they are needed. Also discuss toxic side effects of antiepileptics with children and families, as appropriate.

The sequelae from a head injury in childhood can become a lifetime burden. Seizure activity becomes post-traumatic epilepsy. Postconcussion syndrome can be apparent for a year or more after the injury. Hydrocephalus can occur as the result of an infectious process. The most difficult aspects of long-term outcome are the ensuing personality and behavioral changes that can prevent the child from achieving a completely independent life-style. Persistent physical difficulties may affect independence. Nevertheless, most pediatric head injuries are minor occurrences that require no hospitalization and engender no long-term damage.

Acute Spinal Cord Injury (SCI)

Although SCI is an infrequent occurrence in the general pediatric population, the incidence of these injuries increases substantially in middle and late adolescence. Boys are twice as likely to sustain an SCI as girls (Vitale, Goss, Matsumoto et al., 2006). Motor vehicle accidents account for 55% of pediatric SCI in the United States; in these, about 70% were not wearing a seat belt and 30% were under the influence of drugs or alcohol (Vitale et al.). Other causes of SCI are falls, and firearm and athletic injuries. Birth injuries can affect the cervical spine.

caREminder

Treat all injured children as if an SCI has occurred until the potential for this problem has been eliminated. This approach includes immediately immobilizing the head and spine on a "spine board" before transfer from the scene of the injury.

Most spinal fractures result in no neurologic deficit. However, SCI with no evidence of radiographic abnormality is well documented in children.

Pathophysiology

SCIs are often described in relation to the mechanism and anatomic location of injury. Flexion–dislocation, hyperextension, vertical compression, and rotation are the major mechanisms of injury. Flexion–dislocation injuries are common in motor vehicle accidents, whereas vertical compression injuries are associated with diving or trampoline injuries. The location and classification of an SCI is usually referred to as the level of injury below which sensory and motor function are impaired (Chart 21–4).

Several factors influence the severity of the actual injury to the spinal cord. The mechanism for cellular damage and functional impairment is usually compression and contusion, rather than actual transection. During the first hours after injury, decreased blood flow and ischemia result in extensive tissue destruction. Compression injuries may result from spinal epidural or subdural hematomas that can be surgically alleviated.

The immediate response to SCI is called *spinal shock*. In this phenomenon, the reflexes controlled by nerves below the level of the injury are temporarily suppressed. Spinal shock can last from a few hours to many months.

CHART 21-4 AMERICAN SPINAL INJURY ASSOCIATION IMPAIRMENT SCALE

A = Complete: No sensory or motor function is preserved in the sacral segments S4–S5

B = Incomplete: Sensory but not motor function is preserved below the neurologic level and includes the sacral segments S4–S5

C = Incomplete: Motor function is preserved below the neurologic level, and more than half of key muscles below the neurologic level have a muscle grade of less than 3 (grades 0–2)

D = Incomplete: Motor function is preserved below the neurologic level, and at least half of key muscles below the neurologic level have a muscle grade greater than or equal to 3

E = Normal: Sensory and motor function are normal

From American Spinal Injury Association. (2000). *International standards for neurological classification of spinal cord injury*. Chicago: Author. Reprinted with permission.

The appearance of perianal reflexes signifies the end of spinal shock and the beginning of recovery. During the recovery period from the acute phase, hyperreflexia and spasticity may appear.

A common physiologic consequence of SCI is a phenomenon referred to as *central cord necrosis*. As further edema and ischemia develop, vascular stasis and thrombosis occur, propagating the vicious cycle; the eventual outcome is necrosis of gray matter.

Assessment

Immediate signs and symptoms of SCI vary, depending on whether the injury is complete or partial. Because complete SCI is rare, this section focuses on partial injury. A symmetric flaccid paralysis and loss of reflexes below the portion of damaged cord occur. Pain, temperature, and proprioception below the level of the injury may be preserved somewhat. Moderate vasomotor instability and lowering of the blood pressure usually occur.

Cervical cord injury is characterized by respiratory insufficiency caused by disruption of innervation to the diaphragm. Another condition that occurs immediately after injury is called *neurogenic shock*. This condition is characterized by hypotension, caused by vasodilation of the vascular bed below the level of injury, bradycardia, and loss of the ability to sweat below the level of injury.

Quadriplegia results from injuries at the cervical level and implies complete loss of leg function and limited, if any, use of the arms. Paraplegia results from thoracic or high lumbar injury and is characterized by a loss of leg function alone. Most SCIs are incomplete and result in variable degrees of motor and sensory loss below the level of the lesion. Neurologically complete lesions are rare.

Clinical manifestations in chronic SCI are related to the degree of recovery and functional return after the initial injury. Complications, such as autonomic dysreflexia and bladder dysfunction, occur during the postacute phase.

Any child who has sustained an injury is presumed to have SCI until proved otherwise. The child with cervical spine injury frequently requires intubation to maintain the airway. Assess and maintain the airway while maintaining the neck in a neutral position. Immobilize the neck and spine before moving the child. Perform frequent assessments of vital signs and neurologic status to monitor for signs of shock or other injuries. Assess sensory and motor functions systematically to determine the level of injury. Obtain a history of the injury if possible for clues to the type of injury the child may have suffered.

Diagnostic Tests

After the clinical examination has been carried out, a thorough radiographic examination is completed. Anteroposterior, lateral, and oblique views of the spine, down to the suspected level of injury, are obtained. Routine films of the spine and pelvis below the level of the injury are necessary to rule out any other hidden fractures. Spinal CT scans and MR images may each be useful, depending on the type of injury and information desired.

Nursing Diagnoses and Outcomes

Nursing Plan of Care 21-1 presents a variety of nursing diagnoses that may be applicable to the child with a neurologic condition. The following diagnosis applies specifically to the child with SCI:

Impaired skin integrity related to limitation of voluntary movement

Outcome: Child's skin will remain intact.

Interdisciplinary Interventions

Treatment of acute SCI begins immediately. Initial management at the scene of the trauma includes stabilizing the spine and establishing an adequate airway. Other appropriate measures during the acute phase include administering intravenous dexamethasone to reduce swelling around the spinal cord and initiating aggressive pulmonary hygiene measures to prevent pneumonia. Stress ulcer is common and is often prevented by administering antacids or histamine blockers. Frequent repositioning is ordered. The child may be placed in a special frame or bed for turning. Urinary catheterization is also necessary until bladder function can be determined.

Throughout the acute care phase, institute rehabilitative measures to ensure the best possible outcome for the child. Safe and early mobilization is attempted by using a variety of stabilizing devices.

Monitor the child for cardiovascular complications, which may include *orthostatic hypotension* and *autonomic hyperreflexia* (also called *dysreflexia*). Orthostatic hypotension associated with changes in position is caused by interruption of the reflex arc in the upright position, which produces vasoconstriction and pooling of blood in the abdomen and lower extremities. Some patients with

quadriplegia may not be able to tolerate even a slight elevation of the head, which makes mobilization difficult. Closely observe vital signs before and after position changes. Compression stockings and abdominal binders can be used to improve venous return and to reduce the incidence of orthostatic hypotension.

Autonomic hyperreflexia occurs when an uncontrolled increase in sympathetic activity occurs that cannot be inhibited because of the SCI. The syndrome is characterized by acute pounding headache, paroxysmal hypertension, profuse diaphoresis, nausea, nasal congestion, and bradycardia. The sudden increase in blood pressure may rupture cerebral blood vessels. Autonomic hyperreflexia can be caused by a variety of avoidable triggers, including overdistended bladder, distension of visceral organs, such as the bowel by constipation, or stimulation of the skin. If symptoms are observed, immediately place the child in a sitting position to lower the blood pressure. Quickly assess the child to identify and relieve the triggering stimuli. If these measures do not alleviate hypertension, administration of a ganglionic blocking agent may be necessary.

After acute SCI, children are at risk for thromboembolism and respiratory compromise. Many children with cervical lesions require a tracheostomy. Bowel and bladder care to prevent urinary tract infection need to be adapted as mobility increases. Prevention of skin breakdown is a task assumed by all personnel who provide care for the child with SCI. Physical, occupational, and speech therapies, as well as an assessment of learning and nutritional and psychosocial needs, are essential. The complex and emotional medical care of these children is best managed in an interdisciplinary rehabilitative center. Reintegrating the disabled child into the family requires a group of individuals committed to the ultimate goal of providing the child with the best possible quality of life. Chapter 12 provides more information regarding the rehabilitation needs of these children.

SCI has a profound effect on both the child and family. The family experiences shock, denial, and anger as they grieve the loss of their healthy child. Many families require professional counseling to come to terms with their child's injury. In addition, the family must learn complex medical procedures to care for their child. The amount of time that must be spent meeting basic needs changes the structure of daily family life. Financial burdens may be overwhelming as well. Besides the medical costs, the family home may need structural changes to accommodate the change in the child's mobility. Early recognition of family coping strategies, anticipatory guidance, and referral to appropriate community agencies will help the family deal with the effects of their child's injury.

To help prevent injuries, nurses can participate in vehicle safety, substance use education, and violence prevention programs, and give anticipatory guidance to deal with conflict and avoid violence.

The Child With a Malignancy

Case History

George Tran is Ashley Tran's younger brother. They were introduced in Chapters 1 and 13. George is 14 years old and an eighth grader. As Ashley often laments, George is an excellent student. He is not involved in any sports, but spends most of his leisure time on the computer.

George has always been small for his age. This summer he started a growth spurt and is now more than 5 ft tall. He started having pain in his right leg, in his "shin bone," several months ago. George's parents, Tung and Loan, told him it was "a growing pain" and it would go away on its own. He has been keeping off his leg as much as possible, keeping it elevated while he is on the computer, and taking over-the-counter analgesics for the pain. The pain, however, has not gone away. His leg hurts when he walks, and is swollen and tender when compared with the left leg. George's parents take him to the doctor. An x-ray of his leg shows a lesion in the tibia. The doctor tells George and his parents, Tung and Loan, that it could be cancer, such as an osteogenic sarcoma. He refers them to the oncologist at a tertiary medical center.

George's diagnostic procedures include a radiograph, magnetic resonance imaging

(MRI), and computed tomography (CT). The physician's report on the radiograph of the right leg documented "an area of radiolucency in the proximal right tibia measuring approximately 12 cm with a pattern of permeative destruction: poorly defined borders, cortical destruction, periosteal elevation, and extraosseous extension into soft tissue." In other words, there is a cancerous tumor of the bone. The MR image of the extremity confirmed these findings and also indicated a pathologic fracture through the lesion. A CT scan was then performed to determine the extent of metastasis. The CT showed 10 pulmonary nodules consistent with metastatic disease.

George has been a healthy child with no serious illnesses or hospitalizations. There is a family history of cancer, including osteogenic sarcoma. His family genogram in Chapter 8, Figure 8-1, shows his maternal grandmother died of breast cancer and his mother's older brother died as a teenager in Vietnam from a "leg bone cancer." Loan, George's mother, remembers only a little about her brother's disease because she is 11 years younger than her brother and both of her parents are dead. George's story continues in this chapter.

CHAPTER OBJECTIVES

1. Identify abnormal findings that can be identified by physical assessment of a child with a malignancy.
2. Describe the nursing care for children undergoing diagnostic tests to detect and diagnose pediatric malignancies.
3. Describe the treatment modalities used for children with malignancies.
4. Describe the interdisciplinary interventions to minimize the treatment-related side effects associated with each type of malignancy.
5. Identify the psychosocial needs of children with malignancies and their families.
6. Differentiate the types of malignancies commonly found in the pediatric population.

See [thePoint](#) for a list of Key Terms.

Cancer is the second leading cause of death in children, exceeded only by accidents. In the United States, approximately 12,500 new cases of cancer in children and adolescents (younger than age 20 years) are reported each year, with cancer being accountable for an estimated 2,500 deaths (U.S. SEER Program, National Cancer Institute, 2009). The likelihood that a child will be diagnosed with cancer by age 20 years is approximately 1 in 300 for males and 1 in 333 for females (Gurney & Bondy, 2006).

Caring for children with cancer presents the healthcare provider with unique challenges and opportunities. The challenge of pediatric oncology is to provide the aggressive therapy needed to eradicate the disease or slow its progress, while at the same time minimizing toxicities and improving long-term quality of life by decreasing late effects. The opportunities arise from working in a field that has demonstrated dramatic advances in treating and curing childhood cancer during the past few decades. The mortality rate among children with cancer has decreased by 42% since the 1960s. The 5-year survival rate for all childhood cancers combined has increased from 58% (1975–1977) to nearly 80% (1996–2004) (National Cancer Institute, 2008a). The increasing survival rate is the result of aggressive multimodal therapy and improved supportive care. **Multimodal therapy** is accomplished by providing various combinations of therapies, such as multiagent chemotherapy, radiation, surgery, hematopoietic stem cell transplantation (HSCT), and biologic response modifiers (BRMs). The combination used depends on the type of malignancy and extent of disease at the time of diagnosis or relapse.

The field of pediatric oncology can be as emotionally draining as it is challenging and exhilarating. Various healthcare personnel (physicians, nurses, advanced practice nurses) are involved in the short- and long-term care of the child with cancer. The interdisciplinary team involved in the care of the child with cancer may also include social workers, psychologists, child life specialists, teachers, pharmacists, dietitians, religious advisors, and a

rehabilitation team. The interdisciplinary team must work in harmony, collaborating and communicating effectively to develop a trusting therapeutic relationship with the child and family, and to demonstrate support and confidence in the plan of care that is selected for each child.

DEVELOPMENTAL AND BIOLOGIC VARIANCES

Cancers in children differ substantially from cancers in adults (Developmental Considerations 22–1). Most childhood cancers arise from the embryonic mesodermal germ layer, which becomes connective tissue, muscle, bone, cartilage, kidneys, sex organs, blood, blood and lymph vessels, and lymphoid organs. As a result, 92% of childhood cancers (sarcomas, leukemias, and lymphomas) develop from primitive embryonal tissue. The remaining 8% of childhood cancers arise from neuroectodermal tissue and give rise to central nervous system (CNS) tumors (Ruccione, 2002). In contrast, most adult cancers involve the epithelial tissue and are called *carcinomas*. Epithelial cancers are quite rare in children younger than 15 years.

Tumors derived from mesodermal and neuroectodermal tissue are more deep seated than epithelial tumors and, thus, are not easily detected until they are quite large. In almost 80% of pediatric oncology cases, distant **metastasis** (spread) has occurred by the time of diagnosis (Ruccione, 2002).

Certain pediatric malignancies clearly occur at times of peak physical growth and cellular maturation (Fig. 22–1). This coincidence suggests that cellular growth and development are central to the mechanism of cancer in children. In contrast, environmental exposures are a primary component of carcinogenesis in adults.

Data gathered by the Surveillance, Epidemiology, and End Results (SEER) Program from 1975 to 2004 have clearly demonstrated that cancer incidence rates for persons younger than 20 years are related to age, sex, race, and body site. Environmental exposures at geographic sites have not been conclusively proved as epidemiologic causes of cancer in children (National Cancer Institute, 2008a). Peak incidence classically occurs in the 0- to 4-year age group for many childhood cancers (e.g., leukemias, hepatoblastoma, retinoblastoma, Wilms' tumor, and neuroblastoma), and incidence increases with age in others (e.g., CNS and bone tumors, Hodgkin's disease, and lymphomas). Age is also an important factor because prognosis for some histologically identical cancers differs based on the age at onset. For example, acute lymphoblastic leukemia (ALL) has a favorable prognosis in children age 1 to 9 years, but a very poor prognosis for infants younger than 1 year and for children 10 years and older. For all sites combined, cancer incidences are generally higher for males than females. For example, males younger than 15 years have almost double the incidence rate of non-Hodgkin's lymphoma (NHL). In 2000 to 2004, black children had significantly lower cancer incidence rates than white children overall for many specific sites (U.S. Seer Program, National Cancer Institute, 2009).

DEVELOPMENTAL CONSIDERATIONS 22–1

Comparison of Childhood and Adult Cancers

Factor	Childhood Cancers	Adult Cancers
Incidence	Rare; 2% of all cancer cases in United States	Common; more than 98% of all cancers
Sites	Involves tissue (e.g., reticuloendothelial system, CNS, muscle, bone)	Involves organs (e.g., lung, breast, colon, prostate)
Histology	Most common type: nonepithelial sarcomas, embryonal, leukemia, lymphoma	Most common type: epithelial carcinomas
Time period from initiation to diagnosis	Relatively short period	Long period; can be well more than 20 years
Influence of environmental factors in causation	Some environmental factors; few lifestyle factors; overall, no strong influence shown; more likely interaction of genetic alterations and environmental factors (i.e., ecogenetics)	Strong relationship to environmental exposures and lifestyle factors
Prevention	Minimal strategies known	Eighty percent estimated to be preventable
Early detection	Generally accidental; small percentage known as genetically at high risk can be followed more closely	Possible with adherence to early detection screening tests and examination recommendations
Stage at diagnosis	Metastatic disease present in 80%	Local or regional disease
Response to treatment	Very responsive to chemotherapy; higher doses tolerated	Less responsive to chemotherapy
Treatment of side effects	Less difficulty with acute toxicity but more substantial long-term consequences	More difficulty with acute toxicity but fewer long-term consequences
Prognosis	Leading cause of death from disease in United States; survival rate approximately 80%	Second leading cause of death from disease in United States, less than 60% cure

Sources: Baggott (2008) and Smith & Hare (2004).

ASSESSMENT OF THE CHILD WITH A MALIGNANCY

Childhood cancers may be detected early during the course of the illness or may be diagnosed after symptoms have been present for several weeks or months. Delayed diagnosis may be attributable to the vagueness and nonspecificity of symptoms or to a clinician's lack of experience and knowledge of childhood cancers. In some cases, a child may have been under the recent care of a health-care provider and no malignancy was suspected. Yet, within a few weeks, a fast-growing cancer can completely alter the child's previous healthy status. In other cases, the child may have already undergone treatment for vague symptoms that characterize many common childhood illnesses such as the flu, gastroenteritis, or headaches. In most instances, the child's health history and physical examination are limited to the chief complaint.

For example, a child complaining of headaches and blurred vision may appear to have eye strain requiring glasses and is referred to an optometrist for follow-up.

Cancer is usually not suspected until the primary healthcare provider has ruled out a variety of different diagnoses based on clinical presentation. Diagnostic tests may reveal an abnormal complete blood count, or a mass detected on plain radiographic films may cause the healthcare provider to suspect cancer. At this point, the child is usually referred to an oncologist for a diagnostic workup.

The signs and symptoms of childhood cancer are different from those associated with cancer in adults. Adult cancers are generally detected as a result of changes in bowel or bladder habits, rectal bleeding, an unusual lump, a chronic cough, a nonhealing wound, a nosebleed, or complaints of pain when certain body areas are palpated. In contrast, the signs and symptoms of cancer in children are primarily the result of one or more of the following factors:

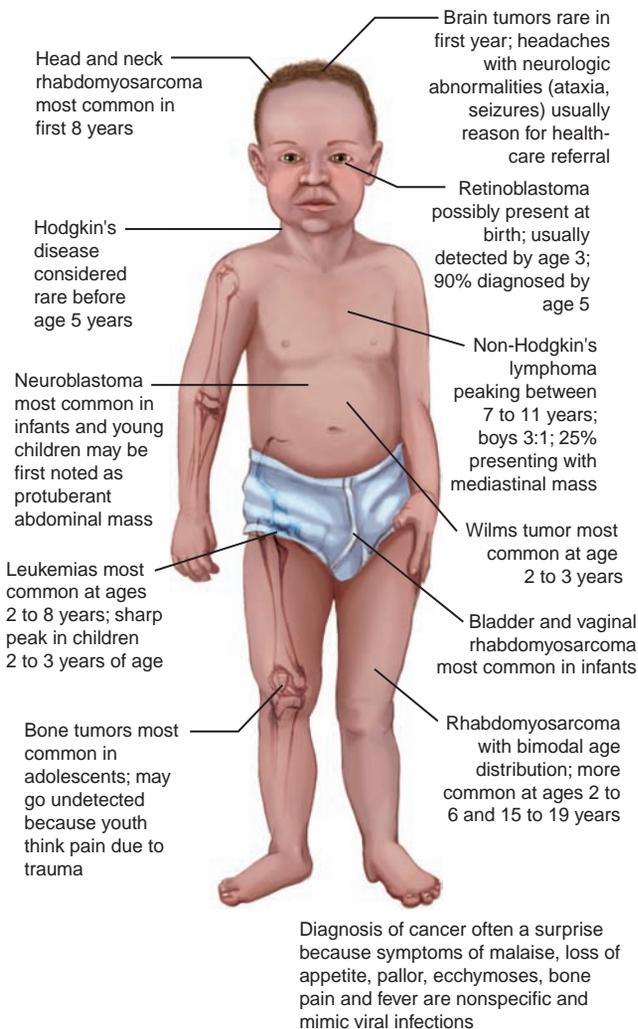

FIGURE 22-1. Developmental and biologic variances: pediatric malignancies.

- Compression, infiltration, or obstruction caused by the tumor (e.g., bone pain, abdominal pain)
- Changes in blood cell production such as decreased hemoglobin, hematocrit, white blood count, or platelets (e.g., the child is pale, tired, bruises easily, and has petechiae)
- Secretion of a substance by the tumor that interferes with normal organ functioning
Metabolic, electrolyte, hormonal, or immunologic alterations caused by tumor metabolism or cell death (e.g., increased frequency of infections, hypercalcemia)

A limited health history and physical assessment can lead to delays in the detection and diagnosis of cancer in children. Conversely, a systematic health history and complete physical examination can assist in the early detection and diagnosis of a suspected malignancy.

Focused Health History

QUESTION: What is George's presenting symptom? Knowing that George is Vietnamese American,

what is an important topic to assess during the health history interview?

A systematic approach to obtaining a focused health history is necessary to elicit the most relevant data for detecting a possible malignancy in a child (Focused Health History 22-1). The presenting signs and symptoms and the chief complaint, as stated by the child or parent, provide the most important clues regarding the type of cancer that should be suspected. Elicit specific information about the sequence of events related to the current illness, such as the date the symptoms appeared, the sequence and duration of symptoms, and any diagnosis that was made or treatment that was prescribed by another practitioner. Determine whether culturally based remedies (e.g., vitamins, organic compounds, holy water, or herbs) were tried before conventional medical treatment was sought.

Ask pertinent questions about each body system to elicit additional symptoms that the parent has not recognized or considered important. Check the child's past medical history to assist in identifying clinically important symptoms that the family or other healthcare providers may not have associated with the current diagnostic evaluation. Often parents downplay or self-diagnose certain symptoms and attribute them to normal childhood findings (e.g., "growing pains," frequent colds, "finicky eater"). Information regarding past medical history should include the child's prenatal and neonatal history, allergies, immunizations, childhood illnesses, and previous hospitalizations.

If the child has a history of a previous malignancy, obtaining information regarding the malignancy and all treatments used is especially important. This information is crucial in assessing the potential for a secondary malignancy. Chemotherapy and radiotherapy are themselves powerful carcinogens. In children who survive 5 years after the diagnosis of cancer, another cancer is 10 to 20 times more likely to develop than is expected in children without a history of cancer (National Cancer Institute, 2008a). Certain childhood cancers are associated with an increased incidence of a secondary cancer site. Children with Hodgkin's disease, leukemia, ovarian cancer, retinoblastoma, or the genetic form of Wilms' tumor, and children who received radiation or alkylating agents, are among those at particularly high risk (National Cancer Institute, 2008a). Hodgkin's disease is the most common tumor that precedes both hematologic and nonhematologic secondary tumors. A secondary malignancy may also be associated with the treatment of the primary tumor, or there may be a genetic association between the primary and secondary cancer (e.g., children with retinoblastoma are at risk for secondary osteosarcoma).

The family medical history is a very important aspect of history taking when cancer is suspected. Familial and genetic diseases such as autoimmune diseases, immune deficiencies, Down syndrome, and neurofibromatosis have been linked to various types of cancer in children.

FOCUSED HEALTH HISTORY 22–1

Pediatric Malignancies*

Current history	<p>Recurrent fever, nausea, vomiting, diarrhea, constipation</p> <p>Fatigue, pallor, bleeding of mucous membranes</p> <p>Cough or dyspnea unrelated to infectious illness</p> <p>Bruising, unexplained injuries, tissue pain unrelated to an injury</p> <p>Recent traumatic injury associated with current complaint of pain in bone or tissue</p> <p>Masses, swollen or tender lymph nodes</p> <p>Morning headache with vomiting</p> <p>Unsteady gait, limping</p> <p>Visual disturbances</p> <p>Chronic drainage from ear</p> <p>Immunizations up to date</p> <p>Allergies</p> <p>Current medications, including prescription, over-the-counter, and home remedies</p>
Past medical history	<p>Prenatal/Neonatal History</p> <p>Maternal drug or substance use</p> <p>Maternal history of miscarriage, fetal death</p> <p>Parental exposure to chemicals, radiation, alkylating agents</p> <p>Newborn infection; mass noted at birth</p> <p>Previous Health Challenges</p> <p>History of persistently occurring infections, nontraumatic bone fractures, unusual bleeding (nose, mouth, rectum), unusual bruising, failure to thrive, anemia</p> <p>Childhood Illnesses</p> <p>History of childhood illness (e.g., chickenpox)</p> <p>Recent contagious exposure</p>
Nutritional assessment	Weight loss, decreased appetite, nausea, vomiting, constipation, diarrhea
Family medical history	<p>Family history of cancer, especially childhood malignancies, immune disorders</p> <p>Family history of genetic abnormalities (e.g., Down syndrome, neurofibromatosis)</p>
Social and environmental history	<p>Primary cultural group of the family</p> <p>Family support systems</p> <p>Past experiences with stressors and coping mechanisms</p> <p>Recent out-of-country travel</p> <p>Exposure to environmental hazards:</p> <ul style="list-style-type: none"> • Drugs containing radioisotopes or immunosuppressive agents, in utero or during childhood • Toxic chemicals, fumes, aerosols, smoke, radiation • Household members' smoking behaviors • Power lines, chemical treatment plants, waste dumps
Growth and development	<p>Significant variation from or delay in achieving normal patterns of growth and development</p> <p>The child's habits, including toileting, sleeping, speech patterns, and daily activities</p> <p>Previous exposures to and coping mechanisms for stress and illness</p>

*This history is focused on the child with a malignancy. See Chapter 8 for a comprehensive format.

WORLDVIEW: The incidences of certain cancers differ notably among ethnic groups from different geographic locations. For instance, ALL is the most common cancer among white children in the western countries, but its incidence is low among black children in the United States and in Africa, and among Arab and Indian children. In tropical Africa, Burkitt's lymphoma accounts for more than half of all cases of childhood cancer. In Ankara, Turkey, acute myelomonocytic leukemia accounts for more than half the childhood cases of cancer (National Cancer Institute, 2008a).

A family genogram completed by the healthcare prescriber is helpful in plotting health problems of parents, grandparents, aunts, uncles, siblings, and first cousins. The information collected should include ages, a list of serious illnesses, and, if deceased, the cause of death. Give special attention to a family history of malignancies.

A history of environmental exposures may be important whenever a malignancy is suspected. Environmental

factors have long been implicated in the increased risk of certain cancers, most commonly *ionizing radiation* (such as radiographs, or radiation given off by radioactive materials), electromagnetic fields, radon, drugs, viruses, and alkylating agents or topoisomerase II inhibitors. Information collected should include exposures to these and other hazardous materials, pollutants, insecticides, and exposure to environments where the child may have been in contact with hazardous substances. Exposures to these elements by parents before conception, by the mother during fetal development, or by the child after birth have all been associated with cancer development. Some cancers are associated with certain genetic syndromes, such as Li-Fraumeni syndrome, neurofibromatosis, and Down syndrome.

Collect a social history, which provides important information about family functioning and support systems. Include psychosocial and cultural aspects such as parents' race, marital status, age, socioeconomic status, names and ages of all children and their familial relationship to the ill child, and cultural beliefs. In addition, assess the strengths and weaknesses of each family member to determine the effect of the diagnosis, previous experience with stressors, and ability to cope with the stress. Assess the group dynamics within the family and determine whether there are other stressors present (e.g., financial difficulty, divorce). Cancer is a chronic illness that affects the entire family. Over time, family relationships and dynamics change as the family adjusts to the varying demands of the child's illness. An early understanding of family roles, strengths, and coping mechanisms assists the healthcare team in helping the family to deal with the emotional impact of the illness.

Document baseline physical and developmental milestones, as well as the child's eating, sleeping, and toileting habits. Also note any recent regressions in behavior that may be related to the current illness. For example, a 14-month-old child who has been walking and drinking from a cup may regress to crawling and have difficulty sitting unsupported or holding a bottle. These regressions are common in young children with brain tumors.

ANSWER: The presenting symptom is pain in the tibia. The pain was first noticed about 3 months prior to seeking medical assistance, but it did not interfere with his George's normal activities. An important topic to ask is what cultural remedies George's family may have tried at home. In fact, when the nurse asked, George's mother described several Vietnamese traditional methods of healing have been performed on George. His mother placed a silver coin inside a hard boiled egg and rolled it over the affected area of his shin. They also placed suction cups over the painful area of his leg. This was not painful for George but it did leave little pink circles over his shin.

Focused Physical Assessment

QUESTION: What do you anticipate a focused physical assessment of George will reveal?

When cancer is suspected in a child, perform a head-to-toe assessment, with special attention to areas related to symptoms. Focused Physical Assessment 22–1 provides a detailed review of findings by body region that should be evaluated during the physical assessment when a malignancy is suspected.

Begin the assessment by observing the child's overall appearance. Note skin color, presence of ecchymoses or petechiae, nutritional status, asymmetry of facial features or extremities, lymph nodes, and level of activity. A child with cancer often appears pale and thin, with symptoms of lethargy and generalized malaise. Children may have experienced recent weight loss and appear malnourished if they have experienced prolonged nausea, vomiting, or loss of appetite. The presence of pallor, ecchymoses, and petechiae may indicate that the cancer has invaded the bone marrow and is interrupting the normal production of red blood cells and platelets, as in leukemia. Asymmetry of facial features may indicate a retinoblastoma or nasopharyngeal rhabdomyosarcoma (RMS). Asymmetry of an extremity may indicate a bone tumor or soft-tissue sarcoma. Enlarged lymph nodes that are firm and painful on palpation and that are associated with weight loss, fever, and an abnormal chest radiograph may indicate a lymphoma, such as Hodgkin's disease or non-Hodgkin's lymphoma (NHL).

The presence of pain, limping, or decreased range of motion requires further investigation. Obtain a thorough history of the location, onset, duration, frequency, and intensity of the pain, as well as precipitating and alleviating factors. Headaches, especially when associated with vomiting, must be further evaluated to rule out a possible brain tumor.

ANSWER: George's physical assessment is unremarkable except for his complaint of pain with activity and a firm soft-tissue mass fixed to the underlying bone with slight tenderness.

Diagnostic Criteria

QUESTION: Identify measures you could implement to support George and his family during his diagnostic procedures. Each diagnostic test has given the family "bad news." What kind of strategy would help to communicate the results of the tests?

Diagnostic and staging procedures are used to detect the presence of cancer malignancy, to identify the type of malignancy, to identify the location of the malignancy, and to determine the extent of disease. When cancer is suspected, these procedures are usually carried out expeditiously so that the appropriate treatment plan can be initiated quickly. The cancer evaluation process includes clinical assessment, laboratory and radiologic tests, and, most important, a biopsy of tissue or fluid for pathologic confirmation. Recent advances in radiologic techniques have dramatically improved the ability to diagnose cancer. Noninvasive imaging studies such as CT, ultrasonography, positron emission tomography, and MRI enable earlier detection of a malignant growth (Tests and

FOCUSED PHYSICAL ASSESSMENT 22–1

Pediatric Malignancies

Assessment Parameter	Alterations/Clinical Significance
General appearance	Unexplained weight loss, fever, and night sweats may indicate cancer. Weight loss may be secondary to decreased appetite, nausea, and vomiting, or diarrhea. Fever may be secondary to infection or disease process. Night sweats may be present in Hodgkin's disease.
Integumentary system	Pallor, bruising, petechiae, mucous membrane bleeding may indicate leukemia or other cancer involving the bone marrow.
Head and neck region	Masses on the cranium may indicate a soft-tissue or bony mass. Drainage from ear, asymmetry of face, jaw pain, or swelling may indicate an infection or the presence of a soft-tissue mass. Bruising or swelling around eyes (proptosis) may indicate soft-tissue mass. Bleeding gums may indicate thrombocytopenia; pallor of the gums may indicate anemia. Enlarged or tender cervical lymph nodes may indicate lymphadenopathy caused by cancer cells in the lymph nodes. Presence of white reflection in pupil of the eye may indicate retinoblastoma.
Thoracic and axillary region	Asymmetry may indicate the presence of a soft-tissue mass. Difficulty breathing or respiratory distress may indicate mediastinal mass (may be seen on a radiograph). Enlarged or tender axillary lymph nodes may indicate lymphadenopathy caused by cancer cells in the lymph nodes.
Gastrointestinal system	Asymmetry, a palpable mass, rectal bleeding, or vaginal discharge may indicate the presence of an abdominal tumor. Hepatomegaly or splenomegaly (enlargement of the liver or spleen) may be caused by an infection or tumor in the liver or abdomen.
Musculoskeletal system	Asymmetry, bone pain or tenderness, limited range of motion, palpable bony or soft-tissue mass may indicate a bone tumor such as osteosarcoma or Ewing's sarcoma.
Neurologic system	Cranial nerve abnormalities, ataxia, gait disturbances, alterations in level of consciousness, or diminished reflexes may indicate the presence of a brain tumor.

Procedures 22–1). However, a definitive diagnosis of cancer cannot be made without pathologic confirmation. In addition, the use of radiolabeled isotopes and monoclonal antibodies is making scanning procedures more thorough and cancer specific. These techniques enable the oncologist to follow treatment response or disease progression.

The nurse caring for children suspected of having cancer is in a unique position to offer support and guidance to the child and the family as they undergo the numerous diagnostic and staging procedures. The nurse must possess a thorough understanding of these procedures and the usual sequence in which they are completed. In most instances, the child's nurse plays a key role in preparing the child and family for tests and procedures, and for ensuring the child's safety.

KidKare ■ Establishing an open, honest nurse–child relationship is important. One of the easiest ways to do this is to give simple, honest answers when children ask questions. If the procedure is going to hurt, the child should be told and be prepared for it. Let the child know that it is OK to be afraid and to cry. Do not tell the child to “act like a big boy” or “big girl.”

Provide children who are undergoing tests with an age-appropriate explanation of the procedure and why it is necessary. Children are more apt to cooperate if they understand what is being done and why the test or procedure is necessary. During diagnostic tests, avoid restraining the child if possible. Avoid asking the parent or family member to restrain the child. They should be present for emotional support and comfort. If children have some freedom of movement, they feel they have some control over the situation.

Evaluation and treatment for cancer frequently requires painful procedures such as needle sticks, lumbar punctures, bone marrow aspirations, and biopsies. The nurse caring for children with cancer must intervene to prevent or minimize pain from such procedures or from the cancer itself. Pharmacologic and biobehavioral interventions can be implemented to maximize the child's comfort. Pharmacologic interventions include sedation and analgesia or general anesthesia for invasive procedures (e.g., lumbar punctures and bone marrow aspirations or biopsies), topical anesthetic for injections and venipunctures, and nonsteroidal anti-inflammatory drugs to decrease cancer pain. Biobehavioral interventions such as age-appropriate preparation, reassurance, diversion, relaxation, breathing exercises, music therapy, and

Tests and Procedures 22–1 Evaluating Pediatric Malignancies

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
Complete blood count with differential	<p>Determines abnormal loss or destruction of cells that may indicate cancer or bone marrow suppression.</p> <p>Changes in values may indicate complications such as anemia, neutropenia, and thrombocytopenia</p>	<p>Increased white blood cell count with the presence of lymphoblasts can indicate leukemia.</p> <p>Malignancies with bone marrow involvement may cause hemoglobin, hematocrit, and platelet levels to be low.</p> <p>Decreased red blood cells, hemoglobin, seen in anemia.</p> <p>Decreased neutrophil count indicates neutropenia, which is often a presenting sign of malignancy, or indication of a relapse in cancer treatment or immunosuppression secondary to chemotherapy and/or radiation treatment.</p> <p>Platelet count less than 150,000/mm³ indicates thrombocytopenia.</p>	<p>Be aware that children who require numerous venipunctures may become fearful and uncooperative.</p> <p>Provide good explanations, use topical anesthetic before initiating a venipuncture; consider using an intermittent infusion device for obtaining venous blood samples.</p>
Absolute neutrophil count (ANC)	<p>Measures the number of neutrophil granulocytes (type of white blood cell that fights infection) present in the blood.</p>	<p>The normal range for the ANC is 1.5 to 8.0 (1,500–8,000/mm³).</p> <p>An ANC less than 1,000 in infants 2 weeks to 1 year or less than 1,500 in children older than 1 year indicates neutropenia.</p>	<p>ANC is not measured directly; it is calculated by multiplying the white blood count by the percent of neutrophils (segmented [fully mature] + and bands [almost mature]) in the differential white blood cell count.</p> <p>Utilize good infection control measures during lab draw to protect child from exposure to infection.</p> <p>Advise family of neutropenic precautions if ANC is low.</p>
Serum chemistries	<p>Helps to evaluate the body's response to the cancer process.</p> <p>Indicates metabolic state as well as renal and liver function.</p>	<p>Elevations in potassium, calcium, phosphorus, magnesium, blood urea nitrogen, and lactate dehydrogenase levels may be seen at the start of chemotherapy and indicate tumor lysis syndrome.</p> <p>High uric acid and creatinine levels are associated with renal failure.</p> <p>Changes in levels are important as prognostic indicators and evidence to manage disease and evaluate treatment response.</p>	<p>Ensure that proper tubes are used and that volume of blood is adequate for lab analysis.</p>
Urinalysis	<p>Provides general information about renal function.</p>	<p>May indicate urinary tract infection secondary to child's immunosuppressed state.</p> <p>May indicate altered renal function secondary to chemotherapy and/or radiation treatments.</p>	<p>When obtaining urine sample from adolescent females, question about presence of menstruation.</p> <p>Obtain midstream clean-catch sample to avoid contamination.</p>

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
Urine catecholamines VMA, HVA (catecholamine metabolites)	Identifies specific tumor markers used to differentiate neuroblastoma from other tumors.	VMA and HVA levels are elevated in 90% to 95% of children with neuroblastoma.	Obtain sample before CT scan, because the contrast medium affects the results. All urine is collected for a 24-hour period starting with morning urine on day 1 and ending with morning urine on day 2. Urine is kept in closed container in refrigerator or other cool location.
Tumor markers	A characteristic or substance that indicates the presence of a specific tumor	Alpha-fetoprotein levels are commonly elevated more than 20 ng/mL in children with hepatoblastoma, hepatocellular cancer, or germ cell tumors. Beta human chorionic gonadotropin is elevated in children with hepatoblastoma and germ-cell tumors.	Prepare child for venipuncture to obtain blood sample. Ensure that proper tubes are used and that volume of blood is adequate for lab analysis.
Immunophenotyping of monoclonal antibodies and cytogenic studies	Used to identify, classify, and describe specific types of cells in a sample of blood, marrow, or lymph node cells. Determines whether a chromosomal abnormality exists within a tumor. This procedure can be important in helping to decide on the best treatment for a child.	Findings include distinguishing myelogenous leukemic cells from lymphocytic leukemic cells. Normal lymphocytes can be distinguished from leukemic lymphocytes, and B-cell lymphocytes can be distinguished from T-cell lymphocytes. Also provides information about whether the patient's cells are monoclonal (derived from a single malignant cell).	Prepare child for specific lab test (venipuncture bone marrow aspiration or lymph node biopsy) to obtain cell sample for analysis.
Lumbar puncture	Introduces a hollow needle with stylet into the lumbar subarachnoid space of spinal canal to withdraw CSF. Used to introduce chemotherapeutic agents into the spinal canal and circulating CSF.	Provides diagnostic or staging workup in children with leukemia, lymphoma, parameningeal RMS, and medulloblastoma.	Nurse may need to assist with positioning, securing, and calming child (see thePoint , Procedure: Lumbar Puncture). Encourage fluids before and after lumbar puncture. Empty bladder before lumbar puncture, because child must remain supine for 4 to 6 hours after the procedure. Premedicate for pain and monitor for signs and symptoms of headache related to decreased amount of CSF. Maintain strict asepsis. Contraindicated in patients with substantially increased ICP because brain stem may herniate downward, causing tissue compression, which may lead to death.
Bone marrow aspiration and biopsy	Aspirated bone marrow is used for microscopic examination of cell type and morphology.	When leukemia is present, bone marrow aspiration can reveal	Procedure is done using aseptic technique.

(Continued)

Tests and Procedures 22–1 Evaluating Pediatric Malignancies (Continued)

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
	Test performed to determine when leukemia is present, if the tumor has spread to the bone marrow, or when a complete blood count suggests malfunctioning bone marrow.	more than 25% blasts (immature and undifferentiated cells). In tumor metastasis, carcinogenic cells may be present in bone marrow.	Topical anesthetic is used to anesthetize the skin; an injectable anesthetic is used to anesthetize the bone. Prepare the child for the procedure; explain where the sample will be obtained. Position the child properly based on the site of aspiration; place pillows or folded blanket under the child's abdomen to elevate the hips (for iliac crest site). Allow parents to stay in the room during the procedure. Position the parent at the head of the table, allowing the parent to provide verbal and physical support. The parent should not help to restrain the child. Provide procedural sedation monitoring for children receiving sedatives and analgesics in a treatment room; the procedure can also be done while the child is in the operating room for biopsy, resection, or line placement. Apply pressure dressing to site after aspiration. Remove dressing and inspect site after 24 hours.
Radiographs	Uses radiation to examine soft tissue and bony structures of the body. Aids in detecting tumors and metastasis to bones and vital organs.	Abnormal masses in the chest wall, lungs, and mediastinum may indicate tumors in this area. Lesions on the bone may indicate tumors (e.g., Ewing's sarcoma, osteosarcoma) or metastasis of tumors and warrant further investigation by bone scan, CT, or MRI.	Determine whether adolescent female patients may be pregnant. Advise the child to hold absolutely still. Provide age-appropriate explanations (such as the radiograph machine being a "camera" that takes pictures of "your insides") to assist in gaining the child's cooperation. Provide reassurance that parents are nearby. Anticipate the need for assistance in positioning and maintenance of the positioning for infants and young children.
CT scan	Uses serial scans of each plane in the area studied to provide a three-dimensional view and represents a cross-sectional view of body structures. Uses a contrast medium (IV for brain CT; oral for abdominal	CT of chest may reveal presence and extent of pulmonary lesions. Abnormal body masses, lesions, or enlarged organs provide further evidence of presence of tumors or metastasis.	Inform the child that he or she must remain very still for 30 to 90 minutes. Anticipate the need for immobilization or sedation in young children.

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
	<p>or pelvic CT) to enhance visualization.</p> <p>Visualizes known or suspected solid tumors.</p> <p>Detects masses, locates lesions, and evaluates response to treatment.</p>		<p>IV or oral contrast dye may be ordered. If oral contrast medium is used, mix in a clear fluid, and ensure that the medium is cold and that the child drinks the entire volume within 45 to 60 minutes. The oral contrast dye is usually given the night before the tests and again 2 hours before the test. The child may then have nothing else to eat or drink until the test is completed. If the child is unable to tolerate the contrast by mouth, expect to administer the oral contrast medium via nasogastric tube. Ensure IV access, especially if IV contrast medium is to be used.</p> <p>Educate child and parents about the scan, especially if the scan is done on an outpatient basis.</p>
Magnetic resonance imaging (MRI)	<p>Uses radio waves and magnets to produce a highly defined, computerized image of the body.</p> <p>Provides extremely precise visualization and information (as much as direct visualization).</p> <p>Helps to determine exact location and size.</p>	<p>Abnormal body masses, lesions, or enlarged organs provide further evidence of presence of tumors or metastasis.</p>	<p>MRI is the image of choice for brain stem and bone tumors. Keep in mind that the strong magnetic field precludes MRI study of persons who have any implanted metallic objects in their body.</p> <p>Inform the child and parents that the test lasts about 60 minutes and that the child must lie very still.</p> <p>Anticipate sedation for children who cannot lie still, who may become frightened by the loud noise made by the machine, or who become claustrophobic because of the close quarters. Provide continuous monitoring of pulse oximetry and heart rate during and after the scan for children who are sedated. Ensure that jewelry and other metallic objects are removed.</p>
Bone scan	<p>A nuclear scanning test to rule out cancer involving the bones.</p> <p>Determines the extent of bone involvement.</p>	<p>Abnormal body masses, lesions, or enlarged organs provide further evidence of presence of tumors or metastasis.</p> <p>Areas of disease will have an increased uptake of the radioactive dye.</p> <p>Highly sensitive method of detecting bony lesions, but does not distinguish between cancer and inflammatory processes.</p>	<p>Inform the child and family that the scan lasts 30 to 60 minutes. Two to 4 hours before the scan, a radioisotope dye is injected intravenously into the child. Encourage the child to lie still during the test; instruct in measures to facilitate lying still. Sedation may be required to keep the child still.</p>

(Continued)

Tests and Procedures 22–1 Evaluating Pediatric Malignancies (Continued)

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
Positron emission tomography (PET) scan	Combines conventional nuclear medicine techniques with transaxial tomography to study blood flow and volume, and protein metabolism of specific regions or organs. Uses isotopes to detect physiologic and metabolic activity. Aids in differentiating viable tumors from necrotic or scar tissue.	Abnormal body masses, lesions, or enlarged organs provide further evidence of presence of tumors or metastasis. Most effective for diagnosis and evaluation of neuroblastoma, Hodgkin's disease, NHL, bone tumors, lung and colon cancers, and brain tumors.	Inform child to avoid intake of caffeine, nicotine, and alcohol for 24 hours before scan. Child must fast at least 4 hours prior to the scan. IVs with dextrose should be avoided 6 hours before the scan to prevent a false-positive result. Ensure adequate IV access, which is required for isotope injection. Child may need sedation to remain still. PET scans are clearer than conventional radionuclide scans.
Ultrasound	Uses sound waves to create images that visualize body structures and locate masses.	Unusual mass or enlarged lymph nodes or organs may indicate a tumor.	Be aware that ultrasound is the initial screening test for the child with a palpable mass. Inform child and parents that this test is noninvasive, but that it may take as long as 30 minutes to complete. Allow parents to stay with child during the procedure, if appropriate. Inform the child that the transducer may "tickle" and that a gel is used that may feel cold. Provide infants with a juice bottle during the procedure to alleviate crying. Check to determine if a full bladder is needed for the test; some ultrasounds require this to differentiate organs.
Tissue specimen biopsy	Analyzes tissue such as lymph node or unidentifiable mass to determine pathology of tissue cells. Identifies specific type of tumor cells for initiating optimal treatment	Tissue specimen reveals abnormal cells.	Ensure proper labeling and handling. Local anesthetic is used. After the procedure, the area may be tender or sore for a few days.

HVA, homovanillic acid; VMA, vanillylmandelic acid.

imagery have been cited as effective measures to reduce the pain of a child or adolescent during invasive procedures. The nurse can easily teach these interventions to the parents and to the child or adolescent, thereby increasing their sense of control. (See Chapter 10 for a comprehensive discussion of pain management techniques.)

ANSWER: During this diagnostic period, the Tran family will meet many new healthcare providers.

Nurses, however, are the ones who remain with the Tran family throughout George's illness. Nurses should provide preprocedure explanations and should prepare George and his family for the diagnostic tests. Unlike the difficulties with younger children, George is able to cooperate even in a lengthy test and is fascinated by the different technology involved in imaging. Nurses should also help the family understand the results of the diagnostic procedures. One strategy both to facilitate communication and to allow the presence of the tumor to become real is to allow the adolescent and his

family to see all the images. The challenge is to relay the results in a manner that is well understood despite language barriers. The nurses should provide emotional support when the family receives the diagnostic results showing a lesion, and again when the results show metastases.

TREATMENT MODALITIES

The therapeutic plan for the child with a malignancy includes initial and ongoing treatment, plus supportive care, all using an interdisciplinary approach. Supportive care includes managing the numerous side effects and adverse outcomes associated with the therapies to eradicate the cancer. This section will discuss the interdisciplinary interventions that may be selected to treat the child with cancer. Decisions about the course of treatment are based on the type of cancer, the location of the cancer, and the extent of the disease. The primary goal of treatment is to *cure* the child without causing substantial harm or impairment. Advances have been made during the past decade in understanding cancer, and technologic advances have enabled development of multimodal therapy that is considered the gold standard (the best possible treatment).

An individualized therapeutic plan is developed for each child based on the child's unique presentation, using multimodal therapy to offer the best chance of survival. The modes of therapy currently include surgery, chemotherapy, radiation therapy, BRMs, and HSCT. Gene therapy for treating childhood cancers is still in the early phases of clinical application. The therapeutic plan is also individualized to treat the adverse outcomes that may present as a result of surgery, chemotherapy, and radiation. Supportive care measures include, but are not limited to, managing pain, nausea, and vomiting; promoting growth and development; and providing psychosocial support. A discussion of these issues is included in this section.

The Children's Oncology Group is a large group of multidisciplinary healthcare professionals who collaborate with one another, as well as with other national and international treatment groups. Their focus is to conduct clinical trials aimed at increasing the long-term survival rates and at minimizing late effects associated with aggressive cancer treatment. The Association of Pediatric Hematology Oncology Nurses is the professional nursing organization for the nursing care of children, adolescents, and young adults with blood and cancer disorders, and their families. Their core purpose is to support and advance nurses in optimizing outcomes for this patient population and their families.

Surgery

QUESTION: Surgery is an important treatment for George. If the sarcoma has not metastasized, a limb salvage or limb-sparing procedure may have been an option. This procedure is designed to save the limb while removing the tumor. However, because of the presence of a pathologic fracture and metastatic disease, the consultants feel that an amputation is the best option. How can the nurses support

George after he is told that his best chance of survival includes amputating his right leg?

The primary goal of surgery in pediatric oncology is to remove all visible disease while maintaining or restoring normal body function. The best prognosis is related to early detection and removal of disease. Thus, surgery is considered a definitive treatment in more than half of all cancer patients. Surgery may also be used for diagnosis. In this case, a biopsy is performed in which a tissue sample is taken and examined for evidence of cancer. Surgery is also likely for insertion of central venous catheters (CVC) or implantable infusion devices that will be used to administer chemotherapy, antibiotics, and total parenteral nutrition, and to obtain blood specimens (Wallace, 2008).

Recent advances in surgical oncology have provided major improvements in the surgical management of children with cancer. These improvements have allowed a better quality of life for the child, both physically and psychosocially. Surgery is most frequently combined with chemotherapy, radiation therapy, or biologic response modifiers (BRMs). Surgery and adjuvant therapy can lengthen disease-free and long-term survival for children with cancer. Nursing care of the child with cancer following surgical treatment is similar to the care given to any child who undergoes surgery. (See Chapter 11 for more discussion of presurgical and postsurgical care.) Monitor the child for complications from the surgery and for pain control, using an age-appropriate pain rating scale (see Chapter 11). Assess the surgical site for any bleeding or signs of infection. Offer support to families anxiously awaiting biopsy results or news of the effectiveness of the surgical intervention.

ANSWER: Nurses will give George his preoperative and postoperative information just as they would for any surgery. George requires additional assessment for hopelessness and interventions that include focusing on what he will still be able to do and enjoy after the amputation. In addition, the nurses need to address George's psychosocial needs, especially related to how the amputation may affect his body image.

Chemotherapy

QUESTION: Chemotherapy is also an important component of George's treatment. He will receive two courses of chemotherapy before the surgical resection of the tumor. Then he will receive additional courses after surgery. The consultants have recommended a combination of three drugs including Doxorubicin. What is the role of George's nurses related to his chemotherapy treatment?

Chemotherapy is a systemic mode of cancer treatment. This approach has been extremely effective in childhood cancers, especially with certain cancers such as leukemia

and lymphoma, that cannot be managed effectively by surgery or radiation therapy alone. The development of new drugs and administration techniques has resulted in advanced treatment regimens and increasing survival rates. Children with cancer undergo chemotherapy regimens for periods ranging from a few months to years. Side effects range from minimal to severe. The nurse plays a key role in providing children and their families with the appropriate information and support throughout treatment. The side effects of chemotherapy include neutropenia, thrombocytopenia, anemia, nausea, vomiting, and mucositis. Nursing management of these side effects is discussed later in Treatment Modalities under Supportive Care.

Chemotherapy affects the **cell cycle**. Cells go through four phases to complete cell growth cycle: G1 (the first “gap”), S (synthesis phase), G2 (the second “gap”), and M (mitosis). Cells move into G0 (the resting phase) after mitosis; during the G0 phase, cells are not actively dividing. The G1 phase varies the most in duration (8–48 hours) and is the phase in which DNA synthesis is beginning and active RNA and protein synthesis occurs. Cells then enter the S phase, during which most DNA synthesis occurs. This phase takes from 10 to 30 hours, during which time the DNA content of the cell doubles. After the S phase, cells move into G2. During this phase, the RNA and protein necessary for mitosis are synthesized. This process takes 1 to 12 hours. During the last phase of the cell cycle, the M phase, mitosis (cell division) takes place, which takes approximately 1 hour. Mitosis is a four-step process (prophase, metaphase, anaphase, and telophase) that results in two identical daughter cells.

Cancer cells are difficult to treat in the G0 phase, because the cell is not dividing. Malignant cells are believed to have a shorter cell cycle time and grow at a faster rate because of their uncontrolled, erratic growth patterns.

Chemotherapeutic Agents

Generally, chemotherapeutic agents fall into one of two classifications: *cell cycle-specific* or *cell cycle-nonspecific agents*. Cell cycle-specific agents exert their maximal effect during a specific phase of the cell cycle. Cell cycle-nonspecific agents act on cells regardless of their phase. The maximal amount of cell destruction is directly proportional to the dose and combination of drugs given. Combining drugs that act at different phases of the cell cycle produces optimal cell cycle disruption and cell destruction. Combining drugs also helps to prevent drug resistance, which occurs when a cancer cell builds up a tolerance to a single agent, thus rendering therapy with that agent ineffective. Finally, combination therapy allows multiple drugs to be given at safe dosages, an approach that minimizes toxic side effects while maximizing cancer cell destruction.

Chemotherapeutic agents are pharmacologically classified into seven categories. Table 22–1 summarizes the action of these agents and lists examples. Some agents cause more severe side effects than others. Chemotherapy

agents do not distinguish between cancer cells and other rapidly dividing normal cells, and therefore cause predictable side effects. The hematopoietic system, the gastrointestinal (GI) tract, and the integumentary system are composed of rapidly dividing cells and thus are highly susceptible to toxic effects. Nursing care of these side effects is discussed in the section of this chapter on supportive care. **Myelosuppression** (suppression of bone marrow function), nausea, vomiting, diarrhea, hair loss, and skin problems are common side effects in children receiving chemotherapy.

Chemotherapeutic Regimens

A chemotherapy regimen is composed of several phases. During *induction*, the initial phase, intensive therapy is given to kill enough cancerous cells to induce a remission. **Remission** occurs when a temporary or permanent response to therapy causes a decrease or absence of the primary malignancy. During the next phase, the *consolidation phase*, intensive therapy is given to destroy the remaining cancer cells. The *maintenance phase* is a designated period during which treatment is continued to destroy any residual cancer cells. This phase can continue for several years. During the *observation phase*, therapy has ended and the child is monitored for recurrent disease or late effects of treatment. The observation phase can be a stressful period for the family. Although they are thankful to have completed chemotherapy and frequent monitoring, they may experience increased anxiety related to the possibility of a relapse. During any of these phases, the child may relapse. In these cases, the treatment protocol is changed and the child goes through each of the phases again, beginning with induction. A child is considered to be a cancer survivor when he or she has been disease free for 5 years past the end of the maintenance phase.

Chemotherapy Administration

Chemotherapy doses for children are most often calculated according to the child’s body surface area or are based on the child’s weight in kilograms (for infants younger than 1 year of age) to minimize toxic effects to tissues and organs (see nomogram in Fig. 9–1 for calculating body surface area). Chemotherapeutic agents are administered intrathecally via lumbar puncture; into the veins either peripherally or via CVCs; into the lateral ventricle using the Ommaya reservoir; or into intraperitoneal, intracavitary, or intra-arterial sites using implantable pumps. Portable infusion pumps deliver continuous therapy to children in ambulatory settings.

Chemotherapy administration necessitates safety precautions for both the child and the nurse or caregiver administering the medication (Nursing Interventions 22–1). The National Institute for Occupational Safety and Health (NIOSH) has developed guidelines to protect healthcare workers from unwarranted exposure to cytotoxic agents caused by accidental absorption, inhalation, or ingestion (NIOSH 2004).

TABLE 22-1

Types of Chemotherapy Agents

Type	Action	Examples
Alkylating agents	Cell cycle nonspecific, destroying both resting and dividing cells. During alkylation, the hydrogen atoms of some molecules within the cell are replaced by an alkyl group. This group interferes with DNA replication and RNA transcription.	Busulfan Carboplatin Carmustine Cisplatin Cytosin Dacarbazine Ifosfamide Lomustine Mechlorethamine hydrochloride Melphalan Procarbazine Temozolomide Thiotepa
Antimetabolites	Cell cycle specific, most active during the S phase and acts similar to normal cellular metabolites that are necessary for cell function and replication. These drugs damage cells by acting as a substitute for a natural metabolite in an important molecule, thereby altering the function of the molecule.	5-Fluorouracil Cladribine Clofarabine Cytarabine Fludarabine Gemcitabine Hydroxyurea Mercaptopurine Methotrexate Thioguanine
Antitumor antibiotics	Cell cycle-nonspecific agents, synthesized naturally by various bacterial and fungal species. They interfere with cellular metabolism, thereby blocking DNA transcription, RNA transcription, or both.	Bleomycin sulfate Dactinomycin Daunomycin Doxorubicin Idarubicin Mitoxantrone
Plant products	Cell cycle specific because they crystallize microtubular proteins and arrest mitosis. Agents are derived from the periwinkle plant (<i>Vinca rosea</i>) and are sometimes called vinca alkaloids.	Etoposide Paclitaxel Teniposide Vinblastine Vincristine
Hormones (corticosteroids)	Not chemotherapeutic drugs per se, but are effective in treating cancers that arise in tissues that depend on hormones for cellular proliferation. The hormonal environment of the cancer cell is altered, thereby affecting cancer cell division. Hormones and corticosteroids can interfere with protein synthesis and modify the DNA transcription process.	Dexamethasone Hydrocortisone Prednisone
Miscellaneous agents	Medications with a mechanism of action that is not fully understood, or their action not like any of the other categories described. This group includes enzymes inhibitors, platinum agents, and nonclassic alkylating agents.	Asparaginase Carboplatin Cisplatin Gleevec Hycamtin Hydroxyurea Procarbazine Retinoic acid Trisenox

NURSING INTERVENTIONS 22–1

Safety Guidelines for Chemotherapy Administration

Event	Guidelines
Preparation	<p>Use a central venous catheter for administration whenever possible to minimize the risk of extravasation.</p> <p>A healthcare provider who is competent in peripheral IV access selects the peripheral vascular access site and places the catheter.</p> <p>Mix and prepare chemotherapy agents in a biologic safety cabinet, wearing protective gear (i.e., latex gloves, gown, face shield) using sterile techniques.</p> <p>Wear protective gear, ensure IV connections have a Luer-Lok and are secured, and use a plastic-backed absorbent pad under the site of administration to catch any leakage when administering chemotherapy.</p>
Disposal	<p>Consider equipment that has contained chemotherapy drugs, body excretions after chemotherapy administration, and linens and clothing contaminated with chemotherapeutic agents or excretions as hazardous waste.</p> <p>Chemotherapeutic agents may be excreted in the urine for up to 48 hours after administration. Dispose of these materials in designated, properly labeled hazardous waste containers.</p>
Extravasation	<p>Notify a physician immediately if suspected or definite extravasation is identified.</p> <p>Immediately perform procedures (i.e., elevate extremity, apply ice, apply topical or injectable antidotes) according to institutional guidelines for extravasation.</p>
Spills	<p>Clean up accidental spills of chemotherapy drugs immediately.</p> <p>Confine spills and restrict the area until appropriate cleaning procedures have been completed.</p>
Family teaching	<p>Teach family members safety procedures for home chemotherapy administration and disposal. These procedures should be used for a minimum of 48 hours after administration.</p>

Source: Kline (2008).

ANSWER: George's physician or nurse practitioner is primarily responsible for discussing the need for chemotherapy and the delivery system that will be used to administer the chemotherapy (e.g., infusion devices). George's nurses should follow up with the family and further explain the procedure of receiving chemotherapy as well as the expected side effects in order for George and his family to know what to expect. The nurse will assess for side effects and use interventions to reduce those side effects as needed.

In response to metabolizing, detoxifying, and excreting many chemotherapy agents, certain organs may succumb to toxic side effects. Every child must be evaluated for baseline organ function before chemotherapy administration. Liver and renal function blood tests (i.e., blood urea nitrogen, creatinine clearance tests, bilirubin levels) are conducted and evaluated for normal function. An electrocardiogram or echocardiogram may be indicated to evaluate heart function. Pulmonary function tests are used to evaluate lung elasticity. Neurologic examinations indicate any loss of deep tendon reflexes or sensory function. Increased creatinine levels, the presence of proteins, or hematuria in urine

indicate drug toxicity. Changes in organ function or laboratory values require appropriate drug modifications, dose deletions, or modified timing of drug delivery. The decision to modify therapy is complex, because the goal of eradicating the cancer must always be maintained while supporting the child through the toxic side effects.

Radiation Therapy

Radiation therapy is used frequently in conjunction with chemotherapy or surgery to treat cancer in children. It can be used as curative treatment or as a palliative measure to reduce the size of a tumor and thus relieve symptoms. New advances in the delivery of radiation have led to less acute and long-term side effects and to better targeted sites of delivery.

Radiation is cytotoxic by damaging the synthesis of nucleic acids, causing breaks in the DNA or RNA molecule, or causing double-stranded breaks in the molecules. Radiated cells cannot divide, or they lose their function and die during division. Thus, normal and malignant cells that divide frequently are most susceptible to the effects of radiation.

Many of the acute side effects of radiation are the result of damage to normal cells that divide frequently, including the cells of the mucous membranes, hair follicles, and bone marrow. Acute side effects are usually anticipated 7 to 10 days after treatment has been initiated and may last for several weeks or even several months after therapy is completed.

Nursing responsibilities for the child receiving radiation treatments include providing concrete explanations to the child and the child's family regarding the radiation procedure and its side effects (Nursing Interventions 22–2). Before therapy is started, the area on the child's body to define the radiation field is marked (Fig. 22–2). During the procedure, the child must lie still and not change position. Plastic casts and molds may be used to immobilize the child during the treatment. Shielding devices made of lead are used to protect surrounding healthy tissues and organs against unnecessary radiation exposure. These shields may feel heavy to the child. The machinery involved in the treatment can create a variety of noises that may frighten the child. The child is alone in the treatment room, although he or she can communicate verbally with the staff. All of these sensations can make the child feel uncomfortable, claustrophobic, anxious, or bored. Young children may need sedation or general anesthesia. Older children can be taught distraction techniques. Parents, who are located outside the room, can talk or read to the child to focus attention away from the procedure. After radiation treatment, nursing and family interventions focus on managing the side effects of the therapy and preventing further complications.

Biologic Response Modifiers (BRM)

For many years, researchers have studied the complex functions of the immune system as it relates to cancer. Through research and technologic advances, *biotherapy*, the use of *biologic BRMs* has emerged as a mode of cancer treatment. Researchers have long known that certain substances in the body can influence the immune system, thereby helping to fight cancer or the side effects of cancer treatment. These substances, include a host of naturally occurring or synthetic agents that elicit clinically important immune responses in cancer patients (Nursing Interventions 22–3).

The exact mechanism of action of BRMs is unclear. However, they apparently can

- Modify the immune response to the cancer
- Act directly against the tumor by suppressing tumor growth or killing the tumor cell
- Alter other biologic factors that can directly or indirectly influence the viability of the tumor (McCune, 2008, p. 109)

Management of children receiving BRMs is a challenge, because each individual is biologically different, so reactions or side effects from receiving these agents may differ. Some side effects associated with administration include general flulike symptoms, fluid retention, low-grade fevers, bone pain, chills, rash, and neuropathic pain.

Obtain baseline assessments of the child's vital signs prior to BRM administration, and continue to monitor these vital signs during infusion per protocol. Premedications (e.g., acetaminophen, diphenhydramine, hydrocortisone) may need to be administered prior to infusion to decrease the flulike symptoms and other unwanted side effects.

Alert! Report adverse reactions (e.g., temperature >103.3 °F (39.6 °C), shortness of breath) to the primary healthcare provider and be prepared to discontinue administration. Emergency supplies should be readily available should the child experience a hypersensitive reaction.

Use interventions to minimize the discomfort associated with side effects and complications of BRM therapy.

Hematopoietic Stem Cell Transplantation (HSCT)

Current advances and technologic progress in HSCT have benefited many children with cancer. More recently, the terminology *hematopoietic progenitor cell transplant* has also been used when referring to this type of treatment modality. All the body's blood and immune cells originate as stem cells in the bone marrow, in a process called *hematopoiesis*. Stem cells for HSCT are obtained from bone marrow, or from peripheral or cord blood. HSCT is used to treat solid tumors and diseases that affect the hematopoietic (blood-forming) system, the immune system, and metabolism.

Types of Stem Cell Transplantation

Two types of stem cell transplantation are performed: **autologous** (auto HSCT), which uses the child's own stem cells; and **allogeneic** (allo HSCT), which uses a matched donor's stem cells (Fig. 22–3). An allo HSCT donation comes most often from a sibling, sometimes from a twin (syngeneic HSCT). However, it can also come from a parent or an unrelated donor. Healthy stem cells for reinfusion can also be donated from cord blood from the child's newborn sibling or from an unrelated donor from a cord blood bank. The goal is to provide the child with the most genetically compatible bone marrow donor, achieved by matching the histocompatibility types of patient and donor.

Human leukocyte antigen (HLA) and DNA blood analyses are used to determine histocompatibility. HLAs, protein antigens on the cell surfaces of all nucleated cells, recognize foreign tissues and activate the immune system to fight them. The HLA types of donor and recipient must match to prevent the recipient from rejecting the donor marrow or having an increased potential for developing graft-versus-host disease.

Phases of Hematopoietic Stem Cell Transplant

Before undergoing HSCT, the child undergoes extensive physical and psychosocial evaluation to confirm that he or she is eligible. The child is hospitalized, isolated, and monitored, sometimes for several weeks or months.

NURSING INTERVENTIONS 22–2

Management of the Side Effects of Radiation Therapy

Site	Response	Nursing Interventions
General	Fatigue	Address possible causes such as anemia, poor nutrition, pain, medications. Encourage light or moderate activity with frequent rest breaks.
Skin	Loss of epidermal layer Erythema, dryness Wet desquamation	Keep skin clean with daily baths. Avoid applying creams, perfumes, or lotions during radiation treatments. After treatments, moisturize skin with vitamin E, aloe vera, or lanolin. Help child to avoid sun exposure and to use sunscreen with minimum SPF 30. Do not remove radiation markings. Contact skin care specialist for severe skin toxicities. Avoid applying tape adhesives when radiation is to be delivered.
Gastrointestinal tract	Mucositis Pain Dysphagia Ulceration Swelling of esophagus, stomach, or intestines Nausea, vomiting Diarrhea	Provide daily oral and dental care. Recommend dental visit prior to initiation of radiation. Treat mucositis per healthcare prescriber orders. Give antiemetics before and during radiation treatments. Encourage oral fluid intake. Encourage small, frequent meals. Advise avoidance of spicy, fried, or high-fiber foods. Assess for dehydration. Give analgesics as needed.
Salivary glands and parotid glands	Decreased formation of saliva Dryness of mucous membranes Taste disorder Parotiditis	Encourage daily oral hygiene. Give analgesics as needed. Encourage oral fluid intake.
Kidney or bladder	Cystitis Ulceration	Encourage fluid intake. Assess for blood in urine.
Bone marrow	Myelosuppression Anemia Thrombocytopenia	Exercise infection precautions. Observe for temperature more than 38 °C and notify physician. Observe for signs of bleeding. Teach child to avoid crowds. Observe for any signs of inflammation or infection.
Hair follicle	Alopecia	Recommend wigs or hair accessories. Help with skin hygiene.
Lungs	Decreased levels of surfactant in lungs Shortness of breath	Assess respiratory status. Provide oxygen as ordered. Encourage frequent rest periods.

Site	Response	Nursing Interventions
Heart	Less tolerance for physical activity Pneumonitis Pulmonary fibrosis Myocarditis or pericarditis	Assess cardiac status. Note palpitations and complaints of chest pain that is relieved by sitting up and leaning forward.
Brain or spinal cord	Edema	Assess neurologic status. Assess for memory loss. Assess achievement of cognitive milestones (see Chapter 3).
Ovary/pelvic area	Permanent sterility possible Scarring in pelvic area Thinning and inflammation of vaginal lining	Inform patient and family about potential sterility. Provide sexually active adolescents with guidelines for intercourse during radiation.
Testes/pelvic area	Produces temporary low-sperm count Azoospermia (complete absence of sperm in the ejaculate) may persist for several years	Encourage use of water-soluble lubricant during intercourse. Provide sperm banking option when appropriate for the older adolescent.

During *conditioning*, the initial 7- to 10-day phase of HSCT, the child receives very high (lethal) doses of chemotherapy or total-body radiation, depending on the child's diagnosis and type of bone marrow he or she is to

FIGURE 22-2. Prior to radiation treatment, the child is evaluated by the radiologist, and the areas to be radiated are marked on the child's skin.

receive. Conditioning, which ablates (destroys) bone marrow, is an attempt to eliminate any remaining disease and to prepare the child's body to accept the new, healthy bone marrow. During this time, the bone marrow is unable to make neutrophils. The child develops **neutropenia**, an unusually low blood concentration of these immune cells, and is therefore at high risk for infection. Protective measures must be instituted. For children receiving allogeneic stem cell transplants, such measures include use of high efficiency particulate air filtration (HEPA) and positive pressure to reduce pathogens in the child's room, a low microbial diet, and strict handwashing technique. Many institutions do not require such strict isolation precautions, and children receiving autologous stem cell transplants may be managed on the oncology unit simply with careful handwashing and standard precautions. Intravenous (IV) gamma globulins and acyclovir may also be administered to prevent infection. If infection occurs, antibiotics are used as needed.

After conditioning, there is 1 day of rest (day -1). On the following day, day 0, the patient's or donor's hematopoietic stem cells are infused into the patient, using a process similar to a blood transfusion. These healthy stem cells migrate into the empty spaces in the child's bone marrow, where they take root, grow, and ideally repopulate into healthy, new bone marrow.

During the *post-HSCT phase*, the child is at high risk for complications, including susceptibility to infection, until new blood cells and immune cells are present and

NURSING INTERVENTIONS 22–3

Biologic Response Modifiers

Type of BRM	Potential Side Effects
<p>Hematopoietic growth factors (erythropoietin, granulocyte macrophage–colony stimulating factor [GM-CSF], granulocyte–colony stimulating factor [G-CSF]): A family of glycoproteins responsible for stimulating and regulating hematopoiesis. Includes CSFs, which encourage the growth of bone marrow stem cells.</p> <p>Interleukins: Cytokines that relay information between leukocytes to modulate their activities. Interleukin is a recombinant growth factor that activates the body’s immune system.</p> <p>Monoclonal antibodies: A cancer-specific antibody produced in a laboratory for a target antigen. Used to detect the presence of tumors and linked with chemotherapy as a treatment measure.</p> <p>Interferons: Members of the cytokine network, capable of inhibiting viral replication, modulating immune responses, and altering cellular proliferation</p> <p>Protein tyrosine kinase inhibitors: Protein tyrosine kinase inhibitors are enzymes that are involved in many cellular processes such as cell proliferation, metabolism, survival, and apoptosis. Several protein tyrosine kinases are known to be activated in cancer cells and to drive tumor growth and progression. Protein tyrosine kinases inhibitors are used to block the interactions of these enzymes and thus stop cancer growth.</p> <p>Vaccines: Therapy being developed to initiate an immune response to foreign antigens. In this case, vaccines are investigational in pediatrics. Some vaccines have been developed to prevent cancer development and reoccurrence (e.g., hepatitis B vaccine and Gardasil [for cervical cancer caused by human papillomavirus]).</p>	<p>Erythropoietin (Epogen): Hypertension, headaches, fever, myalgia, rashes, flulike symptoms</p> <p>GM-CSF: Flulike symptoms (e.g., fever, bone pain, headache) and “first-dose phenomena” (flushing, hypoxia, tachycardia, oxygen desaturation)</p> <p>G-CSF: Bone pain, joint pain, fever, rashes, pain at injection site</p> <p>Flulike symptoms, vascular leak syndrome, skin and mucosal changes, nausea, vomiting, CNS changes, altered laboratory values</p> <p>Allergic reactions, fever, chills, rigors, malaise, nausea, vomiting, hypotension</p> <p>Flulike symptoms, fatigue, malaise, anorexia, diarrhea, changes in mental status, abnormal liver function tests, neutropenia, thrombocytopenia, skin irritation, bone pain</p> <p>Diarrhea, cardiac dysfunction, skin rash, pruritus, folliculitis, hair changes, paronychia inflammation of nails, hand–foot syndrome, skin discoloration, hypertension</p> <p>Soreness at infection site</p>

Nursing Interventions

- Assess child and family knowledge of the drug administration, including purpose, side effects, dosing instructions, and food–drug interactions. Provide additional education when needed.
- Ensure emergency supplies are on hand during drug administration should the child have an adverse reaction to the substance.
- Obtain baseline vital signs and mental status. Monitor changes in these baseline parameters during administration.
- Administer premedications (acetaminophen, diphenhydramine, hydrocortisone) when needed.
- Monitor for signs and symptoms of BRM side effects.
- Ensure measures to maintain skin integrity are followed by all caregivers.
- Administer supportive medical therapies for capillary leak syndrome (e.g., IV fluids, blood product administration, vasopressors).
- Monitor intake and output. Monitor child’s weight.

Source: McCune (2008).

FIGURE 22-3. In preparation for an autologous stem cell transplant, the child's peripheral blood stem cells are harvested, frozen until needed, then given back (transplanted) after the child has received high doses of chemotherapy, radiation therapy, or both to destroy the cancer cells.

optimally functioning. **Engraftment** is the process by which the hematopoietic stem cells begin making new blood cells; it is considered successful when the absolute neutrophil count (ANC) reaches $500/\text{mm}^3$ for 3 consecutive days. An effective transplant produces new, cancer-free hematopoietic and immune systems in the recipient.

Throughout the phases of HSCT, complications can occur and these are weighed against the benefits of curing the child's disease (Nursing Interventions 22-4, Fig. 22-4). The acute toxicities can be life threatening; thus, the nurse must assess the child daily for any organ toxicities, infections, bleeding complications, fluid and electrolyte imbalances, or skin and mucous membrane toxicities. Management of these side effects is addressed in the supportive care section of this chapter.

Late effects also can occur. These may include cataracts, growth hormone deficiency, thyroid dysfunction, delayed puberty, pulmonary fibrosis, cardiomyopathy, renal toxicity and renal failure, amenorrhea, and sterility. Interventions vary depending on the exact effect (Fig. 22-5). For all complications, provide supportive care.

Educational Interventions

QUESTION: What topics related to George's care would be critical for the nurse to explore with George and his family?

Education for children and families dealing with childhood cancer begins at the time of diagnosis and continues through each phase of the child's treatment, being maintained to assist the child in the years after treatment or to assist the family after the death of the child. From the moment that cancer is suspected, the family is thrown into a new world in which they must learn new medical terms, procedures, and methods to care for the needs of

their child. Through education, most families become sophisticated in their base and depth of knowledge of pediatric oncology. All members of the healthcare team play a critical role in providing information to help the child and family cope and make informed decisions.

Topics to address during the long-term educational process with the child and family include

- Pathophysiology, prognosis, and signs and symptoms of the malignancy
- Diagnostic testing methods, including interpretation of laboratory test results
- Treatment options and outcomes, treatment-induced side effects
- Pain management techniques
- Infection prevention measures
- Management of treatment side effects, such as nausea, vomiting, stomatitis, alopecia, diarrhea, constipation, dehydration
- Nutritional needs and measures
- Care of devices such as central venous catheters
- Promotion of growth and development, including at home and at school
- Home management of medications, medical equipment, and assistive devices
- Needs of child, parents, and siblings
- Coping techniques
- Management of long-term sequelae

These topics are not discussed at a single visit; rather, they are introduced and reviewed as the need arises. As the child grows and develops new levels of cognitive understanding, topics should be revisited to ensure that the child's understanding is age appropriate.

WORLDVIEW: In some cultures, children's autonomy is not encouraged. Parents and children are not likely to discuss difficult issues. Information about the child's illness may be filtered or not discussed at all among family members. The healthcare team should share their beliefs about the importance of fully disclosing information to the child. The family may agree to have the healthcare provider discuss the illness and treatment with the child, but they may choose not to participate in these discussions.

ANSWER: Initially, the focus of patient and family education will be to understand the implications of George's diagnosis and treatment modalities. During his chemotherapy treatments, infection prevention will be an important topic of education. Throughout George's care, pain management will also be a subject of education.

Psychosocial Interventions

QUESTION: The diagnosis and treatment of a child with a malignancy is inherently stressful for families. Nurses should identify stressors that can be changed. How might you help the Tran family get through this stressful time?

NURSING INTERVENTIONS 22-4

Complications of Hematopoietic Stem Cell Transplantation

Complication	Manifestation	Nursing Interventions
Nutritional alterations	Nausea Vomiting Mouth ulcerations	Administer total parenteral nutrition as indicated. Provide meticulous oral care. Provide diet to maximize caloric intake. Administer antiemetics.
Infection risk	Neutropenia	Implement neutropenic precautions. Administer prophylactic antimicrobials as ordered to prevent herpes, cytomegalovirus, and fungal and bacterial infections. Use radiated and leukocyte-depleted blood products. Obtain cultures when clinically indicated. Provide routine personal hygiene. Ensure good skin integrity. Avoid rectal medications or temperature measurements.
Thrombocytopenia and anemia	Platelet count less than 100,000/mm ³ Hemoglobin less than 8 g/dL Fatigue Tachycardia Shortness of breath Pallor Dizziness Bruising, petechiae, epistaxis, oozing from the gums or central venous catheter Blood in urine, emesis, or feces	Administer platelet and red blood cell transfusions as needed (all blood products should be radiated and leukocyte depleted). Initiate bleeding precautions and safety precautions to avoid injury. Administer oxygen to prevent tissue hypoxia.
Mucositis	Deterioration of mucosa and GI tract Excessive secretions Difficulty swallowing and breathing Anorexia Difficulty eating Abdominal cramping Watery diarrhea	Provide meticulous oral care, including use of oral rinses. Anticipate intubation to facilitate breathing. Provide measures to control pain such as viscous lidocaine, diphenhydramine, and sucralfate. Treat diarrhea with antidiarrheal medications (e.g., loperamide, octreotide).
Veno-occlusive disease	Sudden, unexpected weight gain Thrombocytopenia refractory to platelet infusions Jaundice Hepatomegaly Right upper quadrant pain Ascites Encephalopathy	Observe oral and IV fluid restrictions. Obtain daily weights and abdominal girth measurements. Elevate head of bed. Monitor hepatic function. Assess mental status.

Complication	Manifestation	Nursing Interventions
Interstitial pneumonia	Nonproductive, dry cough Fever Tachypnea Nasal flaring Dyspnea Hypoxia	Assess respiratory and ventilation status, including use of pulse oximetry and blood gases. Provide respiratory treatments as needed. Administer supplemental oxygen or ventilation as needed. Raise head of bed. Promote rest.
Renal complications	Dehydration Third spacing Hemorrhage Hypovolemia Septic shock Hypoproteinemia	Assess fluid and electrolyte status. Maintain adequate intravascular volume and renal perfusion (e.g., administer renal dose of dopamine to promote renal transfusion). Adjust dose and frequency of medications that are toxic to renal function. Correct fluid and electrolyte imbalances. Minimize use of nephrotoxic agents. Implement dialysis if renal failure is severe. Ensure daily evaluation of blood counts.
Graft-versus-host disease, acute: Occurring within the first 100 days after HSCT	Maculopapular rash on the palmar and plantar surfaces of the hand and feet evolving into erythematous rash over most of body (ranging from slight redness of the skin to complete skin desquamation [see Fig. 22-4])	Provide platelet infusion. Provide packed red cell transfusion. Administer immunosuppressive/antigraft-versus-host disease medications.
Graft-versus-host disease, chronic: Occurring 100 days or more after HSCT	Diarrhea (guaiac positive) Fever Jaundice Hepatomegaly Hypertension Infection (especially fungal and viral for children with chronic graft-versus-host disease)	
Graft rejection or failure	Fever Infection Decrease in blood counts	Reinfuse blood stem cells into child. Check complete blood count with differential on a daily basis. Provide supportive measure to prevent infection.

Children with cancer and their families are placed in stressful situations throughout the course of the child's illness. Stressors include the diagnosis itself, chemotherapy or radiation treatments, unplanned hospitalizations, added financial demands, unexpected complications, involvement of other family members (or lack of involvement), relapse or progression of the disease, completion of therapy, awareness of other children's deaths, and pos-

sibly the impending death and actual death of the child. Peer support groups (Fig. 22-6) and assistance from other healthcare providers such as recreational therapists, social workers, and psychologists can assist with stress management and coping strategies.

Establishing open communication and trust with the child and family is key to providing optimal psychosocial support. At the time of diagnosis, family members are

FIGURE 22-4. Graft-versus-host disease typically presents as a maculopapular rash that starts on the palms and soles and evolves to an erythematous rash over most of the body.

often in a state of shock or denial and are unable to accept or comprehend the vast amount of information that is given to them. After the initial family conference, at which time the diagnosis and treatment plan are discussed with the family, review and clarify the information. When the child is hospitalized, daily contact with a consistent oncology team member allows for ongoing guidance, education, and support. It also provides an opportunity for the family to ask questions and to verbalize concerns, and enables them to participate in daily decision making about their child's treatment plan.

The nurse is the healthcare provider who has the most direct contact with the child and thus plays a key role in providing psychosocial support. Useful strategies include establishing a trusting relationship with the child by

FIGURE 22-5. High-dose corticosteroid therapy for this child after HSCT has produced a characteristic "moon face" appearance.

FIGURE 22-6. Summer camps and other planned social activities provide opportunities to build relationship with other children who have cancer. These friendships provide sources of support, understanding, and encouragement (Courtesy of Camp Ronald McDonald for Good Times).

communicating honestly and answering questions directly. In addition to providing age-appropriate explanations for daily routines and procedures, encourage the child to verbalize fears and concerns regarding his or her disease and treatment. Many pediatric oncology patients will be asked to participate in clinical drug trials or other research studies to test the efficacy of new treatment regimens. In such cases, it is the investigators responsibility to discuss the specifics of the research with the family. Nurse participation in these discussions is essential to ensure that required protocols are followed and to serve as an additional source of information and support to the family as needed. See Chapter 2 for further discussion of the role of nurses in pediatric research and the rights of children and their families.

KidKare ■ Children age 7 years and older have a right to decide whether to participate in clinical research studies. The nurse caring for these children should assess the child's basic understanding of the clinical research study and provide adequate time for the child to ask questions regarding his or her treatment. Equally important is the nurse's role as the child's advocate if the child refuses to participate.

Give special attention to adolescents, because they sometimes experience greater difficulties adhering to their treatment regimens and grappling with the consequences of their disease (Developmental Considerations 22-2). The social isolation from their peers as a result of hospitalization or homebound illness adds to feelings of loneliness and depression. Nonadherence, excessive anxiety, moodiness, depression, and fear of changes in body image are common reactions expressed by adolescents who delay, modify, or stop their treatment.

Strategies used by healthcare personnel to help children and adolescents cope with their chronic condition include therapeutic play, art therapy, music therapy, story

DEVELOPMENTAL CONSIDERATIONS 22-2

Concerns of the Adolescent With Cancer

Concern	Family and Healthcare Provider Interventions
Peer acceptance Changes in friendships	Use school reentry program to educate peers about child's condition. Assist adolescent to find new supportive relationships. Encourage relationships with other adolescents who have cancer. Encourage participation in activities such as summer camps and rap sessions with other adolescents with cancer. Be a friend.
Physical changes	Help adolescent to maintain normal appearance by using wigs and wearing loose clothing. Emphasize the temporary nature of many of the side effects of therapy.
Desire to be "normal"	Encourage adolescent to engage in usual activities. Control the amount of information given out about the adolescent's condition.
Desire to be independent and have sense of control	Respect adolescent's privacy during physical care. Assist adolescent to learn measures to control anxiety and pain related to procedures or treatment modalities (e.g., biofeedback, self-hypnosis, progressive muscle relaxation, guided imagery). Encourage participation in decision making regarding care. Do not encourage adolescent to be overly dependent on nurses and family for physical care.
Poor self-esteem	Communicate confidence in adolescent's ability to succeed. Assist adolescent to participate in activities in which he or she will be successful. Plan for adolescent to return to school as soon as possible after an illness or hospitalization. Assist adolescent to develop effective mechanisms to cope with stress.
Future life expectations	Ensure that parents' expectations for the adolescent and how the adolescent sees such expectations are congruent and realistic. Encourage adolescent to make plans for the future. Openly discuss the long-term sequelae of cancer.

telling, guided imagery, relaxation, biofeedback, and social interaction with other children (see Chapters 10 and 11).

When cancer is diagnosed in a child, parents experience overwhelming stress as a result of coping with their own feelings and needs, and with the physical and emotional needs of the ill child and other family members, especially those of the siblings. Stressors include the following:

- The shock of the diagnosis of cancer
- Role changes necessary to meet the demands of caring for a chronically ill child
- The financial burden caused by medical costs and a possible loss of income, because it may be necessary for one parent to stay home with the child
- Fear of losing the child
- Marital discord
- Feelings of guilt related to spending less time with the siblings and with one's spouse
- The need to learn technical and medical information to better understand the child's disease and its treatment

Many of these stressors continue throughout the course of the child's illness and posttreatment period. Although parents know that the child's illness will include periods of exacerbations and remissions, additional stress comes from constantly being on the alert for the situation to get worse. Chapter 12 provides an in-depth discussion of the effects of a child's chronic condition on the family and gives practical interventions to assist family members as they cope with these stressors. The nurse is often the healthcare team member who initially provides psychosocial support for the parents and facilitates consultations with other healthcare team members.

TRADITION OR SCIENCE 22–1

Do parents recognize that the brothers and sisters of children with cancer may have emotional difficulties as a result of the changes brought by the diagnosis?

MORE INQUIRY NEEDED

Nurses have long been concerned about the effect of childhood cancer on well siblings. Recognition of this need has prompted development of sibling classes, educational materials for siblings, and sibling support groups. But are siblings using these interventions, and are parents assisting and encouraging siblings to use them? Ballard (2004) obtained views from parents in 86 families about siblings' needs and support being offered. About one half of all parents of children with cancer did not expect their well children to have any problems as a result of the experience. They were not willing to have the siblings participate in interventions aimed at providing for the needs of the well child. This finding indicates that families may not see their well children as being at risk for problems. This research was consistent with that of Murray (2002), who found that siblings and parents did not agree on the types of support most helpful for the siblings, and that siblings are not being provided with the type of support they believe would be most helpful. This research is both a call and a challenge to nurses to critically evaluate participation in sibling programs to determine whether these programs are useful and helpful to the sibling population. Gursky (2007) provided educational interventions to well siblings of hospitalized children. Her pretest/posttest design demonstrated that the children who participated in the educational interventions had significantly lower anxiety levels after interventions than did siblings who did not participate in the interventions. It is clear that measures are needed to better inform parents about the needs of well siblings and to provide easier access to professional support for siblings in the form of literature, video materials, support groups, and individual counseling as needed.

Siblings must also adjust to the diagnosis of cancer, although this may not be acknowledged by the parents (Tradition or Science 22–1). The major stressors experienced by siblings include short- or long-term separation from one or both parents, decreased attention from the parents even in the presence of the ill child, the need to assume additional household responsibilities, fear of losing their brother or sister, and guilt that their thoughts or wishes may be responsible in some way for causing the cancer (Fig. 22-7). These stressors may become evident through changes in the sibling's behavior both at home and in school. (See Chapters 12 and 13 for more information about supporting siblings of the ill child.)

The child and the family members also experience grieving. Grieving and disappointments may occur along various points of the child's treatment regimen. The loss of hair or a

limb; inability to achieve remission using a certain combination of chemotherapeutic agents; and missing school dances, plays, and family vacations because of unexpected hospitalizations are a few of the events that can intensify the child's or family's sense of grief. Grieving also may be a result of the actual death of the child. Members of the healthcare team must be cognizant of and sensitive to the issues that may cause great disappointment to a particular child or member of the child's family. Chapter 13 summarizes interventions to help the family deal with grief and loss.

ANSWER: Discovering George's illness was quickly followed by the shock of amputation. The loss of his leg profoundly affects George and his family. George is the only son in his family, and his parents have ambitions and dreams of his career and success. Another stressor that nurses can help alleviate is the language barrier. George's mother's English is not very fluent and she does not understand the medical explanations. She is relying on Tung or George to translate for her. Obtaining a medical translator is more appropriate than using the patient to translate.

The hospital nurses and a nurse case manager can provide information and some support. However, a more critical role of the nurse is to assist the family to mobilize its own social and emotional support systems. Ask the family about their religious affiliations such as church or a community group. Question them about whom they would want to know about George's illness. The Health Insurance Portability and Accountability Act (HIPPA) regulations prevent the release of information, so it must be given by family.

Loan and Tung look first to their family for support and then to the Vietnamese community and their church. Loan is very close to her sisters and they have offered to help in any way they can. As members of the community hear about George's disease, they begin dropping by the Tran home to give food, and offer prayers and support. George's family is his primary support. His friends are initially frightened to come see him, but Ashley returns to live at home and spends her afternoons with her brother. She feels that she cannot add any further stress to her family.

Interventions to Promote Growth and Development

QUESTION: How can you assess and promote growth and development for George?

Children with cancer face challenges to their physical, social, emotional, and intellectual growth. The treatment regimen and its side effects may inhibit normal physical development. For instance, chemotherapy and steroids can cause delays in pubertal development. *Radiation* can impair bone growth and growth hormone production. Chronic malnutrition, anorexia, and lethargy can affect weight gain and development of muscles.

The child's social, emotional, and intellectual development may be impaired because of frequent hospitalizations

FIGURE 22-7. Brothers share time together in the hospital.

and chronic health problems that restrict the child's activities to the home. Absence from school and social activities can impair the child's ability to sustain meaningful relationships with peers. Overprotection by well-meaning parents can prevent the child from learning self-care and decision-making skills.

Many measures can be used to promote age-appropriate development for the child with cancer. Allow children of all ages to maintain a sense of control by providing them choices in their daily care whenever possible. Establish a schedule of daily activities with the child. The schedule incorporates necessary healthcare interventions with the child's usual activity schedule (such as attending school). If the child is hospitalized, ensure that the schedule provides opportunities for visits from school friends and activities with other hospitalized children. If the child requires isolation, ensure that visitors and items are screened so that activities and schoolwork can be brought to the child's room to maintain the child's social and intellectual development.

caREminder

The Centers for Disease Control (CDC) does not recommend allowing flowers and plants in the rooms of patients who are immunocompromised.

School reentry may be difficult for the child who is returning after a prolonged absence or with notable changes in his or her appearance. These children may fear that other children will make fun of them, try to pull off their wig, or gossip about them. Classmates may be afraid that they will "catch" cancer, or they may wonder whether the child is going to die. Community Care 22-1 summarizes interventions that can be used to help children rejoin their classmates. These interventions focus on easing the transition to the classroom through peer programs and by providing medical information to key school officials.

Children returning to the classroom should be encouraged to participate in sports and in musical and artistic activities that they enjoy and in which they find a sense of accomplishment. Activities need only be limited by the child's imagination and his or her physical ability to perform, especially during periods of disease exacerbation.

ANSWER: Consider all aspects of George's development: emotional, intellectual, and social. Discuss with George and his family his specific needs as a 14-year-old with cancer. George has always been an excellent student. Determine how will he continue his intellectual

COMMUNITY CARE 22–1

School Reentry

The child with a malignancy may experience problems that can affect school attendance and performance. These problems include periods of absenteeism, increased school anxiety, negative attitudes by school officials, taunting by peers, social isolation, and learning difficulties induced by illness or treatment. Reentering the classroom can be emotionally, physically, and mentally difficult for the child, the teacher, and the other students.

To facilitate the child's successful reentry into the classroom, include the following:

- Contact the school nurse and the child's teacher to discuss the child's reentry, providing teachers and school officials with adequate information regarding the child's condition.
- Use federally mandated education planning for students with special needs (individualized education plan) to establish educational goals for the child and to identify mechanisms to achieve these goals.
- Provide teachers with books and other resources about cancer.
- Provide teachers with a toll-free number so they can contact a healthcare provider regarding any questions or concerns they may have about having a child with cancer in their classrooms.
- If the child, the family, and school officials agree, have a nurse attend the child's classroom before the child reenters the class and discuss with classmates the causes of cancer and the physical changes caused by treatment. Classmates should be allowed to ask questions, but respect the child's privacy at all times.
- Use skits or puppet shows to educate peers and gain their support.
- Film the child with cancer in the hospital setting. Include a tour of the hospital, views of the child's room and places where procedures are done, and footage of the child. Take the movie to the child's class for viewing before the child's reentry. Use the video as a means to discuss the child's cancer.
- Provide instruction at home until the child is able to return to school.
- During home instruction, encourage the child to remain in contact with peers and teachers through pictures, letters, e-mail, and visits.
- Refer family to counseling if school phobia or truancy is a problem.
- Monitor for any problems related to school performance or to relationships with teachers or peers at school.

development. Will he be able or willing to return to a large public high school? Discuss alternative opportunities for him to keep up on his academics. Discuss what can be done to continue his school friendships if he does not return to school.

Home Care Interventions

QUESTION: As an adolescent, George wants to feel in control of his life. The osteogenic sarcoma has a series of repercussions that cause George to feel out of control. He has experienced the amputation of his leg, which causes a profound change in body image. George does not want to return to school. The prognosis for George is not yet known. What aspects of George's care do you think can be managed at home? What will be some of the challenges of providing home care?

Given the current demands of managed care as well as the technologic advances related to medical and nursing care, home care and palliative care services for children with cancer have become considerably more common.

Professional home care services may be requested by a family when a child becomes terminally ill. Hospice care provides psychosocial support and interdisciplinary healthcare for dying children and their families. Home care and hospice services allow such children to remain with their families in familiar surroundings while continuing to receive interventions that make them comfortable and that minimize visits to the hospital.

The scope of home care in pediatric oncology ranges from single interventions, such as antibiotic administration, to complex plans of care requiring multiple services. Infusion therapy is a common regimen that can be used to provide total parenteral nutrition, pain medications, chemotherapeutic agents, antimicrobials, and blood products in the home. Other routine home care that can be provided by the family with little or no assistance from a home care nurse include caring for and maintaining the CVC, supporting daily oral hygiene, providing daily skin care, administering oral or subcutaneous medications, and staying vigilant for signs and symptoms of infection.

The home care nurse conducts ongoing assessments of the family's ability to care for the ill child in the home, assists in the procurement of medical equipment and supplies, provides needed healthcare interventions, and

coordinates the delivery of home care services by other members of the team. Collaboration with the home care pharmacist, primary oncologist, physical and occupational therapist, nutritionist, speech therapist, and respiratory therapist is essential to ensure that all aspects of the child's development are supported. (See Chapter 12 for more detailed information regarding the nurse's role in home care.)

When cancer treatment is completed, home care management is not finished. Research indicates that many children and families experience difficulty reintegrating the child into family, school, and community settings, and transitioning to less intensive medical oversight of the child's health status (Labay, Mayans & Harris, 2004). Obstacles to successful reintegration include the lack of ongoing community and extended family support structures, lack of reimbursement for medical and psychological interventions to assist the family in the reintegration process, and the child's state of physical and psychological well-being. Nurses need to conduct more research to better assess the needs of the reintegration process. In addition, nursing care to provide ongoing assessment and intervention of the family must be extended to promote optimum family adjustment.

ANSWER: Most of George's care will take place at home. After the amputation, George spent several days in the hospital but was then discharged home. A home care nurse visits to continue to monitor and change the dressing on his stump. One of the challenges is Loan's lack of English fluency. The home care agency is trying to find a nurse who speaks Vietnamese to be the case manager for the Tran family. Loan does not work outside the home and is very willing to provide the care her son needs. The challenge is communicating accurately.

Pain Management Interventions

QUESTION: While George was in the hospital after his amputation, the nurses noted that he was reluctant to admit his pain. Identify issues related to George's age and stoicism, and effective management of his pain. What plan would you develop to assess and manage George's pain?

Children with cancer may experience pain for a variety of reasons. Initially, children may experience pain caused by the disease itself—for example, bone pain in leukemia, headaches in brain tumors, abdominal pain for abdominal tumors. More commonly, children with cancer experience pain from the numerous procedures and tests that are done at the time of diagnosis and throughout the treatment course, and from side effects of treatment, such as postoperative pain, oral mucositis, skin irritation and breakdown, and esophageal and abdominal pain from GI irritation or ulcerations. Interest in pediatric cancer pain research is strong, and the literature is growing. Initially, most literature focused on the pain and discomfort asso-

ciated with certain diagnostic procedures, such as bone marrow aspiration and lumbar puncture, although, even in this area, pain management techniques vary considerably among practitioners. Topics of ongoing research include describing the trajectory of a child's pain over the course of the illness, the late effects of pain, the reported incidence of pain after the disease has been eradicated, and evaluating traditional and nontraditional pain management approaches that can be effective before, during, and after procedures and treatments.

Both pharmacologic and biobehavioral interventions are important in managing pediatric pain. Mild analgesics, topical anesthetics, and opioids can be used to treat pain. Sedatives such as midazolam (Versed) or anesthetic medications such as ketamine, or propofol may be used to assist children undergoing painful procedures that are required routinely during their cancer treatment.

Chronic or terminal pain may be managed in the home with continuous administration of opioids, orally or intravenously, as a bolus injection or infusion (see Chapter 10). Managing pain in the home setting requires a collaborative effort among the child and family, home health nurse, home care pharmacist, and oncologist.

Several biobehavioral pain management strategies have been successful in dealing with the pain associated with procedures. These interventions include music therapy, hand holding, imagery, hypnosis, relaxation, diversion, rest and sleep, massaging, heat, breathing exercises, and biofeedback. Chapter 10 discusses these pain management techniques in detail. A variety of techniques can be taught to the child and the child's family to provide a repertoire of coping skills and an effective alternative or adjunct to pain medications.

ANSWER: George is old enough to report and describe his pain accurately, so the issues of pain assessment for a younger child do not apply in his case. However, George's vital signs and physical symptoms indicate he is reluctant to admit his pain. Rather than have him receive pain medications on an as needed basis, the hospital nurses established a round-the-clock schedule of pain relief to help maintain a constant blood level of pain medication, a schedule that continues at home. The home care nurse developed the idea of establishing a database in George's computer for him to enter his pain rating and any descriptions of his symptoms at regular intervals throughout the day. George prefers the privacy of documenting his symptoms on the computer, which provides the physician and nurse with more data to develop George's pharmacologic pain management interventions.

Interventions Related to Venous Access

A **central venous catheter**, (CVC) also called a *central line*, is a device inserted for children undergoing cancer treatment to enable easy administration of chemotherapy, blood products, nutrition, IV fluids, and IV medications. It also provides a means for obtaining blood samples without the need for repeated venipunctures. The types of devices include percutaneous CVCs, Silastic catheters, implanted

ports, and peripherally inserted central catheters. The child, if age appropriate, and the primary caregivers are thoroughly instructed on how to manage these devices at home. Use and maintenance of the external device at home include dressing changes, cap changes, heparin flushes, blood draws, medication administration, and emergency care guidelines. In addition to nursing instruction, aids such as booklets, videos, and hands-on demonstration with a doll should be used to support teaching interventions (Fig. 22–8). A thorough discussion of these devices is presented in Chapter 17, including information regarding home management of the child with a CVC and developmental considerations when securing the CVC. If a child with a CVC returns to school, school officials must be notified (see Community Care 22–1 and Chart 10–2).

Children with CVCs often develop infections in the blood or at the exit site, a primary portal for entry of microorganisms. Children may tamper with the dressing covering the site, or the solutions, tape, and dressings used to clean the site may cause irritation, potentially leading to infection. Thus, careful local skin care is imperative to reduce the incidence of infection and sepsis. Institutions vary in their approach to CVC site maintenance. In most, an antiseptic solution is used to clean the site, which is then covered by a sterile occlusive dressing. The length of time between dressing changes also varies with institutional policy and the condition of the CVC site.

When chemotherapy is administered peripherally or through a CVC or an implantable access device, extravasation can occur when the drug leaks into surrounding areas, causing cellular tissue damage (see Nursing Interventions 22–1). The extent of damage may range from a small, reddened area to a large lesion that becomes necrotic and requires plastic surgery. Most extravasations can be prevented by maintaining good assessment techniques before, during, and after chemotherapy administration. Note the vein size and device location and patency. If areas of redness or ulceration occur at the administration site during the infusion, stop the chemotherapy immediately and assess patency. The child may also complain of burning or loss of sensation or movement. If extravasation does occur, prompt intervention using an antidote to the particular chemotherapeutic agent is indicated.

FIGURE 22–8. The child life specialist encourages the child with cancer to participate in playroom activities.

Nutritional Interventions

Many factors contribute to appetite suppression and decreased food intake in the child undergoing cancer treatment. Anorexia and weight loss may result from anorexia-inducing substances secreted by the tumor cells, pain, nausea, vomiting, stomatitis, metabolic disturbances, and alterations in taste. A child may experience increased appetite, fluid retention, and weight gain with the use of steroids. Nutritional problems may also be psychosocially related. The child may feel apathetic, depressed, or fearful and not wish to eat. These children may use eating or drinking as a way to manipulate parental behavior and responses to them and to feel some control over the events occurring to them.

Maintaining the child's nutritional status is important because it allows the body to better tolerate the cancer treatment. Nutritional assessment should include daily weights, intake and output, calorie counts, and laboratory test results of such elements as sodium, potassium, albumin, calcium, magnesium, glucose, and protein. Also assess the child for factors that may be contributing to the anorexia, such as pain, nausea, diarrhea, or stomatitis. Side effects associated with the treatment regimen must be prevented, alleviated, or minimized before the child's nutritional status can be improved.

KidKare ■ Supplemental nutrition can be achieved orally by providing small, frequent meals; high-protein shakes; and nutritional supplements such as Ensure or Sustacal; and by allowing the child to eat whatever he or she desires and can tolerate.

The oral route is always preferable for supplemental nutrition. If increasing oral intake is not possible, the enteral route (tube feedings) is the second choice in children whose GI tract is intact and can tolerate it. Nasogastric or nasojejunal tubes are used on a short-term basis; gastrostomy tubes are considered if prolonged support is required. Parenteral nutrition is indicated if the child cannot tolerate the oral or enteral route.

The dietitian can be an excellent resource in designing a diet plan to address the child's health problems. For the child experiencing weight gain related to steroid therapy, for example, the plan must meet the child's nutritional needs while minimizing fluid retention. Low-sodium foods without added salt are recommended. The child may be experiencing an increase in appetite; thus, meals and snacks should be satisfying but not overly high in calories. If rapid weight loss is a problem, then foods high in protein and carbohydrates are recommended.

Oral Hygiene Interventions

The oral cavity is a common site of stomatitis, mucositis, infections, or bleeding. The terms *stomatitis* and *mucositis* are often used interchangeably. Some clinicians distinguish between the two by clarifying that **stomatitis** can be any oral mucosal reaction to local factors (e.g., infection,

injury, poor oral care). **Mucositis** is the mucosal reaction that can occur throughout the GI system as a side effect of systemic administration of chemotherapeutic agents (Chen, Wang, Cheng, & Chang, 2004).

The rapidly dividing mucosal epithelial cells lining the oral cavity and the GI tract are easily damaged by chemotherapeutic agents, with mucosal changes appearing within 2 to 3 days after chemotherapy administration. Changes in the oral mucosa can also be a result of anorexia, radiation to the oral cavity, and poor oral care. Radiation to the oral cavity decreases saliva production. Saliva is needed to provide a natural defense against tooth decay. Poor nutritional status and dental care can indirectly affect the oral cavity and the integrity of the mucous membranes (Fig. 22–9). In addition, children who are neutropenic are more at risk for oral infections such as with *Candida*, herpes simplex, herpes zoster, gram-negative organisms (*Pseudomonas*), and gram-positive organisms (*Streptococcus*).

Obtain a baseline assessment of the child's oral cavity, including evaluation of the integrity and color of the lips, tongue, gingivae, and mucous membranes. Note if child has any orthodontic hardware. Determine the child's ability to produce saliva, swallow, and eat. Baseline dental examinations should be performed before beginning therapy and on a routine basis to assess and treat any dental problems. Perform oral assessments daily during chemotherapy treatments, when radiation to the head or neck regions is being given, or when the child has undergone HSCT.

caREminder

An ulcerated or inflamed oral area can cause emotional distress to the infant and young child who use sucking on a thumb or pacifier as a form of coping. Diligent assessment of the oral cavity to prevent stomatitis is important.

FIGURE 22–9. Oral inflammation (stomatitis) and ulceration around the lips and in the mouth (mucositis) causes great discomfort and makes it difficult for the child to open the mouth, eat, and swallow.

The goals of oral care are to preserve the integrity of the oral cavity, to promote oral comfort, and to promptly treat any oral problems that occur. Teach the child and family how to perform meticulous oral care, which is essential in the home, school, and hospital settings (TIP 22–1). Measures to treat the discomfort caused by tender gums or oral lesions can be used to ensure that the child can speak, eat, and swallow.

A variety of interventions have been developed to reduce the severity of mucositis; however, available evidence does not recommend any particular treatment as optimal for all patients. The type of disease and the chemotherapeutic agents the specific child is receiving affect decisions about oral care. If oral infections occur, appropriate medications specific to the suspected organism are prescribed. Children with severe mucositis may be hospitalized, because the effects are likely to involve other parts of the GI tract such as the esophagus, stomach, or intestines. Severe mucositis with excessive secretions may cause localized swelling or tissue sloughing, which can place the child at risk for airway occlusion and aspiration.

Interventions for Nausea and Vomiting

Nausea and vomiting may be mild to severe, depending on the chemotherapeutic drug being administered and the tolerance of the child receiving the drugs. The key to optimal prevention and control of chemotherapy-induced nausea and vomiting is the timing of the antiemetic that is given (Nursing Interventions 22–5).

caREminder

It is vital that antiemetic therapy be given orally or intravenously before the start of chemotherapy and that it be continued on a regularly scheduled basis. This treatment plan provides the maximal effect to minimize nausea and vomiting.

Ondansetron (Zofran) is an antiemetic drug that is commonly administered to children receiving chemotherapy. Other agents used include metoclopramide (Reglan), diphenhydramine (Benadryl), lorazepam (Ativan), promethazine (Phenergan), dexamethasone (Decadron), granisetron (Kytril), dolasetron (Anzemet), and palonosetron (Aloxi). A combination of drugs and modifications of timing are useful in individualizing a child's antiemetic regimen.

Biobehavioral measures may help to control nausea and vomiting. For example, salty dry foods such as soda crackers and toast can be offered. Carbonated beverages that are consumed through a straw to ensure slow fluid uptake may be acceptable to the child. The child may have specific food preferences as he or she begins to feel less nauseous. Every effort should be made to provide food and fluid that is palatable to the child and that provides optimal nutrition.

Maintain accurate records of the child's intake and output; measure emesis and test it for blood using guaiac measures. A guaiac-positive result can indicate irritation

TIP 2 2–1 Teaching Intervention Plan for Oral Hygiene for the Child With Cancer

Nursing diagnoses and outcomes

- Nursing Diagnosis: Impaired oral mucous membranes related to radiation therapy, chemotherapy, dehydration, or ineffective oral hygiene

Outcomes:

- Child and family will demonstrate measures to prevent or minimize mucous membrane breakdown.
- Child will demonstrate mucous membranes that are intact, free from infection, soothed, and healed.

Teach the child/family

Daily Care

- Oral hygiene should be completed by the child or primary caregiver three to four times a day and as needed whether the child is hospitalized, at home, or participating in activities away from home.
- To promote healthy oral mucosa, the child needs to do the following:
 - Brush with soft toothbrush (that is changed on a regular basis) to prevent bleeding of the gums. Floss when oral mucosa is healthy and platelet counts are at acceptable levels.
 - Rinse and spit with 0.1% chlorhexidine mouthwash (Peridex), saline, or sodium bicarbonate after meals, at bedtime, and as needed to clean the oral mucosa. These solutions should not be swallowed, because they kill the normal flora of the GI tract.
 - Avoid hard foods that can cause abrasions to the gum line.
 - Avoid acidic foods that can irritate tender or sore areas in the mouth.
 - Avoid chewing gum and candy.
 - Maintain good fluid intake to keep mucous membranes moist.
 - Keep the lips lubricated with Vaseline or some type of lip balm to prevent cracking.
 - Participate in regular dental checkups.

Stomatitis or Mucositis Management

- To promote comfort in the presence of stomatitis or mucositis, the child may
- Use oral analgesic agents that contain an antacid, diphenhydramine (Benadryl), and a topical anesthetic (Dyclone or viscous lidocaine) for mild discomfort. These agents can be applied directly to sore areas of the mouth or swished and spit.
 - Avoid spicy, salty, and bitter foods
 - Avoid hot foods; choose tepid or cold liquids

- Choose foods that require little chewing (e.g., pudding, cottage cheese, soft cheeses, bananas, applesauce, milkshakes, smoothies, popsicles)
- Use a straw to ingest liquids
- Cut food into small pieces prior to ingestion
- Use topical analgesics before eating
- When moderate to severe stomatitis or mucositis is present,
 - Continue meticulous oral hygiene. Oral rinses can be used to clean the teeth, with a toothette used to remove debris loosened by the rinse.
 - Do not use chlorhexidine to treat established oral mucositis
 - Use nutritional supplements (e.g., Boost, Ensure) or supplemental IV fluids and nutrition as appropriate, depending on the child's ability to eat and swallow
 - If the pain from mucositis is moderate to severe, be aware that IV analgesics (opioids, such as morphine or fentanyl) may be needed
 - When severe mucositis is present, premedicate to manage pain before completing oral care

Alert! The side effects of viscous lidocaine include a decreased gag reflex, tingling, and seizures. Teach the child never to swallow a solution containing this agent.

Management of Infection

- For antifungal infections, swish and swallow with nystatin or other antifungal agents as ordered. Oral intake should be restricted for 30 minutes afterward to promote absorption of the medication into the mucosa.
- Per physician's orders, administer medications for treatment of systemic candidiasis or herpetic lesions.

Contact Healthcare Provider if:

- Stomatitis or mucositis does not show signs of healing with improved tissue integrity
- Child develops new lesions that appear different in color, shape, and location than previous/current mucositis lesions
- Child refuses to eat or drink
- Child develops a fever
- Child complains of oral pain

Sources: Keefe et al. (2007) and Landers & O'Hanlon-Curry (2008).

NURSING INTERVENTIONS 22–5

Interventions to Minimize and Manage Nausea and Vomiting

- Formulate an individualized plan of care for the child based on previous responses and mechanisms that are successful in assisting the child to cope with nausea and vomiting.
- Encourage fluids and small, frequent meals as tolerated. The child should avoid spicy or strongly odorous food.
- Assist the child in using relaxation techniques such as guided imagery and distraction (videos, video games, other games, reading) to focus thoughts away from physical discomforts.
- Monitor environmental triggers such as sights, smells, and sounds that may heighten feelings of nausea and vomiting. Administer oral dose of lorazepam (if ordered) the night before and the morning of the chemotherapy administration.
- Administer antiemetic agents, as ordered, 30 minutes before initiating chemotherapy, and on a regularly scheduled basis for up to 24 hours after the chemotherapy ends.
- Keep accurate records of intake and output.
- Test all emesis for blood.
- Give IV fluids as ordered to maintain hydration.

of the GI tract from vomiting. These results should be discussed with the physician, because a more effective antiemetic regimen may be needed.

The child and parents should be prepared to handle posttreatment nausea and vomiting that may occur at home. TIP 22–2 summarizes the content to cover in discussions with the family about home management of nausea and vomiting.

Bowel Elimination Interventions

QUESTION: What are some strategies that George can undertake to prevent constipation from the narcotics that he takes?

Constipation or diarrhea can occur in the child being treated for cancer. Certain chemotherapeutic agents, particularly vincristine, and many opioids cause constipation. In addition, tumor growth, decreased mobility, and altered fluid and nutritional intake also may play a role in constipation that could then lead to the development of hemorrhoids and aggravation of rectal fissures or perineal abscesses. Diarrhea may occur as a side effect of surgery, radiation therapy, or chemotherapy. The use of antibiotics and nutritional supplements, tumor growth, infections, and stress can also cause diarrhea. If prolonged, diarrhea can lead to fluid and electrolyte imbalances, dehydration, and perineal discomfort.

Question the child or parent about the child's usual pattern of bowel elimination. In the acute care setting, maintain accurate intake and output records, noting the number, amount, color, and consistency of the stool. If changes have been noted in the child's elimination patterns in the home, instruct parents to keep a record of the child's elimination pattern (see TIP 22–2). The stool can be tested for occult blood as an indication of bowel integrity.

Also monitor the child's weight, noting any significant losses. If diarrhea is the problem, assess for signs of dehydration, including dry mucous membranes and sunken fontanel, and poor skin turgor. Check laboratory test results for fluid and electrolyte imbalances. Obtain stool cultures, if ordered, to determine the presence of infectious agents.

Measure abdominal girth daily in the presence of constipation. Palpate the abdomen, noting areas of tenderness, swelling, or rigidity. Inspect the perineal and perianal area for redness, skin breakdown, hemorrhoids, fissures, or abscesses.

caREminder

The use of enemas, suppositories, digital manipulation, or rectal thermometers should be avoided to help prevent trauma to the rectal mucosa.

For the constipated child, a stool softener such as docusate sodium (Colace) can be administered. A sitz bath or perineal irrigations can be used to treat abscesses or fissures in the perineal and rectal area. A high-fiber diet, an active lifestyle, and good perineal and rectal hygiene can prevent such complications. Reducing distractions and allowing ample private quiet time for bowel elimination are important.

KidKare ■ High-fiber foods that may entice the older child include granola bars, cookies with raisins, popcorn, and apple slices.

In the presence of severe dehydration or electrolyte imbalances resulting from diarrhea, administer IV fluids as ordered. Anticipate the need for medications to thicken the child's stool, decrease peristalsis, or treat

TIP 22–2 Teaching Intervention Plan for Gastrointestinal Complications

Nursing diagnoses and outcomes

- Deficient fluid volume related to nausea, vomiting, mucositis, or diarrhea

Outcomes:

- Child is able or assisted to maintain adequate fluid intake by mouth or by nasogastric or IV access.
- **Imbalanced nutrition: Less than body requirements related to disease process and medication-induced vomiting, anorexia, changed taste sensations, depression, or changes in intestinal epithelium**

Outcomes:

- Child is able to eat frequent, small nutritious meals.
- Child's caloric intake is adequate for age.
- Child is able to maintain weight that is normal for age.
- **Constipation related to effects of chemotherapeutic agents**

Outcomes:

- Child and family use measures to prevent or minimize constipation.
- **Diarrhea related to effects of chemotherapeutic agents**

Outcomes:

- Child and family use measures to prevent or minimize diarrhea.

Teach the child/family

Management of Nausea and Vomiting

- Implement diet measures such as eating small, frequent bland meals, avoiding noxious smells, eating food high in protein, providing plenty of fluids.
- Administer antiemetic as ordered.
- Recognize side effects of antiemetic.
- Recognize signs and symptoms of dehydration.
- Stress importance of oral hygiene.

Management of Mucositis (also see TIP 22–1)

- Recognize signs and symptoms of dehydration.
- Recognize signs and symptoms of fungal infection.
- Eat small, frequent meals to prevent feelings of bloating, indigestion, and heartburn

Management of Constipation

- Maintain toileting routines.
- Increase fiber and fluids in diet.
- Avoid rectal manipulation and medications.
- Promote physical activity.

Management of Diarrhea

- Recognize signs and symptoms of diarrhea.
- Maintain accurate records of stool patterns.
- Recognize signs and symptoms of fecal impaction.
- Institute meticulous perianal hygiene and strict handwashing.

infection. A bland, low-residue diet or a lactose-free diet may be instituted to curb further problems with diarrhea (see TIP 24–2).

ANSWER: For a 14-year-old boy, bowel movements are a topic that he may not want to discuss with either his parents or the nurses. Strategies that provide George with lots of information and options would increase his sense of control and his privacy. Specific guidelines for when to alert the healthcare team would help prevent George from becoming impacted. George would be instructed to monitor his bowel movements, to increase his water intake, and how to add natural fiber and fiber supplements to prevent constipation. Promoting activity and exercise would be helpful as well.

Infection Prevention and Control Interventions

QUESTION: A review of George's immunizations shows that he is current on vaccines. The state where George lives requires the hepatitis A vaccines and the series

of hepatitis B prior to seventh grade. He had chicken pox when he was 6 years old. What interventions are appropriate for George to implement, and those that his family can implement, to prevent George from developing an infection?

Children receiving cancer treatment are **immunosuppressed**—their immune systems are suppressed—and thus are at increased risk for infection, particularly 7 to 10 days after receiving chemotherapy. This period is called the **nadir**, because the immune cell count is lowest at this point. Preventing infection is essential during the management of these children, because any infection can become serious and could lead to death. Neutropenic precautions is one measure to reduce or prevent infection. Community Care 22–2 highlights key aspects of neutropenic precautions in the home.

Children receiving chemotherapy may also receive prophylactic medications to help prevent certain opportunistic infections. For example, trimethoprim-sulfamethoxazole (Bactrim) is administered to prevent severe respiratory infections such as *Pneumocystis jirovecii* pneumonia, acyclovir may be administered to prevent herpes virus infections, and fluconazole or ketoconazole may be

COMMUNITY CARE 22-2

Neutropenic Precautions at Home

- Practice good handwashing habits.
- Do not share eating utensils, drinking glasses, baby bottles, pacifiers, and so on.
- Eat a well-balanced diet.
- Include high-fiber foods and maintain good fluid intake to prevent constipation; notify the physician if constipation occurs.
- Avoid unpeeled raw vegetables and fruits, salad bars, raw eggs, natural cheeses, and raw meats or fish because they might carry bacteria.
- Avoid exposure to molds (e.g., digging in soil).
- Practice good oral care (brush teeth after each meal and before bedtime, using a soft toothbrush).
- Practice good personal hygiene, with particular attention to keeping the perineum and other skin-fold areas clean.
- Avoid crowds and decrease the child's exposure to others when the child's ANC is less than $500/\text{mm}^3$.
- Keep the child away from individuals known to have an infection.
- To prevent perianal fissures and infection, do not insert anything into the rectum (e.g., no rectal thermometers, no suppositories, no enemas).
- Do not use tampons.
- Avoid fresh flowers and plants because of the germs in the soil and leaves.
- Postpone immunizations until infections or anemia resolve.
- Contact a healthcare provider if the child has a temperature more than 101°F (38.3°C) or has any signs of infection.

administered to prevent fungal infections. Another preventive medication, granulocyte–colony stimulating factor, is administered by subcutaneous injection or IV route for up to 14 days after chemotherapy. This agent stimulates the bone marrow to repopulate granulocytes more quickly and efficiently, decreasing the duration of neutropenia and thereby reducing the risk of infection.

Alert! Varicella zoster infection (chicken pox) can be life threatening to the immunosuppressed child. The child with cancer who is exposed to chicken pox should receive varicella zoster immune globulin within 5 days of exposure if the child has not had this communicable disease. The varicella vaccine has not yet been approved for use in children with cancer.

With regard to vaccine administration, children who have decreased immunity (e.g., those receiving chemotherapy) have compromised immune systems and are thus not able to fight infection effectively. Live-bacteria and live-virus vaccinations are contraindicated for all immunosuppressed children. Inactivated vaccines may be administered. These include diphtheria–tetanus–pertussis (Tri-Immunol), hepatitis B (Engerix-B), inactivated polio virus (Poliovax), and pneumococcal (Pneumovax) and influenza virus (Fluogen) vaccines (American Academy of Pediatrics, 2009).

ANSWER: The obvious interventions include reviewing hand hygiene techniques with George and his family, and limiting contact with visitors for 2 weeks.

Unfortunately, even with these prevention measures, the child may develop sepsis, a common complication of

chemotherapy treatment. Fever can be the first sign of sepsis; however, symptoms can be subtle in the immunosuppressed child. Thus, the family and the nurse must assess the child for fever and must recognize and prevent its progression to septic shock (TIP 22-3).

Alert! If a child's temperature spikes to 101.5°F (38.6°C), or remains at 100.5°F (38.1°C) or higher for 4 hours or longer, the child must be evaluated by a provider immediately.

Blood and other specimen cultures (e.g., urine, wound drainage) are obtained from all possible sources, including the CVC if indicated. In the presence of fever, broad-spectrum antibiotics are administered immediately, and the child is closely monitored until the origin of the fever is established. If no source of fever is identified, the child continues to receive broad-spectrum antibiotics for approximately 48 to 72 hours and then is reevaluated for continuing treatment (Tradition or Science 22-2 and [thePoint](#). Care Path: An Interdisciplinary Plan of Care for the Child With Neutropenia and Fever). If an organism is isolated, more specific antimicrobial agents are given. IV fluids are given to prevent dehydration and further complications, such as septic shock. In severe cases of septic shock, the child is at risk for disseminated intravascular coagulation and liver failure.

Blood Component Therapy

Anemia, neutropenia, and **thrombocytopenia** (an abnormally low concentration of platelets in the blood) are common results of bone marrow suppression after chemotherapy. Blood counts are monitored closely, a

TIP 2 2–3 Teaching Intervention Plan for the Child at Risk for Infection

Nursing diagnosis and outcomes

- Risk for infection related to neutropenia, immunosuppressive therapy, and presence of vascular access device

Outcome:

- Child and family will recognize and report signs of infection to their healthcare provider.

Teach the Family

Interventions

- If the child appears to be sick,
 - Observe the child's skin for pallor or bruising
 - Observe venous access device site for signs of infection or leaking
 - Check the child's temperature (under the arm or by mouth) any time that he or she feels warm to the touch or is uncomfortable; do not check the temperature rectally
 - Do not give the child medication for fever unless instructed by healthcare provider; if prescribed, administer acetaminophen; *never* give aspirin

- Encourage intake of fluids and small, frequent offerings of nutritious food
- Observe whether the child's urine or stool appears bloody

Contact Healthcare Provider if:

- Child has a temperature of 101.5 °F (38.6 °C) or higher, or a temperature of 100.5 °F (38.1 °C) or higher lasting more than 4 hours
- Child appears seriously ill without a fever
- Child has shaking chills, fever, or both after flushing the vascular access device
- Child is confused, has slurred speech, or is difficult to arouse
- Child is extremely weak or pale
- Child has bruising or bleeding
- Child has repeated excessive vomiting or diarrhea
- Child has decreased urinary output or blood in urine
- Child exhibits redness, swelling, or leakage at the central venous access site, or if the device has cracks, is pulled out, or does not flush

TRADITION OR SCIENCE 22–2

Can children with febrile neutropenia be treated on an outpatient basis?

MORE INQUIRY NEEDED

Outpatient strategies to manage the child with fever and neutropenia focus on two methods: no hospitalization, with symptoms managed entirely with oral antibiotics administered at home; or early hospital discharge with conversion to oral antibiotics administered at home. Holdsworth et al. (2003) reviewed available clinical trials and determined that although these two practices are common in the literature, such interventions should only be used in low-risk populations (children with negative blood cultures, evidence of hematopoietic recovery, and no comorbid condition). Sung et al. (2004) evaluated parent and healthcare professional preferences regarding outpatient management of low-risk febrile neutropenic children. Fifty-three percent of parents chose oral antibiotic outpatient management as the preferred model of care because they felt this was associated with higher patient comfort and higher level of anticipated quality of life. The costs of inpatient versus outpatient care of neutropenic patients must also be considered in the evaluation of the efficacy of outpatient services (De Lalla, 2003). More guidelines must be provided to safely manage children with neutropenia and fever at home, and more comparative studies are needed between inpatient and outpatient services of febrile neutropenia to evaluate factors such as costs, time to clinical response, and survival rates.

minimum of once a week, or more frequently if clinically indicated.

Alert! Spontaneous bleeding may occur at platelet counts of less than 10,000 to 20,000/mm₃.

Red blood cells and platelet transfusions are given to maintain a hemoglobin concentration of at least 7.0 to 8.0 g/dL and a platelet count of 10,000 to 20,000/mm₃ or more. Some oncologists advocate that children with brain tumors should maintain platelet counts of more than 50,000/mm₃ to minimize the risk of intracranial bleeding. Other precautions for the child with thrombocytopenia include

- Avoiding aspirin and aspirin-containing products
- Using a soft toothbrush or sponge for mouth care
- Avoiding contact sports, rough play, and amusement park rides using increased centrifugal force
- Postponing elective procedures such as dental work
- Avoiding intramuscular injections, rectal temperatures, rectal stimulation, and enemas
- Increasing intake of roughage and fluids to prevent constipation and straining

Certain chemotherapy drugs may alter blood coagulation studies, and children may need to receive fresh-frozen plasma, cryoprecipitate, or factor VIII to correct coagulopathy. For example, the drug L-asparaginase, which is used to treat acute leukemia, may decrease the fibrinogen level, which then necessitates checking of weekly fibrinogen levels.

Interventions for Oncologic Emergencies

At the time of diagnosis and during cancer treatment, certain emergencies may arise that must be swiftly recognized and treated by the healthcare team (Table 22–2). These emergencies can arise from secondary effects of the cancer or from toxicities of chemotherapy administration. Critical ongoing nursing assessment and immediate expert medical attention are required to treat and minimize deleterious outcomes of these emergencies.

Interventions for Late Effects

QUESTION: What long term sequela is important to discuss with George and his family?

More than 75% of children with cancer become long-term survivors, defined as being disease free for at least 5 years after treatment ends. Currently in the United States, 1 in 900 people between the ages of 15 and 45 years is a survivor of childhood cancer. Almost 80% of childhood cancer survivors will be alive at 5 years after treatment ends, and almost 75% will be alive after 10 years (U.S. SEER Program National Cancer Institute, 2009). Survival rates have increased dramatically during the past three decades because of increases in medical and technologic care related to surgery, radiation therapy, chemotherapy, biotherapy, and supportive care. As a result of increased long-term survival, considerably more *late effects* of treatment are being observed. Late effects may be caused by direct cancer care or by tissue injury, scar tissue formation, or impaired cell growth resulting from treatment. All cells and organs of the body can experience some late effects. Some of the systems and organs that more commonly experience late effects are discussed in Nursing Interventions 22–6.

To help the child and family identify and monitor late complications, pediatric oncology nurses need to be knowledgeable about the possible late effects of cancer treatment. Pediatric nurses have a great responsibility and opportunity to provide this family education and to reinforce the importance of short- and long-term follow-up examinations. They must also provide guidance to children and adolescents regarding healthcare decisions and risk-taking behaviors (e.g., smoking, drug use). The child's treatment history and potential for late effects place the child at higher risk for injury from these behaviors.

Long-term psychosocial issues may also arise for childhood survivors. Interruptions in the child's developmental trajectory, alterations in family dynamics, and concerns regarding return of the malignancy, defining a new identity, and coping with long-term physical complications are issues that must be addressed to ease psychosocial rehabilitation. The nurse plays a pivotal role in providing anticipatory guidance for the child and the family to assist them in coping with uncertainty, living with compromised health and possible disabilities, and fear of discrimination. The Children's Oncology Group

provides late effects guidelines for children with cancer and their families through the group's website (see [thePoint](#) Organizations).

ANSWER: One of the late effects of chemotherapy can be sterility. Adolescents should be given the information about their future ability to become parents. Boys have the option of banking sperm before chemotherapy treatments. Nurses need to assess the physical and psychosocial maturity of the boy to determine whether this is an appropriate topic for a family. The religious and cultural values of the family should also be discussed and considered in this decision-making process.

Palliative Interventions

Palliative care is designed to prevent or diminish the emotional and physical suffering of children dying a cancer-related death. The goal of the healthcare team is to promote quality of life for the child and the family as the child transitions from curative care to end-of-life care. Interventions focus on managing symptoms (e.g., pain, nausea, anorexia), and providing emotional and spiritual support to the child and family. Care for the family extends beyond the child's death, to provide support as family members grieve the loss of the child and adapt to a world without their beloved child's presence. Chapter 13 covers pediatric palliative care in depth, including interventions to support the dying child, the family, and the professionals caring for the child.

NURSING PLAN OF CARE FOR THE CHILD WITH A MALIGNANCY

QUESTION: Applying the information related to supportive care, what are the nursing diagnoses that may be relevant to George's care at this time?

The nursing plan of care for a child with cancer and the child's family reflects the complex nature of the disease and the need to implement creative care strategies (Nursing Plan of Care 22–1). Whenever possible, the child's treatment should be guided by an interdisciplinary team at a specialized facility with the technology to quickly diagnose and treat the child's disease. The interdisciplinary treatment plan is focused on eradicating the cancer and minimizing and treating the effects of the multimodal treatment regimen (see [thePoint](#) Care Path: An Interdisciplinary Plan of Care for the Child With Neutropenia and Fever). In addition, the Nursing Plans of Care in Chapter 10 (pain management), Chapter 12 (chronic conditions), Chapter 13 (palliative care), and Chapter 23 (the child with altered hematologic status) also describe nursing diagnoses and interventions useful in managing care of a child with cancer.

TABLE 22-2
Interventions to Manage Oncologic Emergencies

Oncologic Emergency	Description	Clinical Presentation	Healthcare Interventions
Hyperleukocytosis	Peripheral white blood cell count is $>100,000/\text{mm}^3$, causing increased blood viscosity, blast cell aggregates, and thrombi in the microcirculation.	Shortness of breath Tachypnea Cyanosis Blurred vision Papilledema Agitation Ataxia Confusion, delirium, stupor	Infusion of IV fluids (approximately $3,000 \text{ mL}/\text{m}^2/\text{day}$), sodium bicarbonate and allopurinol or rasburicase. Exchange transfusion or apheresis may be necessary to substantially decrease the number of circulating white blood cells.
Tumor lysis syndrome	Rapid release of large quantities of electrolytes and metabolites from the cancer cells during induction of chemotherapy resulting from rapid lysis (break-down) of tumor cells agents.	Hyperuricemia Hyperkalemia Hyperphosphatemia Hypocalcemia Flank pain Hematuria Decreased urine output Lethargy Muscle cramps and twitching Seizures Respiratory distress Diarrhea Renal failure Cardiac dysfunction	Provide IV hydration to flush cell by-products through the kidneys. Administer diuretics. Administer allopurinol or rasburicase to reduce uric acid production. Monitor serum chemistry levels. Manage hyperkalemia, hyperuricemia, hyperphosphatemia, and hypocalcemia using oral and IV solutions specific to electrolyte needs. Monitor intake and output. Provide dialysis if renal failure occurs.
Septic shock	Presence of infection and the subsequent systemic inflammatory response to that infection that results in physiologic alterations that occur at the level of capillary endothelial level. This can lead to decreased tissue perfusion, cellular hypoxia, and death.	Fever or hypothermia Tachycardia Tachypnea Peripheral vasodilation Leukocytosis Leukopenia Reduced mental alertness Organ failure	Initiate volume resuscitation with isotonic or crystalloid boluses. Administer broad-spectrum antibiotics. Provide supportive care and symptom management to maintain organ function.
Disseminated intravascular coagulation	Pathologic activation of coagulation factors and mechanisms that happens in response to the child's disease. Alterations in blood-clotting mechanisms are manifested by decreased platelets, increased prothrombin, and decreased fibrinogen.	Uncontrolled bleeding Petechiae, ecchymosis, purpuric rash Prolonged prothrombin time and partial thromboplastin time Platelet count, $100,000/\text{mm}^3$ Increased D-dimer assay Decreased antithrombin III levels Below-normal fibrinogen levels Increased fibrin degradation products	Manage symptoms. Provide blood product transfusions (fresh-frozen plasma, cryoprecipitate, platelets, red blood cells). Apply pressure to bleeding sites. Monitor urine, stool, emesis, and needle puncture sites for presence of blood.
Typhlitis	Bacterial infection of the cecum. May lead to necrotizing colitis.	Neutropenia Fever Severe abdominal pain in right lower quadrant Distended abdomen Diminished or absent bowel sounds Diarrhea Nausea Vomiting	Administer broad-spectrum antibiotics intravenously. Provide supportive care to manage symptoms. Anticipate surgical intervention to remove area of inflammation, or infarct may be necessary.

TABLE 22-2

Interventions to Manage Oncologic Emergencies (Continued)

Oncologic Emergency	Description	Clinical Presentation	Healthcare Interventions
Spinal cord compression	Compression of the spinal cord caused by tumor mass on or near the spinal cord. This can be a result of primary tumor of the spine or from spinal metastases.	Motor weakness Difficulty bearing weight Paresthesia Shooting back pain Changes in bowel and bladder function	Arrange a neurosurgical consult to determine extent of neurologic impairment. Use MRI or myelography to assess location and extent of cord compression. If indicated, perform emergency surgery to relieve compression.
Syndrome of inappropriate antidiuretic hormone secretion (SIADH)	Inappropriate release of antidiuretic hormone resulting in fluid retention. Vincristine and cyclophosphamide administration can precipitate SIADH.	Hyponatremia Low serum osmolality High urinary specific gravity and osmolality Decreased urinary output	Restrict fluids to below maintenance levels. Monitor intake and output. Monitor specific gravity of each voiding. Monitor serum sodium levels. Administer diuretics. Monitor for seizure activity.
Superior vena cava syndrome	Mediastinal compression of the superior vena cava caused by size and location of tumor mass, usually a lymphoma	Airway obstruction Respiratory distress Edema Changes in mental status	Arrange emergency radiation consult. Initiate emergency radiation or steroids to reduce tumor mass from vena cava.
Anaphylaxis	Acute and severe allergic reaction	Individual responses vary, including eruption of skin and mucous membrane, lesions, and itching; respiratory symptoms (coughing, sneezing, stridor, dyspnea); cardiac complications (tachycardia, hypotension, decreased peripheral perfusion); and gastrointestinal symptoms (diarrhea, nausea, vomiting)	Test doses of medications that are at high risk for causing an anaphylactic reaction should be given prior to medication administration. Pretreat child with diphenhydramine (Benadryl) or hydrocortisone (Solu-Cortef) prior to medications likely to cause anaphylaxis. Administer epinephrine and oxygen if reaction occurs. Intubate as indicated by child's respiratory effort.

Source: Secola and Reid (2008).

The nurse plays an instrumental role in humanizing the cancer experience to enhance the dignity, strengths, and uniqueness of each child and his or her family. Providing education to the family is an ongoing part of the plan of care. Concerns about the child's ability to achieve developmental goals and about the family's ability to maintain effective levels of coping must be addressed during all phases of the child's treatment program.

ANSWER: Examples of appropriate nursing diagnosis include

Deficient knowledge: Diagnosis, treatment plan
Anxiety related to the uncertainty of future
Acute pain related to operative procedure
Risk for constipation related to opioid use
Risk for infection related to neutropenia

PEDIATRIC MALIGNANCIES

Pediatric malignancies can arise in almost any tissue, including blood, organs, bone, and nervous tissues, and therefore affect many body systems. Prognosis varies with the type of cancer and the extent of disease at diagnosis.

CHILDHOOD LEUKEMIAS

Leukemia is a cancer of the blood or bone marrow characterized by an abnormal proliferation of blood cells, usually white blood cells (leukocytes). Leukemia is the most common childhood cancer and accounts for approximately one third of all leukemia cases diagnosed under 15 years of age. The French–American–British cooperative group has established a classification system for acute leukemia based on the form, structure, and chemistry

NURSING INTERVENTIONS 22–6

Interventions to Manage the Late Effects of Cancer Therapy

System/Organ	Long-Term Effect	Nursing Interventions
Endocrine: Ovaries/ testes	Infertility Sterility	Refer patient to endocrinologist. Refer patient for counseling, sperm banking, egg harvesting before treatment, and replacement hormones.
Endocrine: Thyroid, hypothalamus	Hypothyroidism Thyroiditis Graves' disease Benign or malignant tumor of the thyroid	Refer patient to endocrinologist and for replacement hormones for hypothyroidism or persistent thyroiditis. Prepare child for possible surgical removal of part of all of thyroid if Graves' disease or tumor present.
Cardiovascular	Cardiomyopathy Pericarditis Valvular damage Coronary artery disease	Monitor cumulative lifetime anthracycline dosages. Refer patient to cardiologist. Anticipate need for medications such as digoxin and diuretics. Prepare for possible sodium restriction and low-fat foods. Prepare child for surgical replacement of damaged valves or cardiac transplantation (in extreme cases of cardiomyopathy).
Musculoskeletal	Scoliosis Kyphosis Spinal shortening Osteoporosis Osteopenia Avascular necrosis Delayed or arrested tooth development	Refer patient for rehabilitation services. Encourage nutritional balance and maintenance. Prepare patient for shortened growth of bones. Refer patient to orthopedic surgeon. Advise patient to avoid rough sports. Calcium supplementation, biphosphonates may be needed for osteopenia and osteoporosis. Encourage frequent dental evaluations.
Vision	Cataracts	Refer patient to ophthalmologist. Prepare patient for surgical removal.
Hearing	Hearing loss	Refer patient to audiologist; hearing aid may be needed. Refer patient for speech therapy consult.
Respiratory	Pulmonary fibrosis	Encourage smoking prevention. Provide immediate care for respiratory infections. Encourage yearly flu vaccines.
Gastrointestinal	Chronic enteritis Cirrhosis or fibrosis of the liver	Refer patient for nutrition consults. Assist patient in dietary modifications if necessary.
Genitourinary	Chronic nephritis Chronic hemorrhagic cystitis Nephrectomy	Refer patient to nephrologist; dialysis may be needed. Ensure adequate hydration. Plan for possible bladder irrigations and antibiotics if needed and ordered.
Hematopoietic	Prolonged immunosuppression	Teach infection control precautions. Administer adequate antibiotic therapy and prophylactic antibiotics, as ordered. Monitor blood count.

NURSING PLAN OF CARE 22–1: THE CHILD WITH A MALIGNANCY

Nursing Diagnosis: Deficient knowledge: Diagnosis, treatment plan, and healthcare needs of the child

Interventions/Rationale

- Assess current knowledge level. Educate the child and family about the treatment plan and health needs.
- Answer questions in a nonthreatening, brief, and honest manner; provide information at child's level of understanding.

The diagnosis of cancer will evoke anxiety in the child and parents because treatment is complex and, in some cases, prognosis for the child may be poor. The family will need information to be given many times to help them better understand the complex and unfamiliar changes in their life that will occur as a result of their child's diagnosis.

- Enlist assistance of interdisciplinary team to provide education to the child and family. Give child and parents written instructions to enhance verbal instruction and to enable them to review information at their own pace. Provide opportunities to demonstrate care skills on manikins and on child before discharge.

If knowledge deficit exists, families cannot appropriately maintain the child's level of functioning or prevent complications.

- Give instructions at a developmentally appropriate level in terms of what the child will see, hear, feel, taste, and smell. Encourage the child to participate (as age appropriate) in discussions about the treatment plan, and provide the child as many opportunities as possible to make decisions about daily care (e.g., when to take a bath, complete a dressing change).

Respect for a child's developing capacity for autonomy and emerging self-determination requires that the child's wishes be considered. Doing so involves the concept of assent, which is the child's agreement with the decision. To involve the child in the decision-making process, and to decrease anxiety, provide information in a manner that the child understands.

- Refer child and family to community support/home healthcare services as appropriate to help reinforce, review, and reeducate.

Family may need assistance, reinforcement, and reeducation at home to manage the child's care and to adapt to lifestyle changes. This support is especially important immediately after the diagnosis and first discharge home from the hospital.

Expected Outcomes

- Child and family will verbalize understanding of diagnosis, treatment, and child's healthcare needs.

- Child and family will participate in the informed consent process and care of the child based on their understanding of the child's illness and treatment options.

Nursing Diagnosis: Acute (or chronic) pain related to effects of disease process, diagnostic procedures, and/or treatment modalities

Interventions/Rationale

- Assess pain using a reliable and valid method that is developmentally appropriate and appropriate for the situation. Elicit parent's assessment of child's pain.

The subjective rating of pain is most reliable, but it may not be an option in a nonverbal child (infant, intubated, comatose). Validated tools provide the most accurate assessment. The absence of behaviors that indicate pain does not necessarily mean that the child is not experiencing pain. Parents know their child best and are familiar with typical behaviors.

- Implement pharmacologic and biobehavioral interventions to alleviate pain, including anticipated procedural pain (see Nursing Plan of Care 10–1). Use a preventive approach to keep pain at or below an acceptable level. Involve the family in pain management. Instruct them in using oral anesthetics as ordered for mouth pain.

Unrelieved pain has deleterious physiologic effects such as tachycardia, suppressed immune function, and atelectasis, as well as negative psychological effects. Opioid analgesics are indicated for moderate to severe pain. Pain is better managed if it is not allowed to escalate. Having the family provide pain relief measures may be more comforting to the child than having them provided by a nurse. Pain from oral mucositis may prevent the child from eating, drinking and taking their oral medications.

- Assess for the probable cause of the pain, to direct the choice of pain relief measures. Monitor for changes in the child's condition that may identify a need to change pain relief methods.

For the child with a malignancy, pain may come from the tumor site as rapidly growing cancer cells invade bone and tissue, and from the administration and side effects of chemotherapy, radiation, and surgery (e.g., mucositis, skin blistering, and incision site pain). Techniques of pain relief may have to be added or changed to relieve the pain.

- Assess response to pain and coping strategies, including medications and distraction. Assess cultural, environmental, personal, and psychic factors that may contribute to pain, expression of pain, and relief or pain.

(Continued)

NURSING PLAN OF CARE 22–1: THE CHILD WITH A MALIGNANCY (CONTINUED)

Assessment of responses identifies strategies that may have worked previously. Identification of factors enables evaluation of patient's unique response to pain and helps to individualize management strategies.

- Provide periods of rest and sleep.

Fatigue can contribute to the perception of pain.

- For the child with chronic pain, encourage the child to keep a diary to help identify aggravating stressors and relieving factors.

Maintaining a diary may help the child and family identify factors contributing to pain, strategies to modify lifestyle, and alter plan of care to relieve or prevent pain.

Expected Outcomes

- Child will experience minimal discomfort during and after procedures.
- Child will state that adequate pain relief has been obtained.
- Child and family will demonstrate use of effective pain relief measures.

Nursing Diagnosis: Risk for infection related to neutropenia, immunosuppressive therapy, or presence of CVC

Interventions/Rationale

- Monitor white blood cell counts, differential, and ANC for decreases that indicate the child is at greater risk for infection.

The large numbers of immature white blood cells that proliferate in the body during the malignancy process do not provide a defense against infection, and at the same time drastically reduce normal composition of the blood. Treatment regimens of chemotherapy and/or radiation further reduce the bone marrow's ability to produce necessary blood components.

- Isolate the child from any persons with infectious diseases, especially chicken pox. Use neutropenic precautions (prevention measures for infection) when ANC is less than $500/\text{mm}^3$.

Neutropenia means that the neutrophil count is too low to adequately fight infection. Precautions must be used to keep the child from exposure to infectious agents. Immunocompromised children are at higher risk for chicken pox. In addition, children who have had varicella in the past are at risk for viral reactivation as herpes zoster when in states of immune compromise.

- Maintain good hygienic practices and ensure that child and family follow these practices; ensure that all children wash hands after toileting.

Hygienic practices prevent transmission of microorganisms.

- Monitor the child for signs of infection (e.g., increased temperature, pulse, and respirations). Examine child's skin and mucous membranes daily

for lesions or breaks; provide oral care several times a day (see TIP 22–1). Monitor IV sites and incision sites for signs of infection.

Early identification leads to prompt treatment.

- Obtain cultures as appropriate.

Cultures provide data about microorganisms causing infection and about antibiotic drug sensitivity.

- Administer antibacterial, antifungal, and antiviral medications as prescribed.

Use of appropriate medications is essential in treating infections and preventing progression to sepsis.

- Teach family to recognize early the signs and symptoms of infection (e.g., fever, chills, productive cough, and malaise) and to use neutropenic precautions in the home (see Community Care 22–2).

The child and family can learn to avoid situations that will increase the likelihood of infection, and can implement wellness behaviors that will enable the child to remain healthy.

Expected Outcomes

- Child will remain free from infection.
- Child and family will recognize and report signs and symptoms of infection to their healthcare providers.
- Child and family will describe measures to reduce risk of infection.
- Child and family will demonstrate measures to reduce the likelihood of infection from the CVC.

Nursing Diagnosis: Impaired urinary elimination related to chemotherapy or disease process

Interventions/Rationale

- Determine whether child is at risk for urinary retention.

Tumors involving the abdomen (Wilms' tumor, neuroblastoma) can alter normal bowel and bladder function; these changes can be reversed by tumor removal or shrinkage. Treatment measures (chemotherapy, radiation, surgery) may cause urinary retention.

- Assess pretumor bladder patterns and current bladder patterns.

Assessment provides baseline of child's habits.

- Monitor intake and output. Observe for signs of urinary retention or infection (e.g., voiding small amounts, dysuria, frequency, fever).

Close monitoring provides evidence of fluid balance and prompt identification of problems to ensure adequate intake and fluid replacement. Urinary retention may indicate urinary tract infection.

- Assist with bladder function until the tumor effects are diminished (e.g., Credé method, diapering, catheterization).

Assisting with bladder function facilitates emptying of the bladder, thereby reducing the risk for an infection.

Expected Outcome

- Child will demonstrate adequate voiding patterns with evidence of adequate renal function during course of therapy.

Nursing Diagnosis: Diarrhea and/or constipation related to effects of chemotherapeutic agents, radiation, or disease process

Interventions/Rationale

- Determine whether the child is at risk for bowel dysfunction.

Tumors involving the abdomen (Wilms' tumor, neuroblastoma), graft-versus-host disease, and bacterial endotoxins can alter normal bowel and bladder function. Treatment measures (chemotherapy, radiation, surgery) may cause constipation or diarrhea.

- Assess pretumor bowel patterns and current bowel patterns. Assess quantity, consistency, color, odor, and frequency of stools. Maintain accurate intake and output. Auscultate bowel sounds every 4 hours.

Assessment provides baseline of child's habits, hydration status, and bowel activity. Hyperactive bowel sounds are present with diarrhea; hypoactive sounds, with constipation.

- Monitor general condition, vital signs, skin turgor, and mucous membranes every shift and as necessary. Monitor child's daily weight.

Diarrhea can quickly lead to dehydration and electrolyte imbalances in the pediatric population. Severe dehydration will cause dry mucous membranes, absence of tearing, and weight loss.

- Check stools for reducing substances (Clinitest) and for occult blood (guaiac) every shift. Obtain stool cultures as ordered.

Evaluation of stool identifies reducing substances (unabsorbed sugars), blood, and bacteria in stool and assists with differential diagnosis of cause of diarrhea.

- Change diapers with each stool. Clean and dry perineal area, wear gloves, and practice scrupulous handwashing when in contact with stool. Provide sitz baths or tub baths for comfort and cleaning.

Perianal skin care prevents skin breakdown in perineal area. Sitz or tub baths provide comfort measures for tender skin and mucosal areas.

- Assess ongoing nutritional status; provide roughage and fluids for constipation. Offer low-residue, low-lactose foods for diarrhea. Administer adequate hydration and high-fiber diet for constipation.

Low-residue and low-lactose foods do not irritate the GI mucosa. Fiber, when it reaches the colon, absorbs

water and adds bulk to stool, thus making defecation easier.

- Assist with bowel function (e.g., with stool softeners, laxatives) until the tumor effects or effects of chemotherapy and radiation are diminished. Instruct the child and family to place nothing in the rectum.

Use of stool softeners or laxatives helps to prevent constipation. Tearing of the rectal mucosa in the neutropenic child can occur with rectal insertion.

- Administer antispasmodic medication as prescribed. Administer laxatives, stool softeners, or emulsifiers as ordered. Monitor effectiveness.

Antispasmodic agents help to decrease or prevent diarrhea. Laxatives, stool softeners, or emulsifiers help to relieve and prevent constipation.

- Give the child privacy for toileting. Assist the child to establish a regular bowel pattern.

The child may experience difficulty having a bowel movement using a bedpan or bedside commode. Setting aside time for elimination encourages a regular pattern to be established.

- For constipation, encourage ambulation and other activity as tolerated.

Prolonged bed rest, lack of exercise, and inactivity contribute to constipation.

Expected Outcomes

- Child and family will use measures to prevent or minimize diarrhea and constipation.
Child will maintain normal pattern of bowel elimination.

Nursing Diagnosis: Risk for injury related to defect in hemostasis (e.g., factor deficiency, low platelet count)

See Chapter 23, Nursing Plan of Care 23–1.

Nursing Diagnosis: Risk for impaired skin/tissue related to radiation therapy, chemotherapy, presence of a venous access device, graft-versus-host disease, and immobility

Interventions/Rationale

- Inspect the child's skin and mucous membranes for signs of radiation effects (erythema and darkening, desquamation, thin epidermis, blistering).

Melanocytes in the skin are stimulated during radiation treatment, making skin darker in color. Basal cells of the epidermis are affected during radiation. Epithelial cells of the GI tract proliferate rapidly. Because chemotherapy affects fast-growing cells, it causes stomatitis and mucositis.

- Change the child's position every 2 hours.

Frequent position changes relieve trauma and pressure over bony prominences, and may prevent skin breakdown.

NURSING PLAN OF CARE 22–1: THE CHILD WITH A MALIGNANCY (CONTINUED)

- Provide meticulous hygiene practices, keeping skin dry and clean, and keeping mucous membranes moist and intact:
 - Assist with daily bath; avoid rubbing the skin. Use mild, nonperfumed soap and tepid water.
 - Complete CVC dressing changes per institutional policy.
 - Complete perineal care after each voiding or defecation.
 - Apply lubricating lotions or creams.

Keeping skin and mucous membranes intact reduces potential sites of entry for organisms and the development of opportunistic infections.

- Use topical and systemic antibiotic or antifungal medications as ordered.

Medications may be ordered to prevent infection or for treatment for specific causative organism of skin infection.

Expected Outcomes

- Child and family will demonstrate measures to prevent or minimize skin and mucous membrane breakdown.

Child's skin and mucous membranes will remain intact, free from infection, soothed, and healed.

Nursing Diagnosis: Impaired oral mucous membrane integrity related to radiation therapy, chemotherapy, dehydration, or ineffective oral hygiene

Interventions/Rationale

- Assess oral health and oral pain using a valid and reliable oral assessment tool. Assessment should include inspection of oral mucosa for
 - Bleeding, sores, ulcerations involving intraoral soft tissue, palate, tongue, gums, and lips in and around mucous membranes
 - Evidence of infection (e.g., candidiasis, herpes simplex, bacterial infections)

Assess for impairments in speech, swallowing and drooling.

Chemotherapy affects fast-growing cells, thus causing stomatitis and mucositis. Cottage cheese-like white or pale patches on the tongue, buccal mucosa, and palate may indicate candidiasis. Painful itching vesicles (especially on the upper lip) may indicate herpes simplex.

Yellowish brown plaque (gram-positive bacteria) and creamy white patches (gram-negative bacteria) located on the buccal mucosa indicate presence of oral infection. Speech and swallowing difficulties may result from ulcerated, bleeding, and painful oral mucosa.

- Assess child's nutrition status, including child's ability to eat and drink. Weigh child daily.

Dehydration may lead to dry mucous membranes and subsequent open lesions on the lips. Inability to chew

and swallow may occur secondary to painful and inflamed oral mucous membranes. Weight loss may indicate inadequate nutritional consumption.

- Provide meticulous hygiene practices, keeping mucous membranes moist and intact:
 - Implement oral hygiene protocol (see TIP 22–1), including brushing teeth with soft toothbrush that is replaced on a regular basis and rinsing mouth with chlorhexidine or other recommended oral solution.
 - Apply lubricating ointment to the lips.

Keeping mucous membranes intact reduces potential sites of entry for organisms and the development of opportunistic infections. Oral rinsing using sterile water or solutions such as chlorhexidine will decrease the incidence of developing mucositis.

- Use topical and systemic antibiotic or antifungal medications as ordered.

Medications may be ordered to prevent infection or for treatment for specific causative organisms of oral mucous membrane infection. Topical anesthetics may be necessary to decrease oral pain. Thinning of oral mucous membrane linings increases sensitivity to oral pain.

- Use measures to promote adequate dietary intake (see TIP 22–2), including referral to a dietitian.

Dietary modifications may be necessary to ensure the child remains hydrated and receives adequate caloric intake to promote healing and tissue integrity.

Expected Outcomes

- Child and family will demonstrate measures to prevent or minimize mucous membrane breakdown.

Child's mucous membranes will remain intact, free from infection, soothed, and healed.

Nursing Diagnosis: Imbalanced nutrition: Less than body requirements related to nausea, vomiting, or oral mucositis

Interventions/Rationale

- Obtain nutritional history to include food likes and dislikes, daily consumption, patterns of nausea and vomiting, and effective strategies for increasing nutrient intake and managing nausea and vomiting.

The child's nutritional patterns and responses to nutritional interventions are individual. Plan of care should build on successful strategies used at home or during previous hospitalizations.

- Document intake and output, daily weights, enteral or parenteral intake, and episodes and amounts of vomiting and diarrhea.

Assessment provides baseline information and evidence of change in dietary patterns.

- Monitor for signs of increasing dehydration (e.g., less elastic skin turgor, depressed fontanels, sunken eyes, weight loss, rapid pulse, dry mucous membranes, decreasing urine output, changes in urine specific gravity).

Early recognition may decrease or prevent dehydration.

- Monitor laboratory tests indicative of nutritional status (e.g., hemoglobin, red blood cell indices, and total protein).

Evaluation of laboratory test results provides information about whether intake of nutrients is adequate.

- Adjust diet based on child's specific needs and challenges (e.g., nausea, mucositis). Institute and teach measures to reduce or prevent nausea and vomiting (see Nursing Interventions 22–5).

Behavioral and dietary interventions can be effective to enhance dietary intake and manage nausea and vomiting.

- Use creative and developmentally appropriate approaches to enhancing nutritional intake (e.g., offer attractive, colorful foods in small, frequent servings; encourage family and friends to bring in favorite foods; allow child to select foods; reward intake with stickers, stars, special privileges); allow child to use feeding skills already mastered (e.g., sit young child in high chair if able and encourage self-feeding); and experiment with food textures and temperatures to find foods most palatable to the child.

Participation in care may encourage the child to ingest fluids and nutrition.

- Administer supplemental vitamins and minerals as prescribed. Provide between-meal protein supplements.

Supplements replace missing nutrients and assist with tissue repair.

- Administer IV fluid (including total parenteral nutrition and hyperlipids) as ordered (see Nursing Plan of Care 17–1).

IV fluid replacement may be necessary to maintain hydration.

- Administer antiemetics as ordered.

Medications can be effective in controlling nausea and vomiting. Regimen must be tailored to child's specific needs.

- Brush teeth with soft toothbrush or sponge, provide oral care every 2 to 4 hours, and rinse mouth with water after feedings.

Oral care provides a clean, fresh mouth; may decrease or prevent infection; and may enhance nutritional intake.

- Coordinate nutritional approaches with nutritionist; request that special foods be available or stocked on the unit around the clock.

Coordinating with nutritionist assists in providing the child with necessary nutrients. Inadequate nutrition further compromises the child's immune system.

- Coordinate with healthcare prescriber about initiating feedings or total parenteral nutrition if child is unable to maintain adequate oral intake.

Feedings or total parenteral nutrition may be necessary to ensure that the child receives adequate nutrition.

Expected Outcomes:

- Child will be able or assisted to maintain adequate fluid intake by oral, nasogastric, or IV access.
- Child's caloric intake will be adequate for age.
- Child will maintain weight that is normal for age.

Nursing Diagnosis: Anxiety related to uncertain prognosis; actual or perceived loss of body integrity; threat to self-concept

Nursing Diagnosis: Disturbed body image related to being different than peers, perceiving self as sick, loss of body part
See Nursing Plan of Care 12–1.

Nursing Diagnosis: Spiritual distress related to crisis of the illness, suffering, or death of a child
See Nursing Plan of Care 13–1.

(morphology) of the blast cells. Lymphoblasts occur in three types: L1, L2, and L3. The World Health Organization has developed a more comprehensive system to categorize leukemia based upon morphology, immunophenotyping, and cytogenetic and clinical features. The four major classifications of leukemia are

1. Acute lymphoblastic leukemia (ALL), also known as *acute lymphocytic leukemia*. This is the most common type of leukemia in young children and the most common type of cancer in children, although it also affects adults, primarily those age 65 and older (Gurney & Bondy, 2006).
2. Acute myelogenous leukemia (AML), also referred to as *acute nonlymphoblastic, myeloid, or myeloblastic leu-*

mia. Approximately 15% to 20% of children with leukemia have AML.

3. Chronic myeloid leukemia (CML), also referred to as *chronic myelogenous leukemia*. This occurs predominantly in adolescents and adults. Approximately 5% of children with leukemia have this form of the disease.
4. Chronic lymphocytic leukemia (CLL), which most often affects adults older than the age of 55. It sometimes occurs in younger adults, but it almost never affects children, and therefore is not covered in this chapter.

Some chromosomal abnormalities are associated with childhood leukemia. For example, leukemia is 15 times more likely to develop in children with trisomy 21 (Down syndrome) than in other children and has also been

associated with other autosomal recessive disorders (e.g., Fanconi's anemia). Other less common chromosomal abnormalities and familial tendencies (in identical twins and siblings) have also been associated with an elevated risk for childhood leukemia.

In addition to genetics, environmental factors (e.g., exposure to radiation, toxic chemicals, electromagnetic fields, and chemotherapy), viral infections (e.g., Epstein-Barr virus or HIV), and immunodeficiencies or abnormalities of the immune system have been linked with leukemia (U.S. SEER Program, National Cancer Institute, 2009). The reason that leukemia develops in any particular child is rarely known, but tendencies or similarities that have been documented remain of interest to healthcare providers.

Acute Lymphoblastic Leukemia

ALL accounts for approximately 78% of childhood leukemia in the United States. Annually, ALL occurs at a rate of approximately 30 to 40 per million. Approximately 2,400 children and adolescents younger than 20 years are diagnosed with ALL each year in the United States. The incidence of ALL is highest in Hispanic children and also substantially higher for white children than for black children, with a nearly threefold higher incidence at 2 to 3 years for white children when compared with black children (National Cancer Institute, 2008a). Genetic factors are presumed to play an important role in the origin of ALL.

The initial white blood cell count is perhaps the most important prognostic factor. Children with white blood cell counts greater than 50,000 tend to have a poorer prognosis, and those with white blood cell counts greater than 100,000 have a particularly poor prognosis. Age at diagnosis also influences the prognosis, with children younger than age 2 years and older than age 10 years at diagnosis having a relatively poor prognosis. Children younger than 1 year of age have the least favorable prognosis. In most reports, girls have a better prognosis than boys. Current statistics indicate that almost 85% of children with ALL survive at least 5 years past diagnosis (U.S. SEER Program, National Cancer Institute, 2009).

Pathophysiology

ALL causes extreme proliferation of immature lymphocytes, referred to as **blast cells**. This disease originates in B or T lymphoid cells (with B-lymphoblastic leukemia more prevalent [>80% of cases] than T-lymphoblastic leukemia [National Cancer Institute, 2006]). The leukemic cells proliferate and pack the bone marrow. They compete for space and interfere with normal blood cell development, possibly spreading to other lymph tissues and organs. Therefore, a child with ALL often presents with signs and symptoms related to failure of normal hematopoiesis.

Immunobiologic study of ALL determines which lymphocytes have been transformed into leukemic cells and identifies the stage of cellular development in which the leukemia occurred. Abnormalities in chromosomal num-

bers and structures are also examined to assist in predicting long-term prognosis.

A common feature of ALL is **extramedullary** disease (systemic disease outside the blood and bone marrow). The most common sites of extramedullary spread are the CNS, testes, liver, kidneys, and spleen. Extramedullary disease can be present at time of diagnosis or at the time of recurrence.

Assessment

Most children diagnosed with leukemia usually have been symptomatic for several weeks, with symptoms being assumed by the family to be the flu or other common malady. Signs and symptoms of childhood leukemia are directly related to the degree of bone marrow infiltration and the spread of the disease (Chart 22-1). A complete blood count followed by a lumbar puncture, bone marrow aspiration, and biopsy are the first diagnostic procedures completed to confirm the diagnosis of leukemia.

Interdisciplinary Interventions

Treatment for children with ALL is governed by the child's symptoms, age, chromosomal abnormalities, and type of disease. When all factors have been evaluated, a risk category is determined and combination therapy is initiated as indicated. The first goal is to induce a remission with combination chemotherapy. Children with ALL achieve remission 98% of the time with induction therapy. After remission is attained, children receive further intensive chemotherapy and then maintenance

CHART 22-1 CLINICAL AND DIAGNOSTIC FEATURES OF LEUKEMIA

Fatigue, weakness
Pallor
Fever
Bruising
Bleeding (e.g., petechiae or purpura)
Weight loss, anorexia
Swollen gums
Sore throat, recurrent infections, flulike symptoms
Abdominal pain, nausea, vomiting
Bone pain

Hepatosplenomegaly
Elevated leukocyte count
Decreased hemoglobin
Decreased platelet count

chemotherapy over a 2- to 3-year period. Males traditionally are treated for a longer time than females. Chemotherapy and possibly radiation therapy to the CNS may also be used to ensure that no leukemia cells are present in, or return in, the cerebrospinal fluid, because the cerebrospinal fluid is considered a hidden sanctuary for leukemia. Supportive care is ongoing throughout treatment to prevent acute bleeding or infectious complications.

Alert! Acute bleeding can be a potentially life-threatening emergency for children with leukemia. The platelet count should be more than 10,000 to 20,000/mm³ at all times, and the child with evidence of bleeding or extreme bruising should receive a platelet transfusion.

Thorough hand washing, limited visitors and exposure to germs, and prophylactic antibiotics are key components for the care of the child with leukemia.

Children with extremely high-risk prognostic factors at diagnosis, children in whom initial therapy fails to achieve remission, and children who relapse receive more intensive combination chemotherapy and possibly HSCT. This aggressive approach has helped to increase disease-free long-term survival rates. Supportive care and observation are more prolonged and intense for this group of children.

Community Care

Children with all types of leukemia are primarily managed in the home. Hospitalizations are required for infusion of certain chemotherapeutic agents and when the child's health status is severely compromised (e.g., ANC is <500/mm³, child is dehydrated). Many tertiary care centers are able to provide chemotherapy infusions on an outpatient basis in an infusion center specifically designed to manage providing these types of treatments. Managing the child's care needs in the home depends on the side effects of treatment the child is experiencing. The Treatment Modalities section of this chapter discusses these therapeutic interventions in detail. The goal of home care is to promote the child's personal growth and development while managing the complex physical and psychosocial challenges the diagnosis of cancer brings to the child and their family. The child is encouraged to participate in school and community activities, while always being mindful of his or her current health status, and limiting activities as needed to prevent injury, protect from harm, and ensure the child is pain free.

Acute Myelogenous Leukemia

AML, also called *acute nonlymphoblastic leukemia* or *acute myeloid leukemia*, represents approximately 15% to 20% of all cases of childhood leukemia. AML is equally distributed among races and sexes. Most research indicates that children with a high white blood cell count at diagnosis have a poorer outcome (Creutzig et al., 2004). Although much progress has been made during the past decade in treating this disease, the 5-year survival rate for

children younger than age 15 is 55% (U.S. SEER Program, National Cancer Institute, 2009).

The exact cause of AML is unknown; however, certain risk factors are associated with the development of this disease, including radiation exposure in utero, treatment with alkylating agents, maternal cigarette or marijuana use during pregnancy, history of a previous malignancy, trisomy 21, Fanconi's anemia, and environmental exposure to chemicals (especially benzene) and pesticides (U.S. SEER Program, National Cancer Institute, 2009).

Pathophysiology

Most cases of AML are believed to result from a malignant transformation of a single blood stem cell in the bone marrow. Most often, this transformation occurs on a nonlymphoid cell line, thus the reason for calling it acute nonlymphoblastic leukemia. The malignant clone causes a proliferation of immature, relatively undifferentiated cells that replace healthy bone marrow elements. The immature cells accumulate in the bone marrow and in extramedullary sites, interfering with bone marrow function.

The term *AML* refers to a heterogeneous group of malignancies that have been classified into subtypes according to the pathology and biology of the malignant cells. The French–American–British system is the standard classification used to describe the eight subtypes of AML, which range from M0 and M1 for acute myeloblastic leukemia without differentiation, through M7, which indicates acute megakaryoblastic leukemia.

Assessment

Children with AML may present with a few seemingly benign, flulike symptoms or they may have severe symptoms that may be life threatening (see Chart 22–1). Bleeding or severe hemorrhaging, as well as extremely high white blood cell counts (>100,000/mm³), is often seen in these children. Extramedullary spread of disease, particularly in the CNS at diagnosis, may occur. Initially, the same diagnostic procedures and nursing assessments are done as for the child with ALL, including bone marrow aspiration biopsy and a lumbar puncture.

Interdisciplinary Interventions

Initial treatment of AML is targeted at preventing life-threatening complications and achieving remission. Immediate blood component therapy, infection prevention, and initiation of combination chemotherapy drugs to reduce leukemia burden are crucial treatments.

After remission is achieved and complications are no longer life threatening, treatment of the CNS with more intensive chemotherapy is recommended. HSCT is often recommended, particularly if the child has an HLA-matched sibling as the donor to provide a better chance of long-term survival. Biotherapy has also been incorporated into the treatment plan for some children with AML. Children are often hospitalized for extended periods to undergo aggressive treatment and for treatment of subsequent infections that require vigilant supportive care and protective isolation (Clinical Judgment 22–1).

CLINICAL JUDGMENT 22–1

The Immunosuppressed Child With Fever

Jasmine is a 4-year-old girl with leukemia. She completed her most recent course of chemotherapy 7 days ago. She is now being admitted to the hospital with a fever of 101.8 °F (38.8 °C), chills, a white blood cell count of an ANC of 475/mm³, a platelet count of 59,000/mm³, and hemoglobin level of 8.8 g/dL.

Questions

1. What additional assessment data should be obtained at this time by members of the healthcare team?
2. The father states that Jasmine has not been around any sick people. He is confused as to how she could have gotten ill. What should the nurse tell him?
3. The physician orders include blood cultures, a chest radiograph, urine and throat cultures, IV fluids, and antibiotics. Which of these orders should be completed first?
4. What precautions should be taken given the child's vital signs and blood analysis findings?
5. Jasmine's 6-year-old brother is standing outside the room crying. He says, "It's all my fault she's sick. I spit on her." What should he be told about his sister's current situation?

Answers

1. Vital signs, type of chemotherapy last received, presence of mouth sores, redness or irritation at

the venous access device site, intake and output history, ANC, and oxygen saturation measured using a pulse oximeter

2. Most infections are from commonly occurring bacteria in the child's system; these bacteria are harmful to Jasmine only because of her depressed immune system.
3. Cultures of the blood, urine, and throat should be taken before starting antibiotics. As soon as these tests are completed, the IV fluids should be started and antibiotics given immediately. Vital signs should be monitored carefully. Chest radiographs can be obtained after antibiotic therapy has been initiated.
4. Jasmine is neutropenic, thrombocytopenic, and anemic. Neutropenic precautions (see Community Care 22–2) as well as precautions to prevent and reduce the risk of bleeding should be used.
5. Reassure the boy that his spitting did not cause his sister to be sick. Encourage him to go in the room and be with his sister. Instruct him on good handwashing techniques to help protect his sister from getting sicker and explain how he can do this at home to help her avoid getting an infection.

Chronic Myelocytic Leukemia

CML is a proliferation of mature myelocytic cells in which mutation can begin years before the onset of symptoms. This disease presents, is diagnosed, or may progress through three different phases: chronic phase, accelerated phase, and blast crisis phase. A hallmark chromosomal abnormality is the translocation of chromosomes 9 and 22 t(9;22), identified as the *Philadelphia chromosome*. CML presents as a hyperproduction of myeloid cells, up to 100 times the normal amount. The elevation of the white blood cell count and the degree of organ and lymph node involvement reflect the prognosis. The phase of the disease at the time of clinical presentation also determines the outcome.

Pathophysiology

Little is known about the cause of CML. It is a rare disease in children, accounting for 1% to 3% of all cases of childhood leukemia (National Cancer Institute, 2008a). There are no significant differences in incidence among

race or sexes. Ionizing radiation exposure may be the only environmental risk factor associated with this disease.

Most patients are diagnosed during the chronic phase of the disease. During this phase, CML symptoms are less intense and the white blood cells can still fight infection. During the accelerated phase, the child may develop anemia, the number of white blood cells may increase or decrease, or the number of platelets may decrease. During this phase, the number of blast cells increases. The spleen may swell and the child may truly feel ill. During the blast crisis phase, the number of blast cells increases in the bone marrow and blood. Red blood cells and platelets decrease and the child is prone to infection. The child may also be lethargic, have shortness of breath, stomach pain, bone pain, and/or bleeding during this phase.

Assessment

As mentioned, children with CML may present during the chronic, accelerated, or the blast phase of the disease. In many cases, the onset of the disease is chronic: slow and not easily detected. The diagnosis may be made

when a blood count is performed for another reason. During this chronic phase, children may present with nonspecific symptoms of pallor, low-grade fever, weight loss, anorexia, and night sweats. The chronic phase can last up to 3 to 4 years before progressing to a myeloid or lymphoid **blast crisis**, in which only immature leukemia cells are produced. In this case, the blast phase symptoms appear more like those of acute leukemia, with the presence of splenomegaly, bone marrow depression, and lymphadenopathy.

Interdisciplinary Interventions

The initial goal of therapy is to achieve remission utilizing chemotherapy and BRMs. Children in the chronic phase of CML respond very well to tyrosine-kinase inhibitors such as oral imatinib (Gleevec) or dasatinib (Sprycel). The treatment usually returns the level of blood cells to normal and the spleen shrinks to normal size. Most children will not experience bleeding or unusual infections at this time. Some may need chemotherapy initially to decrease their white blood cell count. Most children being treated for chronic-phase CML can participate in their day-to-day activities. With drug treatment, most children are in remission and are symptom free for long periods of time. However, drug treatment does not cure these children of CML. Regular checkups, including blood analysis and bone marrow analysis, are needed to assess for any signs that a relapse has occurred and the CML has returned. CML is likely to return if drug treatment is stopped. Children who do not respond to these oral agents, who develop resistance to the drugs, or who progress to the accelerated or blast phase may undergo an allogeneic HSCT for curative treatment.

Central Nervous System Tumors

QUESTION: What is the incidence, prognosis, and treatment of brain tumors compared to bone tumors such as what George has?

Tumors of the CNS are the second most common malignancy in childhood. In the United States, approximately 2,200 children younger than 20 years of age are newly diagnosed each year (U.S. SEER Program, National Cancer Institute, 2008). Brain tumors, although rare during the first year of life, tend to occur most frequently in children younger than age 10 years. Incidence is roughly equal in males and females. Approximately 74% of all children with CNS tumors demonstrate a 5-year survival rate (National Cancer Institute, 2008a).

There are important differences between the types and locations of tumors in children when compared with adults. Gliomas account for 75% of intracranial tumors in children, compared with 45% in adults. In children, 50% to 60% of brain tumors are *infratentorial* (located in the cerebellum, fourth ventricle, or brain stem), whereas in adults they are primarily *supratentorial* (located in the cerebrum). Also, 75% or more of brain tumors in chil-

dren occur in the midline (third and fourth ventricles, optic chiasm, and brain stem) (Kuttish & Ater, 2004).

The cause of CNS tumors remains unknown. Direct correlations exist between certain hereditary and familial syndromes (e.g., neurofibromatosis [50-fold increased risk], tuberous sclerosis, Li-Fraumeni syndrome, retinoblastoma) and CNS tumors (National Cancer Institute, 2008a). Environmental factors also are related to the incidence of CNS tumors and include industrial and chemical toxins, ionizing radiation, and exogenous immunosuppression, as seen in transplant recipients. Studies have investigated prenatal and perinatal exposures to these risk factors that may correlate with the increased incidence of brain tumors in children. Brain tumors have been associated with certain parental occupations, particularly those in which parents were exposed to electromagnetic fields or ionizing radiation (National Cancer Institute, 2008).

Various types of ionizing radiation exposures in children also have been associated with CNS tumors. These events include therapeutic doses of ionizing radiation to the head (i.e., treatment of tinea capitis, exposure to radiographs, radioisotopic contrast media, ultraviolet radiation, and nuclear bomb fallout). Several reports document the development of a primary brain tumor after cranial radiation received for a prior malignancy such as ALL (National Cancer Institute, 2008).

Pathophysiology

Brain tumor is a general term for many histologic categories. Each type has distinctly different clinical manifestations, modes of treatment, and outcomes. Of all pediatric CNS tumors, astrocytomas located at cerebellar, cerebral, and brain stem sites are the most common (approximately 50% of cases), followed by primitive neuroectodermal tumors (22%), other gliomas (15%), ependymomas (10%), and others (3%) (Blaney, Kun, Hunter, et al., 2006). Table 22-3 summarizes the major types of pediatric CNS tumors.

CNS tumors are categorized by their histologic characteristics and degree of malignancy. This is termed **tumor grading**. CNS tumors are frequently described as low grade or high grade. Low-grade tumors are slow growing, contain a few mitotic cells, and show no evidence of necrosis or vascular proliferation. Although they are less malignant than high grade tumors, their progress may go undetected for some time, causing major damage to adjacent tissue. High-grade tumors are rapid growing, contain multiple mitotic cells, and show evidence of necrosis and endothelial and vascular proliferation.

Assessment

Children with a suspected CNS tumor require a thorough physical and neurologic examination. The clinical presentation of a child with a CNS tumor depends on the size and location of the tumor and the child's age and developmental stage. Most brain tumors in children arise in the posterior fossa and result in initial symptoms associated with increased intracranial pressure (ICP) and hydrocephalus caused by compression of the fourth

TABLE 22-3

Types of CNS Tumors

Type	Description	Assessment	Interdisciplinary Interventions
Cerebellar astrocytoma	<p>Accounts for 15% to 25% of all types of astrocytomas</p> <p>Occurs most often during the first decade of life, with a peak incidence at age 5 to 8 years</p> <p>Two types: classic or pilocytic</p>	<p>Insidious onset, slow progression, most symptomatic for 2 to 7 months (some possibly several years) before diagnosis</p> <p>Majority presenting with symptoms of increased ICP</p> <p>Focal neurologic signs such as ataxia, nystagmus, and head tilt</p> <p>Decreased muscle tone, abnormal reflexes, and speech characterized by pauses between syllables (scanning speech)</p>	<p>Surgical resection</p> <p>Radiation therapy only if residual tumor exists</p> <p>Chemotherapy not useful; typically reserved for recurrent or progressive tumor growth or as adjunct therapy for children with high-grade astrocytomas</p>
Cerebral astrocytoma	<p>Grading as high (highly malignant) or low</p> <p>Accounts for approximately 25% of all types of astrocytomas</p> <p>Located in cerebrum; infiltrative</p> <p>Prognosis favorable with complete surgical resection, minimal neurologic deficits postoperatively, low-grade tumor, and slower onset of symptoms; poorer prognosis than cerebellar astrocytomas</p>	<p>Initial symptoms variable with tumor location within cerebrum; symptoms progressive and increasing</p> <p>Nonspecific and nonlocalizing signs of increased ICP (75% of children regardless of tumor location)</p> <p>Papilledema (edema of the optic nerve) common at diagnosis</p> <p>Grand mal-type seizures (in 25% of children)</p>	<p>Complete resection difficult (location of tumor dictating extent of surgical resection possible)</p> <p>Preoperative anticonvulsant therapy</p> <p>Adjunctive radiation or chemotherapy (under investigation in national clinical trials)</p> <p>Radiation delayed until evidence of recurrence appears</p>
Medulloblastoma	<p>Cerebellar tumor composed of medulloblasts (undifferentiated neural tube cells)</p> <p>Usually located in the midline of the cerebellum; possibly occurring in cerebellar hemispheres</p> <p>Most common primary posterior fossa tumor (approximately one in five cases of childhood brain tumors [National Cancer Institute, 2006])</p> <p>Peak incidence at age 5 to 7 years</p> <p>Have highest rate of extraneural (outside CNS) spread with bone and bone marrow accounting for 80% of metastatic sites; also possible spread to lungs, liver, and lymph nodes</p> <p>Children younger than age 3 years frequently with poorer prognosis; children older than 3 years who undergo surgery and total neuraxis (brain and spine) radiation with better chance of long-term survival than those younger than 3 years and in whom the entire tumor was not removed and the disease has spread to other areas of the body (National Cancer Institute, 2006)</p>	<p>Symptomatic for less than 2 months before diagnosis resulting from rapidly growing tumor and location in the posterior fossa</p> <p>Initial symptoms associated with increased ICP:</p> <ul style="list-style-type: none"> -Headaches, decreased alertness, visual disturbances, irritability, seizures and motor impairment -Progressive lower extremity ataxia as tumor enlarges and displaces surrounding brain tissue -Diplopia and multiple cranial nerve deficits with pressure and tumor infiltration at the brain stem 	<p>Complete surgical resection</p> <p>CT or MRI at 72 hours postoperatively to evaluate tumor resection</p> <p>Radiation therapy (tumor very radiosensitive) routinely to entire brain and spine</p> <p>Chemotherapy in high-risk cases, such as when child has recurrent disease, and in very young children (younger than age 2-3 years) to delay the use of radiation to the brain</p>

TABLE 22-3

Types of CNS Tumors (Continued)

Type	Description	Assessment	Interdisciplinary Interventions
Brain stem glioma	<p>Accounts for 10% of all CNS tumors</p> <p>Median age of occurrence is 5 to 9 years</p> <p>Pons the most common site of occurrence, although tumors can also arise in the medulla or midbrain (Rosenblum, 2005)</p> <p>Poor overall prognosis; survival rate less than 10% with a median survival time of 2 years (Rosenblum, 2005)</p>	<p>Insidious onset of symptoms, with a duration of approximately 3 to 5 months</p> <p>Characteristic triad of signs and symptoms arising from early interference with the functioning of the cranial nerve nuclei, pyramidal tracts, and cerebellar pathways</p> <p>Paresis of conjugate gaze (eye movement not in unison); most important sign for localizing the lesion; occurring in more than half these children</p> <p>Pyramidal tract involvement (present in 80%–90%); possibly masked by the more obvious ataxia or may present chiefly as subtle changes in gait, handedness, or posture of an extremity; hemiparesis and bilateral reflex changes</p> <p>Cerebellar pathway signs: horizontal nystagmus (in almost one third of cases) and truncal and extremity ataxia, indicating involvement of corticopontocerebellar fibers running through the brain stem</p>	<p>Most nonresectable because of location</p> <p>Radiation (main treatment modality)</p> <p>Adjuvant chemotherapy not used because of unproved efficacy; possible use for palliation</p> <p>Biologic response modifiers (BRMs) used</p>
Ependymoma	<p>Third most common infratentorial tumor</p> <p>Accounts for 5% to 10% of posterior fossa tumors; highest incidence among children during first 7 years of life (Blaney, Kun, Hunter, et al., 2006)</p> <p>Arise from ependymal cells</p> <p>Histologically two types: low grade (highly cellular, with a characteristic pattern of rosettes around blood vessels) and high grade (anaplastic ependymomas with rosette formation and necrosis, mitoses, and increased cellularity)</p> <p>Survival variable from several months to 10 years or longer; children with complete resection have best prognosis (Blaney, Kun, Hunter, et al., 2006)</p>	<p>Average duration of symptom: 2 to 3 months. Symptoms variable based on tumor location</p> <p>If tumor in posterior fossa, increased ICP, with papilledema most common</p> <p>If tumor supratentorial, local motor weakness, visual disturbances, and seizures</p>	<p>Complete resection followed by radiation</p> <p>Total and near-total resections more easily achieved in supratentorial tumors; such resections less common in the posterior fossa as a result of common infiltration of brain stem and higher operative morbidity</p>

Other source: Watral (2008).

ventricle. The most common complaint in children older than age 2 years associated with increased ICP is headache (see Chapter 21). Activities such as straining with a bowel movement, coughing, or, in severe cases, changing the position of the head causes the headache to worsen. However, the occurrence of a headache does not always fit the classic picture of headache associated with increased ICP. The head pain may be more vague and nonspecific.

Alert! Any headache associated with vomiting or lethargy should be evaluated immediately by a physician to rule out increased ICP.

An array of symptoms specific to certain tumor locations assists the healthcare team in localizing the particular tumor region in the brain (Chart 22–2).

Diagnostic Tests

Initial evaluation for a child with a suspected brain tumor can be achieved by either CT or MRI. A CT scan is more appropriate for children in whom sedatives are contraindicated—for example, children with increased ICP, a history of seizures, or changes in neurologic status. When performed with and without contrast, CT can detect 95% of CNS tumors. MRI is the image of choice for a medically stable and cooperative child because of its safety and its ability to collect detailed information. Because of its ability to image in three planes, MRI is particularly useful in diagnosing infiltrative tumors of the brain stem. The presence of calcification, hemorrhage, or cysts may assist in identifying certain types of tumors. Sedation and analgesia or general anesthesia may be used to keep the infant or younger child quiet and calm during the procedure. Positron emission tomography, where available, is also used to image the tumor and assess its level of activity.

A lumbar puncture is usually performed to obtain cerebrospinal fluid for analysis when no signs of obstructive hydrocephalus or increased ICP are present (see Fig. 21–9). The fluid is tested for the presence of tumor cells as well as for decreased sugar, increased protein, and increased enzymes.

Nursing Diagnoses and Outcomes

General nursing diagnoses and desired outcomes are presented in Nursing Plan of Care 22–1. In addition, the following diagnosis may apply to the child with a brain tumor:

Risk for injury related to seizure activity

Outcome: Child will remain free of injury during a seizure.

Interdisciplinary Interventions

Complete surgical resection, when possible, is the treatment of choice for children with brain tumors. The location of the brain tumor is the factor that determines the surgical approach and resectability of the mass and surrounding brain tissue. In some instances, a resection is too risky, and a biopsy is done for histologic confirmation.

CHART 22–2 SIGNS AND SYMPTOMS OF BRAIN TUMORS

Infratentorial Tumors (Brain Stem and Cerebellar)

- Increased ICP
- Ataxia (gait, truncal)
- Nystagmus
- Head tilt
- Diplopia
- Cranial nerve deficits
- Hypotonia
- Abnormal reflexes
- Changes in speech
- Hemiparesis
- Positive Babinski sign

Supratentorial Tumors (Tempoparietal, Temporal Lobe, Frontal Lobe, Occipital, Midline)

- Headaches
- Seizures
- Hemiparesis
- Hyperreflexia
- Sensory losses
- Visual disturbances
- Aphasia
- Personality changes
- Growth failure
- Endocrine changes

The child usually requires monitoring in a pediatric intensive care unit for 48 to 72 hours postoperatively (Clinical Judgment 22–2). Frequent assessment of vital signs, neurologic status, and mental status is crucial to identify early signs of increased ICP secondary to cerebral edema. IV steroids are used intraoperatively to minimize edema of the brain tissue. Anticonvulsants may also be ordered prophylactically to prevent seizures. Children who have hypothalamic, pituitary, or other suprasellar tumors are at high risk for syndrome of inappropriate antidiuretic hormone secretion or diabetes insipidus and should be managed in collaboration with an endocrinologist.

Radiation therapy may be used alone or in combination with surgery. The success of radiation therapy depends on the location and radiosensitivity of the tumor and on the expertise of the radiation oncologist. Young children are at high risk for severe sequelae associated with radiation

CLINICAL JUDGMENT 22-2

Postoperative Care of a Child With a CNS Tumor

Remus, a 4-year-old boy, was brought to his pediatrician with complaints of irritability, headaches, morning vomiting, and clumsiness. Examination of the child revealed papilledema, photophobia, and ataxia. A CT scan was performed that revealed a large mass in the fourth ventricle with significant hydrocephalus. The child was started on steroids overnight and had a craniotomy the next day. The pathologic diagnosis was medulloblastoma. You are caring for the child 3 days after surgery on the pediatric hematology/oncology unit.

Questions

1. What aspects of the physical assessment are of particular importance?
2. Which information might reveal the presence of neurologic compromise?
3. The grandparents come to visit Remus and are overheard telling his mother that no therapy will do any good and that she should just take him home to die. Using your knowledge of medulloblastoma treatment and outcomes, how would you intervene?
4. In anticipation of the child's future needs for chemotherapy and ongoing IV therapy, placement of a central venous catheter (CVC) was completed at the same time as the craniotomy. What are the nursing interventions associated with care of Remus' CVC?
5. Based on the treatment plan of chemotherapy and radiation therapy, what teaching elements will be necessary for the family before discharge?

Answers

1. Vital signs, neurologic assessment, signs of infection, drainage from surgical or external ventriculostomy site, intake and output
2. Decrease in level of consciousness, vomiting, ataxia, major variations between intake and output
3. Reassure the grandparents that successful treatments are available for children with brain tumors. If approved by the child's parents, invite the grandparents to the patient care conference during which the plan for determining the spread of disease and the accompanying treatment plan will be discussed.
4. Assess the CVC for patency and the CVC site for signs of infection; ensure that the dressing is dry and intact. Make sure the CVC is properly secured. Participate in educational interventions with the family to ensure they know all aspects of CVC care and medication administration.
5. A comprehensive teaching plan with the child and family will include assessment of and managing for side effects/toxicities of the treatment regimen (chemotherapy and radiation); medication administration; managing nutritional needs; home care of the CVC managing pain and providing comfort measures; mouth care instruction; and information about neutropenia, anemia, thrombocytopenia, signs and symptoms of infection, and fever precautions.

of immature brains (learning disorders, varying degrees of cognitive challenge). Thus, radiotherapy is not recommended in children younger than age 3 years.

The nurse plays a key role in educating the child and family, and in managing side effects related to radiation therapy, such as nausea, hair loss, and anorexia (Fig. 22-10). It is extremely important that the child lie still during the entire radiotherapy session. Precision is required to maximize the dose of radiation delivered to the tumor and to minimize the effects in surrounding tissue. Very young children require sedation or general anesthesia for each therapy session. Special devices such as soft blocks, Styrofoam molds, tape, and Velcro straps may also be used to immobilize the head and neck. The nurse is responsible for preparing the child for sedation and for monitoring the child's status during sedation and during the recovery period. (See Chapter 10 for an in-depth discussion of sedatives and nursing responsibilities associated with sedation and analgesia.)

The efficacy of chemotherapy in treating brain tumors requires further investigation. Many studies have demonstrated either regression of symptoms or tumor regression with the use of several chemotherapeutic agents that are capable of penetrating the blood-brain barrier. Care of children under going treatment for a brain tumor with either one or a combination of the modes discussed requires collaboration among many disciplines, and clear and effective communication with the family.

ANSWER: CNS tumors usually affect children younger than 10 years of age and osteogenic sarcoma usually occurs during mid adolescence. The CNS tumors and bone tumors have about the same statistical rate of survival—around 65%. For both, the first treatment of choice is surgery and, for both, there is an indication of genetic predisposition.

FIGURE 22–10. A young girl wears a bandanna to conceal her lack of hair.

Community Care

As with most pediatric malignancies, after the diagnostic phase and initial treatment phase (e.g., surgery) are complete and the child is clinically stable, the child is discharged home. Ongoing care for a CNS tumor will include both inpatient admissions and outpatient visits for chemotherapy and radiation treatments (see Treatment Modalities earlier in this chapter for a comprehensive review of interventions to manage complications of therapy, growth and development concerns, and late effects of therapy).

Children with CNS tumors may need additional support such as physical therapy, speech therapy, and other rehabilitative services, depending upon the degree and extent of neurologic loss as a result of the tumor and/or treatment sequelae. Recovery may take weeks or months, depending upon the severity of symptoms the child is experiencing. Some children may never fully regain certain physical and cognitive functions.

LYMPHOMAS

Malignant lymphomas represent the third most common type of childhood cancer. These neoplasms occur in the lymphoid and reticuloendothelial systems, which are widely distributed throughout the body. Hodgkin's lymphoma and NHL are the two major types of lymphomas. Hodgkin's lymphoma is generally fairly localized and can be treated as a solid tumor. NHLs are often disseminated and must be treated as systemic disease.

Hodgkin's Lymphoma

Hodgkin's lymphoma is a lymphoid malignancy that arises from a single lymph node or lymph node region. It

accounts for 5% of pediatric malignancies diagnosed in the United States. The annual incidence in the United States is 7.3 per million white children and 5.2 per million black children younger than age 15 years. The exact cause is unknown, but epidemiologic studies suggest an infectious agent. Studies have reported an increased risk of Hodgkin's lymphoma in close relatives, particularly same-sex siblings and twins. Children who have had Epstein-Barr virus are also known to have higher risk for Hodgkin's lymphoma (Gurney & Bondy, 2006). This higher risk may be linked to genetic or environmental factors associated with immunocompetence.

Pathophysiology

The lymphoma spreads by extending to contiguous (connected) lymph node areas. In advanced disease, it disseminates and may involve any organ in the body, but particularly involves the spleen, liver, bones, lungs, and bone marrow. Histologic diagnosis of Hodgkin's lymphoma is determined by the presence of Reed-Sternberg cells. The presence of these cells alone is not diagnostic, however, because similar cells can be seen in infectious mononucleosis, other reactive lymphoid hyperplasias, and other neoplasms. Hodgkin's lymphoma is classified by the predominating cells. The most common classification system for Hodgkin's lymphoma, the Rye classification, lists four types of Hodgkin's lymphoma: (1) lymphocytic predominance, (2) nodular sclerosis (more common in affluent societies), (3) mixed cellularity (more common at younger ages), and (4) lymphocytic depletion (Hudson, Onchi, & Donaldson, 2006). They are listed in relative prognostic order, from best to worst.

Staging is a method of defining the anatomic extent of detectable disease at the time of diagnosis. The standardized staging system for Hodgkin's lymphoma provides prognostic information and serves as the primary rationale for treatment decisions. Children with stage I and stage II lymphoma have 10-year survival rates of more than 90% and relapse-free survival rates of 70% to 90%. Children with stage III lymphoma have 5-year survival rates of 95%. The prognosis for children with stage IV lymphoma continues to improve, with a 5-year survival rate of 80% (U.S. SEER Program, National Cancer Institute, 2009).

Assessment

Characteristically, the first sign of Hodgkin's lymphoma is painless, progressive lymph node enlargement, with two thirds of the cases involving a site above the diaphragm and one third of the cases involving a site below the diaphragm. Other signs and symptoms vary according to the sites of the enlarged nodes, resulting in local tissue compression. For example, mediastinal lymphadenopathy may produce a persistent nonproductive cough. Signs and symptoms of Hodgkin's lymphoma include

- Cervical or supraclavicular lymphadenopathy (60%–90% of cases)
- Painless, firm nodes that are movable in surrounding tissue

- Hepatomegaly, splenomegaly, or both in generalized disease
- Anorexia
- Weight loss
- Malaise
- Lethargy
- Night sweats
- Fever in 30% of cases; intermittent elevations of 1 to 2 °C above normal

Certain systemic symptoms are considered prognostically important. Children with unexplained weight loss of more than 10% during the past 6 months, unexplained fever with temperatures of more than 100.4°F (38°C), or night sweats are classified “B” in the staging procedure. The absence of these symptoms places the child in the “A” classification. The percentage of children with B classification increases in advanced disease.

Diagnostic Tests

Diagnostic evaluation of the child with suspected Hodgkin’s lymphoma involves many tests and studies including a complete blood count; erythrocyte sedimentation rate; serum copper, liver, and renal function tests; alkaline phosphatase assay; baseline thyroid stimulating hormone; and free T4 measurement. Bilateral bone aspiration and biopsy are completed to assess for the presence of leukemia. Posteroanterior and lateral chest radiographs, chest CT scan, gallium scan (optional), bone scan (optional), abdominal and pelvic CT scan, and MRI are utilized to determine location and extent of lymph node and organ involvement. Surgical biopsy of the involved site is necessary to analyze tissue for histologic, morphologic, cytogenetic, immunophenotypic, molecular, and enzymatic properties.

Interdisciplinary Interventions

The goal of treatment is to cure the child of the disease while minimizing treatment-related toxicities. Children with localized lymphoma may be treated with radiation therapy alone. However, most children are treated with both radiation and chemotherapy (Yahalom, 2006). Radiation treatment may be involved field for localized lymphoma (radiation limited to areas of confirmed lymph node involvement) or extended field for advanced disease (treatment of adjacent uninvolved lymph node regions). In unfavorable or advanced disease, the child may receive total nodal radiation. When possible, radiation therapy is delayed until the child is 8 years old to prevent retardation of bone growth and soft-tissue development. Chemotherapy is the primary treatment in advanced disease.

Community Care

Care of the child at home focuses on managing side effects of therapy (e.g., nausea, vomiting, risk for infection) and supporting the child’s desire and ability to maintain normal developmental activities. The Treatment Modalities section discusses such issues as reentry into school and coping with the psychosocial effects of

the diagnosis of cancer on the child, parents, and siblings. Most relapses of Hodgkin’s lymphoma occur within 3 years of diagnosis (Androkites, 2008). Thus, the need to ensure the child completes all chemotherapy and radiation treatments is paramount, as is the need to be evaluated on a regular basis to ensure no relapse has occurred, and the child and family are coping adequately with the diagnosis, treatment, and long-term outcomes.

Non-Hodgkin’s Lymphoma

NHL is a malignant disorder of the lymphocytes that affects the cells and organs of the immune system. Generally there is rapid onset, with widespread disease noted at the time of diagnosis. Peak incidence occurs at age 7 to 11 years. Incidence in boys is three times that in girls. The highest incidence rates of NHL exist in the United States and Canada (U.S. SEER Program, National Cancer Institute, 2009). A higher incidence of NHL has been noted in several population groups, specifically individuals infected with HIV or Epstein-Barr virus and those with congenital immunodeficiency syndromes such as Wiskott-Aldrich syndrome, Bloom syndrome, and severe combined immunodeficiency syndrome. In addition, patients whose immune systems have been suppressed with medications for other illnesses have a higher risk for this cancer (Gurney & Bondy, 2006; National Cancer Institute, 2008a).

Tumor burden (the number and size of tumors present determined by laboratory analysis of lactate dehydrogenase, uric acid, and lactic acid) at the time of presentation is generally considered the most important prognostic factor. Current staging systems do not accurately reflect tumor burden. Whether disease is localized or advanced is also important. For instance, CNS involvement is thought to be a poor prognostic indicator. The 5-year survival rate in children is 86% (U.S. SEER Program, National Cancer Institute, 2009).

Pathophysiology

In NHL, the malignant cells appear undifferentiated, and the pattern of infiltration is diffuse. The disease has a rapid onset and presents with widespread involvement. NHL is believed to result from genetic aberrations that influence cell proliferation, differentiation, and cell death (Androkites, 2008). The World Health Organization classifies NHL by histology into four types: (1) lymphoblastic lymphoma; (2) small, noncleaved cell (Burkitt’s or Burkitt-like lymphoma); (3) diffuse large B-cell lymphoma; and (4) anaplastic large-cell lymphoma. A staging system is also used to identify the extent of the disease and thereby dictate the extent and duration of therapy (Chart 22–3).

Assessment

Because most lymphomas are generalized at the time of diagnosis, most children are diagnosed with stage III or IV disease. The most common sites of nodal involvement are intra-abdominal, mediastinal, peripheral nodal, and nasopharyngeal. The course of symptoms is generally

CHART 22-3 STAGING FOR NON-HODGKIN'S LYMPHOMA

Stage I

- A single tumor (extranodal) or single anatomic area (nodal) with the exclusion of mediastinum or abdomen

Stage II

- Single tumor in only one area and in the lymph nodes around it or
- Two or more nodal areas or two single extranodal tumors on same side of the diaphragm or
- Tumors started in the stomach or intestines, with or without associated mesenteric node involvement

Stage III

- Two single extranodal tumors on opposite sides of the diaphragm
- Two or more nodal areas above or below the diaphragm
- Tumors that originate in the chest, in more than one place in the abdomen, or in the area around the spine

Stage IV

- Any of the previous entries with initial involvement in the bone marrow, brain, or spinal cord (National Cancer Institute, 2006).

brief, ranging from a few days to a few weeks. Signs and symptoms vary, based on the cell type or histologic appearance and the specific organs involved (Table 22-4). For example lymphomas in the abdomen would produce symptoms such as abdominal pain, nausea, vomiting, changes in bowel patterns, and abdominal distention.

Alert! Intussusception (telescoping of the bowel) may be caused by lymphoma. As a rule, symptoms of intussusception in children older than age 5 years are highly suspicious for NHL.

Although lymphomas in the mediastinum would lead to symptoms of wheezing, stridor, dysphagia, and superior vena cava syndrome, bone marrow involvement would cause pallor, anemia, or thrombocytopenia.

Diagnostic Tests

Diagnostic studies include complete blood count; renal and liver function studies; serum electrolytes, calcium, phosphorus, magnesium, lactate dehydrogenase, and uric acid determinations; Epstein-Barr virus titers; urinalysis; chest radiograph; bone marrow aspirate; cerebrospinal fluid cytologic study; and diagnostic images of the involved tumor sites—in particular, CT studies of the head and neck, chest, or abdomen. The stage of disease has important implications, both for prognosis and for selecting optimal therapy.

Accurate staging of lymphomas is extremely important in determining the extent of disease and ensuring that the appropriate treatment regimen is used. The staging system in childhood NHL generally reflects the tumor burden.

In stage I childhood NHL, cancer is found in a single area or lymph node outside the abdomen or chest. In stage II childhood NHL, cancer is found in only one area and in the lymph nodes around it, in two or more areas or lymph nodes on one side of the diaphragm, or in the stomach or intestines and has been completely removed by surgery. The lymph nodes in the area may or may not have cancer.

In stage III childhood NHL, cancer is found in areas or lymph nodes on both sides of the diaphragm, beginning in the chest, in more than one place in the abdomen,

TABLE 22-4

Clinical Presentation of Non-Hodgkin's Lymphoma

Type	Common Clinical Presentation
Lymphoblastic lymphoma (30%–40% of all cases)	Mediastinal mass, pain, cough, wheezing, dysphagia, dyspnea, tracheal compression, tachypnea, pleural effusion, supradiaphragmatic lymphadenopathy; superior vena cava syndrome (swelling in the back, neck, and upper extremities); respiratory distress; propensity for rapid spread to bone marrow, CNS, and gonads
Burkitt's or Burkitt's-like lymphoma (40%–50% of all cases)	Abdominal primary; tumor lysis syndrome (increased uric acid and lactate dehydrogenase); jaw tumor (African); propensity for spread to bone marrow and CNS; tumor burden may be massive May mimic appendicitis; intussusception; ovarian, pelvic, or retroperitoneal masses; ascites, pain, or swelling; nausea, vomiting, GI bleeding; lymphadenopathy of the inguinal or iliac regions
Diffuse large B-cell lymphoma	Two thirds of cases present with advanced disease, most commonly in the abdomen Lymph node involvement Bone marrow, mediastinal, and CNS disease are not common
Anaplastic large-cell lymphoma (8%–12% of all cases)	Hepatosplenomegaly, fever, weight loss Involvement of peripheral, intrathoracic, or intra-abdominal lymph nodes Bone involvement common

or in the area around the spine. In stage IV childhood NHL, cancer is found in the bone marrow, brain, or spinal cord. Cancer may also be found in other parts of the body (National Cancer Institute, 2006).

Stages I, II, and III have relatively clear-cut definitions, whereas stage IV has substages based on the extent of bone marrow involvement. Much controversy surrounds these designations, because more than 25% blasts in the bone marrow usually is classified as ALL rather than as lymphoma. Stage IV NHL is commonly defined as “bulky disease,” as evidenced by large amounts of tumor and less than 25% blasts in the bone marrow.

Nursing Diagnoses and Outcomes

Nursing diagnoses applicable to the child with cancer are presented in Nursing Plan of Care 22–1. In addition, the following diagnosis may apply to the child with NHL:

Impaired urinary elimination related to the effects of tumor lysis syndrome

Outcome: Child will be free from complications of fluid and electrolyte imbalance and renal failure related to tumor lysis syndrome.

Interdisciplinary Interventions

The intensity and duration of therapy are directly related to the extent of disease. Children in stages I and II with a relatively low tumor burden generally require briefer and less intense therapy. Children in stages III and IV with a higher tumor burden require more aggressive and longer term therapy.

Alert! As tumor burden increases, as in advanced disease, so does the likelihood of spontaneous or therapy-induced tumor lysis syndrome.

Tumor lysis syndrome may present before the initiation of therapy and often worsens after chemotherapy is begun (see Nursing Interventions 22–6 for a summary of the management of tumor lysis syndrome).

Neuroblastoma

Neuroblastoma is a tumor that primarily occurs in infants and young children. Composed of cells that are very similar to those of the sympathetic nervous system, the tumor can be found anywhere that sympathetic nervous tissue is present. Neuroblastomas most commonly occur on the adrenal gland.

Neuroblastoma is the fourth most common childhood cancer, accounting for 8% to 10% of all childhood tumors (D’Andrea, 2008). It is the most common tumor found in children younger than 1 year of age. Neuroblastoma occurs slightly more in males than females and most frequently in white children (National Cancer Institute, 2008b). The overall 5-year survival rate for children diagnosed between 1996 and 2004 was 69.7%. Two well-known factors predict a favorable prognosis for children with neuroblastoma. Children younger than 1 year who are in stage I, II, or IVS (see Staging) have a favorable prognosis. Children with

these stages characteristically demonstrate disease-free survival rates ranging from 70% to 100% (U.S. SEER Program, National Cancer Institute, 2008).

The cause of neuroblastoma remains relatively unknown. Epidemiologic studies do not have sufficient statistical power to provide evidence of any certain etiologic risk factors.

Pathophysiology

Neuroblastoma is a solid commonly encapsulated tumor that is usually composed of small round cells (rosettes) surrounding a region of neural or ganglion cells. Neuroblastoma may occur at a primary site only, or it may metastasize to other sites, including the bone marrow. Neuroblastomas often secrete two catecholamine metabolites: homovanillic acid and vanillylmandelic acid. These metabolites can be found in the child’s urine (Tradition or Science 22–3).

The International Staging System for Neuroblastoma is the commonly used staging system. Stage I reflects localized minimal disease. Stage II involves incomplete

TRADITION OR SCIENCE 22–3

Is urine catecholamine metabolite screening effective in detecting neuroblastoma?

EVIDENCE-BASED PRACTICE

In Japan, research was conducted to determine whether screening infants by analyzing urine samples could detect neuroblastoma preclinically. These studies indicated that in many children, such screening could detect neuroblastoma before the presentation of any other clinical signs (Sawada, 1992). However, current data do not support neuroblastoma screening. Similar studies conducted in other countries evaluated the effectiveness of screening at ages 3 weeks, 6 months, and 1 year. Screening detected many neuroblastomas that would never have been detected clinically, because apparently the tumors would have spontaneously regressed, as is known to happen with many neuroblastomas. The findings from these studies showed that screening caused no reduction in the incidence of advanced-stage neuroblastomas with unfavorable biologic characteristics in older children, nor did it reduce the number of deaths from neuroblastoma in infants screened at any age (Schilling et al., 2002; Takeuchi et al., 1995; Woods et al., 2002). The National Cancer Institute has completed a PDR (Physician Data Query) analysis of the available literature on this topic and concluded that screening infants for neuroblastoma results in overdiagnosis (diagnosis of some neuroblastomas detectable by mass screening that would not have been clinically diagnosed later). This leads to unnecessary diagnostic and therapeutic procedures with consequent physical and psychological morbidity, including death from treatment complications. There is no evidence from controlled studies or randomized trials of decreases in mortality associated with catecholamine metabolite screening (National Cancer Institute, 2008).

gross total resection and ipsilateral lymph node involvement. Stage III is used when the tumor crosses the midline and includes contralateral lymph node involvement. Stage IV refers to disseminated disease to the bone, lymph nodes, bone marrow, liver, and perhaps organs. Stage IVS is a type of neuroblastoma in neonates that is disseminated to all areas except the bone, which occurs briefly and subsequently spontaneously regresses.

Assessment

The signs and symptoms of neuroblastoma depend primarily on the site of the primary tumor and the extent to which it has metastasized to other sites (i.e., bone marrow involvement). The most common site is the abdomen. Less common sites include the thorax, neck, and pelvis. Metastases are found in approximately 60% of newly diagnosed children, accounting for the poor prognosis rates associated with this disease (D'Andrea, 2008). Bone pain, spinal cord compression, neurologic deficits, and abdominal pain may all be present, depending on tumor size and location. Sphenoid bone and retro-orbital involvement can cause ecchymosis of the eyelids and **proptosis** (protruding eyeballs). The child has a “raccoon-eyed” presentation and may appear to be abused (Fig. 22–11). Manifestations of other bone involvement may cause limping or refusal to walk.

Analysis of the urine for excessive amounts of the catecholamine metabolites vanillylmandelic acid and homovanillic acid is useful in the diagnosis of neuroblastoma.

Interdisciplinary Interventions

To provide an optimal chance of cure, multimodal treatment is based on the stage and important prognostic

FIGURE 22–11. Metastasis of neuroblastoma to the periorbital area can cause a child to have a “raccoon-eyed” or bruise-like presentation around the orbital area.

indicators at diagnosis. Surgery plays a major role in treatment, as does diagnosis. When the tumor is localized, complete surgical resection may be feasible and is often curative. Children with disseminated disease are poor candidates for surgery. In these cases, chemotherapy is the primary treatment method. Chemotherapy may render a large tumor resectable, allowing for the possibility of a delayed or second-look surgery to remove the remaining tumor. Radiation may be used for local control of the tumor or for local palliation of metastatic disease. Children with more advanced neuroblastoma (unresectable or metastatic disease) undergo aggressive chemotherapy and radiation, as well as autologous HSCT and biotherapy.

The child with neuroblastoma requires general oncology supportive care, similar to that previously discussed. Such care includes psychosocial support, teaching, and physical preparation for procedures, surgery, side effects of chemotherapy, and radiation therapy in standard doses or in the higher doses associated with HSCT. Because of this tumor’s commonly poor prognosis, every treatment option is offered to the child and the family.

Wilms’ Tumor

A primary tumor of the kidney, Wilms’ tumor accounts for 6% of cancers in children younger than age 15 (U.S. SEER Program, National Cancer Institute, 2009). The majority of cases are diagnosed before the age of 5 years. The average age at diagnosis is 2 to 3 years. Wilms’ tumors are rare after the age of 10 years. Approximately 500 new cases of Wilms’ tumor occur each year, with a slightly higher than average incidence in black children and females. Five-year survival rate is 92% of all children with the disease (U.S. SEER Program, National Cancer Institute, 2009). Recurrence of disease is possible and most often occurs in the lungs.

Most cases of Wilms’ tumor occur without any genetic predisposition. However, there are a number of congenital anomalies and genetic conditions that are associated with an increased risk of developing a Wilms’ tumor, such as Beckwith-Weidemann syndrome (macroglossia, omphalocele, and visceromegaly), WAGR syndrome (Wilms’ tumor, aniridia, genitourinary abnormalities, and mental retardation), and sporadic hemihypertrophy.

Pathophysiology

Wilms’ tumor is usually a large, rapidly growing tumor, often very soft and vascular. After surgical resection, the composition of the tumor cells is examined microscopically and determined to be either a favorable or an unfavorable tissue type. The tumor may be present in one or both kidneys, which is a very important prognostic factor. The pathologic staging for Wilms’ tumor ranges from stage I, in which disease is limited to the kidney and allows for complete removal, to stage V, in which bilateral kidney involvement occurs. This staging system is currently recommended by the National Wilms’ Tumor Study Group.

Assessment

A firm, nontender abdominal mass is the most common sign in the otherwise asymptomatic child at the time of diagnosis. Some children may experience abdominal pain, hematuria, or hypertension. The tumor is confined to one side, not crossing the midline as neuroblastoma does. The presence of distended abdominal veins may indicate that the mass is occluding the inferior vena cava.

Alert! If Wilms' tumor is suspected, the abdomen should not be palpated. Palpating the abdomen may cause the tumor capsule to rupture, resulting in tumor spillage. Tumor spillage can change the tumor from stage I to stage II or III, depending on the amount of spillage that occurs.

Interdisciplinary Interventions

Multimodal therapy is recommended for the child with Wilms' tumor. Immediate surgical removal of the affected kidney is imperative, even if pulmonary metastasis is present. The goals of surgery are to remove the tumor without producing hematogenous spread, to prevent rupture of the tumor capsule and subsequent spillage of tumor cells, and to provide a tissue sample for pathologic evaluation to determine spread and staging. Members of the healthcare team have an opportunity to provide preoperative education for the child and the family while they await surgical intervention. Preoperative teaching should include a discussion of other treatment modes that may be used, such as radiation and chemotherapy.

Postoperative care involves pain management and ongoing abdominal assessment to observe for intestinal obstruction and signs of infection, bleeding, or fluid and electrolyte imbalance. This care also involves frequently monitoring the child's blood pressure, because manipulation of or pressure on the kidney or the removal of a kidney may alter renin production and cause hypertension. Postoperatively, the tumor site is highly sensitive to radiation therapy, and adjuvant chemotherapy improves overall survival rates. The intensity and duration of chemotherapy is determined by the completeness of the surgical resection and the extent or staging of the tumor. Most children can be cured of this tumor, and ongoing investigations continue to improve outcomes for children with unfavorable or metastatic Wilms' tumor.

Home care includes ensuring the child attends all healthcare visits and completes the chemotherapy and radiation treatment plan. The Treatment Modalities section discusses management of treatment side effects.

Rhabdomyosarcoma (RMS)

RMS is the most common soft-tissue tumor in children, accounting for approximately 3.5% of the cases of cancer among children birth to 14 years and 2% of the cases

among adolescents and young adults 15 to 19 years of age (National Cancer Institute, 2006). Approximately 350 cases are diagnosed each year in the United States. Almost two thirds of RMS cases are diagnosed by 6 years of age. This tumor is slightly more common in males than females.

The cause of RMS is unknown. However, RMS has been associated with familial cancer syndromes, such as Li-Fraumeni, and with neurofibromatosis. Epidemiologic studies of RMS have demonstrated that maternal use of marijuana and cocaine in the year before the child's birth was associated with increased incidence of RMS in the child; similarly, marijuana, cocaine, and other recreational drug use by the father has also been associated with an increased risk of RMS in the child (Wexler, Myer, & Helman, 2006).

The most important factors associated with prognosis appear to be the location and the extent of disease at the time of diagnosis. Children with no detectable metastases at diagnosis (group I) have much better outcomes than those with widespread disease (group IV). Children with tumors of the head and neck have a better prognosis than those with genitourinary tumors. In most children with localized disease, it is a curable disease when multimodal therapy is initiated. More than 72% of children survive 5 years after diagnosis. Relapses are uncommon after 5 years of disease-free survival (National Cancer Institute, 2006).

Pathophysiology

All sarcomas originate in primitive mesenchymal cells. Mesoderm cells form tissue known as mesenchyme. The mesenchyme cells give rise to fibrous and adipose connective tissue, blood vessels, lymphatic structures, and smooth and striated muscles. Thus, sarcomas can arise in many sites throughout the body. Sarcomas differ histologically and are identified by the mature cell type that they most closely resemble. Rhabdomyosarcomas arise from tissue that resembles striated muscle, and are named for primitive muscle cells called *rhabdomyoblasts*, which are located throughout the body. The tumors occur in four anatomic sites: the head and neck, the genitourinary tract, the extremities, and the trunk.

The International Classification of Rhabdomyosarcoma has identified five broad histologic subtypes of RSM:

1. The *embryonal* type is the most common subtype and has an intermediate prognosis.
2. The *spindle cell* type is a less common variant of embryonal RSM and it generally has a superior prognosis. The spindle cell variant arises disproportionately in the paratesticular region, but may also be seen in the head and neck, extremities, and orbit.
3. The *botryoid* type has a particularly favorable prognosis and tends to arise almost exclusively from the bladder and vagina in infants and young children, or from the nasopharynx in the older children.
4. The *alveolar* type most commonly involves the muscles of the extremities and trunk, and is associated with the poorest prognosis.

CHART 22-4 STAGING OF RHABDOMYOSARCOMA

Stage I: A localized tumor that is completely removed with pathologically clear margins and no regional lymph node involvement.

Stage II: A localized tumor that is grossly removed with (A) microscopic disease at the margin; (B) involved, grossly removed regional lymph nodes; or (C) both A and B.

Stage III: A localized tumor with gross residual disease after incomplete removal or biopsy only.

Stage IV: Distant metastases is present at diagnosis.

From: National Cancer Institute. (2009). *Childhood rhabdomyosarcoma treatment*. Retrieved January 18, 2009, from <http://www.cancer.gov/cancertopics/pdq/treatment/childrhabdomyosarcoma/HealthProfessional/page4>

5. The *undifferentiated sarcoma* is the least common subtype, usually arising in the muscles of the extremities. It also has a poor prognosis.

The histologic diagnosis of RMS is based on the overall cellular pattern and the presence of rhabdomyoblasts with or without characteristic cytoplasmic cross-striations.

The most commonly used staging system (Chart 22-4) for RMS in the United States was developed in 1972 by the Intergroup Rhabdomyosarcoma Study Group. This staging system is based on disease extent and resectability, defining groups I through IV by local disease status, the involvement of regional lymph nodes, and the extent of residual tumor after primary surgery.

Assessment

Signs and symptoms of RMS vary according to the location of the primary site and the presence and extent of metastasis. Presenting symptoms can be caused by the primary tumor, by metastases, or by both. The signs and symptoms are usually attributed to the mass lesion or to obstructive phenomena.

RMS in the head and neck occurs predominantly in the orbit, nasopharynx, maxillary antrum, middle ear, and soft tissues of the scalp, face, and neck. Tumors in the orbit grow rapidly and are usually detected early because of the obvious changes they produce. Evaluation of the eyes may reveal symptoms such as ptosis (with or without lid swelling), exophthalmos, orbital cellulitis, or cranial nerve deficits.

Approximately one half of head and neck RMSs and undifferentiated sarcomas arise in nonorbital parameningeal sites (paranasal sinuses, nasopharynx, and middle ear). Tumors originating in the paranasal sinuses can cause nasal obstruction, chronic sinusitis, epistaxis, swell-

ing, or local pain. Symptoms of nasopharyngeal tumors include hypernasal speech, nasal obstruction, discharge, visible polypoid masses in the nasopharyngeal cavity, and serous otitis. Middle ear RMS can present as chronic otitis media. Symptoms may include mucopurulent or sanguinous drainage from the affected ear, facial nerve palsy, conduction types of hearing loss, or a polypoid mass seen in the external ear canal.

Parameningeal tumors have a high probability of direct extension into the meninges. Multiple cranial nerve palsies occur as the tumor invades the neurovascular sheath. As the tumor extends, it may cross multiple foramina and fissures and invade the epidural space. Intracranial spread can produce symptoms associated with increased ICP, such as headache with vomiting or diplopia. Overall survival rates are drastically reduced when intracranial extension is present.

Within the genitourinary tract, RMS in younger children presents in the urinary bladder, prostate, and vagina. In adolescent males, the tumor occurs in the paratesticular soft tissue or spermatic cord. Tumors of the retroperitoneal area are usually asymptomatic until their growth is quite extensive. At the diagnosis, the child may complain of vague abdominal pain or genitourinary or bowel obstruction. A palpable mass may be present. Local lymph nodes are commonly affected. A tumor arising in the bladder may cause urinary retention, straining to void, hematuria, or passage of tissue in urine. Paratesticular tumors usually present as asymptomatic nontender masses in the scrotum, laying above and separate from the testes. They may be associated with abdominal or pelvic masses resulting from metastasis. Half of all vaginal RMSs are associated with abnormal vaginal bleeding, and the other half are associated with a protruding polypoid mass.

Tumors originating in the extremities are usually deep-seated, palpable masses with soft to firm consistency that may be mistaken for a traumatic hematoma, especially in middle childhood. Tumors are relatively fixed to the underlying musculature and occasionally involve the skin. Sarcomas of the extremity are recognized by swelling in the affected limb. Pain, tenderness, and redness may be present.

Tumors of the trunk are similar to those of the extremities in exhibiting all histologic types and in their tendency for local recurrence and for distant spread despite wide local excision. Tumors of the trunk are of relatively large diameter compared with head and neck and bladder tumors.

RMS that involves the bone can produce pain, swelling, and limited function of the affected body part. Bone marrow metastasis can result in symptoms of pancytopenia such as anemia, bleeding, or infection. Most children with bone marrow involvement have extremity or truncal RMS and have concomitant metastases to bone, lung, or lymph nodes. Primary lesions of the prostate and maxillary sinus are also frequently associated with bone marrow metastasis.

Diagnostic Tests

Before biopsy of a suspected tumor mass, imaging studies of the mass and baseline laboratory studies are obtained to

further delineate the location of the mass and any signs of metastasis. After the diagnosis of RMS has been made, an extensive evaluation to determine the extent of the disease is completed prior to instituting therapy. This evaluation should include a chest radiograph, CT scan of the chest, bilateral bone marrow aspirates and biopsies, bone scan, MRI of the base of the skull and brain (for parameningeal primary tumors only), and CT scan of the abdomen and pelvis (for lower extremity or genitourinary primary tumors).

Interdisciplinary Interventions

Multimodal treatment of RMS has greatly improved long-term survival rates. Surgical resection of the primary tumor usually offers the best prospect for local tumor control in limited disease cases. The addition of radiotherapy and multiagent chemotherapy has decreased indications for radical surgery, allowing more limited surgical intervention or potentially eliminating the need for surgery.

The goal of surgical intervention is complete tumor resection whenever possible. It is always desirable to preserve the child's vital or functionally useful structures or organs. In many cases, however, the location of the tumor, the degree of metastasis, and the infiltration of adjacent organs prohibit complete tumor excision. In combined-method treatment, surgery includes the initial incisional biopsy and evaluation of disease extent. Gross total resection is the most rapid way to eradicate the disease and should always be used if subsequent function or cosmetic appearance will not be greatly impaired.

Community Care

After surgical resection and discharge from the acute care facility, radiation and chemotherapy will continue to be administered to the child. Both overnight and outpatient visits are to be expected to ensure the child receives the optimal combination of therapies. As with other pediatric malignancies, it is important to educate the family regarding neutropenia, anemia, thrombocytopenia, signs and symptoms of infection, and fever precautions (see Treatment Modalities earlier in this chapter).

BONE TUMORS

Malignant bone tumors account for approximately 5% of all childhood malignancies. Most of these tumors occur during adolescence. The two most common bone tumors are osteogenic sarcoma and Ewing's sarcoma. The cause of most bone cancers is unknown.

Osteogenic Sarcoma

QUESTION: How typical is George's experience with osteogenic sarcoma?

Osteogenic sarcoma (OS), also called *osteosarcoma*, is a malignant tumor of the bone derived from osteoid tis-

sue. The most common sites are in the long bones such as the distal femur, proximal tibia, and proximal humerus. Osteogenic sarcoma accounts for approximately 35% of all primary sarcomas of the bone. Peak incidence occurs between age 10 and 20 years, coinciding with the time of rapid bone growth (Link, Gebhardt, & Meyers, 2006).

A genetic predisposition for osteogenic sarcoma has been suggested, with some cases developing in multiple members of the same family. Children with a history of hereditary retinoblastoma have an increased risk for osteogenic sarcoma. The p53 oncogene has been associated with this tumor (Link et al., 2006).

The prognosis for osteogenic sarcoma continues to improve. The most important prognostic factor for osteogenic sarcoma is the extent of the disease. Children with overt metastatic disease have an unfavorable outcome. Other factors that affect prognosis include age (children younger than 10 fare worst; those older than 20 have good outcomes), tumor size (the smaller the size, the better the outcome), and sex (females fare better than males) (Link et al., 2006).

Pathophysiology

Osteosarcoma is characterized by the production and proliferation of malignant osteoid tissue and immature bone. The malignant bone growth of osteogenic sarcoma is detected at the time that bone-forming tissue is growing rapidly during the adolescent years. Five distinct tissue types of osteogenic sarcoma have been described: conventional (most common), periosteal, telangiectatic, multifocal, and miscellaneous. Some of these types are more common and some are more aggressive, factors that assist the healthcare professional in determining the chances for the patient's long-term survival.

Assessment

Most children present with pain in the affected limb that increases with activity or weight bearing. Refusal to walk and limited range of motion are common findings. Tenderness and the presence of local edema or redness may also be noted. The older child should be able to specify the location of the pain. In the younger child, irritability, crying, and decreased movement or locomotion may be the only indicators of a problem. Many times, the diagnosis is made after a traumatic injury in which radiographs reveal the presence of a previously unknown tumor site.

Interdisciplinary Interventions

After diagnosis has been confirmed, surgical intervention is a vital treatment for children with osteogenic sarcoma. Tumor removal, limb salvage procedures, and amputation are all viable surgical options. Limb salvage procedures provide tumor removal while preventing the physical and psychosocial complications that occur with amputation (Fig. 22-12). Amputation is used if no other surgical options will provide the child the best chance of disease-free survival.

FIGURE 22-13. The adolescent undergoing treatment for osteogenic sarcoma can grow to accept changes in her appearance and continue to develop a positive self-image. (Courtesy of Camp Ronald McDonald for Good Times)

ANSWER: For the most part George's presentation and treatment are typical of other patients with osteogenic sarcoma. Note the possibility of familial predisposition. George's mother is certain that her older brother also had osteogenic sarcoma. The most atypical aspect is that George represents the minority of patients (10%–20%) who present with metastasis to the lungs.

Ewing's Sarcoma

Ewing's sarcoma is a highly malignant tumor, primarily of the bone, but it also can arise in soft tissue. These tumors may arise in any bone but are most often located in flat bones (pelvis, chest wall, and vertebrae) and the diaphyseal region of the long bones. It is often seen in the extremities with soft-tissue involvement. Ewing's sarcoma is rare in children younger than age 5 years. The incidence is slightly higher in males. It is most commonly seen in whites and rarely seen in blacks. There is no known hereditary factor (Berstein, Kovar, Paulussen, et al., 2006). The extent of the disease at the time of diagnosis is most important in determining outcome. Children with metastatic disease to the bone, bone marrow, or lungs have a poor prognosis.

Pathophysiology

Ewing's sarcoma is characterized by densely packed, small round cells. Even when the tumor detected is very small, there may be microscopic spread to other areas. Ewing's sarcoma commonly occurs in the pelvis, tibia, fibula, and femur. It is not known what causes Ewing's sarcoma or what cells give rise to it. Approximately 10% to 30% of children have metastases at diagnosis (Betcher et al., 2005).

Assessment

Pain and a soft-tissue mass around the affected bone are the common clinical presentations of Ewing's sarcoma. These signs may be misdiagnosed for some time as an injury related to sports or other physical activities. Children who have metastatic disease may present with anorexia, malaise, fever, fatigue, and weight loss. Other clinical signs depend on the location of the sarcoma.

Diagnostic Tests

In addition to a complete medical history and physical examination, the child with suspected Ewing's sarcoma will have diagnostic evaluation that includes blood tests such as a complete blood count and lactate dehydrogenase levels (LDH). Tissue breakdown elevates LDH and this finding is associated with Ewing's sarcoma and other cancers. Red blood cell sedimentation rate may also be elevated.

Radiograph and imaging tests will include bone scans to detect bone disease and evaluate the causes of bone pain or inflammation, and MRI to secure accurate images of the tumor. A biopsy is also completed to distinguish Ewing's sarcoma from any other type of cancer that may be present and to help examine the morphology of the cancer cells to determine treatment. The biopsy may be done under general anesthesia, and if the tumor is small and in an assessable location, the entire tumor may be removed at this time. If the tumor is too large or cannot be removed without risk to adjacent tissue, then only a portion of the tumor may be removed during the biopsy.

Interdisciplinary Interventions

Surgery, radiation, and chemotherapy are used for primary lesions. Surgery is used to resect the primary tumor while maintaining an intact limb. Amputation is rarely indicated. Local radiation is given to primary and metastatic sites. The use of multiagent chemotherapy improves survival rates and has become the mainstay of therapy. Treatment advances for bone tumors result in more long-term survivors, but also more late effects. Skeletal impairments and the risks of secondary malignancies reinforce the necessity for long-term patient follow-up.

The psychosocial adjustments related to Ewing's sarcoma are usually less traumatic than those seen with osteosarcoma, because in most cases the affected limb remains preserved. A thorough explanation of the side effects of chemotherapy and radiation therapy is still a vital component of the child and family's plan of care. A physical therapy program is often needed to strengthen the affected limb or to assist recovery from orthopedic reconstructive surgery that may be required after the tumor is removed or shrunk.

Retinoblastoma

Retinoblastoma, the most common intraocular childhood tumor, is a malignant tumor composed of embryonal

retinal cells. The incidence is 1 in 16,000 live births in the United States, constituting 11% of cancers in the first year of life, but only 3% of all childhood cancers (National Cancer Institute, 2008). Although the tumor may be present at birth, most tumors (63%) are detected before age 2 years. The average age at diagnosis is 11 months for children with bilateral tumors and 22 months for those with unilateral tumors. Incidence does not vary significantly with sex or race (National Cancer Institute, 2008).

The prognosis in retinoblastoma depends on the location and size of the tumor, and the presence and degree of ocular or extraocular involvement. If the tumor is unilateral and small, and the eye is treated promptly, the long-term survival rate is more than 90% (National Cancer Institute, 2008). After the tumor has extended into the optic nerve, the cure rate decreases to 50%. Children with extraocular extension fare poorly, with a 25% survival rate. Numerous studies have indicated that survivors of retinoblastoma are at increased risk for secondary malignant tumors. These tumors are not associated with the ocular disease but are primary tumors of other organs.

Pathophysiology

Retinoblastoma usually develops in the posterior portion of the retina. The malignancy may appear as a single tumor in the retina, appearing in a rosette formation. The tumor can also have multiple foci that extend locally to adjacent structures or spread distantly. Local extension usually occurs within the intraocular space before invading the structures surrounding the globe. Distant spread, or metastasis, occurs when tumor cells grow along the optic nerve, enter the subarachnoid space, and spread to the CNS. Intracranial extension is the most common cause of death.

The tumor has a tendency to outgrow its blood supply, resulting in necrosis. Calcification appears in necrotic areas, especially in large tumors. The intraocular calcium is readily detected on radiographs and is an important diagnostic sign.

Retinoblastoma occurs in two types: hereditary and nonhereditary. The nonhereditary and unilateral type accounts for 60% of cases, 15% are hereditary and unilateral, and the bilateral hereditary type accounts for 25% of cases (National Cancer Institute, 2008). The nonhereditary type of tumor arises by spontaneous mutation in somatic cells such as retinoblasts. Children with nonhereditary retinoblastoma have unilateral disease and no family history or increased risk of other malignancies. Hereditary retinoblastoma is suspected when a positive family history exists or, in the case of sporadic disease, when the child is affected bilaterally.

caREminder

Because of the strong hereditary influence of retinoblastoma and its ability to be cured during early stages, children with a positive family history should be monitored very closely.

The child should receive a complete eye examination a few days after birth, at age 6 weeks, every 2 to 3 months until age 2 years, and then every 4 months until age 3 years.

Hereditary retinoblastoma arises in one of three ways: inheritance from an affected parent by autosomal dominant transmission, inheritance from a nonaffected gene carrier parent, or acquired as a new germinal mutation from a parent who did not inherit the gene. Children with the hereditary type of retinoblastoma are at increased risk for other malignancies.

The Reese-Ellsworth staging classification is the standard system for prognostic evaluation of retinoblastoma for the extent of intraocular disease (Chart 22-5). The staging system predicts the likelihood of tumor control and preservation of vision, but it does not predict survival. It classifies children with retinoblastoma according to tumor size, number, and location of tumors, and presence of vitreous seeding. No standard staging system exists for disease that has extended beyond the orbit of the eye.

Assessment

The signs and symptoms of retinoblastoma vary according to the stage at the time of diagnosis. When the tumor

CHART 22-5 REESE-ELLSWORTH STAGING CLASSIFICATION OF RETINOBLASTOMA

Group I: Very Favorable Prognosis

- Solitary tumor, smaller than 4 disk diameters,* at or behind the equator
- Multiple tumors, none larger than 4 disk diameters, all at or behind the equator

Group II: Favorable Prognosis

- Solitary tumor, 4 to 10 disk diameters, at or behind the equator
- Multiple tumors, 4 to 10 disk diameters, behind the equator

Group III: Doubtful Prognosis

- Any lesion anterior to the equator
- Solitary tumors, larger than 10 disk diameters, behind the equator

Group IV: Unfavorable Prognosis

- Multiple tumors, some larger than 10 disk diameters
- Any lesion extending anteriorly to the ora serrata

Group V: Very Unfavorable Prognosis

- Tumors involving more than half the retina
- Vitreous seeding

* 1 disk diameter = 1.5 mm.

is small, the child may initially present with strabismus secondary to impaired vision. As the tumor enlarges, a creamy white pupillary reflex, known as *leukocoria*, or *cat's eye*, develops, and the tumor may be visualized easily. Children with red, painful eyes demonstrate late symptoms, resulting from inflammation, uveitis, or vitreous hemorrhage.

Diagnostic Tests

Early detection and diagnosis is extremely important, because early intervention is effective and may preserve the child's vision. Without pathologic confirmation, the diagnosis must be made by the ophthalmoscopic, ultrasonographic, and radiographic appearance. A definitive diagnosis of retinoblastoma can usually be made during a complete funduscopy examination. Pupillary dilation and examination under sedation or general anesthesia are necessary to evaluate the retina fully. The tumors appear as creamy pink or white masses, but they may be obscured by retinal detachment, hemorrhage, or cloudy fluid in the anterior chamber.

Ultrasonography is a particularly valuable diagnostic tool in demonstrating the presence of a mass in the posterior segment of the eye if the fundus is obscured by retinal detachment or hemorrhage. Radiographic identification of intraocular calcium strongly suggests retinoblastoma, because it is extremely rare for any other ocular disorder of childhood to produce such a finding. CT of the orbit is more sensitive than plain radiographic film in detecting the presence of calcium. MRI is usually not necessary but may be helpful in confirming the diagnosis in the absence of calcium.

Nursing Diagnoses and Outcomes

Nursing diagnoses applicable to the child with cancer are presented in Nursing Plan of Care 22-1. In addition, the following nursing diagnosis may be applicable to the child with retinoblastoma:

Disturbed sensory perception: Visual, related to effects of vision loss resulting from tumor location and or compression

Outcome: Child will adapt to receiving visual input from one eye or to blindness if severe bilateral involvement has occurred.

Interdisciplinary Interventions

The treatment plan for a child with retinoblastoma is individually tailored and based on the extent of disease. The following are considered when planning treatment: unilateral or bilateral involvement; evidence of vision or any potential for vision; extent of disease (confined to the globe or extension to the optic nerve); occurrence of orbital, CNS, or distant metastases. Treatment options include surgery, radiotherapy, phototherapy, and cryotherapy.

The surgical intervention in the treatment of retinoblastoma is enucleation, or removal of the eye. Enucleation must be considered in children with severe retinal

disruption with no possibility that sight can be restored, extension of the tumor into the anterior chamber, painful glaucoma with permanent loss of vision, or unresponsiveness to other forms of treatment. A cosmetic disadvantage for children younger than age 3 years is that the orbit ceases to grow normally after an eye is removed. As the face continues to grow, the orbit appears increasingly sunken.

Preparation of the parents for the child's appearance after surgery or radiation is essential. Initially, the child has an eye patch in place that is changed regularly by the ophthalmologist. The orbit and the face are edematous during the postoperative period, making it difficult to fit a prosthesis until the edema subsides. Fitting for a prosthesis usually takes place 3 weeks after surgery unless complications occur.

Radiotherapy is used to control local disease while attempting to preserve vision. Retinoblastoma is known to be highly radiosensitive. Radiotherapy can be administered via external beam or via radioactive applicators. External beam radiation produces the same appearance as surgery, because it interferes with bone growth. Radioactive surface applicators (plaques) are indicated if recurring small tumors remain after external beam therapy, or as initial therapy for small solitary tumors. A surgical procedure is performed to suture the radioactive applicators to the sclera. The device is left in place for 7 days and then removed. The child is placed under general anesthesia for the application and removal of the radioactive devices.

caREminder

The child with radioactive devices is placed alone in a single room to prevent radiation exposure to other children and staff. Staff members follow radiation precautions and wear radiation-sensitive badges to ensure that their exposure is minimal and within the guidelines determined by the National Council on Radiation Protection and Measurements.

Photocoagulation therapy destroys the blood vessels supplying the tumor. It is generally used in conjunction with external beam radiation in tumors in the posterior part of the eye that fail to respond after 4 to 6 weeks of radiation or that recur after radiation therapy. Photocoagulation must be performed under direct visualization and is appropriate for tumors located posterior to the equator. It may also be used for small tumors that are located away from the optic nerve and macula. Photocoagulation is performed with the child under general anesthesia.

Cryotherapy destroys the tumor cells by forming intracellular ice crystals that interfere with the microcirculation of the tumor, ultimately resulting in cell death. Cryotherapy may also be used in conjunction with external beam radiation. The treatment is indicated for small primary or recurrent tumors in the anterior part of the retina or for small recurrences of the disease after radiotherapy has been administered. Cryotherapy does not

require direct visualization of the tumor. Cryotherapy is performed with the child under general anesthesia.

Chemotherapy may be used in cases of metastatic disease. It is administered intravenously or intrathecally. Despite chemotherapeutic treatment, prognosis is poor in the presence of metastatic involvement.

Community Care

After enucleation, the child and family need support and guidance, including postoperative care of the socket, discharge teaching, and information about the prosthesis. The child's family also may need additional support and counseling if the retinoblastoma is hereditary. They may feel guilty for transmitting the defect to their child. The child and family need preparation for the prospect of the child losing vision in the affected eye as well as loss of the affected eyeball. Emphasize that the vision in the affected eye is probably already lost and that the child can still have a normal life with one functioning eye. It is also helpful to show the child pictures of a child with a prosthetic eye. Doing so helps the child and family to picture how the prosthetic eye will look.

Care of the socket includes maintaining a clean, dry dressing or eye pad. The eye pad should be changed daily until the socket is healed. The parents may need additional discharge instructions on cleaning the socket or applying an antibiotic ointment if one is prescribed.

Initial instructions for care of the prosthesis are given by the ophthalmologist, who fits and manufactures the device. The prosthetic eyeball is removed only when cleaning is necessary. It is cleaned by placing it in water that is slightly warmer than room temperature and soaking for several minutes. Parents are instructed by the ophthalmologist in removing and replacing the prosthesis.

The Child With Altered Hematologic Status

Case History

The Johnson family, an African American family, with the twins J. D. and B.J., were first introduced in Chapter 5, and J. D. reappeared in Chapter 19. The boys have an older sister, Shawanda, who is 6 years old and has sickle cell disease. The parents, James and Lanese Johnson, divorced about a year ago. James knew that he had sickle cell in his family; his aunt also has sickle cell disease. Lanese was surprised to discover that she, too, is a carrier of the trait.

Shawanda was diagnosed as a newborn following the state's neonatal screening. She had mild anemia but very few problems until she turned 2 years of age. One evening shortly after her second birthday, she began crying and saying, "Owie," and holding her chest.

Lanese gave her acetaminophen (Tylenol) and encouraged her to drink juice. When Shawanda could not stop crying, they went to the emergency room and then Shawanda was admitted to the hospital. The admitting nurse on the pediatric floor documented the following: temperature of 102.9 °F (39.4 °C), pallor, irritability, mild nasal flaring, tachypnea, and decreased breath sounds. Her oxygen saturation on room air was 89% and her chest radiograph shows bilateral pulmonary infiltrates. Admitting laboratory studies include hemoglobin, 5.7 g/dL; reticulocytes, 24%; white blood cell count, 35,000/mm³. Arterial blood gases revealed pH, 7.44; PaO₂, 78 mm Hg; PaCO₂, 35 mm Hg.

CHAPTER OBJECTIVES

1. Describe how assessment data are used to identify and manage bleeding disorders, hemoglobinopathies, and anemias in children.
2. Discuss the role of the healthcare team in preparing children and families for various diagnostic studies that help to identify and manage hematologic disorders.
3. Summarize the interventions by the healthcare team during transfusion therapy.
4. Discuss the rationale for the interdisciplinary interventions used in managing pediatric hematologic alterations.
5. Describe the nursing care of children with bleeding disorders, hemoglobinopathies, and anemias.

See [thePoint](#) for a list of Key Terms.

A healthy hematologic system is essential to overall well-being. Composed of blood-forming organs, plasma, blood cells, and blood vessels, the hematologic system is responsible for transporting essential elements to, and waste products from, cells throughout the body. The hematologic system plays a crucial role in **hemostasis** (blood clotting), immunity, and heat regulation. Alterations in hematologic status can result in serious illness and death.

The hematologic system in children and adolescents can deviate from normal in a number of ways. This chapter describes the more important of these hematologic alterations. In addition, this chapter provides information to enhance the nurse's role in collaborating with the interdisciplinary healthcare team as they work together to correct or minimize the effects of pediatric hematologic disorders on patients and families.

DEVELOPMENTAL AND BIOLOGIC VARIANCES

QUESTION: Shawanda has sickle cell disease. What blood cells would be affected with her condition?

The hematologic system begins early during fetal development. Blood formation can be detected by the 14th day of gestation. By the third to fourth week of gestation, blood islands are evident in the yolk sac. The peripheral cells of the blood islands become blood vessel walls in the developing embryo, whereas the central cells of the blood islands become the embryo's primitive blood cells. By the fourth week of gestation, circulation is evident.

The liver shows evidence of **hematopoiesis**, the formation and development of blood cells, by the sixth week of gestation and becomes the major site of blood cell production during the prenatal period. The spleen, thymus, and lymph nodes are also engaged in hematopoiesis in the developing fetus.

About the 20th week of gestation, the bone marrow, primarily the bone marrow of the long bones, pelvis, sternum, ribs, and vertebrae, becomes involved in blood cell production. It is the primary site of hematopoiesis during the childhood and adult years (Fig. 23–1).

Stem Cells

The *stem cell* is the earliest stage in the development of all blood cells. Hematopoiesis depends on the stem cell for two major reasons: (1) the stem cell can differentiate to form progenitor (precursor) cells for red blood cells, white blood cells, and platelets; and (2) the stem cell is

Infants and adolescents are especially susceptible to iron deficiency anemia as a result of high growth requirements and dietary deficiencies.

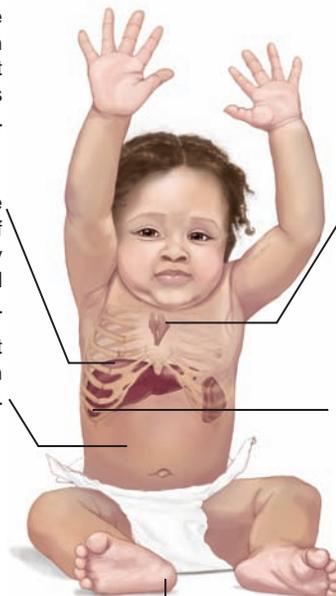

Sickle cell anemia is more common in black children.

Hematopoiesis begins in the liver by the sixth week of gestation and is the primary site of prenatal blood cell production.

The thymus is a site of perinatal hematopoiesis.

The yolk sac is the earliest site of blood cell production in the embryo.

By the 20th week of gestation, the bone marrow becomes involved in hematopoiesis. The long bones, pelvic bones, sternum, ribs and vertebrae are significant sites of blood cell production for children and adolescents.

In most states, newborn screening using a blood sample taken from a heel stick is used to determine the presence of sickle cell anemia.

FIGURE 23–1. Developmental and biologic variances: hematologic system.

capable of self-renewal, providing a continuous supply of the cells required for hematopoiesis. Fetal blood and umbilical cord blood are rich sources of stem cells.

Red Blood Cells

The *erythrocyte* (red blood cell) undergoes several developmental changes as it progresses through the prenatal period to infancy and childhood. These changes include shifts in production rate, life span, appearance, and type of *hemoglobin* (the erythrocyte's oxygen-carrying molecule).

The rate of red blood cell production is relatively high as gestation draws to a close. It decreases after birth, reaching its low point during the neonatal period. Red blood cell production increases somewhat during infancy, again during early childhood, and, for males, during the adolescent years. Those living in high-altitude environments generally produce a greater number of red blood cells and develop physiologic **polycythemia** (an excess of red blood cells).

WORLDVIEW: Ethnic variations exist in red blood cell indices. In particular, black children tend to have lower hemoglobin values than white or East Asian children.

The life span of red blood cells gradually increases with gestational age. Red blood cell survival duration at birth for a full-term newborn is 60 to 70 days. For a premature infant, the red blood cell survival time is briefer, and the amount of decrease is positively correlated with the degree of the infant's immaturity. By the end of the neonatal period, it reaches the normal life span of 100 to 120 days.

Newborns' red blood cells vary in size and shape. These cells are larger and are more likely to be irregularly shaped than the red blood cells of older children and adults.

Hemoglobin is the major component of red blood cells. Normally, it consists of two pairs of globin polypeptide chains. Various types of globin chains exist, differing in their amino acid composition. Hemoglobin F, hemoglobin A, and hemoglobin A₂ are the most common types.

Hemoglobin F, composed of alpha and gamma globin chains, is the predominant hemoglobin during the fetal stage of development and at birth. During the first 6 months after birth, it gradually declines, but it continues to be present in trace amounts throughout life. An excess of hemoglobin F may be associated with hemoglobinopathies, such as sickle cell disease and certain other disorders.

Hemoglobin A, composed of alpha and beta globin chains, is predominant after early infancy, constituting more than 95% of hemoglobin. A deficiency of hemoglobin A is associated with certain forms of sickle cell disease and thalassemia.

Hemoglobin A₂, composed of alpha and delta globin chains, is a minor hemoglobin, constituting only approximately 2.5% of hemoglobin. An increase or decrease in its concentration may, however, contribute important diagnostic information in hematologic disorders such as thalassemia.

Red blood cells experience several phases during their maturation process. Initially, erythropoietin (a hormone) stimulates certain stem cells to commit to the red blood cell lineage. The committed stem cells then sequentially develop into erythroblasts, normoblasts, reticulocytes, and finally red blood cells. Reticulocytes and red blood cells, present in the peripheral circulation, are non-nucleated cells, unlike red blood cells during earlier stages of development.

As previously mentioned, red blood cells have a life span of about 120 days. When the cells die, the iron from the hemoglobin is recycled to make more red blood cells. Sufficient iron is needed to form hemoglobin and thus ensure the red blood cells have enough hemoglobin to carry oxygen to the entire body. As a result of growth requirements, it is essential that children and adolescents have a diet that contains iron-rich foods to ensure adequate intake of iron for hemoglobin production.

ANSWER: Sickle cell disease involves a problem with hemoglobin, which is carried by the red blood cells.

White Blood Cells

White blood cell production begins in the liver at approximately week 5 of fetal development. Additional production occurs in the thymus (8–9 weeks), the spleen (11 weeks), and the lymph nodes (12 weeks). At birth, the number of circulating white blood cells is equal to that found in adults. As with red blood cell development, specific stem cells commit to the various white blood cell lineages: myeloid, monocytic, and lymphoid.

Myeloid Lineage

Stem cells that commit to the myeloid lineage sequentially progress in their development to myeloblasts, then neutrophil/eosinophil/basophil granulocytes or monoblasts, then monocytes, then macrophages. *Bands* or *stabs*, juvenile forms of neutrophils, may increase during times of hematopoietic stress, such as infection. Circulating granulocytes have a short life span of approximately 12 to 14 hours.

After a decline during infancy, the white blood cell differential shows a steadily increasing percentage of neutrophils (also known as *polys* or *segs*). The peak level is achieved during adolescence and continues into the adult years. The percentage of eosinophils and basophils in the differential remains fairly constant throughout the life span (see Appendix F for a summary of all normal laboratory values).

Monocytic Lineage

Stem cells that commit to the monocytic lineage sequentially proceed in their development to monoblasts, promonocytes, and monocytes. Mature monocytes appear in the peripheral circulation for about 12 hours and then enter body tissues. Monocytes phagocytose pathogens,

present antigens, and secrete cytokines. Apart from minor changes during infancy, the percentage of monocytes in the white blood cell differential remains quite steady throughout the life span.

Lymphoid Lineage

Stem cells that commit to the lymphoid lineage sequentially progress in their development from lymphoblast to prolymphocytes to mature T or B lymphocytes. The life span of lymphocytes is variable, ranging from a few days to months or years. After an increase during infancy, the white blood cell differential shows the percentage of lymphocytes gradually decreasing throughout childhood. A plateau occurs during adolescence and remains through the adult years.

T cells, or thymus-derived lymphocytes, are involved in cell-mediated immunity. B cells, or bone marrow-derived lymphocytes, are involved in humoral immunity.

Platelets

Platelets (also called *thrombocytes*) develop from stem cells that commit to the platelet lineage. These committed stem cells sequentially develop into megakaryoblasts, promegakaryocytes, and then mature megakaryocytes or platelets. The number of circulating platelets is relatively constant throughout the life span and ranges from 150,000 to 450,000/mm³ (see Appendix F).

ASSESSMENT OF THE CHILD WITH ALTERED HEMATOLOGIC STATUS

Alterations in hematologic status can affect the function of multiple body systems besides the hematologic system. Thus, when acquiring data during the health history and physical assessment, consider not only the hematologic abnormalities but also how these abnormalities can alter other physiologic processes. Keep normal hematologic developmental and biologic variances in mind when assessing children and adolescents, because what is normal at one age may be abnormal at another age. For instance, the newborn has a higher hemoglobin level than an adolescent (see Appendix F for all laboratory values).

Focused Health History

QUESTION: What additional information would be important for the nurse to obtain when assessing Shawanda's current illness?

A focused health history contributes important information for determining a particular hematologic disorder. Components of this health history are identified in Focused Health History 23-1.

WORLDVIEW: The child's demographic data are important, because some hematologic diagnoses are more commonly associated with a certain age group, sex, race, or geographic location. Examples include iron deficiency anemia (IDA) during late infancy and adolescence, hemophilia in males, sickle cell disease among blacks, and thalassemia among those of Mediterranean ancestry. The child's religious background is important, because some religious groups may not consent to healthcare, or they may refuse specific interventions. Jehovah's Witnesses, for example, may not consent to the use of blood or blood products, even in life-threatening situations. If the patient is a minor and parental consent cannot be obtained, a court order is required to give transfusions.

Because hematologic alterations can affect multiple body sites, ask the family for information that may identify abnormalities involving all body systems. Begin with the birth history and proceed to the child's current age. Ask about bleeding, anemia, and infection. For each occurrence, identify the child's age, prescribed treatment, and subsequent course of events. Note especially instances of abnormal bleeding and delayed wound healing associated with accidental and surgical wounds such as scalp lacerations, circumcision, extraction of teeth, tonsillectomy, and adenoidectomy.

When reviewing childhood illnesses, make particular note of infections, which are frequently responsible for hematologic alterations in children. Note any allergies, which also can cause hematologic alterations, particularly eosinophilia.

The child's nutritional status and dietary habits provide helpful data for assessing and managing hematologic disorders, such as iron deficiency anemia and megaloblastic anemia, that are associated with nutritional deficiencies. The child's environmental history also may be important. For example, exposure to certain chemicals may precede the onset of aplastic anemia, pica may be a sign of IDA and can also be associated with increased lead levels because of heavy metal consumption, and low humidity in the home may lead to **epistaxis**, bleeding from the nose. A child who has lived in or visited other countries may have been exposed to infectious agents not common in the United States. The dengue virus, for example, found in Southeast Asia, Central America, and South America, can interfere with normal hematopoiesis (Kroeger et al., 2004).

The family medical history and the social history provide data that may be important in diagnosing a hereditary hematologic disorder such as hemophilia, von Willebrand disease, sickle cell disease, thalassemia, or hereditary spherocytosis. Inquire about hematologic abnormalities in parents, siblings, aunts, uncles, cousins, and relatives from preceding generations. Note the name or description of the hematologic disorder and the relationship of the affected family member to the child.

When a chronic hematologic disorder such as hemophilia or sickle cell disease has been diagnosed, note the development and management of long-term sequelae, as well as the incidence and course of events associated with acute health problems.

FOCUSED HEALTH HISTORY 23–1

The Child With Altered Hematologic Status*

Current history	<p>Prescribed medications, over-the-counter medications, or home remedies child is taking for a known hematologic condition; note the use of aspirin, aspirin-containing medications, nonsteroidal anti-inflammatory drugs, anticoagulants, or other medications that may alter hematologic status.</p> <p>Time and date of last use of all medications and factor replacement therapy used to treat current condition (e.g., steroids, chelators, factor stimulating products, antifibrinolytic agents, antibiotics)</p>
Past medical history	<p>Prenatal/Neonatal History</p> <p>Prenatal history of mother (for all children); note infections, anemia, nutritional deficiencies, medications, and postpartum hemorrhage</p> <p>History of prolonged bleeding at umbilical cord, circumcision, and injection sites</p> <p>Bleeding from telangiectatic lesions or hemorrhagic bullae</p> <p>Infection, jaundice, anemia during neonatal period</p> <p>Previous Health Challenges</p> <p>Epistaxis or other bleeding episodes and their precipitating events; any other indications of unusual response to injury</p> <p>Surgical procedures (including dental extractions) and traumatic injuries; child's hematologic and immunologic response to those events</p> <p>History of soft-tissue abscesses, cellulitis, wound infections</p> <p>Presence of known HIV infection or other immunologic disorder, leukemia, or malignant tumor</p> <p>Recipient of blood or blood products; note any adverse reactions and if pre-medication was used prior to administration</p> <p>Childhood illnesses contracted including influenza, chicken pox, hepatitis, mononucleosis, or other infectious diseases; note exposure to parvovirus (fifth disease), which may precipitate aplastic crisis in patients with sickle cell disease</p> <p>Immunizations and whether they are up to date</p> <p>Presence of allergies to medicines, foods, latex, plants, animals, pollen, and so on</p>
Nutritional assessment	<p>Inadequate weight gain or unexplained weight loss</p> <p>Decreased appetite</p> <p>Dietary habits indicative of anemia; particularly note intake of milk, meat, and vegetables, vitamin and mineral dietary supplements; particularly note ascorbic acid intake</p>
Family medical history	<p>Family history of unexplained bruising, bleeding, anemia, thrombosis, neutropenia, immune disorder</p> <p>Family history of specific hematologic disorders such as hemophilia, von Willebrand disease, or sickle cell disease</p>
Social history	<p>Exposure to chemicals, such as home treatment to exterminate insects</p> <p>Observed ingestion of lead, lead-based paint; previous lead level evaluation</p> <p>Dehumidifier or low humidity in the home</p> <p>Ethnicity and geographic origin of ancestors</p> <p>Family history of consanguineous marriages or partnerships</p> <p>Beliefs about healthcare; especially beliefs related to the use of blood and blood products</p>
Growth and development	<p>Child's activities for a typical day and any recent changes in these activities (e.g., reduction in activity level or cessation of specific activities)</p> <p>Failure to achieve developmental milestones</p>

*This history is focused on the hematologic system. See Chapter 8 for a comprehensive format.

ANSWER: It would be important to seek additional information about Shawanda's symptoms and the time of their onset. Ask for further details about what was done at home, particularly the amount of fluid she had and the dose and frequency of the analgesic medication (acetaminophen) given. Also, inquire about any changes in her activities that may provide clues to possible factors contributing to Shawanda's current status, such as inadequate fluid intake, exposure to heat and/or humidity or cold, excessive physical activity, travel to high altitude, or exposure to infectious organisms. Keep in mind that, many times, a precipitating factor cannot be identified.

Focused Physical Assessment

QUESTION: Review Focused Physical Assessment 23-1. Would Shawanda's physical assessment reveal external signs and symptoms specific to her sickle cell disease?

Although a specific hematologic disorder is usually identified or confirmed by laboratory studies, the physical assessment contributes important information for determining which laboratory studies are needed and provides data that aid in management of the hematologic disorder.

Pediatric hematologic alterations usually are characterized by

- Atypical hemostasis (bleeding longer than normal)
- **Anemia** (decreased oxygen carrying capacity of the blood caused by abnormally low red blood cell mass, hemoglobin levels, or blood volume)
- **Neutropenia** (abnormally low percentage of neutrophils compared with total white blood cells; decreases a child's ability to fight pathologic bacteria)

These abnormalities may occur separately or together, and because they can affect multiple body systems, physical assessment must address each system. Particular physical alterations may be associated with bleeding disorders, anemia, and neutropenia (Focused Physical Assessment 23-1).

The skin provides valuable information about the hematologic system. Often it is the first site to provide clinical evidence of a hematologic alteration. For example, petechiae and purpuric bleeding that show initially on extremities or mucosa are typical of platelet disorders (Fig. 23-2). Raised **ecchymoses** (blotchy areas of hemorrhage in the skin) are more typical of vascular disorders. Severe bruising to specific areas, such as the head or buttocks, while indicating the need to evaluate the child for possible abuse, may also be signs of bleeding disorders. For example, children with hemophilia often have bruises in areas such as the chest or buttocks.

The complete documentation of physical findings provides information that may point to, or rule out, specific hematologic disorders. Follow-up physical assessment provides information for evaluating the response to treat-

ment and contributes data for planning for ongoing healthcare needs.

For the child with a chronic hematologic disorder, be alert for changes that may occur with disease or long-term treatment. Examples are the onset and development of cardiac abnormalities in the child with chronic anemia secondary to disease, and iron overload caused by blood transfusion therapy.

ANSWER: No, although Shawanda may be smaller for her age and appear pale, she does not have physical signs indicating the presence of sickle cell disease. Her presentation is that of respiratory distress, pain, and fever. It is the laboratory test results and history of sickle cell disease that lead to a diagnosis.

Diagnostic Criteria for Evaluating Hematologic Status

Laboratory studies provide important data for assessing the physical status of the child with a hematologic disorder. Three common hematologic laboratory studies are

1. Coagulation profile (partial thromboplastin time, prothrombin time, platelet count, fibrinogen, and platelet function analysis [or PFA 100]) to determine clotting status
2. Blood cell profile (complete blood count or [CBC] with differential) to evaluate cellular components
3. Bone marrow examination (aspiration and biopsy) to evaluate blood cell development

Alert! Monitor children with a known or suspected hematologic disorder for prolonged bleeding after a blood specimen collection, bone marrow aspiration, or other invasive procedure.

A number of other laboratory studies provide information related to the hematologic system (Tests and Procedures 23-1). The nurse may be responsible for obtaining blood samples. For more specialized procedures such as bone marrow aspiration, the registered nurse provides ongoing monitoring of the child, particularly during sedation, and assists the physician, advanced practice nurse, and clinical laboratory personnel to obtain the specimen and monitor the child's response to the procedure.

caREminder

Assessment of the hematologic system depends on scrupulous techniques for obtaining, transporting, and testing blood or bone marrow specimens. Pay careful attention to ensure that sufficient quantities of specimen are transported in the appropriate container under appropriate conditions. Invalid or misleading levels can result if specimens are not handled properly. Ensure that the correct technique is used to obtain the specimen, including the use of standard precautions.

FOCUSED PHYSICAL ASSESSMENT 23–1

Hematologic System

Assessment Parameter	Alterations/Clinical Significance
General appearance	<p>Fever may be present with infections related to neutropenia.</p> <p>Fatigue, pallor, inadequate weight gain, unexplained weight loss are common signs of anemia.</p> <p>Bleeding, bruising, petechiae are signs of thrombocytopenias, idiopathic thrombocytopenic purpura, and bleeding disorders.</p> <p>Jaundiced sclera may be present with hemolytic anemia, sickle cell disease, thalassemia.</p> <p>Joint and muscle swelling is a sign of hemophilia.</p> <p>Dactylitis, especially in an infant, is a common sign of sickle cell crisis.</p>
Integumentary system (skin, hair, nails)	<p>Easy bruising, petechiae, ecchymoses, purpura; bleeding from wounds, line sites, or invasive procedure sites; telangiectatic lesions, hemorrhagic bullae may indicate thrombocytopenia, ITP, or bleeding disorders.</p> <p>Pallor, jaundice, bronzed skin, waxy skin, spooned nails, lower extremity ulcers may be indications of an anemia.</p> <p>Skin lesions, skin breakdown at skinfolds or perianal area, cutaneous cellulitis, abscesses, wound infections at line sites, procedure sites, surgical sites, or trauma sites may indicate neutropenia.</p> <p>Vascular changes are associated with telangiectasia and hemangiomas.</p>
Head and neck	Frontal bossing is common with thalassemia.
Eyes	Jaundiced sclera can be present with hemolytic anemias, sickle cell disease, thalassemia.
Face, nose, and oral cavity	<p>Pale mucous membranes are present with anemia.</p> <p>Epistaxis (common) and hemoptysis (rare) are associated with bleeding disorders.</p> <p>Angular stomatitis is a sign of anemia.</p> <p>Thrush, sores in oropharynx may indicate neutropenia.</p>
Thorax and lungs	<p>Tachypnea may be present with anemia or infection.</p> <p>Sinusitis, pharyngitis, bronchitis, pneumonia may be signs of neutropenia.</p> <p>Fungal respiratory infections should present a high index of suspicion of neutropenia.</p>
Cardiovascular system	<p>Tachycardia and hypotension are associated with loss of blood in bleeding disorders, decreased hemoglobin level in anemias, and fever and infection in neutropenia.</p> <p>Palpitations, arrhythmias, and murmurs may be associated with anemia.</p> <p>Sepsis or septic shock may be a complication of neutropenia.</p> <p>Enlarged heart and heart failure are associated with anemia.</p>
Vasculature	Swelling proximal to central line sites, presence of collateral blood vessels, or both may indicate thrombosis.
Gastrointestinal system	Enlarged spleen is often present in sickle cell disease, hemolytic anemias.
Lymphatic system	Persistently swollen lymph nodes may indicate neutropenia.
External genitalia and breasts	Delayed development of secondary sex characteristics is common in sickle cell disease and other anemias.
Musculoskeletal system	<p>Short stature and absent or triphalangeal thumbs are associated with Fanconi's and Diamond-Blackfan anemias.</p> <p>Avascular necrosis is often a cause of hip pain in children with sickle cell disease.</p> <p>Joint or muscle swelling, especially after trauma, is associated with hemophilia.</p>
Neurologic system	<p>Headache, scleral or conjunctival bleeding, retinal hemorrhage, intracranial hemorrhage, focal neurologic changes, seizures, and altered level of consciousness may all be associated with bleeding disorders.</p> <p>Headache, dizziness, decreased ability to concentrate, irritability may occur with anemia.</p> <p>Dizziness, decreased ability to concentrate, altered level of consciousness, listlessness, confusion may be associated with infection resulting from neutropenia.</p>

FIGURE 23–2. Petechiae are 1- to 2-mm red or purple spots under the surface of the skin caused by blood leaking from capillary vessels.

Validate that the correct sample amount is secured. The specimen should be appropriately smeared on a slide or placed in the correct specimen receptacle (e.g., blood tube, Microtainer). Last, be sure that the sample is correctly labeled with the patient's name and other identifying data.

Transporting blood samples requires properly preserving the specimens so that accurate test results can be secured. Handle specimens gently to prevent **hemolysis** (destruction of the red blood cells). Place the specimen on ice if appropriate and transport all samples to the laboratory as soon as possible to avoid specimen deterioration.

Laboratory testing of blood samples is conducted by specific criteria to provide reliable test results. However, normal values for some hematologic tests, such as coagulation studies, may vary from laboratory to laboratory, depending on the specific test methodology and the reagents used. To evaluate test results, use the normal values from the laboratory that performed the test. When feasible, use the same laboratory for all testing, for consistent test results.

Whenever blood or bone marrow sampling is required, the nurse has an important role in preparing the child and family. Accurate information about the test's purpose and procedure, and appropriate responses to questions such as “Will it hurt?” help the child and family know what to expect before, during, and after the procedure. Offer topical anesthesia such as LMX or EMLA cream (see Chapter 10). In addition, involve parents in comfort holding, distraction techniques, and developmentally appropriate play to help the child prepare for and cope with the test.

TREATMENT MODALITIES

Primary interventions for the child with a hematologic disorder begin with environmental measures that prevent complications associated with the disorder, such as padding the pant knees for the crawling child to prevent bruising, using good handwashing technique and avoid-

ing crowds for the neutropenic child to prevent infection, and providing dietary modifications for the child with anemia to enhance iron stores. Treatment for children with hematologic abnormalities may involve intravenous transfusion and chelation therapies. In certain circumstances, splenectomy may be required.

Bleeding Precautions

Nursing interventions for the child with a potential for excessive bleeding begins with teaching the child and family measures to prevent bleeding (Nursing Interventions 23–1). Instruct families to provide a safe environment for children with bleeding disorders but also to normalize the environment as much as possible. Review with parents the child's developmental milestones and anticipate sources of injury based on each new developmental stage. Although infancy rarely is a period of stress or bleeding problems, the early childhood stages may expose the child to new sources of trauma and thus, in some cases, reveal the presence of a bleeding disorder. In general, the safety precautions used for all children (Chapters 4–7) apply also to the child with a bleeding disorder. Reassure parents of children with the potential for bleeding that age-appropriate toys are generally safe. Encourage children to participate in age-appropriate physical activities and sports to enhance muscle strength and coordination, and to develop a sense of well-being. Advise parents and children to implement precautions when the child engages in contact sports and any activities that carry risk for injury and trauma (e.g., ice hockey, football). Developmental Considerations 23–1 addresses sports guidelines for the child with a bleeding disorder.

Instruct parents, older children, and adolescents to notify healthcare providers of a bleeding disorder before any invasive procedures to enable use of specific measures to prevent bleeding. Such prophylactic measures include applying pressure for at least 10 minutes after a procedure such as a venipuncture, the use of antifibrinolytics for dental work, and the use of factor replacement therapy for surgical procedures. Good dental hygiene is important to reduce bleeding caused by gingival disease. Children with bleeding disorders are encouraged to wear medical IDs that describe their conditions and treatment.

Fever and pain in children with bleeding disorders are often managed with acetaminophen or acetaminophen with codeine.

caREminder

Aspirin, ibuprofen, and ibuprofen-containing medications, such as Excedrin, Midol, Pepto Bismol, and Percodan, are contraindicated in children with bleeding disorders, because they interfere with normal platelet function.

Control of Hemorrhage

When bleeding occurs, healthcare interventions focus on managing the bleeding promptly. Oral cavity

Tests and Procedures 23–1 Evaluating Hematologic Status

Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Responsibilities
CBC with differential	Determines abnormal loss or destruction of cells that may indicate blood disorders. Changes in values may indicate complications such as anemia, neutropenia, and thrombocytopenia.	Decreases in red blood cell number, size, and hemoglobin content identify anemias. Reduced platelet numbers identify thrombocytopenia. Increased white blood cell number and distribution identify infection; decreased granulocytes and white blood cells suggest neutropenia.	Obtain specimens when child is calm; specimens obtained when child is upset may show increased white blood cell count. Mix blood sample with anticoagulant in tube gently to prevent clotting.
Absolute neutrophil count (ANC)	Measures the number of neutrophil granulocytes (type of white blood cell that fights infection) present in the blood.	The normal range for ANC is 1.5 to 8.0 (1,500–8,000/mm ³). ANC less than 1,000/mm ³ in infants 2 weeks to 1 year or less than 1,500/mm ³ in children older than 1 year indicates neutropenia.	ANC is not measured directly, but is calculated by multiplying the white blood cell count by the percent of neutrophils (segmented [fully mature] + and bands [almost mature]) in the differential white blood cell count. Use good infection control measures during lab draw to protect child from exposure to infection. Advise family of neutropenic precautions if ANC is low (see Chapter 22).
Antithrombin III	Assesses level of antithrombin III.	Normal levels vary with age. Antithrombin III deficiency indicates hypercoagulability, as in genetic antithrombin III deficiency or DIC.	Keep in mind that normal levels vary with age. Fill tube to line with blood; mix gently with anticoagulant in tube to prevent clotting. Transport specimen to laboratory quickly.
Bilirubin fractions	Measures direct (conjugated) and indirect (unconjugated) bilirubin levels.	Elevated levels of unconjugated bilirubin may be associated with hemolytic conditions.	Protect sample from light.
Bleeding time	Screens for platelet function and von Willebrand factor.	When test is done correctly, prolonged time shows that platelets have decreased ability to adhere to blood vessel wall and form a platelet plug.	No longer used routinely in pediatrics because accuracy depends on technician's skill and on child remaining still for more than 5 minutes. As an alternative, use platelet function analysis.
Coagulation Tests			
Activated partial thromboplastin time	Measures intrinsic clotting system, which needs factors VI, VIII, IX, X, XI, XII, fibrinogen, and prothrombin.	Values may be prolonged during heparin administration, in hemophilia, von Willebrand disease, and DIC, and in the presence of circulating inhibitors.	Must be drawn swiftly with a clean venipuncture (no hematoma). May be performed on the same collection tube as prothrombin time and fibrinogen.

Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Responsibilities
			Apply cotton or a bandage to the puncture site if there is any continued bleeding.
Prothrombin time	Measures extrinsic clotting system, which needs fibrinogen, prothrombin, and factors V, VII, and X.	Values may be prolonged in vitamin K-associated factor deficiencies, DIC, during warfarin administration, or in the presence of circulating inhibitors; also in malabsorption, liver disease.	Apply cotton or a bandage to the puncture site if there is any continued bleeding.
Platelet function analysis	Screens for platelet function and von Willebrand disease.	Positive results indicate need for hematology workup.	Be aware that adequate hemoglobin level is needed for test. Send with CBC or hemoglobin and hematocrit.
Coombs test direct (antiglobulin test)	Detects antibodies attached to red blood cells.	Antibody presence helps detect hemolytic disease of newborn.	Handle specimen gently to prevent hemolysis. Transport to laboratory immediately.
Disseminated intravascular coagulation (DIC) profile	Provides data for various indicators of DIC.	Test includes prothrombin time, activated partial thromboplastin time, fibrinogen, platelet counts, thrombin, D-dimer assay for fibrin derivatives. Prolonged or altered values will indicate presence of DIC.	Anticipate need for additional testing; no standard exists.
Factor assays	Detects specific factor deficiencies.	Low level of factor VIII may indicate von Willebrand disease or hemophilia A. Low level of factor IX may indicate hemophilia B. Levels of factors V, VII, X, XI, XII, and XIII, and fibrinogen may also be ordered but are rare.	If sending out for processing, ensure that laboratory knows that samples must be spun and frozen until processed. Apply pressure to venipuncture site for 10 minutes; apply cold pack. Be aware that factor assays do not routinely need to be repeated for patients who have been diagnosed with a factor deficiency.
Folate, red blood cells	Evaluates for folate deficiency.	Low levels present in megaloblastic anemia.	Protect sample from light.
Hemoglobin electrophoresis	Quantifies hemoglobins.	Identifies hemoglobinopathies such as sickle cell disease (+hgb S). Used to confirm positive results from newborn screening for specific hemoglobinopathy.	May be inaccurate if drawn within 4 months of blood transfusion.
Osmotic fragility	Determines presence of spherical red blood cells.	Positive results are diagnostic for spherocytosis.	Check CBC or hemoglobin and hematocrit with test. Low hemoglobin level may give false-positive test results.

(Continued)

Tests and Procedures 23-1 Evaluating Hematologic Status (Continued)

Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Responsibilities
Peripheral blood smear	Identifies morphologic alterations in blood cells.	Shape abnormalities help to detect sickle cells, spherocytes, abnormal platelets, and so forth.	Gently mix blood sample with anticoagulant in specimen tubes to prevent clotting.
Plasminogen activity	Determines plasminogen levels.	Low levels are associated with DIC and thrombosis.	Place collected specimen on ice. Note use of medications that may interfere with normal coagulation. Draw blood for coagulation studies last when more than one blood sample is being obtained.
Protoporphyrins (free erythrocyte protoporphyrins)	Determines levels of iron stores.	Low iron stores identify iron deficiency anemia, lead poisoning.	Note current hematocrit, send with CBC or hemoglobin and hematocrit. Send to lab on ice.
Reticulocyte count	Determines red cell production by the bone marrow.	Low production may be caused by a lack of vitamin B ₁₂ , folic acid, or iron in the diet; or by illnesses affecting the bone marrow such as cancer. The reticulocyte count increases when the bone marrow produces more red blood cells in response to blood loss or treatment of anemia.	Apply cotton or a bandage to the puncture site if there is any continued bleeding. Request CBC to be completed at the same time because the reticulocyte count is dependent on red blood cells.
Ristocetin cofactor	Determines activity of von Willebrand factor present.	Low levels are associated with von Willebrand disease.	Anticipate repeat testing necessary to confirm von Willebrand disease diagnosis. Be aware that stress elevates levels. Send blood type sample along with testing because levels vary by blood type.
Schilling test	Determines whether a vitamin B ₁₂ deficiency exists. Detects pernicious anemia and intestinal malabsorption syndrome.	Low level of vitamin B ₁₂ in urine suggests impaired absorption caused by lack of intrinsic factor. Intestinal malabsorption results in less vitamin B ₁₂ being excreted in urine.	Administer capsule of radioactive 57-cobalt-tagged liquid vitamin B ₁₂ , followed 1 to 2 hours later by administration of an intramuscular injection of vitamin B ₁₂ . Collect urine to determine whether vitamin B ₁₂ is being absorbed normally. If not, less is excreted in the urine. Prepare child in advance for this procedure, including withholding foods and fluids for 4 hours before starting the test. After the test is started, allow the child to eat normally.

Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Responsibilities
Serum ferritin	Identifies levels of iron stores.	Low levels are associated with iron deficiency; high levels are associated with iron overload.	Transport specimen on ice.
Total iron binding capacity and transferrin	Total iron binding capacity evaluates iron binding capacity and levels. Transferrin evaluates levels of circulating iron. The tests are typically drawn and measured at the same time.	Increased levels are associated with iron deficiency anemia, polycythemia vera. Low levels are associated with anemia of chronic disease, hemolytic anemia, sickle cell anemia.	Ensure that the child is fasting in the morning (circadian rhythm affects iron) prior to lab draw. Have sample drawn before child is given therapeutic iron or blood transfusion. Keep in mind that iron determinations in children who have had blood transfusions should be delayed for at least 4 days.
Type and cross-match	Identifies blood type, and presence or absence of Rh factor.	Results aid in matching donor cells with host cells for compatibility.	Be aware of institutional policies for blood typing and cross-matching procedures.
von Willebrand factor antigen	Determines amount of von Willebrand factor present.	Low levels are associated with von Willebrand disease.	Anticipate repeat testing to confirm diagnosis of von Willebrand disease. Be aware that stress causes elevated levels. Send blood type sample along with specimen; levels vary by blood type.
von Willebrand factor multimer analysis	Quantifies amounts of multimers present.	Reduced amount of large multimers assists in determining subtype of von Willebrand disease.	Call laboratory for sample requirements; usually must be sent out to specialty lab.
Vitamin B ₁₂	Assesses levels of serum B ₁₂ .	Low levels identify B ₁₂ deficiency, megaloblastic anemia.	Protect sample from light.
Bone marrow aspiration and biopsy	Aspirated bone marrow is used for microscopic examination of cell type and morphology. Identifies and evaluates specific hematologic disorders.	Abnormalities of cells in fluid or tissue can differentiate between malignant and nonmalignant hematologic conditions.	Know that procedure is done using aseptic technique. Topical anesthetic is used to anesthetize the skin; an injectable anesthetic is used to anesthetize the bone. Prepare the child for the procedure; explain where the sample will be obtained. Position the child properly based on the site of aspiration; place pillows or folded blanket under the child's abdomen to elevate the hips (for iliac crest site). Allow parents to stay in the room during the procedure. Position the parent at the head of the table, allowing the parent to provide verbal and physical support. Do not have the parent help to restrain the child.

(Continued)

Tests and Procedures 23-1 Evaluating Hematologic Status (Continued)

Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Responsibilities
			<p>Provide procedural sedation monitoring for children receiving sedatives and analgesics in a treatment room. The procedure can also be done while the child is in the operating room for biopsy, resection, or line placement. Apply pressure dressing to site after aspiration. Remove dressing and inspect site after 24 hours.</p>

NURSING INTERVENTIONS 23-1

Preventing Bleeding and Controlling Hemorrhage

Signs and Symptoms of Bleeding

- Bruising
- Bleeding from a cut or other wound
- Reddish pinpoint rash on skin or in mouth
- Bleeding from nose or mouth
- Blood in sputum
- Blood in vomit
- Blood in stool
- Black, tarry stool
- Blood in urine (urine may appear tea or coke colored)
- Increase in bleeding with menstrual period
- Intracranial bleeding as evidenced by
 - Headache
 - Vomiting
 - Irritability
 - Seizure
 - Sleeping more than usual
 - Difficult to wake up

Interventions to Prevent Bleeding

- Avoid intravascular, intramuscular, and subcutaneous injections and lab specimen collection.
- Administer intramuscular injections (e.g., immunizations) using Z-track technique; apply pressure and cold for 10 minutes after injection.
- Instruct child to use soft toothbrushes or toothettes for oral care. Rinse and brush teeth after each meal.
- Discourage nose picking, vigorous wiping of the nose, or vigorous nose blowing.
- Avoid rectal procedures (temperatures, suppositories, enemas).

- Promote diet and adjunct therapies to help child avoid constipation.
- Administer oral antifibrinolytic agents before invasive procedures (e.g., dental work).
- Avoid contact sports, heavy lifting, and strenuous activity.
- Shave with an electric razor, not a razor blade.
- Use an emery board for trimming nails, avoid use of nail clippers and/or scissors.
- Teach child and family to avoid activities that can cause trauma.
- Teach child and family signs of bleeding and appropriate actions to take if bleeding occurs.

Interventions to Manage Hemorrhage

- RICE (rest, ice, compression and elevation)
 - Maintain bed rest when child is actively bleeding.
 - Place ice pack over area of bruising.
 - Apply manual pressure over the bleeding area.
 - Elevate the bleeding extremity.
- Apply pressure dressings to a potential bleeding area.
- Assess vital signs.
- Monitor the child's hemoglobin and hematocrit levels before and after blood loss.
- Monitor for signs of persistent bleeding (e.g., blood in secretions).
- Administer factor replacement, DDAVP, or blood products as appropriate (e.g., fresh-frozen plasma, platelets).

DEVELOPMENTAL CONSIDERATIONS 23–1

Sports Guidelines for Children With a Bleeding Disorder

Usually Safe	Riskier and May Be Discouraged; However, Physical and Psychosocial Benefits Likely Outweigh Risks	Risks Outweigh Benefits; Not Recommended
Archery	Baseball	Boxing
Badminton	Basketball	Diving
Fishing	Bicycling	Football
Golf	Bowling	Hockey
Hiking	Cross-country skiing	Motorcycling
Ping-pong	Frisbee play	Racquetball
Swimming	Gymnastics	Rugby
Walking	Horseback riding	Skateboarding
	Ice skating	Wrestling
	Jogging	
	Roller skating	
	Running	
	Soccer	
	Tennis	
	Volleyball	
	Water-skiing	
	Weight lifting	

bleeding can result from injury, tooth extraction, or surgery such as a tonsillectomy. Other areas of bleeding are revealed by ecchymoses, epistaxis (nosebleeds), **hematuria** (blood in the urine), **hematemesis** (vomiting blood), and **hematochezia** (bloody stool, also called *melena*).

First aid for someone with a bleeding disorder is the same as it would be for other children. RICE measures (rest, ice, compression, and elevation; see Fig. 20–21) should be used to treat minor bumps and bruises. Children with a bleeding disorder do not bleed more than others, just longer (Curry, 2004).

Teach the child, family, and school or sports activity personnel how to manage epistaxis: Apply constant pressure for 10 minutes to the soft mid nose, with the head tilted forward, and repeat for an additional 10 minutes if necessary. Instruct the child not to blow his or her nose if it is bleeding. Bleeding that persists after this treatment may require treatment with factor replacement, antifibrinolytic therapy, or both. More severe trauma may require use of a synthetic hormone, desmopressin acetate (DDAVP; see discussion later in this chapter). Teach children and their families the skills necessary to administer DDAVP and factor replacement therapy in the home. Many children with more severe bleeding disorders have central venous access; their families are taught to use these devices to infuse factor doses at home.

Nutritional Therapy

QUESTION: How could nutritional therapy potentially improve Shawanda's well-being?

Several nutrients play important roles in blood cell formation. For example, production and maturation of red blood cells is affected by nutritional intake of iron, vitamin B₁₂, and folic acid.

Iron is essential to the formation of hemoglobin. Iron is also a component of myoglobin, a protein located in muscle tissue, and is also present in enzymes that permit the oxidation of glucose to produce energy for the body. About 80% of iron in the body is available to carry oxygen. The remainder is stored in the body as a protein iron compound called *ferritin* (Lutz & Przytulski, 2006). Vitamin B₁₂ is a coenzyme used in the synthesis of DNA, RNA, and myelin, and is necessary for red blood cell formation. Folic acid is involved in the maturation of red blood cells and is closely involved with the functions of vitamin B₁₂. Without vitamin B₁₂, folic acid is unable to assist in the manufacturing of red blood cells.

Intake of iron, vitamin B₁₂, and folic acid is enhanced by ensuring a balanced, healthy diet that includes foods high in these substances (Chart 23–1). The healthcare

CHART 23–1 DIETARY SOURCES OF IRON, VITAMIN B₁₂, AND FOLATE

Iron

Liver, other red meats
Clams, oysters
Lima and navy beans
Dark-green leafy vegetables
Dried fruit

Vitamin B₁₂

Poultry
Fish
Meat
Eggs
Milk products (e.g., cow's milk, cheese, yogurt)
Fortified breakfast cereals

Folate

Leafy green vegetables (e.g., romaine lettuce, cooked spinach, broccoli, brussels sprouts)
Whole-grain cereals and fortified breakfast cereals
Wheat germ
Legumes
Oranges
Beets
Cooked asparagus
Beef liver

provider may also recommend over-the-counter vitamin supplements as an integral part of the child's home therapy. Acute episodes of sickle cell disease, bleeding associated with hemophilia, and IDA may require increased dosages of these vitamins and minerals, and in some cases (e.g., use of interferon with severe IDA) intravenous administration may be required to replenish depleted stores. Collaborate with the nutritionist to provide family education about dietary sources of these vitamins and minerals, and ensure that parents know appropriate sources and the signs and symptoms of deficiencies.

ANSWER: Shawanda would most likely benefit from a diet high in iron, vitamin B₁₂, and folic acid. Iron is essential to the formation of hemoglobin. Vitamin B₁₂ is important in red blood cell formation. Folic acid is involved in the maturation of red blood cells.

Transfusion Therapy

Transfusion therapy involves the administration of blood or a blood component from a healthy donor to a recipient whose blood has a specific quantitative or qualitative deficiency. Transfusing specific components of blood is routine in pediatrics. It decreases the risk of circulatory overload and allows the donor blood to benefit more than one person in need. The most frequently transfused blood components are packed red blood cells (PRBCs), platelets, and fresh-frozen plasma (Table 23–1).

The primary concern associated with transfusion therapy is safety. Meticulous care is required when obtaining, processing, typing, and cross-matching blood to ensure compatibility between donor and recipient, and to prevent the transmission of disease-causing microbes such as HIV and hepatitis viruses.

Before administration, blood products may be radiated. Radiation interferes with lymphocyte proliferation and prevents transfusion-associated graft-versus-host disease in the recipient who is immunodeficient. Also, blood products are often purposely leukocyte depleted, by means of special microaggregate filters, to minimize the probability of febrile reactions and to decrease the incidence of alloimmunization. PRBCs are occasionally washed to remove residual leukocytes.

Ensuring that the right child is the recipient of any transfused blood product is essential. Adhere carefully to specific institutional policies and procedures when administering blood products to ensure patient safety. When preparing to give blood products, educate the child and family regarding the purpose and procedure of the transfusion.

Be alert for signs and symptoms of a transfusion reaction during and after a transfusion of blood products (Table 23–2). Most transfusion reactions occur during the first 15 minutes of transfusion, so begin the transfusion slowly at first and monitor the child closely. If no transfusion reactions are apparent, increase the infusion rate as appropriate. Continue regular monitoring throughout the transfusion. If a transfusion reaction occurs, stop the transfusion immediately, keep the intravenous line patent with normal saline, monitor the child closely, and notify the physician. Additional interventions depend on the nature and severity of the reaction.

Experiencing transfusion reactions, especially severe ones, is likely to be stressful for the child and family. Be sure to provide emotional support and ongoing progress reports about the child's status.

Exchange Transfusion

Exchange transfusion involves substituting donor red blood cells for recipient red blood cells. During exchange transfusion, small quantities of the recipient's blood are alternately removed and replaced with donor blood until the desired volume of blood has been exchanged.

Clinical situations in which exchange transfusions might be prescribed include the following:

- When the increased blood volume from a simple transfusion might not be tolerated. Examples include the newborn who is at risk for fluid overload and the child with severe anemia who is at risk for heart failure.

TABLE 23-1

Commonly Transfused Blood Components

Product	Indications for Use	Administration
Packed red blood cells	Symptomatic anemia Replacement therapy (e.g., during surgery)	Children usually receive 10 to 15 mL/kg, generally transfused over 2 to 3 hours, with 4 hours being the maximum infusion time. Severely anemic children are at risk for heart failure if PRBCs are given too rapidly. Anemic state must be gradually corrected with separate transfusions.
Platelets	Bleeding associated with thrombocytopenia or platelet dysfunction Preoperatively when thrombocytopenia present High risk for bleeding related to severe thrombocytopenia	Given as quickly as the child can tolerate, usually over 20 to 30 minutes.
Fresh-frozen plasma	Replacement of noncellular coagulation factors	Given as quickly as the child can tolerate, usually over 20 to 30 minutes.

- To decrease the quantity of an abnormal element in the blood or to remove an excessive amount of a normal component. Examples include the child with a severe sickle cell crisis (caused by a large number of sickled red blood cells) and the child with polycythemia.

Exchange transfusion is described in more detail in Chapter 14.

Chronic Transfusion therapy

Chronic transfusion therapy is an ongoing program in which blood transfusions are given at regular intervals (usually about every 3 weeks). Chronic transfusion therapy is used when the benefit—avoiding potentially serious medical complications—justifies the risks of alloimmunization, infection, and iron overload. By regularly providing normal red blood cells, chronic transfusion suppresses production of abnormal erythrocytes. Beta-thalassemia major (Cooley anemia) and certain severe vaso-occlusive crises associated with sickle cell disease are clinical situations in which a chronic transfusion program may be prescribed.

Goals of a chronic transfusion therapy program for children with severe chronic anemia include

- Maintaining a hemoglobin S level between 30% to 50% in children with sickle cell disease
- Providing primary stroke prevention or preventing stroke recurrence
- Treating chronic debilitating pain, pulmonary hypertension, and anemia associated with chronic renal failure
- Increasing the quality of life for children with chronic heart failure
- Delaying the onset of splenomegaly with hypersplenism and the accompanying need for splenectomy

Children receiving chronic therapy are at increased risk for infection from blood-borne viruses; therefore, they should receive immunization against hepatitis A and hepatitis B.

The major complication of an ongoing transfusion therapy program is the development of toxic iron overload, which leads to pathologic changes in body systems, including the hepatic, endocrine, and cardiac systems. Hepatic changes are among the earliest to occur and include fibrosis and cirrhosis. Endocrine changes include pancreatic destruction, which causes insulin-dependent diabetes mellitus, and hormone deficiencies that impair growth and delay the appearance of secondary sex characteristics. Cardiac changes include arrhythmias and heart failure. If iron chelation therapy is not started during early childhood, the cardiac alterations become severe and often lead to death during the teenage years.

Iron chelation therapy, usually started by age 3 or 4, is accomplished with the use of deferoxamine. The drug acts by binding free iron in the bloodstream and excreting it via urine from the kidneys. Deferoxamine is contraindicated for children with severe renal disease. Chelation therapy is prolonged and painful, which makes adherence difficult for many children and adolescents. Safe and effective oral chelating agents such as deferasirox (Exjade) given once daily only recently have been developed (Morris, Singer, & Waters, 2006). Long-term effectiveness at preventing cardiac complications has yet to be established.

KidKare ■ To improve compliance with parenterally administered chelation therapy, combine behaviorally oriented programs with education and include family members.

TABLE 23-2

Transfusion Reactions

	Hemolytic Reaction	Febrile Reaction	Allergic Reaction
Description	Red blood cell destruction that occurs when the blood product is not compatible with the recipient's blood type or when the donor blood contains minor blood group antigens to which the recipient has been previously sensitized (alloimmunized). Reactions can be immediate or delayed.	Not associated with hemolysis. Generally occurs when the recipient has developed antibodies to leukocyte, platelet, or plasma protein antigens in the donor blood. These reactions are more likely in children who have previously received blood products.	Nonhemolytic reactions that occur when the donor blood contains plasma proteins or other antigens to which the recipient is hypersensitive.
Signs and symptoms	Fever Chills Urticaria Restlessness Headache Chest pain, tachycardia, hypotension Abdominal/lower back pain Oliguria Shock	Fever Chills Diaphoresis	Rash, pruritus Hives Urticaria Swelling Severe reactions: respiratory distress, bronchospasm, hypotension, and shock Anaphylaxis
Treatment	Fluids, corticosteroids, vasopressors, and mannitol may be required to maintain circulation and urinary output.	Febrile reactions are usually treated with acetaminophen and corticosteroids.	Rash and pruritus usually respond to the antihistamine, diphenhydramine. Severe reactions require treatment with epinephrine, intravenous fluids, airway protection, oxygen, vasopressors, and other interventions as needed.
Preventive measures	Sensitization is most likely in children who have previously received multiple transfusions and have been exposed to allogeneic antigens. Type and crossmatch accurately. Use leukocyte-depleted blood products to help prevent alloimmunization.	Pretreat with antipyretic and corticosteroid. Use leukocyte-depleted blood products.	Pretreat with antihistamine and corticosteroid. Wash red blood cells before transfusing.

Splenectomy

Removal of the spleen is sometimes necessary for children with severe hematologic abnormalities or those refractory to transfusion, nutritional measures, and pharmacologic treatment. Although splenectomy is the most effective treatment available for some conditions such as sickle cell disease, hereditary spherocytosis, and chronic idiopathic thrombocytic purpura (ITP), it leaves children

immunologically impaired and therefore is not first-line therapy for most diseases of the hematologic system. Children should receive *Haemophilus influenzae* type b and polyvalent pneumococcal vaccines before splenectomy to stimulate antibody production for future protection against sepsis. A splenectomy may be done via a laparotomy. However, laparoscopic splenectomy provides a less invasive technique for children who need this treatment.

Supportive Care

QUESTION: When caring for Shawanda and her family, what supportive care would be necessary?

Management of the child with a hematologic disorder requires attention to the psychosocial needs of the child and all members of the family.

The Child

Helping children with any hematologic disorder requires accurate knowledge about the disorder, its management, and its complications to promote their physical and psychological well-being. Although children with these conditions score well on quality-of-life measures (Bullinger & von Mackensen, 2003; Yalcin et al., 2007), they need to develop effective coping skills. They may fear bleeding, pain, or infection. They may wonder what will happen to them when they do experience a bleeding episode or vaso-occlusive crisis. Knowing the signs and symptoms that require attention, how to respond when they occur, and what to expect others to do helps children cope. Instruct them to notify their parents, teachers, or other caregivers when they experience any concerns or symptoms so that interventions can be implemented promptly. For children with hemophilia, for example, these measures usually include factor replacement. Older children and adolescents have probably learned how to prepare and administer their own factor, whereas parents or home health nurses usually perform this procedure for younger children. School visits by a nurse or social worker knowledgeable in the child's specific care can provide support for school personnel.

Children may be concerned about pain associated with intravenous insertion and laboratory testing. The use of topical anesthetic creams and parental involvement with comfort holding techniques and distraction can help children cope (see Chapter 10).

Children with hematologic conditions must establish their identities as individuals with a particular chronic disorder. Help them to identify their positive qualities, realize what they can do, develop healthy self-images, and formulate realistic goals for their futures (see Nursing Plan of Care 12–1).

Parents, Siblings, and Other Caregivers

Parents of a child with a hematologic condition are likely to have psychosocial concerns. Provide informational and emotional support to meet parents' needs. Informational support means providing parents with timely information regarding the disorder and its effect on their child. Develop an ongoing teaching plan that includes the information that parents commonly require (see TIPs throughout this chapter). Families also need counseling about specific aspects of the disease—for example, the genetic nature of sickle cell disease and what it means for their other children, both now and in the future.

Although the desired outcomes of providing information include improved parental coping and ability to parent a

child with a hematologic condition effectively, the information they receive is likely to be emotionally disturbing at first. As they begin to learn about their child's condition, parents may worry that they will not recognize a bleeding episode or will not respond appropriately. They may also fear that their child will easily become anemic or neutropenic. For example, the diagnosis of a bleeding disorder, the early bleeding episodes thereafter, and any painful or serious bleeding episodes are all sources of emotional stress for most parents. Also, parents (especially the mother) may feel guilty if the child's condition was transmitted genetically.

Healthcare expenses may generate stress, especially if the child has a severe condition and frequently requires costly factor replacement therapy or medications. Factor products are very expensive, and children can surpass insurance lifetime maximums quickly. A social worker or financial counselor can advise families about available benefits and offer other resources for support.

Emotional support for the parents of a child includes listening, identifying previously effective coping skills, providing positive reinforcement, and offering practical information. Support groups provide an opportunity for caregivers to share, learn from others, and encourage one another.

As in other chronic or genetic disorders, the well siblings of children with a hematologic condition need attention. Sometimes they feel left out, or they may feel guilty because they are well. Siblings need a sense of belonging within the family. They need to feel that their parents have time for them and value them just as much as they value the child with the chronic condition. Also, siblings need accurate knowledge about the child's condition, its etiology, its management, and its complications; information about how they can help during bleeding episodes or other complications; as well as their own need for genetic testing for the condition if necessary.

ANSWER: Supportive care needs to be focused on all members of the family. Supportive care for Shawanda would involve teaching her about her disease at an age-appropriate level and assisting her to develop age-appropriate coping skills and a positive self-image. Pain relief measures also are important. Supportive care for the family would include providing emotional support to the parents and siblings, and providing them with information about the disorder and effective coping strategies. Shawanda's brothers need attention, too. They need to feel that their parents have time for them. In addition, they need teaching to assist them in understanding what is happening with their sister so that they can help out, if appropriate.

NURSING PLAN OF CARE FOR THE CHILD WITH ALTERED HEMATOLOGIC STATUS

The primary foci of healthcare interventions for pediatric hematologic alterations are to prevent injury to the child and to provide the child and family with a strong knowledge base about the disorder, crisis prevention, and supportive measures. Nursing Plan of Care 23–1

NURSING PLAN OF CARE 23–1 FOR THE CHILD WITH ALTERED HEMATOLOGIC STATUS

Nursing Diagnosis: Risk for injury related to effects of hematologic disorder (e.g., factor deficiency, low platelet count)

Interventions/Rationale

- Assess child's vital signs and hydration status. Assess for any increase in active bleeding, bruising, or petechiae. Assess for frank bleeding from nose, mouth, or urinary and gastrointestinal tract. Monitor stools and urine for occult blood.

Promotes early assessment to facilitate prompt treatment.

- Assess child's tissue perfusion including skin color, warmth, pulses, capillary refill, complaints of numbness or tingling of extremities, vital signs, and oral mucosa.

Indicates fluid balance; level of hydration, and effectiveness of fluid replacement.

- Monitor laboratory values (i.e., hemoglobin, hematocrit, red blood cells, platelets, white blood cells).

Evaluates for reduced oxygen carrying capacity of blood, potential infection, and ability to stop bleeding.

- Encourage consolidation of laboratory blood sampling.

Reduces the number of venipunctures and risk of blood volume depletion.

- Institute supplemental oxygen as needed.

Increases oxygen carrying capacity of the blood.

- Institute measures to prevent bleeding or control hemorrhage, as indicated (see Nursing Interventions 23–1). Monitor for effectiveness of interventions, including any adverse reactions such as transfusion reactions (see Nursing Interventions 23–2).

Ensures effective and prompt administration of interventions such as administering factor replacement to reduce the incidence and severity of bleeding episodes and resultant complications.

- Review with the family the child's treatment plan, including medications and their common side effects, injury prevention, and hemorrhage control measures. As requested by the parents, provide information to school/daycare about child's condition (see Community Care 23–1).

Enables correction of misunderstandings and increases knowledge.

Expected Outcomes

- Child will remain free of injury, experiencing minimal to no bleeding as a result of injuries such as falls, punctures, cuts, or other environmental hazards.
- Child will maintain laboratory values consistent with normal hemostasis.

- Child will exhibit signs and symptoms of adequate tissue perfusion.
- Child and family will identify common types of bleeding associated with the child's particular bleeding disorder.
- Child and family will identify signs and symptoms associated with overt and covert bleeding, and will use interventions to prevent or immediately treat bleeding.

Nursing Diagnosis: Acute pain related to vaso-occlusive crisis, hemarthrosis associated with trauma to a limb, bleeding in joints and/or traumatic injury to muscles

See also Nursing Plan of Care 10–1.

Interventions/Rationale

- Assess pain using a reliable and valid method that is developmentally appropriate and appropriate for the situation. Elicit parent's assessment of child's pain.

The subjective rating of pain is most reliable, but it may not be an option in a nonverbal child (infant, intubated, comatose). Validated tools provide the most accurate assessment. The absence of behaviors indicative of pain does not necessarily mean that the child is not experiencing pain. Parents know their child best and are familiar with their typical behaviors.

- Assess location and character of pain. Assess for ability to move affected limbs. Assess for paresthesia.

Frequent episodes of bleeding or vaso-occlusive crises can result in joint inflammation, impaired mobility, and resulting nerve compression. Pain may be occurring in other sites, related to soft-tissue hemorrhage.

- Use comfort measures. Position child comfortably, using pillows, lightweight blankets, and other measures to decrease pressure on tissues. Use splints for joint discomfort. Use foam overlay mattresses. Use ice packs or moist heat as indicated. Offer use of whirlpool bath.

Excessive bleeding in the joints and from traumatic injury can cause joint pain, swelling of the joints, and tenderness to affected sites. Positioning devices and use of splints can increase the child's comfort. Ice may decrease swelling. Moist heat may increase circulation to the area.

- Implement pharmacologic and biobehavioral interventions to alleviate the pain (see Chapter 10 for a detailed discussion). Use a preventive approach to keep pain at or below an acceptable level. Involve the family in pain management.

Unrelieved pain has deleterious physiologic effects such as tachycardia, suppressed immune function, and

atelectasis, as well as negative psychological effects. Opioid analgesics are indicated for moderate to severe pain. Pain is better managed if it is not allowed to escalate. The family can provide measures that may be more comforting to the child than those provided by a nurse.

- Administer treatments (e.g., factor VIII, cold treatment, oxygen therapy) to control bleeding and/or underlying cause of pain such as a vaso-occlusive crisis.

Treating the primary hematologic cause will help control current pain and prevent future pain.

- Reassess pain level and evaluate effectiveness of interventions frequently.

Frequent reassessments are required to ensure effective control and to prevent exacerbation of the pain.

Children respond differently to interventions; what is effective for one may not work for another.

- Provide rest periods. Encourage child to progress from passive range of motion to active exercise as tolerated. Provide assistive devices as needed to help child be mobile.

These measures assist child in maintaining optimum physical mobility while remaining pain free.

Expected Outcome

- Child will state that adequate pain relief has been obtained.
- Child will demonstrate pain relief by absence of crying, restlessness, agitation, irritability, facial grimacing, splinting, or rigid body posture.
- Child will perform activities of daily living and developmentally appropriate activities with minimal interference from pain and medication side effects.

Nursing Diagnosis: Anxiety related to perceptions about receiving a transfusion

Interventions/Rationale

- Allow family to express fears, concerns, and anger. Acknowledge concerns; reassure that others have expressed similar concerns.

With public awareness of AIDS and other blood-borne pathogens, the family is likely to express some concerns about receiving blood/blood products. Likewise, the family may have concerns about their ability to complete other aspects of the treatment plan. Listening to their concerns provides the opportunity to identify their fears and problems. Fears may immobilize the family and interfere with adequate care. These fears must be addressed to facilitate patient care.

- Assess family ethnic, cultural, and religious background.

Information about family background provides clues about potential resistance or concern of family members about having the child receive blood, be sedated, or undergo other procedures or therapies.

- Reinforce healthcare prescriber explanations about the proposed treatment plan. Offer a brief explanation of precautionary measures used by the blood bank to ensure safety of blood product administration.

Transfusions and many other procedures and treatments require informed consent for treatment. Sufficient information prior to administration is required for informed consent.

- Explain the usual protocol for administering blood products (e.g., taking vital signs before, during, and after administration; having two nurses validate that the correct product is being administered).

Knowledge of the protocol helps to alleviate parent and child concerns when these measures are enacted.

Expected Outcomes

- Child and family will express concerns regarding blood/blood product transfusion.
- Child and family will describe protocol for administering transfusion.

Nursing Diagnosis: Risk for injury related to effects of transfused blood/blood product

Interventions/Rationale

- Allow child and parents to express feelings, fears, and concerns (see previous diagnoses).

Provides opportunities to clear up misconceptions and to provide accurate and factual information.

- Follow hospital policy and procedure manuals for blood transfusions.

Administration protocols follow evidence-based practice guidelines to ensure patient safety.

- Use measures to prevent transfusion reactions:
 - Identify child and verify blood (i.e., type, Rh factor, donor number, expiration date) with another nurse or physician.
 - Prime infusion line with normal saline to decrease risk of hemolysis of red blood cells.
 - Monitor prescribed flow rate of infusion, use an infusion pump to regulate flow, administer slowly during the first 15 minutes of infusion for all children, and continue slow rate for children at risk for fluid overload.
 - Remain with the child during the first 15 to 30 minutes of transfusion.
 - Note and report changes in skin color (i.e., pallor, duskiness) and mentation (i.e., restlessness, confusion, agitation) when taking vital signs. Note facial flushing, bounding pulses, and complaints of headache and flank or chest pain.
 - Auscultate lungs for the presence of rales, rhonchi, or muffled breath sounds prior to initiating transfusion and when changes in vital signs, skin color, or mentation occur.
 - Identify possible transfusion reactions promptly (see Nursing Interventions 23–2).

NURSING PLAN OF CARE 23–1 FOR THE CHILD WITH ALTERED HEMATOLOGIC STATUS (CONTINUED)

- Inform child and parents of key symptoms of adverse reactions before leaving child and show them how to notify nurse should such reactions occur.

Early identification of transfusion reaction allows for prompt treatment. Most reactions will occur during the first 30 minutes of administration. Administration of blood/blood products increases circulating blood volume. If the child is unable to compensate for this additional fluid volume, pulmonary congestion may develop, altering the ventilation-to-perfusion ratio and impairing gaseous exchange.

Parents can assist in identifying problems.

- Initiate immediate measures to correct transfusion reactions (see Nursing Interventions 23–2).

When a hemolytic reaction occurs, an antibody–antigen response causes blood cells to agglutinate, resulting in obstruction of blood flow to vital organs, including the lungs. Emergency treatment may be necessary for respiratory distress, hypotension, shock, or fluid overload.

- Continue to monitor vital signs; report significant changes.

The child requires ongoing assessment to evaluate effectiveness of treatment and resolution of reaction.

- Obtain blood sample, and forward specimen and remaining blood product with attached tubing to laboratory.

Follow-up specimen collection enables repeat typing and cross-match of blood to determine compatibility.

Expected Outcomes

- Child will remain free of complications of blood/blood product administration.
- Child will maintain adequate ventilation and perfusion of all body tissues.

Nursing Diagnosis: Deficient knowledge: Hematologic disorder, treatment, care, and potential complications

Interventions/Rationale

- Assess child and parent’s perceptions and knowledge of child’s condition, treatment regimen, and preventive care.

Teaching requires a solid base from which to start. It helps enable correction of misconceptions and provides opportunity for additional teaching as indicated.

- Provide genetic counseling as indicated.

Many hematologic conditions have an underlying genetic basis.

- Schedule a team conference with parents, child, friends (as appropriate), and teachers to provide information, and explore feelings and attitudes.

Encourage child to take part in selecting conference participants.

Child becomes a co-manager; assists in having mutual support and information.

- Stress importance of regular, frequent follow-up appointments to ensure that healthcare needs are met properly. Initiate referrals, appointments with community support groups, mental health clinics, and so forth, as needed for continued psychosocial support.

Healthcare needs are constantly changing. Frequent follow-up enhances opportunities to alter regimen as healthcare needs improve or deteriorate and provides for continued support after discharge.

- Teach child and parents how to administer medications, factor replacement, dietary therapy/modifications in the home and school.

Effective home management of the child’s condition can reduce subsequent complications of the child’s condition.

- Instruct family regarding safety procedures to use to prevent a hematologic crisis (e.g., avoid contact sports for child with hemophilia, avoid high altitudes for child with sickle cell disease).

Preventive measures are essential to reduce injury and the need for hospitalization.

Expected Outcomes

- Child and family will verbalize understanding of child’s condition, its treatment, and ongoing home care.
- Child and family will demonstrate interventions to provide emergency care for child if child sustains a hematologic injury or insult at home or school.
- Child and family use measures to create a home environment that protects the child from injury.

Nursing Diagnosis: Ineffective protection related to neutropenia, thrombocytopenia, bleeding, and/or loss of macrophage activity after splenectomy
Also see Nursing Plan of Care 22–1.

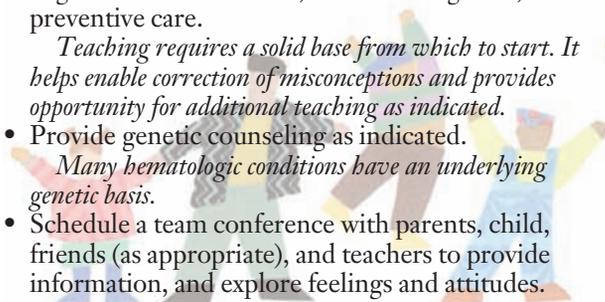

Interventions/Rationale

- Monitor laboratory values that indicate hematologic deficiencies (e.g., white blood cell count, partial thromboplastin time, platelet count).

Reduced values indicate need to implement strategies to protect the child from infection and bleeding.

- Assess for bleeding (frank blood from nose, gums, wounds, and so forth, and blood in urine and stools). Assess for infection (elevated temperature, increased heart rate, diaphoresis, and so on).

Risk of bleeding is increased as platelet counts decrease. Risk of infection occurs in the presence of neutropenia.

- Institute bleeding precautions, including minimizing number of venipunctures for laboratory tests; avoiding rectal procedures (temperatures, enemas, suppositories); using a soft toothbrush for oral care; not using ibuprofen or aspirin; avoiding contact sports, heavily lifting, or strenuous activity; using bed rails, pads, blankets on and around furniture to protect child from injury (see Nursing Interventions 23–1).

Venipuncture sites will ooze and bleed more in the presence of low platelet counts. Anything placed in the rectum may cause tearing and bleeding of the anal mucosa. Ibuprofen decreases the ability of the blood to clot. Aspirin can increase bleeding, especially when platelets are low. A soft toothbrush is more gentle on the gums, and thus prevents bleeding. Vigorous and rigorous activity can cause bruising and injury to soft tissue. Younger children are prone to falls and the environment can be altered to protect them from hurting themselves against furniture and beds.

- Administer factor replacement, DDAVP, or blood products as ordered.

Transfusion therapy may be warranted to ensure restoration of lost or depleted platelets.

- Teach family to recognize early the signs and symptoms of infection (e.g., fever, chills, productive cough, malaise) and to use neutropenic precautions in the home (see Community Care 22–4).

The child and family can learn to avoid situations that will increase the incidence of infection and to implement wellness behaviors that will enable the child to remain healthy.

- Stress importance of handwashing by child and family caregivers.

Handwashing reduces transmission of microorganisms and the risk for infection.

- Instruct family regarding administration of prophylactic antibiotics. Monitor child's adherence in taking medication.

Prophylactic antibiotics counteract opportunistic infections.

- Instruct family to ensure that child completes routine immunizations.

Immunization ensures child remains protected from certain childhood diseases.

- Instruct child to avoid contact with persons who have colds or infections.

Avoiding sick people protects child from contacting bacterial and viral infections from others.

- Reinforce importance of need for daily hygiene, mouth care, and perineal care.

Proper hygiene protects against bacterial invasion.

- If child is hospitalized, provide a private room for protective isolation.

Isolation may be necessary if the absolute neutrophil count is less than $500/\text{mm}^3$. These children are at high risk for infection.

Expected Outcome

- Child will remain free from infection; any infection will be detected and treated early.
- Child and family will institute measures to prevent infection and injury (e.g., careful hygiene, immunizations up to date).
- Child will have reduced risk of bleeding as indicated by adequate platelet levels and absence of bruising and petechiae.

Nursing Diagnosis: Anxiety related to prognosis; actual or perceived loss of body integrity; threat to self-concept

See Nursing Plan of Care 12–1.

Nursing Diagnosis: Disturbed body image related to being different than peers, perceiving self as sick, loss of body part

See Nursing Plan of Care 12–1.

Nursing Diagnosis: Spiritual distress related to response to crisis of the illness, suffering, or death of a child

See Nursing Plan of Care 13–1.

summarizes the nursing diagnoses and outcomes that might apply to the child experiencing a disorder of hemostasis or a form of anemia. In addition, the nursing plan of care in Chapter 12 is applicable to the child with a chronic hematologic condition.

ALTERATIONS IN HEMATOLOGIC STATUS

Alterations in hematologic status can be broadly categorized as disorders of hemostasis, anemias, and hemoglobinopathies.

DISORDERS OF HEMOSTASIS

Hemostasis is a complex process designed to prevent hemorrhage. Effective hemostasis requires ongoing interaction among the vascular walls, platelets, and certain plasma factors. Hemostasis comprises four major events that occur in a set order following the loss of vascular integrity:

1. Injury to a blood vessel evokes a vasoconstrictive response that slows blood loss from the damaged vessel.
2. Platelets become activated by thrombin and aggregate, leading to the formation of a platelet plug at the site of injury. The protein *fibrinogen* is primarily responsible

for stimulating platelet clumping. Platelets clump by binding to collagen that becomes exposed after rupture of the endothelial lining of vessels. Upon activation, platelets release adenosine diphosphate and thromboxane A₂ (which activate additional platelets), serotonin, phospholipids, lipoproteins, and other proteins important for the coagulation cascade. In addition, activated platelets change their shape to accommodate formation of the plug.

- A fibrin mesh (called a *clot*) forms and entraps the plug, ensuring the stability of the initially loose platelet plug. Platelet plugs are usually adequate to seal off tiny ruptures in blood vessels, but clot formation is necessary to close larger vascular injuries. If the plug contains only platelets it is called a *white thrombus*; if red blood cells are present it is called a *red thrombus*.
- When bleeding is controlled, plasmin degrades and dissolves the clot, and releases fibrin degradation products. This final step enables normal blood flow to resume after tissue repair.

Two biochemical pathways lead to the formation of a fibrin clot: the intrinsic pathway and the extrinsic pathway. Although these pathways are initiated by distinct mechanisms, the two converge on a common pathway that leads to clot formation. The **intrinsic pathway** leads to formation of a red thrombus or clot in response to an abnormality in the vessel wall in the absence of tissue injury. The **extrinsic pathway** leads to formation of a fibrin clot in response to tissue injury. Both pathways are complex and involve numerous different proteins called *clotting factors* (Table 23–3).

A disorder in hemostasis is called a **coagulopathy**. These disorders are caused by deficiencies or imbalances of clotting factors. The most common deficiencies seen in children involve factor VIII (hemophilia A), factor IX (hemophilia B), and von Willebrand factor (von Willebrand disease). These disorders can cause rapid, excessive blood loss, which can quickly place a child in a life-threatening situation. Prompt interventions are necessary to prevent and control hemorrhage (see Nursing Interventions 23–1).

Hemophilia

Hemophilia is a serious bleeding disorder, affecting an estimated 17,000 males in the United States. About 400 children are born with this disorder each year (National Heart, Lung, and Blood Institute, 2008). The most prevalent forms, hemophilia A (classic hemophilia) and hemophilia B (Christmas disease), are usually inherited in a recessive manner through a genetic defect on the X chromosome (see Fig. 3–3). Among the offspring of a carrier female and a normal male, half the daughters are carriers of hemophilia and half are disease free. Half the sons have hemophilia and half are disease free. Among the offspring of a normal female and a male with hemophilia, all the daughters are carriers of hemophilia and all the sons are disease free. Some females who are carriers have an increased tendency to bleed, similar to a male with mild hemophilia, and require treatment. In some rare genetic

TABLE 23–3

Clotting Factors

Clotting Factor	Name
Factor I	Fibrinogen
Factor II	Prothrombin
Factor III	Tissue thromboplastin
Factor IV	Calcium
Factor V (no factor VI)	Proaccelerin
Factor VII	Proconvertin
Factor VIII	Antihemophilic factor
Factor IX	Plasma thromboplastin component; Christmas factor
Factor X	Stuart's factor
Factor XI	Plasma thromboplastin antecedent
Factor XII	Hageman's factor
Factor XIII	Fibrin-stabilizing factor Prekallikrein; Fletcher's factor High-molecular weight kininogen; Fitzgerald's factor Platelets

circumstances, females can have moderate to severe hemophilia.

Hemophilia also can result from a spontaneous genetic mutation, with approximately one third of children with hemophilia having no family history of this disorder. Among people who have hemophilia, 9 out of 10 have hemophilia A, and 70% of those individual have the severe form of the disease (National Heart, Lung, and Blood Institute, 2008). Hemophilia affects all ethnic groups.

The prognosis for children with hemophilia has improved considerably during recent years. The development of comprehensive treatment centers and the availability of virally inactivated and recombinant factors for replacement therapy and the advent of home infusion therapy have improved treatment success.

Pathophysiology

Hemophilia A and hemophilia B are distinguished by the particular procoagulant factor that is decreased, absent, or dysfunctional. In hemophilia A, it is factor VIII; in hemophilia B, it is factor IX. A disorder in either factor inhibits the formation of thrombin, which is essential to normal coagulation.

Hemophilia A and hemophilia B are subclassified as mild, moderate, or severe on the basis of the level of factor VIII and factor IX, respectively:

- *Mild hemophilia* is characterized by a factor level of 5% to 50%. People with mild hemophilia experience prolonged bleeding only when injured. Thus, their condition may not be diagnosed unless they have trauma or surgery.
- *Moderate hemophilia* is distinguished by a factor level of 1% to 5%. People with moderate hemophilia usually have prolonged bleeding only with trauma, surgery, or muscle overuse, but they may experience occasions of spontaneous bleeding as well.
- *Severe hemophilia* is characterized by a factor level less than 1%. People with severe hemophilia have prolonged bleeding with trauma or surgery. They also may have frequent episodes of spontaneous bleeding (bleeding that occurs in the absence of injury).

Regardless of the type, if bleeding is not treated effectively, target joints are particularly at risk for deterioration and the development of chronic, disabling hemophilic arthropathy (joint disease). Other common types of bleeding in children with hemophilia are intramuscular **hematomas** (localized masses of extravasated blood) and oral cavity bleeding. Any extensive internal or external blood loss, particularly episodes involving the head or central nervous system, neck, or abdomen (e.g., iliopsoas intramuscular hemorrhage), is potentially life threatening.

Assessment

The clinical hallmark of hemophilia A or hemophilia B is **hemarthrosis** (deep bleeding into joints, muscles, and soft tissue). Frequently, the person with hemophilia develops a “target” joint that is repeatedly the site of bleeding episodes. Assess the child for hemarthrosis, which most often affects the knee, elbow, and ankle joints. Monitor for tingling, tenderness, pain, warmth, swelling, and decreased mobility at the affected site. Gently assess range of motion of all extremities. Repeated bleeding into a joint causes cartilage erosion and joint space narrowing, decreased range of motion, and proximal muscle weakening; disabling arthropathy may follow.

Intramuscular hematomas cause swelling, heat, and tenderness, and can restrict movement. If deep, they can be difficult to palpate and the child may complain of only a vague sense of discomfort or pain, even when serious hemorrhage has occurred. Hematomas that block the airway, compress vital organs, or result in extensive internal bleeding and shock can be life threatening. Some hematomas compress nerves and cause paralysis.

Bleeding episodes can also be related to the child’s stage of development. For example, neonates may have a marked cephalhematoma, bleeding with circumcision, or bleeding from the umbilical cord or site. Infants may experience oral bleeding with eruption of a tooth. Young children are prone to falls and injuries. In middle childhood children are more likely to experience bleeding episodes when they dare to engage in high-risk physical activities, or during loss of deciduous teeth. Adolescents are at risk for bleeding episodes when they yield to peer pressure and participate in high-risk physical activities.

Diagnostic Tests

Laboratory data identify hemophilia A or hemophilia B. In both disorders, fibrinogen levels, platelet count, and prothrombin time are normal, and partial thromboplastin time is prolonged. However, factor VIII is decreased in hemophilia A whereas factor IX is decreased in hemophilia B. If substantial blood loss occurs, the blood cell profile (CBC) may also point to anemia.

Interdisciplinary Interventions

Hemophilia treatment centers employ professionals from various disciplines such as physical therapy, social work, hematology, orthopedics, gynecology, nutrition, and genetics who provide complete, comprehensive health-care for children with hemophilia. Teaching is a critical aspect of the child’s care. The primary treatment for hemophilia includes the use of factor replacement therapy to replace clotting factors and the use of adjunct medications to increase clotting factors prior to undergoing certain medical or dental procedures.

Factor Replacement Therapy

The most important aspect of management is prompt and appropriate factor replacement to raise the factor level as quickly as possible, thereby shortening the bleeding episode and decreasing the probability of long-term complications. Prompt therapy is so essential that treatment usually precedes diagnostic testing to assess fully the current injury or bleeding episode.

Alert! Begin factor replacement as soon as an injury occurs or the child indicates that bleeding has started, even when bleeding is not clinically evident.

Factor replacement therapy, is the intravenous infusion of *factor VIII and IX concentrates* to prevent or control bleeding. *Factor VIII concentrates* are used for hemophilia A. *Factor IX concentrates* are used to manage acute hemorrhage or to decrease the risk of bleeding associated with surgery in patients with hemophilia B. These concentrates are derived from either human plasma or a genetically engineered cell line made by DNA technology, called *recombinant*. For both types, the factor VIII or IX protein is nearly identical to the protein that is lacking in the blood of hemophiliacs. After the infusion is complete, the recipient now has all the proteins needed for clotting to occur. This replacement of missing clotting factors is not permanent. Half the infused clotting factor activity is removed by the body every 12 to 24 hours. Thus, within 2 or 3 days almost all the infused factor VIII or IX concentrate is gone within the bloodstream and the patient may not be able to form clots again. However, by this time, the factors will have been effective in assisting to form a clot at the site where the bleeding occurred that initiated the need for factor replacement.

The level of factor correction required to achieve hemostasis depends on the nature of the injury or specific bleeding episode. Mild to moderate hemorrhage requires

factor correction to 30% to 50% of the normal factor level. This goal is often achieved with a one-time infusion of factor, but an additional one or two doses may be needed. Severe or life-threatening hemorrhage necessitates immediate factor correction to 100%, followed by a 50% to 100% factor level, maintained for a number of days. Similar factor correction and maintenance are prescribed when surgical procedures are required. Maintenance levels are achieved by intermittent or continuous infusion.

Factor replacement therapy is not curative. However, the genes for factor VIII and factor IX have been cloned, and gene transfer methods are currently being developed that are likely to have future clinical application. The goal of gene transfer therapy is to facilitate endogenous production of factor VIII and factor IX in quantities that cure hemophilia or at least decrease its severity (Hasbrouck & High, 2008; Pierce, Lillicrap, Pipe & Vandendressche, 2007).

Management of Complications

The child with hemophilia will require management for complications caused by replacement therapy. Two major concerns include the development of inhibitors (antibodies) and transmission of viral diseases.

Approximately 46% of patients with factor VIII deficiency develop an inhibitor, 15% to 20% of them at high titers. Five percent of patients with factor IX deficiency develop an inhibitor, and many of them also develop anaphylactic reactions to factor IX infusions. The presence of an inhibitor is suspected when a child does not achieve the expected factor level or clinical response after replacement therapy (Kessler, 2008).

Most children with inhibitors receive the same factor replacement as children without inhibitors. However, they may need a larger dose to attain the desired factor level. Some children with inhibitors require individualized alternative therapy with procoagulant factor bypassing agents, such as factor VIII inhibitor bypassing agent or activated factor VII (NovoSeven).

The transmission of viral diseases, particularly hepatitis and HIV infection, was a major concern among those who received factor VIII or factor IX concentrates before the mid 1980s. Since 1985, factor replacement concentrates have been treated with heat or chemicals to inactivate HIV and substantially reduce the risk of hepatitis and other viral diseases. Recombinant factor products greatly reduce viral exposure risk; thus, concerns families may have about HIV transmission from products administered to their child are not substantiated.

Medications

Certain medications can be used in conjunction with factor replacement therapy or can be used independently in situations when there are concerns that the child may experience bleeding (dental procedures, surgery).

DDAVP, a synthetic analogue of a natural antidiuretic hormone, can be used to increase the level of factor VIII by causing its release from endogenous storage sites. *DDAVP* is used only for patients with mild hemophilia A

who demonstrate a satisfactory response to a trial of *DDAVP* therapy. For these children, *DDAVP* is the treatment of choice for mild to moderate hemorrhage. *DDAVP* is not prescribed for patients with hemophilia B. *DDAVP* is usually given diluted in normal saline for a 30-minute intravenous infusion or by nasal spray once daily. Two forms of *DDAVP* nasal spray are available. One type is used for enuresis and is not effective for hemostasis. *Stimate* is the only *DDAVP* nasal spray that can be used to control bleeding. Side effects of *DDAVP* (as an antidiuretic hormone) include headache, hypertension, and flushing. *DDAVP* should not be used for more than 3 consecutive days (Curry, 2004).

Two antifibrinolytic agents useful in treating both hemophilia A and B and von Willebrand disease are tranexamic acid (Cyklokapron) and aminocaproic acid (Amicar). These drugs do not help to form a clot; rather, they act by stopping the activity of the enzyme plasmin, which dissolves blood clots in the mucous membranes of the mouth, nose, and urinary tract. The medications are used alone or in conjunction with clotting factor replacement for treating nosebleeds (epistaxis) and to prevent bleeding in the mouth prior to dental surgery. Amicar is contraindicated for children with disseminated intravascular coagulation (DIC) and renal bleeding. It should be used cautiously in those with cardiovascular, renal, or hepatic disease and in those receiving estrogen therapy.

KidKare ■ During antifibrinolytic therapy, do not allow children to use drinking straws, baby bottles, or pacifiers; and prevent them from sucking on hard candy, eating chips, or placing any hard objects in their mouths. These measures help to avoid clot dislodgment.

Fibrin glue is a product made of solutions of fibrogen and thrombin. When these substances are mixed together they mimic the last stages of the clotting cascade to form a fibrin clot. The pasty substance can be applied topically on a wound and is most often used to stop bleeding after dental procedures or to stop bleeding from other types of wounds. *Thrombin powder* is a dry powder that can be applied directly to the top of a wound to stop minor bleeding. These products are used for individuals with hemophilia or von Willebrand disease to help control bleeding.

Preservation of Joint Mobility

Complications associated with bleeding most often involve joints and muscles. Adjunct measures include RICE (see Nursing Interventions 23–1). In addition, corticosteroids such as prednisone may be used to reduce inflammation in the joint.

Hemarthroses in target joints frequently lead to weakness and dysfunction in adjoining musculature. Thus, muscle strengthening exercises that do not cause tissue damage or bleeding are likely to be incorporated into a rehabilitation program for those with hemophilia. A

physical therapy program designed to maintain normal range of motion may also be instituted.

Community Care

Healthcare for the child with hemophilia is a coordinated effort between parents, school nurses, and the child's outpatient healthcare team. Major points of focus include ensuring smooth transitions from inpatient to outpatient care, providing education about the disorder, and preventing bleeding episodes. In addition, ongoing psychological support of the family is essential.

Outpatient Care

Outpatient visits for ongoing assessment and management generally occur at a comprehensive treatment center at least once per year. Desired outcomes for these visits are related to the child's physical and psychosocial needs on the basis of an updated history and current physical assessment.

Discharge planning for outpatient visits can include referral or follow-up information for a local physician, a home care company, and a community health agency. It may entail contact with community groups, such as the child's daycare center or school (Community Care 23-1). It might involve assisting a family with travel plans by informing them of sources of healthcare for the child

while away from home and by identifying an appropriate storage place for the child's particular type of factor replacement.

KidKare ■ Summer camps specific for children with bleeding disorders provide them opportunities to learn more about their conditions and to be with other children who have hemophilia in a supportive and mentored environment.

Child and Family Education

An important component of the teaching process is to assess the family's understanding of the child's home care needs and the family's ability to care for the child at home. Be alert for the developing child's readiness to learn more about hemophilia and for the need to correct misconceptions the child and family may have. Also, as the child and family reach new developmental milestones, be alert for the need to discuss the child's activities and specific concerns associated with each developmental phase.

Teaching may encompass a variety of topics, depending on the specific nature of the child's visit to the healthcare provider. For example, when a child with hemophilia has orthopedic surgery on a lower extremity, teaching is likely

COMMUNITY CARE 23-1

The Child With Hemophilia in School

Children with hemophilia usually attend school on a regular basis when they are not having active bleeding. It is important that their teachers know they have a bleeding disorder. Also, the teaching staff should know the guidelines that have been established to prevent and manage an individual child's bleeding episodes and to promote the child's normal growth and development.

The school nurse collaborates with the comprehensive healthcare team and joins the child and family in providing information to the teaching staff. Outcome objectives for teachers and teaching assistants include the following:

- State the type and severity of the child's hemophilia, and correlate an increased severity with an increased risk of bleeding, including spontaneous bleeding.
- Identify body joints and muscle tissue as the hallmark sites of bleeding for the child with hemophilia.
- Describe signs and symptoms associated with covert bleeding, such as tingling, tenderness, pain, warmth, and altered motor function of the affected body site (e.g., refusal to walk or to participate in usual physical activities).
- Discuss the need for prompt factor replacement for bleeding episodes to prevent joint injury, tissue damage, and possible life-threatening hemorrhage.
- State the rationale for not giving aspirin to the child with a bleeding disorder.
- Discuss the importance of the child's participation in physical activities except for activities that are identified as high risk and inappropriate for the child. School personnel should be informed of the activities in which the child is not to participate.
- Explain the importance of telephoning the designated family member whenever the child is injured or says he is bleeding, *even when there are no signs and symptoms of bleeding*. Parents may advise school personnel that it is not necessary to telephone them regarding small, superficial cuts and scrapes, because factor replacement is usually not required in such situations.
- Describe the significance of treating the child as the classmates are treated. Although there is a need to be aware of the bleeding disorder, the teaching staff should not focus on it or single the child out for special attention or privileges.

to include cast care, crutch walking, pain management, signs and symptoms of bleeding at the surgical site, administration of factor replacement therapy at home, and a schedule for outpatient follow-up appointments. It will emphasize the need to call the physician if bleeding, fever, increased pain, or other complications occur (Clinical Judgment 23–1).

Thoroughly teach the child and family about measures to prevent and control bleeding (see Nursing Interventions 23–1). The potential for serious, life-threatening bleeding underscores the need for prudence in selecting daily activities. This may prove to be somewhat difficult as the child grows and begins to participate in activities, including sports. All children need regular exercise to help them develop a strong musculature that supports their joints and decreases the risk of bleeding. Decisions regarding sports participation can be especially challenging (see Developmental Considerations 23–1). The family should consult with the comprehensive healthcare team and must consider the child’s developmental level and physical ability, as well as the severity of the hemophilia.

von Willebrand Disease

von Willebrand disease is the most common hereditary bleeding disorder. It results from a quantitative, struc-

tural, or functional abnormality of von Willebrand factor.

In general, von Willebrand disease is inherited in an autosomal dominant fashion through a genetic defect on chromosome 12. The exact incidence of von Willebrand disease is not known because, in its mild form, it may not be diagnosed until an episode of prolonged bleeding occurs at a time of surgery or trauma. The estimated incidence is close to 1.3% of the population (James, 2006). Males and females and the various racial groups are affected in equal numbers. In general, the prognosis for children with von Willebrand disease is good, particularly because most of them have a mild form of the disease.

In addition, von Willebrand disease may be acquired with certain clinical disorders such as hypothyroidism, collagen vascular disease, and Wilms’ tumor. Acquired von Willebrand disease usually resolves when the accompanying clinical disorder has been treated.

Pathophysiology

von Willebrand factor consists of groups of glycoprotein or multimers of varied molecular weight. von Willebrand factor has two primary functions in hemostasis. First, it acts as an adhesive bridge between platelets and injured vascular subendothelium. After vessel injury, plasma von

CLINICAL JUDGMENT 23–1

A Child With Hemophilia A

Jason is a 7-year-old boy with severe hemophilia A. He is admitted to the hospital this morning for a scheduled tonsillectomy later today. The health history reveals that hemophilia was diagnosed during infancy shortly after prolonged bleeding occurred with circumcision. Recently, he experienced a tonsillar bleeding episode in conjunction with pharyngitis. Today’s physical examination findings are within normal limits. There is no evidence of bleeding or pharyngitis. Admission laboratory studies are within normal limits except for a prolonged partial thromboplastin time of 74.2 seconds and a factor VIII level of less than 1%.

Questions

1. What additional information would you elicit to assess Jason’s readiness for surgery?
2. Is Jason’s hemophilia classified as mild, moderate, or severe? Why?
3. Why is Jason a candidate for a tonsillectomy?
4. How can Jason’s bleeding be controlled after surgery?
5. Identify two significant clinical findings associated with posttonsillectomy bleeding.

Answers

1. Inquire about what Jason has been told regarding his surgery and what to expect after surgery. Ask whether he has attended a preoperative class for children and, if so, ask about his response to it. Ask what Jason knows about the precautions that will be taken to control bleeding during and after surgery—that is, continuous infusion of factor VIII and close monitoring by nursing staff for signs and symptoms of bleeding.
2. Jason has severe hemophilia because his uncorrected factor VIII level is less than 1%.
3. A history of a tonsillar bleeding episode together with severe hemophilia places Jason at increased risk for another tonsillar bleeding episode, particularly if there is recurrent pharyngitis.
4. Jason’s bleeding can be controlled after surgery by factor VIII infusion, antifibrinolytic medication, avoidance of hard or sharp foods and objects in the mouth, and a soft diet with no hot or spicy foods and beverages.
5. Two significant clinical findings associated with posttonsillectomy bleeding are bleeding at the surgical site and rapid pulse rate.

Willebrand factor high-molecular weight multimers, bind to the endothelium and support platelet adherence. The adhered platelets recruit more platelets and promote fibrin clot formation.

Second, von Willebrand factor low-molecular weight multimers serve as a carrier protein for the procoagulant factor VIII. Without von Willebrand factor, factor VIII has a markedly decreased survival time, which may decrease the level of factor VIII.

There are three major categories of von Willebrand disease: type I, type II, and type III (Table 23-4). Types I and III are characterized primarily by a quantitative deficiency in von Willebrand factor. Type II is characterized primarily by structural and functional abnormalities of the factor.

Assessment

The primary clinical manifestations of von Willebrand disease are bruising and mucous membrane bleeding from the nose, mouth, and gastrointestinal tract. Determine whether the child has had recent dental work or accidental injury. Prolonged bleeding after trauma or surgery, including tooth extraction, may be the first evidence of abnormal hemostasis in those with mild von Willebrand disease. For females, obtain a detailed menstrual history, including length of menstrual flow and quantity of bleeding. Menorrhagia and profuse postpartum bleeding may occur. Bleeding associated with von Willebrand disease may be severe and may lead to anemia and shock, but deep bleeding into joints and muscles, like

TABLE 23-4

Major Types of von Willebrand Disease

	Type I	Type II	Type III	
Percentage affected among those with von Willebrand disease	70% to 90%	15% to 20%	1% to 10%	
		Type IIA	Type IIB	
Severity of bleeding	Mild to moderate	Mild to moderate	Moderate to severe	Severe
Distinctive characteristics	Decreased quantities of all sizes of von Willebrand factor multimers Decreased activity of von Willebrand factor	Absence of intermediate-sized and large von Willebrand factor multimers Increased levels of small von Willebrand factor multimers Decreased activity of von Willebrand factor; possibly disproportionate with quantity of von Willebrand factor	Abnormal attraction of von Willebrand factor to platelets Only small and intermediate-sized von Willebrand factor multimers because of large multimers binding to platelet surfaces Increased platelet agglutination Possible thrombocytopenia	Absence (or near absence) of all sizes of von Willebrand factor multimers Absent or minimal activity of von Willebrand factor Low factor VIII level
Interventions	Usually, single dose of DDAVP; may repeat infusions every 12 to 24 hours for major surgery until healing complete	DDAVP for minor bleeding Plasma-based von Willebrand-containing factor VIII replacement therapy for moderate bleeding	Replacement therapy for bleeding episodes and surgery DDAVP contraindicated (facilitates release of additional, abnormal von Willebrand factor, enhancing platelet agglutination and thrombocytopenia) Platelets and von Willebrand factor for severe thrombocytopenia	Replacement therapy with factor VIII concentrates that contain von Willebrand factor Children with this type of von Willebrand disease may have spontaneous bleeding, including deep joint and muscle bleeding.

that seen in hemophilia, is rare except with type III von Willebrand disease.

Diagnostic Tests

The level of von Willebrand factor may vary in conjunction with certain physiologic factors. High estrogen levels during pregnancy are associated with increased von Willebrand factor levels, which decrease the probability of prolonged bleeding during the prenatal period. Inflammation, exercise, and stress also are correlated with increased levels of von Willebrand factor. If blood samples are drawn at these times, or if children experience particular stress from the venipuncture procedure itself, the presence of von Willebrand disease may be masked.

Fluctuating levels of von Willebrand factor may make von Willebrand disease difficult to diagnose, especially in its milder form. Initial screening studies may or may not document a prolonged activated partial thromboplastin time or abnormal platelet function analysis. Factor VIII levels may be decreased or within normal limits. The von Willebrand factor antigen level is usually decreased or absent but can be borderline in mild von Willebrand disease. The *ristocetin cofactor level*, an indirect laboratory measure of von Willebrand disease factor activity (see Tests and Procedures 23–1), generally reflects decreased von Willebrand factor activity, but this level, too, may be borderline in mild von Willebrand disease. A von Willebrand factor multimeric analysis test is helpful in distinguishing among the various types of von Willebrand disease.

A diagnosis of von Willebrand disease cannot be established or ruled out by one set of laboratory values alone. A definitive diagnosis of von Willebrand disease requires documentation of two sets of abnormal von Willebrand factor studies. When the child's history indicates the possibility of von Willebrand disease, laboratory studies should be repeated periodically and can be more definitive when procured at times of active bleeding episodes.

Interdisciplinary Interventions

Management of the child with von Willebrand disease depends on the classification of the disease (see Table 23–4). The most common treatment is DDAVP, which acts to temporarily increase von Willebrand levels, although it may be ineffective in type 2A or type 2B. It is given intravenously or intranasally (see discussion regarding hemophilia treatment). Monitor von Willebrand factor levels before and after the administration of DDAVP, because repeated dosing can cause tachyphylaxis and lessened response (Dietrich, 2007).

When DDAVP is ineffective or tachyphylaxis develops, von Willebrand factor replacement therapy is needed. Such therapy is provided with a plasma-based factor VIII concentrate, such as Humate-P, Koate DVI, or Alphanate, which contain von Willebrand factor as well as factor VIII (see Table 23–4). These medications are given intravenously and may be used for children with type 1 von Willebrand disease in certain situations such as major trauma or major surgery.

Community Care

Steps to prevent bleeding, and measures to provide for the psychosocial needs of children with von Willebrand disease and their families are similar to those described in the section on hemophilia and in the Treatment Modalities section at the beginning of the chapter.

Disseminated Intravascular Coagulation (DIC)

DIC is an acquired coagulopathy that, paradoxically, is characterized by both thrombosis and hemorrhage. Its acuity level ranges from low-grade compensated DIC to fulminant, multisystem, life-threatening DIC.

DIC is not a primary disorder but occurs as a result of a variety of alterations in health status, such as burns, traumatic injuries, hypoxia, severe shock, hemolytic transfusion reactions, cardiovascular disorders, acute myelogenous leukemia, metastatic malignancies, infection or sepsis, liver disease, and hypo- or hyperthermia. Conditions that precipitate DIC may, in turn, be complicated by DIC. The etiology of DIC is not well understood. The prognosis for DIC varies, according to the prognosis for the underlying disorder and the severity of DIC. Fulminant DIC can be life threatening.

Pathophysiology

Although DIC can be precipitated by different disorders, its basic pathophysiology is the same, leading to the development of both thrombosis and hemorrhage. Extensive microvascular damage, accompanied by vasodilation and loosening of endothelial junctions, leads to capillary leaking and shock. Unregulated activation of the coagulation pathways promotes excess thrombin generation, widespread microthrombi, and ischemic damage to multiple organs. Coagulation factors are consumed and platelets are exhausted, leading to disseminated bleeding.

Thrombosis in DIC occurs when the coagulation system is overstimulated by a primary triggering disorder. Overstimulation leads to an excessive amount of circulating thrombin, which in turn leads to increased fibrin clot formation. Microvascular and, at times, macrovascular thrombosis occurs, hindering normal blood flow, and may result in ischemia and organ damage.

Also, red blood cells become fragmented as they circulate among the numerous fibrin deposits in the vasculature. Subsequently, a hemolytic anemia may develop.

Hemorrhage associated with DIC may occur as a consequence of various pathophysiologic events. First, the intravascular thrombi, which form as a result of excessive thrombin in the circulation, trap platelets, resulting in hemorrhage secondary to **thrombocytopenia** (an abnormally low concentration of circulating platelets). Second, excessive amounts of circulating plasmin are produced, leading to excessive fibrinolysis and an abnormally high amount of circulating fibrin degradation (split) products (FDPs or FSPs). FDPs function as anticoagulants, thereby contributing to hemorrhage. Also, FDPs cover platelet membranes, making the platelets dysfunctional

and leading to hemorrhage. Third, levels of clotting factors involved in normal coagulation are substantially decreased or absent in DIC, resulting in hemorrhage.

Assessment

The most obvious clinical feature of DIC is bleeding. However, be alert for clinical manifestations of the other major pathophysiologic event in DIC: thrombosis. Bleeding and thrombosis may occur in multiple, unrelated anatomic locations. All anatomic sites affected by DIC are at risk for ischemia, tissue damage, organ failure, and necrosis. The most common sites affected by DIC involve the kidneys, lungs, skin, gastrointestinal tract, and central nervous system:

- Renal involvement: hematuria, oliguria, and anuria
- Pulmonary involvement: hemoptysis, tachypnea, dyspnea, and chest pain
- Cutaneous involvement: Petechiae, ecchymoses, hemorrhagic bullae, pallor, jaundice, acrocyanosis, and gangrene; also possible bleeding from surgical or traumatic wounds and from invasive procedure sites
- Gastrointestinal involvement: Hematemesis, hematochezia, and absent or hypo- or hyperactive bowel sounds
- Central nervous system involvement: Possible headaches, increased intracranial pressure, sensory deficits, seizures, altered mental status, and decreased level of consciousness

Also, monitor for the systemic manifestations of DIC, such as fever, hypotension, acidosis, and hypoxia.

Diagnostic Tests

Although no test is specifically diagnostic for DIC, certain alterations in hematologic laboratory data can contribute to its identification (Table 23–5). Such laboratory data must be assessed, however, within the context of the child's history, underlying disorder, and general clinical state. Also, the absence of laboratory findings commonly associated with DIC does not necessarily exclude its presence.

Nursing Diagnoses and Outcomes

Nursing diagnoses and outcomes for the child with a bleeding disorder are presented in Nursing Plan of Care 23–1. The following nursing diagnosis and outcome also applies to the child with DIC:

Ineffective tissue perfusion related to intravascular thrombosis and hemorrhage

Outcome: Child will exhibit adequate tissue perfusion of all body systems affected by DIC and regain adequate laboratory values for hemostasis.

Interdisciplinary Interventions

Management of the child with DIC is individualized based on the underlying disorder and the degree of DIC. Thus, specific treatment may vary from no treatment, in

TABLE 23–5

Laboratory Data Commonly Associated With Disseminated Intravascular Coagulation

Laboratory Test	Result
Antithrombin III	Decreased
D-dimer assay	Increased
Fibrinogen	Decreased
Fibrinogen/fibrin degradation (split) products	Increased
Fibrinopeptide A level	Increased
Partial thromboplastin time	Prolonged
Plasminogen	Decreased
Platelet count	Decreased
Prothrombin time	Prolonged
Schistocytes	Present

the absence of clinical manifestations, to intensive treatment in the presence of fulminant DIC.

When clinical manifestations are present, primary interventions are directed toward (1) effective treatment of the disorder that precipitated DIC and (2) supportive care to correct physiologic alterations resulting from DIC.

Treatment of the precipitating disorder may include, for example, surgery to remove diseased body tissue; antibiotic therapy to treat infectious disease; chemotherapy to destroy malignancies; and measures to correct shock, hypoxia, and acid–base imbalance.

Supportive care includes the administration of platelet concentrates, cryoprecipitate, factor concentrates, and fresh-frozen plasma to replace depleted platelets and coagulation factors.

Collaborate with the healthcare team to plan and provide the therapeutic and supportive measures needed. A key aspect of the nurse's role is to assess the child for signs and symptoms of impaired tissue perfusion in the various body systems that may be affected by DIC. Important outcomes objectives for the child and related nursing interventions are delineated in Nursing Interventions 23–2.

Concerns about bleeding, clotting, and organ failure with serious DIC are likely to produce considerable emotional stress in both the child and family. The healthcare team must be sensitive to this stress. Education about DIC, ongoing progress reports, and emotional support for the child and family are important components of the interdisciplinary management of DIC.

Community Care

Posthospitalization care is related to managing the underlying condition that precipitated DIC (e.g., metastatic

NURSING INTERVENTIONS 23–2

Objectives and Interventions for the Child With Disseminated Intravascular Coagulation

Outcome Objectives	Nursing Interventions
Maintain adequate renal function	Measure intake and output accurately Report the following: <ul style="list-style-type: none"> • Intake greater than output • Hematuria • Oliguria, anuria
Maintain adequate pulmonary function	Assess breath sounds for all lobes of the lungs Report the following: <ul style="list-style-type: none"> • Abnormal breath sounds • Tachypnea • Dyspnea • Chest pain • Hemoptysis • Abnormal pulse oximetry readings
Maintain cutaneous integrity	Inspect the skin Report the following: <ul style="list-style-type: none"> • Overt bleeding • Pallor; jaundice • Petechiae; ecchymoses • Hemorrhagic bullae • Acrocyanosis • Poor healing at sites of injury or invasive procedures
Maintain adequate gastrointestinal function	Assess bowel sounds in all quadrants Report the following: <ul style="list-style-type: none"> • Absent or hypo- or hyperactive bowel sounds • Blood in emesis or stool
Maintain adequate neurologic function	Assess neurologic status Report the following: <ul style="list-style-type: none"> • Unstable or abnormal blood pressure, temperature, pulse, and respiratory rate • Unequal size of pupils • Absent or unequal pupillary responses to light • Headaches • Seizures • Changes in sensory perception, such as altered vision or hearing; numbness • Changes in motor function, such as altered speech or mobility • Irritability • Changes in behavior • Decreased level of consciousness • Rigid posturing

malignancy, liver disease, cardiovascular disorder). In addition, ongoing care will be needed based on the degree of organ impairment and limb involvement related to impaired tissue perfusion during the DIC crisis. Rehabilitation services may be required for any loss of extremities (see Chapter 12).

Idiopathic (Immune) Thrombocytopenic Purpura (ITP)

ITP is an acquired, self-limiting disorder of hemostasis characterized by destruction and decreased numbers of

circulating platelets. ITP is primarily an autoimmune disease; the immune system attacks and destroys the body's own platelets, for an unknown reason. Because “idiopathic” means “of unknown cause,” the condition is also referred to as *immune thrombocytopenic purpura* or *autoimmune thrombocytopenic purpura*. ITP is the most common thrombocytopenic disorder among children.

ITP is frequently preceded by a viral illness within 1 month of onset, most often an upper respiratory infection, but sometimes another infection such as varicella or infectious mononucleosis. ITP has also occurred after vaccination for smallpox and measles. Infection or vaccination may somehow “trigger” the immune reaction that leads to ITP in these children. In adults, ITP does not seem to be linked to infections.

ITP can be acute or chronic. The condition occurs in 5 of 100,000 children per year. Acute ITP, the predominant form among children, is characterized by thrombocytopenia of sudden onset, which resolves within 6 months. Typically, acute ITP in children occurs between 1 and 6 years of age; it affects males and females in equal numbers. Chronic ITP is characterized by continuous or recurrent thrombocytopenia of more than 6 months' duration. It is more likely to affect children older than 10 years, females, and have an insidious onset (Blanchette & Bolton-Maggs, 2008; Fogarty & Segal, 2007). The prognosis for ITP is good, especially for children who have had a preceding viral illness.

Pathophysiology

The accelerated destruction of circulating platelets in ITP is mediated by platelet autoantibodies. These antibodies coat the platelets and thereby facilitate platelet trapping and destruction in the spleen. Why these autoantibodies are produced after a viral infection or other event is unknown. Nor is it known what causes the production of these autoantibodies to cease when ITP resolves.

Assessment

A thorough assessment of the skin reveals the hallmark of ITP: random purpura in the presence of an otherwise normal physical examination. In addition to the cutaneous petechiae and ecchymoses, look for petechiae and hemorrhagic bullae of the mouth and pharynx. The extent of purpura is usually related to the degree of thrombocytopenia. When the platelet count is less than 20,000/mm³, spontaneous bleeding is more likely and may occur. Determine whether the child has a history of epistaxis, hematuria, hematemesis, hematochezia, or menorrhagia.

Intracranial hemorrhage, although rare, is a life-threatening form of spontaneous bleeding associated with ITP. Assess for headaches, vomiting, retinal hemorrhage, irritability, seizures, lethargy, and coma as clinical indicators of intracranial bleeding.

Alert! The child with evidence of intracranial hemorrhage requires immediate medical attention. Notify the physician of the child's condition, prepare the child and family for emergent computed tomography of the child's head, monitor closely, and be prepared to provide oxygenation and other supportive care.

Diagnostic Tests

Thrombocytopenia, usually a platelet count less than 150,000/mm³, is the only laboratory abnormality expected with ITP. However, if major blood loss has occurred, a CBC can show evidence of anemia.

Bone marrow examination shows a normal or increased number of megakaryocytes, the precursors of platelets. This finding indicates that the thrombocytopenia is caused by a destructive process, rather than failure of the bone marrow to produce an adequate number of platelets. A bone marrow aspiration is often performed before treatment with corticosteroids to rule out aplastic anemia, leukemia, the presence of malignant tumor cells, and other bone marrow disorders.

Interdisciplinary Interventions

Management of the child with ITP is directed toward preventing serious, life-threatening bleeding and involves supportive care, possible pharmaceutical intervention, and, occasionally, splenectomy (Tradition or Science 23–1). Giving platelet transfusions is not customary, because of the destructive process that affects platelets in ITP. However, at times of surgery or life-threatening bleeding, platelets may be used.

Pharmacologic Interventions

Most children spontaneously recover from severe thrombocytopenia, thus pharmacologic interventions may not be used. Pharmacologic interventions, when used, include corticosteroids or immune globulin (as indicated) for extensive bleeding, or if the child is at risk for life-threatening bleeding related to severe thrombocytopenia (platelet count <20,000 mm³).

Corticosteroid therapy (prednisone) can be given daily to enhance vascular stability, decrease production of anti-platelet antibodies, and decrease clearance of phagocytically susceptible platelets, thereby improving platelet survival, increasing the platelet count, and decreasing bleeding.

TRADITION OR SCIENCE 23–1

Should children with ITP and a platelet count of 20,000 cells/mm³ or less be treated?

EVIDENCE-BASED PRACTICE

Data suggest that 68% to 100% of children recover their platelet counts within 6 to 12 months of diagnosis. Of the remaining children, approximately one third of them will achieve spontaneous remission some time after this initial period (Fogarty & Segal, 2007; George, Woolf, Raskob, et al., 1996; Watts, 2004). Watchful waiting, with no treatment unless clinical symptoms occur in addition to cutaneous signs, is considered valid therapy and should be offered to families in addition to the options of treatment with IVIG, corticosteroids, or anti-D immunoglobulin (Winrho) (Sevier & Houston, 2005; Tarantino & Bolton-Maggs, 2007).

However, prolonged use of corticosteroids is not considered beneficial and may actually suppress platelet production. If severe thrombocytopenia or major bleeding recurs, alternative therapy is recommended.

Intravenous immunoglobulin (IVIG) therapy is given daily, for 2 to 5 days, and usually brings about a quick increase in the platelet count. IVIG is thought to act by interfering with the attachment of antibody-coated platelets to Fc receptors on the macrophage cells of the reticuloendothelial system. IVIG is expensive, but if it decreases hospitalization time and the likelihood of splenectomy, it can be a cost-effective intervention for ITP (Blanchette & Bolton-Maggs, 2008).

Anti-D-RhO (WinRho) immunoglobulin increases the platelet count in most Rh-positive patients with ITP. Response with anti-D is slower than with IVIG, but it is easier to administer, and its cost is less (Blanchette & Bolton-Maggs, 2008).

Alert! Monitor hemoglobin of patients receiving anti-D immunoglobulin. Because anti-D antibody binds to Rh-positive erythrocytes, most patients experience some hemolysis, some severe enough to warrant transfusion.

Ensure that children and their parents know that neither corticosteroids nor IVIG shortens the duration of ITP. The primary purpose of these agents is to increase the number of circulating platelets and, thereby, reduce the risk of life-threatening bleeding. If severe thrombocytopenia recurs, intermittent pharmacologic intervention using IVIG, anti-D immunoglobulin, corticosteroids, or some combination may be used to prevent the platelet count from dropping dangerously low until the ITP spontaneously resolves (Blanchette & Bolton-Maggs, 2008).

Surgical Interventions

Splenectomy is usually reserved for children with life-threatening bleeding or for those with chronic ITP who are at risk for serious bleeding despite supportive care and pharmaceutical intervention. The purpose of splenectomy is twofold: (1) to remove the primary site of antiplatelet antibody production and (2) to remove the major site for the destruction of antibody-coated platelets.

When possible, splenectomy is delayed in children younger than 5 years, because they are at greater risk for developing life-threatening postsplenectomy sepsis. When splenectomy is planned, specific vaccines are given to help decrease the risk of postoperative sepsis. The polyvalent pneumococcal vaccine is given at least 2 weeks before surgery to allow time for an effective antibody response. The vaccine for *H. influenzae* may be given as well. Prophylactic antibiotics are also initiated.

Children who are receiving or who recently received corticosteroids continue to receive steroids during the pre-, peri-, and postoperative periods. Surgery is a time of increased stress, during which the adrenal gland would normally release increased amounts of corticosteroids. When these hormones are supplied from exogenous sources, the release of adrenocorticotrophic hormone is

inhibited. Without adrenocorticotrophic hormone, the adrenal gland is not stimulated to produce corticosteroids. Therefore, be sure the child receives stress doses of corticosteroid medication to prevent life-threatening complications, such as hypotension and cardiovascular collapse, during and after surgery.

The child is hospitalized 2 to 5 days after the splenectomy. Potential complications include bleeding and pancreatitis. Assess the child for signs and symptoms of bleeding and infection. Manage pain aggressively, making use of patient-controlled anesthesia pumps to effectively deliver pain medication (see Chapter 10).

After a splenectomy, the long-term complications include risk for infection and postsplenectomy sepsis. In children, the risk for infection is highest within the first 2 years after surgery. Instruct the child and parents about the increased risk of rapidly progressing, life-threatening sepsis in the asplenic individual and emphasize the importance of immediately calling the physician in the event of fever or illness. Tell the family to expect a septic workup, including physical examination, blood culture, and blood counts. Inform them that during this time period, prophylactic antibiotics may be administered until the physician feels the child is no longer at risk for infection. If the child has an infection, therapeutic antibiotics are administered until the blood culture is known to be negative and any sepsis has been treated. Thereafter, postsplenectomy antibiotic prophylaxis is resumed.

Alert! The child with fever and systemic illness after splenectomy requires immediate evaluation for sepsis.

Postoperatively, ITP often resolves quickly. A reactive thrombocytosis may occur, with a platelet count more than 500,000 or even exceeding 1,000,000 cells/mm³. The platelet count may remain high for several months before returning to normal, but this finding is viewed as a favorable prognostic indicator and it does not increase the child's risk for thrombosis. On the other hand, postoperative thrombocytopenia may indicate that the ITP is not yet in remission.

Treatment for chronic refractory ITP after splenectomy focuses on management of bleeding symptoms. New treatments are being investigated that focus on influencing antigenemia, the T-cell immune response, or the B-cell immune response using chemotherapy agents such as azathioprine (Imuran), cyclophosphamide (Cytoxan), and vincristine. However, most of these treatments have not been tested in the pediatric population (Sevier & Houston, 2005).

Community Care

Bleeding and the fear of bleeding are stressful for children with ITP and their families. Healthcare providers must be sensitive to this stress. Educating about ITP and providing ongoing assessment and emotional support are important parts of the interdisciplinary management of ITP. Steps to prevent bleeding and measures to provide

for the psychosocial needs of children with ITP and their families are similar to those described in the section on Treatment Modalities at the beginning of the chapter and in Nursing Interventions 23–1.

ANEMIAS

QUESTION: Based on the laboratory test results at the time of Shawanda's hospital admission, is her anemia moderate or severe?

Although the anemias of childhood have distinguishing features, they share a common characteristic: the hemoglobin concentration or the red blood cell count is less than normal. Anemias are usually detected or confirmed by CBC analysis. Both moderate and severe anemias (hemoglobin <8g/dL) lead to decreased oxygenation of body tissues. When symptomatic and life-threatening anemia is present, red blood cell transfusions increase hemoglobin levels and improve oxygenation.

Anemias are classified by morphologic features and by physiologic characteristics. Morphologically, red blood cell size categorizes anemias as microcytic (small cell size), normocytic (normal cell size), and macrocytic (large cell size). Physiologic characteristics categorize anemias as disorders of red blood cell production and red blood cell destruction. IDA, megaloblastic anemia, lead poisoning, and aplastic anemia are examples of disorders that interfere with normal red blood cell production. Abnormalities involving the red blood cell membrane, such as hereditary spherocytosis, together with the various hemolytic anemias, are examples of disorders involving red blood cell destruction. In addition to productive and destructive physiologic disorders, anemia may result from major internal and external bleeding.

ANSWER: Shawanda's laboratory test results reveal a hemoglobin level of 5.7 g/dL. Thus, her anemia would be considered severe (<8 g/dL).

Iron Deficiency Anemia (IDA)

IDA is the most common nutritional anemia of childhood. It is a microcytic (red cells are smaller than normal), hypochromic (red cells are paler than normal) anemia that occurs when the body's iron stores are depleted. Severe IDA is present when the hemoglobin concentration is more than two standard deviations below the mean. IDA may be diagnosed if the hemoglobin is less than 11 to 13.3 g/dL (depending on age) and increases after a course of therapeutic iron supplementation (U.S. Preventative Services Task Force, 2006).

IDA is most likely to occur when children experience rapid physical growth, inadequate iron intake, inadequate iron absorption, or loss of blood. IDA develops most commonly during infancy and adolescence, when

physical growth is rapid and iron intake is frequently insufficient.

Iron fortification of food products, greater use of iron-fortified infant formulas, and an increase in breast-feeding have contributed to a substantial decrease in the incidence of IDA in the United States. However, IDA is still the most common cause of anemia in infants and children who are otherwise in good health (U.S. Preventative Services Task Force, 2006). IDA is easily treated and, thus, the prognosis is good if IDA is managed early and effectively (Tradition or Science 23–2).

WORLDVIEW: In developing countries of the world, the World Health Organization estimates that iron deficiency affects 2 billion children and adults (Carley, 2003). This deficiency is the result of poor diets, lack of iron fortification, infections such as malaria, and parasitic infestations such as hookworm. IDA in developing countries is frequently associated with deficiencies in other nutrients such as folic acid, vitamin C, and vitamin A. Thus, when children with nutritional anemia come to the United States, healthcare providers need to consider that lack of iron may not be the only nutrient deficiency.

Pathophysiology

Iron deficiency is described in three stages:

1. Stage one is characterized by depletion of ferritin, hemosiderin, and other iron storage compounds in the liver, spleen, and bone marrow. Anemia is not present during this stage.
2. Stage two is characterized by a lack of transport iron. Iron saturation of transferrin decreases and, although

TRADITION OR SCIENCE 23–2

Do infants with iron deficiency anemia have long-term developmental delays?

EVIDENCE-BASED PRACTICE

Iron deficiency anemia appears to have long-lasting effects on motor development, mental development, and auditory and visual system functioning. Iron is required for normal myelination, which affects both motor and sensory development. Studies have substantiated that infants who had iron deficiency anemia demonstrated motor development delays (Antunes et al., 1997; Surico et al., 2002), lower mental test scores (Grantham-McGregor & Ani, 2001; Lozoff et al., 1996), longer auditory brain stem and visual evoked potential responses (Algarin et al., 2003), alterations in normal development of sleep patterns (Peirano et al., 2007), and adverse social and emotional behavior (Lozoff et al., 2008) during early childhood. Evidence continues to build that the presence of iron deficiency anemia during infancy demands immediate intervention to prevent adverse motor and cognitive sequelae that affect these children as they continue to grow and mature (Lozoff et al., 2000).

anemia is generally not yet present, the hemoglobin concentration trends toward low normal.

3. Stage three is characterized by a marked deficit in transport iron that inhibits normal production of hemoglobin. Erythrocyte protoporphyrin increases, because there is inadequate iron with which it may combine to form heme. Transferrin receptors, located on cell surface membranes in various body tissues, become more numerous in response to the iron-poor environment. A microcytic, hypochromic anemia develops during this stage of iron deficiency.

In addition to inadequate dietary intake, impaired iron absorption may lead to IDA. The intestinal mucosal cells are particularly important because they act as a holding zone and gatekeeper for iron. When the body does not need iron, it is lost with desquamation of intestinal mucosal cells; however, when the body needs iron, it enters the circulation via the intestinal mucosa. Impairment of the intestinal mucosa may inhibit adequate iron absorption. Iron malabsorption may also occur with inflammatory and infectious disorders.

Assessment

The American Academy of Pediatrics recommends screening for iron deficiency at 1 year of age (American Academy of Pediatrics, 2003). IDA may not be readily apparent when the anemia is mild, thus routine screening for at-risk children (low socioeconomic status, poor dietary intake) is important. As anemia progresses, signs and symptoms may become apparent. Note any parental concerns that the child is easily fatigued, experiences shortness of breath, is irritable, and has decreased tolerance for physical work and exercise. Physical assessment may reveal pallor, fissures at corners of the mouth, inflammation of the tongue, and spoon-shaped nails. Heart murmurs and heart failure are noted with severe anemia. Skeletal abnormalities also may be noted.

Dietary assessment is important. Children whose diet consists almost exclusively of cow's milk may have occult blood loss and suppression of appetite along with severe anemia (Hugh, Allen, Driscoli et al., 2008). Pica, the appetite or craving for nonnutritional substances (e.g., soil, chalk, foam), persisting for more than 1 month, is associated with both IDA and celiac disease (Borgna-Pignatti & Marsella, 2008).

Children with iron deficiency absorb greater amounts of lead and, thus, they are at greater risk of developing lead poisoning. In addition, iron deficiency may impair cognitive and psychomotor development. These deficits can occur even with moderate anemia, and they may remain despite correction of the IDA (Eden, 2005). During the assessment process, complete developmental screening to assess for any lags in achieving age-appropriate milestones (see Chapter 3).

Diagnostic Tests

Generally, a hemoglobin test is used when children are initially screened for IDA. As the child progresses through the three stages of iron deficiency, laboratory

evidence of this deficiency increases. During the first stage, the depletion of iron stores is most commonly identified by a decrease in serum ferritin. A normal serum ferritin result does not rule out IDA, however, especially during inflammation or infection. A less practical means of evaluating storage iron is by testing a sample of bone marrow for hemosiderin, which is decreased in IDA.

During the second stage of iron deficiency, the lack of transport iron is identified primarily by a decrease in transferrin saturation. A decrease in serum iron and an increase in total iron-binding capacity are likely to be evident as well. However, these tests individually are not as reliable as transferrin saturation (Hugh et al., 2008). In addition, during this stage, early red blood cell changes may be noted, with the hemoglobin decreasing to low normal.

Laboratory manifestations of the third stage of iron deficiency include changes in red blood cell indices. These changes include an increase in erythrocyte protoporphyrin and transferrin receptors, and a decrease in hemoglobin, hematocrit, mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC).

Nursing Diagnoses and Outcomes

The nursing diagnoses presented in Nursing Plan of Care 23-1 are appropriate for the child with IDA. However, these diagnoses must be individualized to meet the specific care needs of the child and their family.

Interdisciplinary Interventions

In most cases, the child with iron deficiency anemia is managed on an outpatient basis (see discussion in Community Care section that follows). However, severe iron deficiency anemia and iron malabsorption may require treatment with parenteral forms of iron supplementation that include iron dextran (Imferon), sodium ferric gluconate, and iron sucrose. In such cases, hospitalization is required, with careful monitoring of the child during intravenous or intramuscular administration of iron. Adverse effects of administration include skin staining at site of intramuscular injection, severe pain at the injection site, fever, and anaphylaxis. Use the Z-track injection technique when administering the iron intramuscularly.

Children with severe anemia may also require supportive therapy such as supplemental oxygen, intravenous fluids, bed rest, and consultation with a nutritionist. In some cases the child may require PRBC transfusion (see discussion earlier in the chapter in Treatment Modalities). Provide ongoing monitoring of the child's progress as he or she receives these therapies and provide education to parents.

Regardless of the care setting, key interventions include iron supplementation, nutritional recommendations, and child and family education.

Iron Supplementation

Iron supplementation is generally the first line of treatment when there is suspected, but unconfirmed, IDA in a child who is otherwise healthy. Anemia in children is most often caused by iron deficiency, thus a trial period

of administering iron supplementation is often given prior to the completion of costly elaborate laboratory tests. The trial period is usually 1 month. If the hemoglobin concentration increases substantially during this period, the presumed diagnosis of IDA is supported. Iron supplementation continues for up to 4 additional months to complete correcting the anemia and to replenish the iron stores. To avoid iron overload, do not continue therapeutic iron supplementation thereafter.

Iron supplements are generally given orally as elemental iron in the form of ferrous sulfate, a well-absorbed and inexpensive iron preparation. Supplemental iron should be stored out of the reach of children, to guard against accidental poisoning.

caREminder

Iron is absorbed better on an empty stomach, and it is most often given to infants as a single dose before breakfast. For older children, the daily amount of iron supplementation is usually divided into two or three doses and is given between meals. Children receiving oral iron supplements have dark stools and they may experience gastrointestinal side effects such as nausea and constipation. Also, teeth may be temporarily stained by liquid iron preparations. To avoid staining the teeth, give liquid iron using a straw or a syringe, to place the medication toward the back of the child's mouth.

During infancy, iron deficiency is especially common after the iron stores that are present at birth are depleted. Thus, special care must be taken to ensure that infants have an adequate supply of iron. Prophylactic iron supplementation is given whenever an infant's dietary intake is inadequate. Full-term infants require an iron intake of 1 mg/kg/day, starting at 4 to 6 months of age. Formula-fed infants should receive iron-fortified formula, whereas babies continuing to breast-feed should receive iron-fortified infant cereal two times per day.

Preterm infants require an iron intake of 1 to 2 mg/kg/day, starting at 1 to 2 months of age. As with the full-term infant, iron-fortified formula can be given. Infants receiving human milk require iron supplementation, at least until they are old enough to receive iron-fortified infant cereal.

Children between infancy and adolescence with sufficient food intake usually do not require iron supplements. However, supplements may be needed during adolescence, especially among teenagers who are experiencing rapid physical growth and are prone to fad diets and poor nutrition. Also, teenage girls who are pregnant, lactating, or heavily menstruating require iron supplements, because their total iron need is not provided by diet alone.

Nutritional Counseling

Nutritional counseling is an important intervention in treating and preventing IDA. Certain dietary habits

enhance iron intake and increase the bioavailability of iron.

For infants, iron intake is better with iron-fortified infant formula than with fresh cow's milk. In addition to being poor in iron content, fresh cow's milk is associated with intestinal blood loss, which contributes to iron deficiency, especially during the first 6 months of infancy. The distribution of iron-fortified infant formula in the federal Special Supplemental Food Program for Women, Infants and Children is a major factor in the decreased incidence of IDA in the United States. In addition, the increased use of iron-fortified products and better iron availability in some food products may contribute to the continuing decline in the incidence of IDA (Eden, 2005).

Iron intake is enhanced with the use of iron-fortified infant cereal. Including meat in infants' diets, plus foods and juices fortified with ascorbic acid, promotes the absorption of iron from a meal. Also, avoiding solid foods at or near the time of breast-feeding enhances the bioavailability of the limited amount of iron in human milk.

Although many foods for children and adolescents contain iron, this iron may be in different forms. Heme iron, found primarily in foods from animal sources (meat, poultry, and fish), is readily absorbed by the intestinal mucosa, and thus is the best source of iron for the body. In contrast, nonheme iron is found mainly in foods derived from nonanimal sources, such as vegetables, fruits, cereals, and breads. It must be changed from the ferric to the ferrous form to facilitate absorption. Factors that will increase the iron absorption from nonheme foods include eating a heme and nonheme food together (e.g., tuna with beans); eating nonheme foods with foods that are sources of vitamin C (ascorbic acid; e.g., strawberries, oranges, broccoli); and cooking nonheme foods in an iron pot such as a cast iron pan.

Just as the absorption of nonheme iron can be facilitated by certain foods, it can be hindered by other dietary components. Inhibitors of nonheme iron absorption include bran foods, milk, and tannin-containing beverages such as tea and coffee. Certain antacids and antibiotics also may impede the absorption of nonheme iron.

Vegetarians consume mainly nonheme iron. When planning meals, they need to be aware of the role of ascorbic acid in facilitating the absorption of nonheme iron and to avoid those foods and beverages that decrease the bioavailability of their iron intake.

Education

The nurse has an important role in providing education about treating and preventing IDA (TIP 23-1). In addition to providing education to children and families in the healthcare setting, the nurse also provides community education. By arranging for educational programs at schools, daycare centers, health fairs, and so forth, the nurse can make an important contribution to preventing IDA. Children and families who develop dietary habits that facilitate iron intake and absorption, and who receive prophylactic iron supplements during times of increased iron need are less likely to experience IDA (Clinical Judgment 23-2).

TIP 23-1 Teaching Intervention Plan for the Child With Iron Deficiency Anemia

Nursing diagnoses and outcomes

Deficient knowledge: Iron deficiency anemia, sources of dietary iron, and management

Outcomes:

- Child and family describe iron deficiency anemia and the need for adequate dietary iron to prevent this anemia.
- Child and family identify sources of dietary iron.

Risk for injury related to effects of anemia

Outcomes:

- Child and family identify short-term and long-term effects of impaired tissue oxygenation caused by iron deficiency anemia.
- Child and family identify child's need for iron supplements to correct anemia and replenish iron stores.

Teach Child/Family

Managing The Child's Condition

- Instruct about iron deficiency anemia: inadequate iron, decreased hemoglobin in red blood cells; decreased oxygenation of body tissues
- Inform about causes of iron deficiency anemia: inadequate iron intake, especially during times of rapid physical growth (infancy, adolescence); malabsorption of iron; iron loss related to excessive bleeding
- Educate concerning dietary sources of iron
- Heme iron (easy to absorb): meat, poultry, fish
- Nonheme iron (harder to absorb): vegetables, fruits, cereals, breads
- Discuss dietary habits to facilitate absorption of nonheme iron:
 - *Include* meat, poultry, fish, and foods or beverages with vitamin C in the same meal.
 - *Exclude* bran foods, milk, tea, and coffee in the same meal.

Note: Milk is not a dietary source of iron.
- Teach regarding dietary sources of iron for infants: iron-fortified formula and cereal
- Advise breast-feeding mothers to avoid solid foods near breast-feeding time to enhance

bioavailability of the limited amount of iron in human milk.

Note: Breast-fed babies need iron supplements or iron-fortified infant foods because the amount of iron in breast milk is insufficient.

- Suggest meals providing adequate iron intake within the context of family's ethnic group and budget limitations.
- Provide instructions regarding signs and symptoms of iron deficiency anemia in children:
 - Less active, less playful
 - Poor appetite
 - Sleeping more
 - Pale in color
 - Short of breath
 - Irritable
 - Increase in infections
 - Abnormal growth and development
- Inform that children often adapt to a gradual decline in hemoglobin. Thus, signs and symptoms of anemia may not be readily apparent at first.
- Teach concerning iron supplements, when prescribed:
 - For best absorption, give iron with water or juice between meals; do not give with antacids, milk, bran foods, tea, or coffee.
 - If liquid iron prescribed, give with a straw or use syringe to place toward back of child's mouth to prevent teeth staining
 - Give full dose of iron, but do not give extra amounts or extra doses.
 - Expect color of child's stools to become dark while iron is supplemented.
 - Store iron medicine where children cannot reach it.

Contact the Healthcare Provider if:

- Child continues to show signs and symptoms of iron deficiency anemia despite dietary changes and supplement administration
- Child experiences side effects of iron supplementation such as constipation, nausea, or vomiting
- Child takes too much iron (immediately call physician or poison control center for your community)

Community Care

Outpatient management of the child with mild or moderate IDA is aimed at correcting the anemia,

replenishing the depleted iron stores, and preventing further iron deficiency. As with inpatient interventions, these goals are achieved primarily with iron

supplementation, nutritional counseling, and ongoing family education.

Megaloblastic Anemia

Megaloblastic anemia is a nutritional anemia that most often results from a deficiency of either vitamin B₁₂ or folate (folic acid) resulting from inadequate intake, malabsorption, or a metabolic disorder. Vitamin B₁₂ deficiency is more likely to occur among people who are strictly vegetarian than among those who eat meat and other animal products. The newborn may have inadequate vitamin B₁₂ as a result of maternal vitamin B₁₂ deficiency. Malabsorption is associated with pernicious anemia, in which intrinsic factor, which is required for absorption of vita-

min B₁₂, is either absent or dysfunctional. Malabsorption of vitamin B₁₂ may also stem from gastric and intestinal disorders, such as necrotizing enterocolitis, and from HIV infection. In addition, vitamin B₁₂ deficiency may be caused by an inborn error of vitamin B₁₂ metabolism.

Folate deficiency can occur at any age but is more likely to occur among infants, especially among premature infants who are experiencing rapid physical growth and have increased folate needs. Pregnancy, lactation, alcoholism, sickle cell disease, and infections such as hepatitis and HIV infection also increase demand for folate. Malabsorption of folate can occur with intestinal disorders such as chronic diarrhea. Folate deficiency also can stem from altered folate metabolism, such as has been reported with ongoing use of anticonvulsant medication (e.g., phenytoin). In general,

CLINICAL JUDGMENT 23–2

A Young Child With Iron Deficiency Anemia

Cody is a 15-month-old boy who comes to the clinic. His mother reports that he was doing well until about 1 week ago. Since then, he has been less playful and sleeping more than usual. His past history is negative for hematologic disorders and other abnormalities. There is no history of recent illness, injury, or foreign travel, and his mother has not noted any blood loss. Apart from skin pallor and decreased activity, Cody's physical examination is unremarkable. His laboratory results include the following: hemoglobin, 7.7 g/dL; mean corpuscular volume, 54 fL; mean corpuscular hemoglobin, 17 pg.

Questions

1. What additional information would you elicit concerning Cody?
2. Assuming that Cody's diagnosis is iron deficiency anemia, at what stage is it?
3. Why is iron deficiency the most probable reason for Cody's anemia?
4. How is iron deficiency anemia managed?
5. What data would indicate that an iron deficiency anemia is resolving?

Answers

1. Obtain a diet history for Cody. Particularly elicit information to help assess Cody's intake of dietary iron. For example, does Cody drink formula or cow's milk? If formula, is it iron fortified? If cow's milk, is Cody taking iron supplements? How many ounces of milk or formula does Cody drink on a typical day? (Too much may interfere with Cody's appetite for solid foods.) Does Cody eat solid foods? If yes, are they a source of iron?
2. The iron deficiency anemia would be stage III because Cody is anemic (hemoglobin, 7.7 g/dL),

and his red blood cells are small in size and decreased in hemoglobin content (mean corpuscular volume, 54 fL; mean corpuscular hemoglobin, 17 pg). These changes are not characteristic of the first two stages of iron deficiency anemia.

3. Iron deficiency anemia is the most frequent reason for microcytic, hypochromic anemia in infants and young children. Generally, it is the result of an inadequate intake of dietary iron coupled with depletion of the iron stores that are present at birth.
4. When iron deficiency anemia appears to be the result of a dietary deficiency, it is managed with the following:
 - Iron supplementation to correct anemia and replenish iron stores
 - Nutritional counseling to promote an adequate dietary intake of iron and to prevent further iron deficiency

If these measures are not effective, further studies are needed to assess for malabsorption of iron or loss of iron through bleeding.

5. Data that indicate that iron deficiency anemia is resolving include a decrease in the signs and symptoms that are present at diagnosis and a return to normal hematologic laboratory values. With Cody, look for increased activity and playfulness, and the return of normal skin color and normal sleep pattern. Also, note the return of normal-for-age hematologic values. For a 15-month-old, these are as follows: hemoglobin, 9.6 to 15.6 g/dL; mean corpuscular volume, 76 to 92 fL; mean corpuscular hemoglobin, 23 to 31 pg.

vitamin B₁₂ and folate deficiencies are readily treated. Thus, the prognosis for megaloblastic anemia is good.

Pathophysiology

Although megaloblastic anemia can develop with either vitamin B₁₂ deficiency or folate deficiency, anemia takes longer to occur with vitamin B₁₂ deficiency, because the body's stores of vitamin B₁₂ are greater than its stores of folate. The liver is the primary site for storage of vitamin B₁₂ and folate.

A deficit of vitamin B₁₂ or folate interferes with normal DNA synthesis within the red blood cells. The deficient cells fail to synthesize enough DNA for normal **erythropoiesis** (formation of erythrocytes). The result is scant, immature red blood cells in the bone marrow and peripheral blood that appear nucleated and macrocytic, and fail to reproduce normally.

The prolonged reproductive process does not interfere with RNA formation, but the cells acquire more RNA than normal. This alteration appears to increase the amount of hemoglobin and other cellular components, which in turn results in the cellular enlargement commonly associated with megaloblastic anemia.

Megaloblasts evidence immaturity, showing the presence of nuclei and the absence of the biconcave disks that characterize mature red blood cells. They are also fragile, with a life span that is one half to one third that of normal red blood cells. Despite these alterations, circulating megaloblastic cells are capable of transporting oxygen normally.

Assessment

Megaloblastic anemia is not an early manifestation of vitamin B₁₂ deficiency or folate deficiency; it appears after these deficiencies have been present for some time.

Assess children for pallor, weakness, unsteady gait, irritability, poor feeding, failure to thrive, and developmental delay. They may experience abnormal sensations and, with severe anemia, there may be evidence of heart failure and inflammation of the tongue. With vitamin B₁₂ deficiency, in particular, neurologic and gastrointestinal disturbances can occur in the absence of or before the onset of megaloblastic anemia.

Diagnostic Tests

Laboratory evidence of megaloblastic anemia can be categorized as follows: (1) evidence that shows the presence of megaloblastic anemia, (2) evidence that identifies or rules out vitamin B₁₂ or folate deficiency, and (3) evidence that points to the etiology of vitamin B₁₂ or folate deficiency.

Megaloblastic anemia is characterized by typical changes in the bone marrow and blood cell profile. Bone marrow shows the presence of megaloblasts. Blood cell profile changes include decreased hemoglobin and hematocrit, and increased MCV and MCH. In addition to oval, macrocytic red blood cells, hypersegmented neutrophils are present. With severe anemia, neutropenia and thrombocytopenia also may be noted.

Vitamin B₁₂ deficiency may be identified by a low vitamin B₁₂ level in serum, tissue, or both. In megaloblastic anemia, the serum level is usually low before megaloblasts become evident. Tissue vitamin B₁₂ deficiency is indicated by elevated levels of urinary methylmalonic acid, serum methylmalonic acid, and total homocysteine. Tissue deficiency may be evident in patients with neurologic and gastrointestinal disturbances in the absence of megaloblastic anemia. When vitamin B₁₂ deficiency is identified or suspected, the Schilling test (see Tests and Procedures 23–1) is helpful in determining a malabsorptive etiology such as pernicious anemia. However, neither a normal vitamin B₁₂ level nor a normal Schilling test rules out vitamin B₁₂ deficiency.

Folate deficiency is likely to be recognized by a low serum or red cell folate level. Decreased serum folate usually becomes apparent before evidence is seen of a reduced level of red cell folate or the onset of megaloblastic anemia.

caREminder

Folate deficiency may be masked by a normal serum folate level when the folate deficiency exists simultaneously with a vitamin B₁₂ deficiency. Along with serum folate level, expect to check the serum or tissue level for B₁₂ or perform a Schilling test.

Interdisciplinary Interventions

The child with megaloblastic anemia can be managed on an outpatient basis by the interdisciplinary team. Management of the child with megaloblastic anemia has four goals: identifying the cause of the anemia, correcting the anemia, replenishing vitamin B₁₂ and folate stores, and preventing further deficiency and anemia.

The cause of megaloblastic anemia is identified by carefully evaluating the child's history and clinical presentation, and the results of diagnostic laboratory tests. A deficit of both vitamin B₁₂ and folate may be present, rather than deficiency of just a single nutrient. The anemia is corrected, vitamin B₁₂ and folate stores are replenished, and further deficiency and anemia are prevented by supplementation and nutritional counseling. Follow-up care includes physical assessment and laboratory studies to ascertain that the anemia is corrected and that the stores of vitamin B₁₂ and folate are replenished.

Vitamin B₁₂ caused by inadequate intake is replenished by oral supplementation. When the deficiency is secondary to malabsorption, parenteral injections of vitamin B₁₂ are likely to be prescribed, although oral and intranasal routes are being investigated. Children with congenital alterations in vitamin B₁₂ metabolism may receive injections or large doses of oral vitamin B₁₂.

Folate supplementation is given orally. Even when folate deficiency is caused by malabsorption, some folate is absorbed when it is given orally in large doses. However, children who are receiving oral vitamin B₁₂ therapy for vitamin B₁₂ deficiency should avoid large doses of folate, because if vitamin B₁₂ supplements do not correct the

vitamin B₁₂ deficiency, the folate may protect against megaloblastic anemia but fail to prevent the neurologic impairment associated with vitamin B₁₂ deficiency.

Community Care

Preventing further deficiency and anemia entails nutritional counseling, particularly when megaloblastic anemia is caused by inadequate intake of vitamin B₁₂ or folate. The nurse has a key role in ensuring that the child and family receive information concerning dietary sources of these nutrients (see Chart 23–1). In addition, the nurse can instruct staff in daycare centers, schools, and other community groups about the importance of including foods with vitamin B₁₂ and folate in the diets of children and adolescents.

Hereditary Spherocytosis

Hereditary spherocytosis is characterized by loss of surface area on the red blood cell membrane. Spherocytic erythrocytes are prone to premature destruction, placing the child at risk for hemolytic anemia, especially with severe hereditary spherocytosis.

Most often hereditary spherocytosis becomes evident during childhood, but it can be discovered during any phase of life. Hereditary spherocytosis is common; it affects an estimated 1 in 5,000 people. The actual incidence is probably higher, because asymptomatic or mild hereditary spherocytosis may not be diagnosed. Although hereditary spherocytosis can occur in various racial and ethnic groups, its highest incidence is among those of northern European heritage.

For 75% of those with hereditary spherocytosis, the disorder follows an autosomal dominant inheritance pattern; for the remaining 25%, it follows an autosomal recessive inheritance pattern. Hereditary spherocytosis can also occur as a result of a spontaneous genetic mutation in individuals who have no family history of this abnormality. In general, the prognosis for hereditary spherocytosis is good. However, life-threatening complications, such as severe hemolytic anemia and aplastic crises, are possible, especially among children with severe hereditary spherocytosis.

Pathophysiology

The normal red blood cell membrane has a large surface area relative to the cell's volume, which permits red blood cells to adapt their shape to their environment and safely navigate through the vascular system, even through narrow capillaries. Spherocytic erythrocytes have a diminished membrane surface area with a reduced surface-to-volume ratio, which decreases their ability to adapt their shape to their environment. Also, spherocytes are osmotically fragile, leading to premature rupture and a considerably shorter life span than that of normal red blood cells.

The spleen poses the greatest challenge for erythrocytes. Although normal erythrocytes can contort themselves to pass through spaces that are more narrow than they are, spherocytic red blood cells are more likely to be

trapped in the splenic cords or to rupture as they journey through the venous sinus walls.

Assessment

Although the clinical presentation can be quite varied, with some children even being asymptomatic, the primary manifestations of hereditary spherocytosis are anemia, splenomegaly, and jaundice.

The degree of anemia tends to parallel the severity of spherocytosis. Assess the child with severe hereditary spherocytosis for pallor, fatigue, weakness, and other manifestations of anemia such as delayed growth and development.

Palpate the spleen. Splenomegaly is a common physical finding in children with hereditary spherocytosis and may be associated with abdominal distention, tenderness, and pain. Although the degree of splenomegaly may range from minimal to marked, the size of the spleen does not necessarily correlate with the severity of the spherocytosis.

Most children with hereditary spherocytosis intermittently manifest acholuric jaundice (jaundice without bilirubin in the urine). Jaundice in the neonate with undiagnosed hereditary spherocytosis can pose a particular challenge, because neonatal jaundice may occur in conjunction with a variety of other disorders, such as sepsis and hemolytic disease of the newborn.

Anemia, splenomegaly, and jaundice are often accelerated during infection. Children who are otherwise asymptomatic are likely to show these manifestations when viral illnesses and other infections occur.

In addition, children with hereditary spherocytosis may experience indigestion and biliary colic secondary to gallstone formation. This cholelithiasis is more likely to occur in older children and adolescents than in younger children. Complete a nutritional assessment, noting the child's dietary and elimination patterns. Determine whether the child experiences a "stomachache" after eating, and whether any association exists between abdominal pain and the type of foods eaten.

Diagnostic Tests

The primary laboratory evidence for hereditary spherocytosis consists of (1) a positive osmotic fragility test, (2) an elevated reticulocyte count (usually >6%), and (3) the presence of spherocytes on the peripheral blood smear. In addition, the bilirubin level is usually elevated, and the red blood cell indices are likely to exhibit low normal or abnormal hemoglobin and hematocrit levels, with an increased MCHC. MCV and MCH are generally within normal limits.

Interdisciplinary Interventions

Treatment for hereditary spherocytosis includes surgical management (splenectomy) and nutritional interventions.

Surgical Interventions

Splenectomy is the most effective intervention for symptomatic hereditary spherocytosis. Although spherocytic erythrocytes are still present in the blood after removal of

the spleen, their life span generally improves to about 80% of normal as hemolysis decreases. Anemia and jaundice usually disappear soon after splenectomy. In addition, removal of the spleen is associated with a reduction in symptomatic gallbladder disease among children and adolescents with hereditary spherocytosis.

Make sure the child has been immunized with the *H. influenzae* type b vaccine and a multivalent pneumococcal vaccine before splenectomy, and receives prophylactic penicillin after splenectomy.

The benefits of splenectomy must be balanced with the potential complications. The risk of life-threatening sepsis is a particular concern for asplenic individuals, especially young children. Thus, every effort is made to delay splenectomy until the child is at least 5 years of age. When young children with hereditary spherocytosis experience marked hemolytic anemia, they are generally supported with red blood cell transfusions until they reach the age at which the postsplenectomy course is safer.

Nutritional Interventions

Children with hereditary spherocytosis are likely to have an increased need for folic acid. Folic acid supplements may be required to maintain adequate folate stores and to prevent the megaloblastic crises that can complicate hereditary spherocytosis.

Community Care

Instruct children with hereditary spherocytosis and their families to notify their physician or nurse practitioner when signs and symptoms of anemia, splenomegaly, or infection develop. Fatigue, pallor, weakness (anemia), and jaundice may be signs of an aplastic crisis, especially if preceded by a viral or other infection with chills, fever, lethargy, vomiting, diarrhea, and a “slapped cheek” macular–papular rash (parvovirus infection).

Even with mild hereditary spherocytosis, severe hemolysis and splenomegaly can occur with infections. Red blood cell transfusions may be required at such times even though, generally, the child is not transfusion dependent.

Also, instruct children with hereditary spherocytosis and their families about appropriate physical activities. Contact sports and strenuous physical activities should be avoided, because, even with mild hereditary spherocytosis, these activities may increase red blood cell hemolysis and lead to anemia.

Aplastic Anemia

Aplastic anemia is a disorder in which the normal production of blood cells in the bone marrow is absent or decreased. This defect leads to altered peripheral blood counts that reflect **pancytopenia** (abnormally low numbers of all types of blood cells) and not merely the presence of anemia. Aplastic anemia can be acquired, occurring at any age, inherited, or congenital, which may not become evident until some years after birth.

Fanconi’s anemia is the most common type of inherited form of aplastic anemia seen in children.

Acquired aplastic anemia (AAA) is characterized by a lack of precursor cells for the platelets, red blood cells, and white blood cells that are normally present in the peripheral circulation. As a result, the blood cell profile typically shows thrombocytopenia, anemia, and neutropenia. The cause of AAA is often unknown, particularly in children. However, in a number of cases it is associated with a history of exposure to drugs (e.g., chloramphenicol), chemicals (e.g., benzene), toxins (e.g., ionizing radiation), or infection (e.g., hepatitis). Occasionally, AAA has been diagnosed during pregnancy, and increased estrogen levels might contribute to the onset of this disorder during the antepartum period. In addition, genetic factors may play a role in susceptibility to AAA. In general, the disorder affects all racial groups, and its incidence among females and males is similar. The prognosis for AAA is related to the severity of the disorder. Generally, mild to moderate disease can be easily managed and has a good prognosis. However, children with severe disease require more aggressive treatment and, even then, approximately one in five does not survive to adulthood.

Fanconi’s anemia is a rare, inherited form of aplastic anemia that is associated with an autosomal recessive inheritance pattern. The hematologic abnormalities associated with this disorder may occur with other physical alterations. Generally, Fanconi’s anemia is diagnosed during childhood or adolescence. Although current treatment of bone marrow failure associated with Fanconi’s anemia has improved the prognosis for children with this disorder, most do not live beyond the third decade of life. Allogeneic stem cell transplantation has been curative for some patients with Fanconi’s anemia (Alter, 2005; Ayas et al., 2004).

Pathophysiology

Much remains unknown about the pathophysiology of AAA and Fanconi’s anemia. However, it appears that the stem cells of the bone marrow are affected and that these cells incur both qualitative and quantitative deficits. These deficits lead to pancytopenia in the peripheral blood, placing the child at increased risk for bleeding, secondary to thrombocytopenia; tissue hypoxia, secondary to anemia; and infection, secondary to neutropenia. In addition, Fanconi’s anemia is associated with an increased number of chromosomal breaks.

Assessment

The primary clinical manifestations of aplastic anemia are related to bone marrow failure and pancytopenia. Assess for abnormal findings related to bleeding, tissue hypoxia, and infection (see Focused Physical Assessment 23–1). In addition, for the child with Fanconi’s anemia, observe for possible multiple physical anomalies that most commonly include

- Café-au-lait spots and other areas of hyperpigmentation or hypopigmentation
- Short stature, frequently because of a short trunk

- Anomalies of the hands and forearms, such as absent thumb
- Renal anomalies
- Hypogonadism, particularly in males
- Microcephaly
- Characteristic facial appearance, including a broad nasal base, epicanthal folds, small eyes, microdontia, and small jaws

Diagnostic Tests

Thrombocytopenia, anemia, and neutropenia are revealed by respective abnormalities in the blood cell profile. Severe aplastic anemia is evidenced by an absolute neutrophil count of less than $500/\text{mm}^3$, a hemoglobin level less than 7 g/dL , a platelet count less than $20,000/\text{mm}^3$, and a reticulocyte count less than 1%. The anemia associated with AAA is most often normocytic, but at times, the red blood cells appear macrocytic. Bone marrow aspirations and biopsies reveal hypocellular and fatty marrow. These tests are particularly important, not only in diagnosing AAA but also in ruling out other possible reasons for pancytopenia, such as leukemia.

To distinguish between AAA and Fanconi's anemia, chromosome breakage analysis after exposure of cultured cells to DNA cross-linking is performed on peripheral blood lymphocytes. With Fanconi's anemia, an increased number of chromosome breaks are noted. Other physical alterations associated with Fanconi's anemia may be identified or ruled out with additional diagnostic studies such as a skeletal survey or renal ultrasonography.

Nursing Diagnoses and Outcomes

Nursing diagnoses and outcomes for children with bleeding and anemia are given in Nursing Plan of Care 23-1. In addition, the following nursing diagnosis and outcomes apply when the child has aplastic anemia:

Fear related to possibility of child's death resulting from severe aplastic anemia

Outcomes: Child and family will verbalize fears concerning potential for premature death of child.

Child and family identify information and acknowledge the need for emotional support to manage anticipatory grief.

Interdisciplinary Interventions

In addition to necessary supportive care, management of the child with aplastic anemia centers on restoring normal hematopoiesis. Children with mild or moderate aplastic anemia may require only supportive care, provided on either an inpatient or outpatient basis, depending on the severity of current symptoms. However, for those with severe aplastic anemia, bone marrow transplantation is the treatment of choice when a suitable donor is available.

Pharmacologic Interventions

Immunosuppressive therapy is used for children with severe AAA who are not candidates for bone marrow transplantation. Antithymocyte globulin is often the first

line of such treatment. Although this cytotoxic agent is effective in about one third of those who receive it, its mode of action in AAA is unclear. Generally, antithymocyte globulin is administered intravenously, once a day, for about 4 days. Before the first dose, a test dose is recommended to identify hypersensitivity. Observe children receiving antithymocyte globulin for adverse reactions such as fever, chills, rash, urticaria, pruritus, dyspnea, chest pain, nausea, vomiting, leukopenia, and thrombocytopenia. Other less frequent side effects that may occur and can be life threatening include hypotension, pulmonary edema, laryngospasm, and anaphylaxis. Serum sickness may also occur. In addition to antithymocyte globulin, corticosteroids and cyclosporine may be incorporated into the treatment plan for severe AAA.

Generally, children who respond to immunosuppressive therapy do so within 3 months. However, they may continue to have some degree of abnormal hematopoiesis, rather than the complete restoration of bone marrow function that usually follows successful bone marrow transplantation.

Androgen therapy may be used alone or in combination with corticosteroids to stimulate hematopoiesis in a child with Fanconi's anemia. The therapy must be administered continuously to be effective. However, the beneficial effects may not be evident in laboratory tests for several weeks.

Bone Marrow Transplantation

Bone marrow transplantation is the treatment of choice for a child with severe AAA. It is also a possible option for a child with Fanconi's anemia when androgen therapy is no longer effective. Bone marrow transplantation is a complex process, requiring numerous tests and procedures. In addition to the usual tests to identify a suitable marrow donor, the potential donor for a child with Fanconi's anemia must be evaluated for covert Fanconi's anemia. When bone marrow transplantation is successful, it offers the hope of cure for aplastic anemia associated with Fanconi's anemia.

Children receiving such transplants are hospitalized in an environmentally controlled, intensive care setting to prepare for, receive, and await marrow engraftment of donor stem cells. These children require intensive prophylactic and supportive therapy, particularly while they await the restoration of hematopoiesis and the resolution of pancytopenia. Care is provided by specially prepared physicians, nurses, social workers, dietitians, pharmacists, and others. Chapter 22 provides a more information about bone marrow transplants and the care of child undergoing this intervention.

Supportive Care

Supportive care for children with aplastic anemia involves close monitoring of blood counts for evidence of thrombocytopenia, anemia, and neutropenia, as well as close observation for indicators of bleeding, tissue hypoxia, and infection. Although blood product support is sometimes necessary, every effort is made to refrain from such transfusions. Transfusions place the child at

risk for becoming sensitized to the surface antigens on donor blood cells (alloimmunization). Alloimmunization decreases the probability that the bone marrow, when transplanted, will successfully engraft and increases the probability of graft-versus-host disease among bone marrow transplant recipients. When a suitable marrow donor is available, it is likely to be a family member. Thus, to decrease the risk of alloimmunization when pretransplantation blood products are necessary, it is important that the blood products not be from family members. Blood products also are usually radiated and then filtered during administration, a procedure that decreases the number of white blood cells and, in turn, reduces the risk of alloimmunization.

In addition to managing the aplastic anemia, the interdisciplinary team is involved in identifying and treating nonhematologic health problems that may be present in the child with Fanconi's anemia. Referrals for ongoing informational and emotional support and genetic counseling after discharge are important interventions for the child and family experiencing Fanconi's anemia.

Supportive Care for Thrombocytopenia. Therapeutic platelet support is given when there is evidence of bleeding. In addition, antifibrinolytic agents and topical agents are used to control bleeding. Prophylactic platelet support may be considered for children whose platelet count falls to less than $5,000/\text{mm}^3$, primarily to decrease the risk of intracranial hemorrhage. During thrombocytopenia, instruct the child and family to observe certain precautions.

caREminder

For children with thrombocytopenia, apply firm pressure to venipuncture and intramuscular injection sites for 15 minutes immediately after each procedure.

Supportive Care for Anemia. Packed red blood cells are given when transfusion support is required for symptomatic anemia and dangerously low hemoglobin levels. However, children often adapt to chronic anemia, and when they can tolerate hemoglobin levels as low as 6 g/dL, they should be allowed to do so.

If red blood cell transfusion therapy is required for a long time, monitor the child for iron overload.

Supportive Care for Neutropenia. Neutropenia increases risk for infection, especially when the absolute neutrophil count is less than $500/\text{mm}^3$. Fever in the child with neutropenia is a serious sign and is presumed to indicate sepsis until proved otherwise. Common inflammatory responses associated with infection are likely to be absent in patients with neutropenia.

Instruct the child and family on the increased risk of rapidly progressing, life-threatening sepsis during neutropenia and the importance of notifying the physician immediately when fever of 101°F (38.3°C) or higher occurs.

Alert! The child with fever and neutropenia requires immediate evaluation for sepsis, even if the child looks well. When sepsis is suspected, follow hospital protocol to obtain bacterial (both anaerobic and aerobic) and viral blood cultures, as well as cultures from any obvious source (e.g., throat, if child complains of sore throat). Initiate broad-spectrum parenteral antibiotics as ordered, preferably within 1 hour of presentation.

Ensure that the child with fever and neutropenia receives a septic workup, including physical examination, blood cultures, and blood counts, and begins intravenous antibiotics. Antibiotics are continued at least until the child is afebrile, blood cultures are negative, and any sepsis has been treated. However, long-term oral, prophylactic antibiotics are not given to the child with neutropenia associated with aplastic anemia. Neither are granulocyte transfusions used, except in the presence of life-threatening sepsis that is not responding well to intravenous, broad-spectrum antibiotic therapy.

Community Care

Preventing infection in the child with neutropenia, especially sepsis caused by endogenous microorganisms, is not always possible. However, ensure that the child and family are taught infection prevention measures for people with neutropenia (see Community Care 22–2).

Instruct the child and family to identify activities that are tolerated by children with anemia. Typically these activities are less strenuous, help the child conserve energy, and provide adequate oxygenation to support the child's vital body functions and activities of daily living. Remind them to be alert for and report signs that indicate that the child is not tolerating the anemic state, such as dyspnea, irritability, listlessness, and marked fatigue.

Experiencing a life-threatening disorder is usually stressful for children and their families. Healthcare providers must be sensitive to this stress. Education about aplastic anemia, its treatment, and the ongoing need to provide laboratory data, physical assessment data, and emotional support are important components of the interdisciplinary management of aplastic anemia. The Aplastic Anemia & MDS International Foundation, Inc. is an additional source of support (see [thePoint](#) for Organizations).

HEMOGLOBINOPATHIES

Hemoglobinopathies are anemias that result from a structural or quantitative abnormality involving hemoglobin. These alterations range in severity from clinically insignificant to profound and life-threatening disease.

Sickling disorders are hemoglobinopathies in which a structural alteration in the hemoglobin molecule causes red blood cells to assume a sickle shape under certain circumstances. Hemoglobin S is an example of a structurally abnormal hemoglobin. Its presence instead of the normal hemoglobin A is associated with the most common sickling disorder, hemoglobin SS disease.

Thalassemia disorders are hemoglobinopathies in which one or more of the globin chains necessary for the synthesis of hemoglobin is deficient or absent. The normal hemoglobin A molecule is composed of paired alpha and beta globin chains. A deficiency in the alpha chain results in alpha thalassemia, whereas a deficiency in the beta chain is associated with beta thalassemia.

Sickle Cell Disease

QUESTION: If neither of Shawanda's parents have sickle cell disease, what is the probability that any of Shawanda's future siblings will have sickle cell disease?

Sickle cell disease is a hereditary disorder characterized by any one of a number of structural abnormalities in the beta globin chains of the hemoglobin molecule. These abnormalities may be clinically unimportant or may result in serious overt disease.

Sickle cell disease affects approximately 0.1% of the African American population in the United States. In Africa, it is estimated to affect 4% of black Africans (NIH, 2009). About 30% of children with sickle cell anemia also have beta thalassemia (Steinberg, 2005). The widespread distribution of sickle cell disease has led to neonatal screening programs to identify children with this disorder.

WORLDVIEW: Sickle cell disease has a widespread geographic and ethnic distribution. It is most common among those of African descent. Sickle cell disease also affects a large number of children whose ancestral roots are in the Mediterranean, Caribbean, Central American, and South American parts of the world. White children can also have sickle cell disease, although it is rare in this population.

Sickle cell disease follows an autosomal recessive inheritance pattern, with the genetic defect present on chromosome number 11 (see Fig. 3-3). When both parents are heterozygous for the hemoglobin S gene, there is a 25% probability that each child will have hemoglobin SS disease, and a 50% probability that each child will have the sickle cell trait. In addition, there is a 25% probability that each child will have normal hemoglobin. When one parent is heterozygous and the other parent is homozygous for the hemoglobin S gene, there is a 50% probability that each child will have hemoglobin SS disease. Children who do not have hemoglobin SS disease will have the sickle cell trait. Persons with the trait need counseling about the genetics of the disorder, because of the potential consequences for their children. Most children with sickle cell disease are homozygous, having inherited the same abnormal beta globin gene from each parent. The long-term prognosis for sickle cell disease varies, depending on its type and clinical severity. In general, the median survival is 42 years for males and 48 years for females (Quinn et al., 2004).

ANSWER: Shawanda's parents each have the sickle cell trait but not the disease, which means that they are heterozygous for the condition. Therefore, each of her future siblings have a 25% chance of the disease, a 50% chance of having the trait, and a 25% chance of having normal hemoglobin.

Pathophysiology

QUESTION: When Shawanda is 6 years old, her younger brothers have parvovirus infection. How might their infection affect Shawanda and her condition?

The red blood cells of children with hemoglobin SS disease are prone to become sickle shaped and fail to function in a normal manner. Circumstances such as increased body temperature, high hemoglobin concentration, decreased blood pH, dehydration, and decreased blood oxygen level enhance the sickling process. Erythrocytes may be reversibly or irreversibly sickled. The former lose their sickle shape with reoxygenation, whereas the latter remain sickled despite their return to an oxygenated environment.

Sickle cells are characterized by rigidity, which limits their ability to adapt their shape to their surroundings, particularly in the microvasculature (Fig. 23-3). Sickle cells undergo premature hemolysis, accounting for the chronic anemia seen. In addition, sickle cells enhance blood viscosity, increasing adherence of sickle cells to the vascular endothelium, which is an important factor in the vaso-occlusion commonly associated with sickle cell disease.

The clinical hallmark of sickle cell disease is the vaso-occlusive (acute pain) crisis, caused by sickle cells obstructing the circulation. This leads to painful ischemia and infarction. The bones, lungs, liver, spleen, brain, and penis are common sites of crisis events (Fig. 23-4). Other important sickle cell crises include the following:

- *Acute splenic sequestration:* Sickled red blood cells are trapped and a large amount of blood accumulates within the spleen. It occurs among children whose spleen is still functional. With hemoglobin SS disease, the spleen generally ceases to function during early childhood. Thus, the incidence of acute splenic sequestration decreases when children with hemoglobin SS disease reach middle childhood.

Alert! Acute splenic sequestration can rapidly progress to cardiovascular collapse and death. Prepare the child for emergent transfusion with PRBC.

- *Aplastic crises:* Transient episodes of bone marrow suppression in which red blood cell production is markedly decreased. Normally, children with sickle

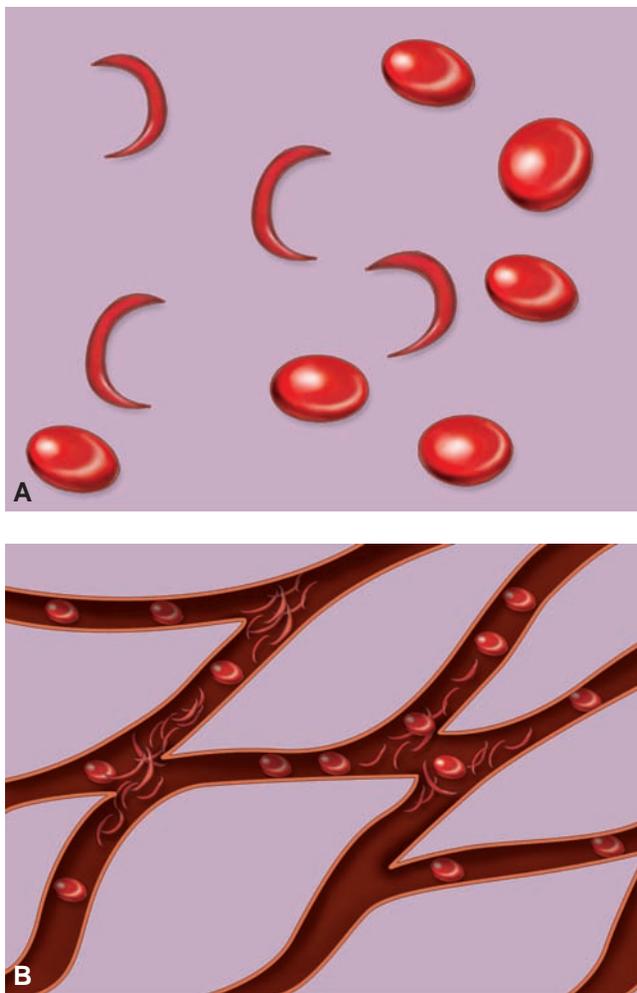

FIGURE 23-3. (A) Sickle cells contain abnormal hemoglobin that causes the cells to have a sickle shape. (B) The cells are rigid and tend to form clumps that block the blood vessels. Blocked blood vessels can cause pain, serious infections, and organ damage (vaso-occlusive crisis).

cell disease have increased bone marrow activity and produce an above-average number of red blood cells to compensate for the shortened survival time of their atypical erythrocytes. In hemoglobin SS disease, red blood cells live for approximately 10 to 20 days, in contrast to the 120-day average in the general population. These crises also may occur in conjunction with bacterial and viral infections, including parvovirus B19, which can interfere with normal erythropoiesis (development of mature red blood cells), triggering erythroid aplasia.

- **Infections:** Frequently occurring and tending to be severe, even life threatening, among children with sickle cell disease, because their immune status is altered. A primary factor is the development of a nonfunctional spleen. Generally, this event occurs early in life among children with hemoglobin SS disease and places them at high risk for sepsis, meningitis, pneumonia, and other infections.

Alert! Even in the absence of other clinical manifestations of infection, febrile children with sickle cell disease require emergency healthcare. A child with sickle cell disease and a temperature more than 101 °F (38.3 °C) should be treated with parenteral antibiotics before obtaining radiographs or laboratory results. A child with a temperature of more than 104 °F should be admitted promptly.

In addition to acute complications, the chronic complications of hemoglobin SS disease may be multiple. They can involve the eyes, ears, heart, lungs, kidneys, liver, and bones (Chart 23-2). General growth (40 °C) and development are often delayed.

ANSWER: Exposure to parvovirus (fifth disease) may precipitate aplastic crisis in patients with sickle cell disease. This virus can interfere with normal erythropoiesis (development of mature red blood cells), triggering erythroid aplasia. In addition, any infection can be severe and possibly life threatening because the child's immune system is altered.

Assessment

QUESTION: Based on Shawanda's manifestations, what would the nurse most likely suspect as her current problem?

The clinical manifestations of sickle cell disease vary considerably. Most children undergo occasional crises, although some children experience frequent crisis events, whereas others rarely encounter such episodes. Ongoing assessment includes monitoring the child with sickle cell disease for signs and symptoms of crisis events and chronic complications (Table 23-6). For example vaso-occlusive crisis may present with bone pain, acute chest syndrome, acute abdominal pain, cerebrovascular accident, or priapism.

Alert! Respiratory failure may occur rapidly with acute chest syndrome. Provide supplementary oxygen, promptly administer medications ordered for pain, provide incentive spirometry, and prepare the patient for transfusion of PRBC.

Also assess the child with sickle cell disease for chronic complications. Children with sickle cell disease are normal in size at birth, but subsequent growth and development are altered. Increases in standing and sitting height occur more slowly than usual. Weight gain and development of secondary sexual characteristics are delayed. Although full height is generally achieved by the completion of adolescence, weight gain frequently continues to be less than normal. This delay in weight gain is thought to stem from the body's increased need for calories to support increased bone marrow activity and cardiovascular compensation.

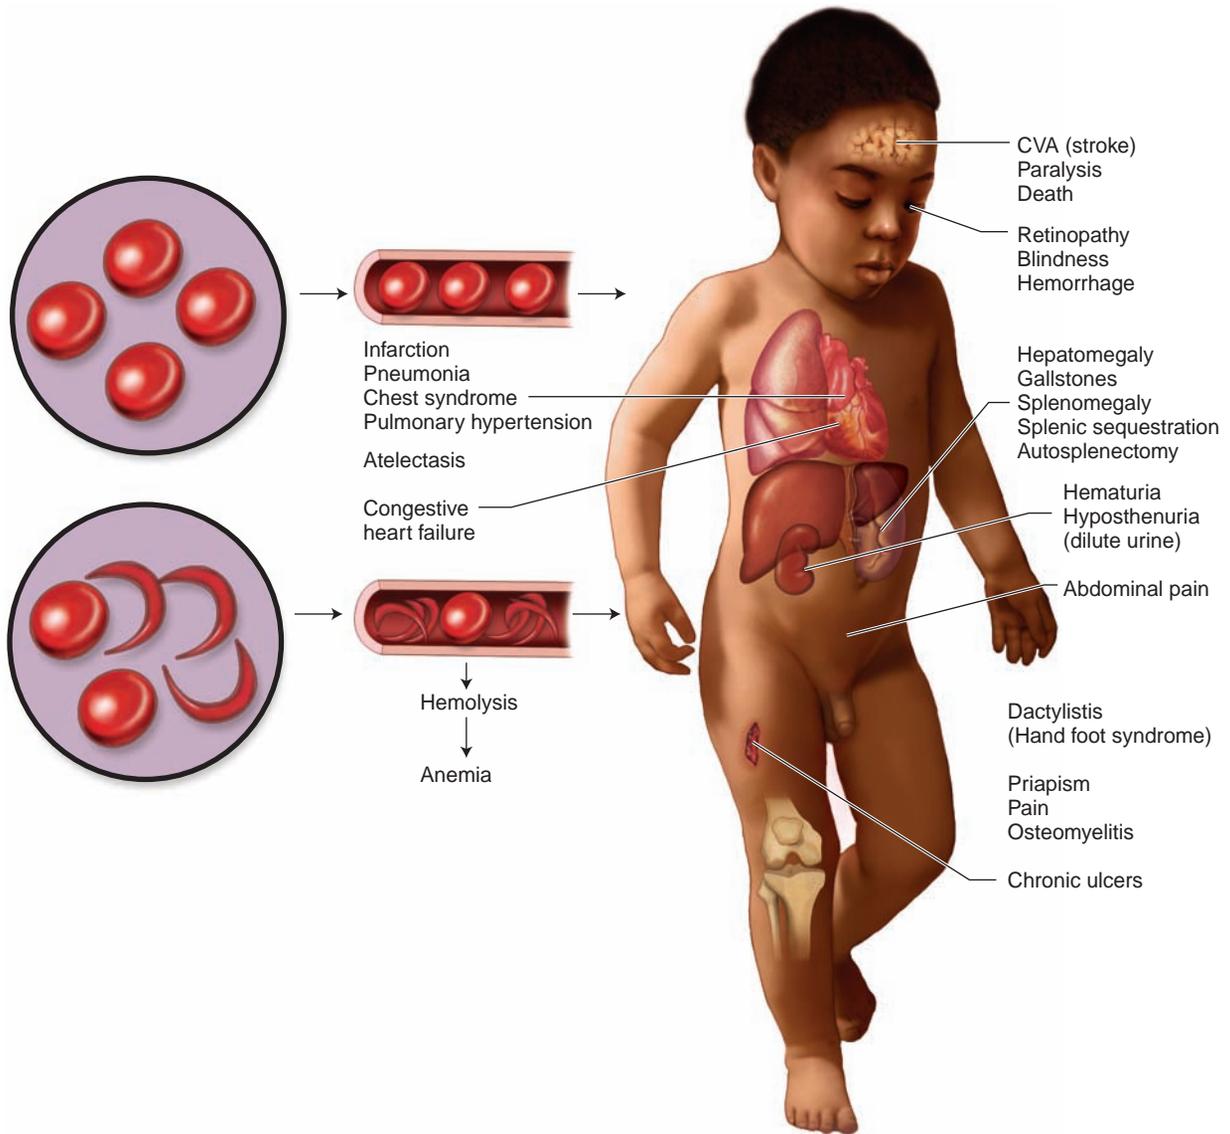

FIGURE 23–4. Effects of sickle cell anemia on various parts of the body.

ANSWER: Children with sickle cell disease who present with respiratory symptoms, chest pain, and fever are generally diagnosed with acute chest syndrome. Its etiology is usually difficult to identify with certainty, and it is assumed that both sickling and infection are present. Manifestations include fever, hypoxia, and tachypnea; decreased hemoglobin concentration; increased reticulocyte count; and leukocytosis. Shawanda’s chest radiograph shows pulmonary infiltrates, also indicative of acute chest syndrome.

Diagnostic Tests

Newborn screening for sickle cell is mandated in the United States. For the initial testing, most states use either thin-layer isoelectric focusing or high-performance liquid chromatography, using blood samples collected by heel stick. These testing materials have high sensitivity and specificity for sickle cell anemia. Regardless of the birth setting, all infants should undergo screening

between 24 and 72 hours of age. Verification of the results are made by the healthcare provider during the infant’s first office visit. If repeat testing is needed, this should be completed no later than 2 months of age (U.S. Preventative Services Task Force, 2007).

caREminder

Specimens must be drawn prior to the administration of any blood transfusions because of the potential for a false-negative result. Also, premature infants may have false-negative results when adult hemoglobin is undetectable (U.S. Preventative Services Task Force, 2007).

Screening is not done widely in older children; if sickle cell disease is suspected in an older child, hemoglobin electrophoresis is used to confirm the diagnosis. Alterations in laboratory studies can differ among the various forms of sickle cell disease.

CHART 23–2 CHRONIC COMPLICATIONS OF SICKLE CELL ANEMIA

Organ/System	Complications
Skin	Skin ulcerations, with ankles and lower legs as the primary sites
Eyes	Vascular changes in the eyes, most of which are not harmful Proliferative retinopathy, which can lead to blindness
Ears	Sensorineural hearing loss resulting from hair cell destruction in the inner ear
Cardiovascular	Increased cardiac output, cardiomegaly Cardiac murmurs
Lungs	Chronic lung disease related to repeated pulmonary infarctions and pneumonia
Kidneys	Some degree of renal impairment Hyposthenuria (inability to produce urine with high specific gravity); excretion of large amounts of dilute urine leading to nocturia and enuresis
Liver and biliary system	Hyperbilirubinemia and high liver enzyme levels resulting from intrahepatic sickling; hepatomegaly Gallstones
Sexual development	Delayed development of secondary sexual characteristics Possible decreased fertility among males
Skeletal	Skeletal changes, usually resulting from expansion of the bone marrow cavity and bone infarction (e.g., frontal bossing, maxillary overgrowth, and flattened vertebrae) Avascular necrosis of the femoral head after repeated bone infarctions (more likely to occur among adolescents than children)

With sickle cell disease, anemia is generally evident by 4 months of age. Reticulocytosis is present, and baseline hemoglobin levels usually range between 6.0 and 10.0 g/dL. By the time the child reaches early childhood, a peripheral blood smear typically shows the presence of abnormal red blood cells, such as sickle cells (crescent or sickle shaped) and target cells (which have a “doughnut” appearance). When the spleen is nonfunctional or absent, red blood cells also may contain inclusions such as *Howell-Jolly bodies* (nuclear fragments of condensed DNA) and *Heinz bodies* (caused by oxidative injury to and precipitation of hemoglobin).

Note current laboratory data for hematologic status, liver function, and renal function. Review the results of special studies such as arterial blood gas studies, pulmonary function tests, electrocardiography, and radiography.

Nursing Diagnoses and Outcomes

QUESTION: What outcomes would be appropriate for Shawanda?

In addition to those presented in Nursing Plan of Care 23–1, general nursing diagnoses and outcomes for the child with sickle cell disease are presented in TIP 23–2 (see also [thePoint](#) for Care Path: An Interdisciplinary Plan of Care for the Child With Sickle Cell Disease and Acute Chest Syndrome). Additional nursing diagnoses applicable to the child with sickle cell disease may be found in Chapters 10 and 12.

ANSWER: Desired outcomes for Shawanda most likely would include afebrile status, evidence of adequate gas exchange and effective breathing pattern with normal respiratory rate and rhythm with no signs of respiratory distress, ability to tolerate oral fluids, pain relief, and return to previous level of age-appropriate functioning (being more talkative and playful) with continued growth and development.

Interdisciplinary Interventions

Whenever possible, management of the child with sickle cell disease is directed by an interdisciplinary professional team that is affiliated with a center for comprehensive treatment of pediatric hematologic disorders. This team collaborates with healthcare providers in the child’s home community to ensure complete healthcare for the child. The interdisciplinary team bases care practices on clinical practice guidelines such as those provided by the National Institutes of Health (2002). These guidelines include recommendations for neonatal screening, health maintenance measures, parent education, and assessment and treatment of the child who presents for emergency care.

Health supervision guidelines have also been recommended by the American Academy of Pediatrics (2002). These guidelines emphasize the importance of an ongoing health maintenance program to manage sickle cell disease effectively. Such a program begins with an accurate diagnosis of the specific type of sickle cell disease. Thereafter, it includes regular visits to the healthcare center to update the

TABLE 23-6

Sickle Cell Crises and Associated Assessment Findings

Type of Crisis	Assessment Findings
Vaso-occlusive crisis	<p>Presentation variable depending on location of vaso-occlusion</p> <hr/> <p>Bone pain</p> <p>Most commonly in lumbosacral spine, knee, shoulder, elbow, and femur</p> <p>Small bones of the hands and feet (dactylitis) in infants and young children</p> <p>Avoidance of activities involving use of affected extremities</p> <p>Leukocytosis, fever, ill appearance</p> <p>Radiographic evidence of bone changes within 2 weeks of the onset of dactylitis (usually reversible over several months)</p> <hr/> <p>Acute chest syndrome</p> <p>Chest pain and pulmonary infiltrates</p> <p>Pneumonia (more extensive and slower to resolve)</p> <p>Abnormal chest findings not immediately evident on radiographic studies</p> <p>Cough, fever, hypoxia, and tachypnea</p> <p>Decreased hemoglobin concentration, increased reticulocyte count</p> <p>Leukocytosis</p> <hr/> <p>Acute abdominal pain</p> <p>Distended abdomen with enlarged liver, spleen, or other organ</p> <p>Guarding, tenderness, including rebound tenderness</p> <p>Elevation of white blood cell count (less than what would be associated with a “surgical abdomen”)</p> <p>Stabilization/improvement of pain with hydration and mild sedation</p> <hr/> <p>Cerebrovascular accident</p> <p>Hemiparesis, hemiplegia, impaired speech, impaired comprehension, visual disturbances, severe headache, seizures, and coma</p> <p>Computed tomography, magnetic resonance imaging, or magnetic resonance angiography identifying sites of sickling and vaso-occlusion</p> <p>Possible resulting chronic impaired motor function and decreased IQ</p> <p>Abnormal results of screening Doppler ultrasonography (initiation of transfusion program if abnormal)</p> <hr/> <p>Priapism</p> <p>Painful nonsexual erection of the penis occurring for an extended time, more than 24 hours, or as a short episode; repeated brief episodes (“stuttering” priapism)</p> <p>Urine retention with prolonged episodes</p>
Acute splenic sequestration	<p>Sudden and quickly progressing splenic enlargement, abdominal distention, pallor, weakness, dyspnea, tachycardia, and hypotension</p> <p>Left upper quadrant abdominal pain and vomiting</p> <p>Decreased hemoglobin, hematocrit (number and size of red blood cells), and platelet count</p> <p>Increased reticulocyte count</p> <p>Presence of nucleated red blood cells</p>
Aplastic crisis	<p>Absence of reticulocytes</p> <p>Decreased hemoglobin and hematocrit</p> <p>Decreased red blood cell precursors in the bone marrow</p>

health history and physical assessment data, and to provide needed interventions. Baseline data obtained during routine clinic visits are especially helpful in managing future crises such as an impending aplastic crisis. For example, a

hemoglobin level of 6.5 g/dL is more likely to indicate an impending crisis in a child whose baseline hemoglobin is 8.8 g/dL than it is in a child whose baseline hemoglobin is 6.8 g/dL.

TIP 23–2 Teaching Intervention Plan for the Child With Sickle Cell Disease

Nursing diagnoses and outcomes

Deficient knowledge: Diagnosis of sickle cell disease

Outcomes:

- Child and family describe sickle cell disease in general and the child's hemoglobinopathy in particular.
- Risk for injury related to sickle cell crises

Outcomes:

- Child and family identify signs and symptoms of the following types of crisis events:
 - Vaso-occlusion
 - Infection
 - Acute splenic sequestration
 - Bone marrow aplasia
- Child and family seek emergency healthcare for fever, and signs and symptoms of life-threatening or severely painful crisis events.

Acute or chronic pain related to blocking or stacking action of sickled cells in the lungs, bone, and muscles

Outcomes:

- Child exhibits adequate hydration status.
- Child reports relief from pain.
- Child and family identify pain relief measures that may be used at home.
- Risk for injury related to chronic complications of sickle cell disease

Outcomes:

- Child and family identify common chronic disorders that may develop with sickle cell disease.
- Child receives ongoing healthcare to identify and manage chronic complications associated with sickle cell disease and, when possible, to prevent such complications.

Disturbed body image related to perceptions of physical alterations associated with sickle cell disease

Outcomes:

- Child and family verbalize concerns regarding physical alterations and receive informational and emotional support.

Risk for impaired parenting related to child's chronic physical disorder

Outcomes:

- Parents identify normal developmental milestones and their role in helping their child achieve these milestones.

- Parents identify positive attributes about their child and ways in which they can promote the child's self-esteem.
- Parents engage in appropriate interactions with their child.

Knowledge of the child's Condition

Teach Child/Family

Outcomes:

- Knowledge of the Child's Condition
- Characteristics of sickle cell disease: abnormal hemoglobin, sickling of red blood cells, abnormal function of sickled cells
- Child's type of sickle cell disease and its usual clinical course
- Etiology of sickle cell disease and the risk of future children having sickle cell disease or sickle cell trait
- Factors that may precipitate sickling of red blood cells:
 - Fever
 - Infection
 - Dehydration
 - Hot and/or humid environment
 - Cold air and/or water temperature
 - High altitude
 - Excessive physical activity

General signs and symptoms of sickle cell crises:

- Fever
- Pain
- Hand-foot syndrome (painful swelling of hands and feet)
- Respiratory distress
- Abdominal distention
- Pallor weakness
- Penile erection
- Neurologic deficits such as impaired vision or speech, impaired motor function or paralysis, seizures

Types of crisis, associated signs and symptoms, and chronic complications:

- Vaso-occlusion: bone pain, acute chest syndrome, acute abdominal pain, cerebrovascular accidents, priapism
- Infection
- Acute splenic sequestration
- Aplastic crises
- Complications: cardiac, renal, hepatic, skeletal, pulmonary, visual, auditory, and dermatologic complications; delayed growth and development

Managing the Child's Condition

- Need for emergency healthcare for fever, severe pain, and other signs and symptoms of crisis events
- Measures to relieve pain associated with sickle cell crises: rest, increased fluid intake, analgesics
- Need for ongoing healthcare to identify and manage chronic complications
- Opportunities to express concerns regarding altered body image related to sickle cell disease; follow up with emotional support and additional information, as needed

Promoting growth and development

- Measures to promote normal growth and development:
- Safety
- Nutrition and extra fluid intake
- Exercise
- Dental care
- Stress management
- Avoidance of tobacco, alcohol, and unprescribed drugs
- Immunizations, including hepatitis B, *Haemophilus influenzae* B, and pneumococcal vaccines

Guidelines for activities that are appropriate for the child's physical state and developmental level

Nonphysical disciplinary measures, balancing overly protective and overly permissive parental behaviors

Communication with siblings and affected child about sickle cell disease

Communication with school and child care personnel about child's needs

Contact the Healthcare Provider if:

- Child has temperature of 101 °F (38 °C) or higher
- Child has pain that is not relieved by oral medication
- Child experiences
 - Chest pain
 - Shortness of breath or trouble breathing
 - Severe headaches or dizziness
 - Severe stomach pain or swelling
 - Jaundice or extreme paleness
 - Painful erection in males
 - Sudden change in vision
 - Seizures
 - Weakness or inability to move any part of the body
 - Loss of consciousness

Vaso-occlusive pain crises that are mild to moderate frequently can be managed at home with increased fluid intake, analgesics, and biobehavioral measures such as relaxation, warmth, and bed rest. Crises with persistent and severe pain require hospitalization to administer intravenous fluids, intravenous analgesics, and other interventions appropriate to the particular crisis event (Clinical Judgment 23–3). Supplemental oxygen is usually reserved for patients who demonstrate hypoxia (Fig. 23–5). Exchange, partial exchange, or simple blood transfusions may be indicated for patients with continuing hypoxia or cerebral hyperemia.

Repeated, severe vaso-occlusive crises or a history of cerebrovascular accident may require an ongoing transfusion program to suppress production of sickled cells. However, such programs carry the typical risks of blood transfusions. In addition, a long-term transfusion program eventually results in iron overload that requires ongoing iron chelation therapy.

An alternative intervention for severe vaso-occlusive disease is bone marrow transplantation (Yesilipek, 2007). It offers the hope of cure and may be recommended when a suitable bone marrow donor is available (see Chapter 22). In the future, children with sickle cell disease may be cured with gene transfer therapy.

Acute splenic sequestration requires emergency intervention to restore normal blood volume and tissue oxygenation. Most often, restoration is achieved with blood transfusions. As normal cardiovascular status is restored, blood trapped in the spleen is again mobilized, and the sequestration episode resolves.

Aplastic crises are generally transient. Although the resulting anemia may become severe, necessitating blood transfusion and other supportive interventions, aplastic crises usually resolve spontaneously.

Pain Management

Pain associated with sickle cell crises can be excruciating, and adequate analgesia is necessary to provide relief. Managing severe pain generally includes the use of strong narcotic analgesics such as morphine sulfate, nalbuphine, and hydromorphone. These medications may be given at higher doses than usual, and they are most effective when given as a continuous infusion with patient-controlled analgesia. Calcium channel blockers are under investigation to reduce pain in patients with sickle cell disease (Smith et al., 2005). As the child improves, patient-controlled analgesia alone, weaker opioids alone, or weaker opioids in combination with nonnarcotic analgesics (e.g., acetaminophen with codeine) are substituted, and the patient is subsequently weaned as the painful crisis resolves.

caREminder

Meperidine is contraindicated for ongoing pain management because it increases the risk of seizures.

Assess the child for verbal and nonverbal indicators of pain (e.g., withdrawal, crying, grimacing) and use a developmentally appropriate pain assessment tool. Collaborate with the interdisciplinary healthcare team to ensure interventions that provide pain relief for children with sickle cell crises (see Chapter 10).

Fluid Therapy

Fluid therapy is initiated during a crisis event to restore circulating blood volume and to decrease the vaso-occlusive effects of the sickled cells circulating in the blood. Provide

CLINICAL JUDGMENT 23–3

A Young Child With Sickle Cell Disease

Tyrone is a 2-year-old boy with hemoglobin SS disease. Last evening he was admitted to the hospital via the emergency room after an acute onset of chest pain. The pain was not relieved at home by increased fluid intake and acetaminophen with codeine. Pertinent findings from the admitting physical examination include fever with a temperature of 104 °F (40.0 °C), irritability, mild nasal flaring, tachypnea, and decreased breath sounds. Tyrone's oxygen saturation on room air is 87%. His chest radiograph shows bilateral pulmonary infiltrates. Admitting laboratory studies include hemoglobin, 4.7 g/dL; reticulocytes, 24%, white blood cell count, 30,000/mm³; platelet count 90,000/mm³.

Questions

1. What additional information would you elicit to assess Tyrone's current illness?
2. What data from Tyrone's medical record will help you interpret his admitting laboratory test results?
3. What is most likely to be Tyrone's current health problem?
4. How can Tyrone's pain be managed?
5. What assessment data would indicate that Tyrone's physical condition has improved?

Answers

1. Seek additional information about Tyrone's symptoms and the time of their onset. Ask for further details about home interventions, particularly the amount of fluid intake, and the dose and frequency of analgesic medication. Inquire about conditions that may have precipitated sickling in Tyrone,

such as inadequate fluid intake, exposure to heat and/or humidity or cold, excessive physical activity, travel to high altitude, exposure to infectious organisms. *Note:* There are many times when the precipitating factor cannot be identified.

2. Tyrone's baseline laboratory values help to interpret his current laboratory values. With certain crisis events, it is not unusual to note a decrease in hemoglobin and an increase in reticulocyte count. Also, the white blood cell count is elevated above its baseline value.
3. Children with sickle cell disease who present with respiratory symptoms, chest pain, and fever are generally diagnosed with acute chest syndrome and infection. The etiology is usually difficult to identify with certainty, and it is assumed that both sickling and infection are related to the current symptoms he is demonstrating.
4. Because Tyrone's pain was not relieved by oral fluids and oral analgesics at home, he should receive intravenous fluids and an intravenous narcotic, such as morphine sulfate, on a regular schedule around the clock. As his condition improves, oral fluids and a weaker analgesic will be substituted. The analgesic will be discontinued when the painful crisis resolves.
5. The following assessment data would indicate that Tyrone's physical condition has improved: afebrile, normal respiratory rate and rhythm with no signs of respiratory distress, tolerating oral fluids, normal sleep pattern, more talkative and playful.

FIGURE 23–5. Oxygen may be needed during a sickle cell crisis or an episode of acute chest syndrome to help relieve symptoms.

intravenous fluids and monitor the child's state of hydration. Intravenous fluids can be combined with oral fluids to ensure the child receives 1.5 times the maintenance fluid requirements for the child based on their age and weight.

Interventions to Treat Infection

Infections among children with sickle cell disease can be caused by various microorganisms, including pneumococcus and *H. influenzae*. The potentially severe nature of these infections requires that fever be regarded seriously and that prophylactic antibiotic therapy be initiated. Broad-spectrum antibiotics are used to manage acute chest syndrome and vaso-occlusive crises caused by infection. Instruct the child and parents about the increased risk of rapidly progressing, life-threatening sepsis in sickle cell disease, and stress the importance of immediately calling their healthcare provider in the event of fever. They should anticipate a septic workup, including physical examination, blood counts, blood culture, urine culture, and chest radiograph as well as parenteral antibiotic therapy.

The availability of ceftriaxone, a broad-spectrum, long-acting antibiotic, permits selected children with a febrile illness to be cared for at home after a few hours of observation in the clinic or emergency room. Outpatient care is a safe, convenient, and less costly option for children who are relatively well and free of complications, and whose caregivers are reliable in providing the prescribed follow-up healthcare. Febrile children who are quite young, especially infants, and children with severe illness and complications are generally hospitalized.

Therapeutic antibiotics are continued at least until cultures are negative and any infection has been treated. Thereafter, antibiotic prophylaxis is resumed. Other measures to prevent serious infection in children with sickle cell disease include immunization with polyvalent pneumococcal and *H. influenzae* vaccines.

Stimulation of Hemoglobin Production

Hydroxyurea may be used to improve hematologic values by stimulating hemoglobin F production, thereby decreasing vaso-occlusive complications. Benefits have included decreasing painful episodes, hospitalizations, number of blood transfusions, and the acute chest syndrome (National Institutes of Health, 2008). Complications from therapy can range from nausea to moderate bone marrow suppression to malignancy. Hydroxyurea does not adversely affect growth. Although strong evidence exists for the therapeutic use of hydroxyurea in adults and adolescents, efficacy of this medication has not been firmly established in infants and preadolescents. Clinical trials of this medication in the pediatric population are ongoing.

Nutritional Interventions

Adequate folic acid intake is especially important during recovery from an aplastic crisis. Normally, the diet supplies a sufficient amount of folic acid. However, to ensure adequate intake in hemoglobin SS disease, folic acid supplements may be prescribed.

Surgical Management

Children who have experienced splenic sequestration crises may subsequently have an elective splenectomy.

However, this surgical procedure is not indicated during times of acute splenic sequestration.

Surgical procedures for children with sickle cell disease require perioperative measures to prevent sickling. Preoperative transfusion corrects anemia and provides an increased number of hemoglobin A erythrocytes. Transfusion also decreases the body's need to engage in erythropoiesis, thereby reducing the number of hemoglobin S erythrocytes entering the circulation. Other common measures that help prevent sickling during the perioperative period are adequate fluid support, oxygenation, environmental warmth, and preventing acidosis.

Community Care

For children with sickle cell disease, view discharge planning from two perspectives. One involves planning related to specific events such as vaso-occlusive crises, infections, and surgical procedures. The second relates to planning associated with outpatient appointments for ongoing assessment and management of sickle cell disease. In both situations, identify desired outcomes and plan appropriate interventions to attain these outcomes by the end of a hospital stay or an outpatient visit.

Discharge planning for episodic events must consider the needs related to the particular event as well as the needs associated with sickle cell disease. When special supplies and services are required, referral to a home care company may be necessary.

Education is a major part of discharge planning (see TIP 23-2). Start teaching as early as possible and plan time for review. Teaching may encompass a variety of topics, depending on the specific situation. For example, when a young child with sickle cell disease has an elective splenectomy after two earlier episodes of splenic sequestration, education is likely to include measures to promote good hydration; signs of abnormal wound healing; signs of wound infection; ways to identify nonverbal indicators of pain; pain management techniques; schedule for outpatient follow-up appointments; and the need to call the physician for bleeding, fever, increased pain, or other complications.

An important component of the teaching process is to assess the family's understanding of the child's home care needs and their ability to provide them. Management of sickle cell disease also requires attention to the psychosocial needs of the child and the family (see the discussion of Treatment Modalities earlier in this chapter).

Outpatient visits for ongoing assessment and management of sickle cell disease generally occur at least two times per year. These visits occur more frequently with children who are newly diagnosed or quite young or whose health needs require close monitoring. Desired outcomes for these visits address physical and psychosocial needs indicated by the updated history and current physical assessment.

Be alert for the developing child's readiness to learn more about sickle cell disease, as well as the need to correct misconceptions that the child and family may have about the disorder, its effect, its complications, and its management. Also, as the child and family reach new developmental milestones, be alert for the need to discuss the child's activities and specific concerns during each developmental phase. As children develop, teaching must be an ongoing process that assesses their previous

knowledge and expands upon it. Knowing the beneficial effects of keeping well hydrated and warm, as well as the negative effects of cold, dehydration, and other physical stressors, can assist children in managing their disorder.

Children with sickle cell disease need to develop effective coping skills for dealing with both physical and psychosocial concerns. They may fear painful crisis events. They may wonder what will happen when they experience a crisis event. Knowing the signs and symptoms of crises, knowing what to do, and knowing what to expect others to do helps children cope with crisis events. Instruct children to notify their parents when they experience pain or other indicators of sickle cell crises and that measures should be taken promptly to abate crisis events.

Like their peers, children with sickle cell disease are involved in establishing their identities. Help them to identify their positive qualities, recognize what they can do, and develop realistic, healthy self-concepts. This process is particularly important for adolescents with sickle cell disease, whose peers achieve physical growth and develop secondary sex characteristics sooner than they do.

Discharge planning for outpatient visits may include follow-up information or referral to a local physician, a home care company, and a community health agency. It may involve contact with community groups such as the child's school or daycare center (Community Care 23–2). It may entail helping a family with planning for camp or

vacation by providing a letter detailing the child's need for emergency healthcare if a crisis event occurs. It may incorporate a referral to the Sickle Cell Disease Association of America for literature and information about the services and local chapters of this and related organizations (see [thePoint](#) for organizations).

Beta Thalassemia

Thalassemia comprises a variety of microcytic hemolytic anemias that are characterized by a decrease or absence of one or more of the normal globin chains in the hemoglobin molecule and by ineffective erythropoiesis. Thalassemias are classified according to the defective globin chain and to the clinical severity. A primary example is beta thalassemia, in which production of beta globin chains is inadequate, whereas in alpha thalassemias the alpha chain is affected (Rassi et al., 2008). Alpha thalassemia, seen primarily in Southeast Asia, is more uncommon than beta thalassemia.

Beta thalassemia is a hereditary disorder. It follows an autosomal recessive inheritance pattern, with the genetic defect present on chromosome number 11. The disorder affects equal numbers of females and males. Children who are heterozygous for the defective gene usually do not show clinically significant disease, but those who are homozygous tend to have serious disease, especially if the disorder is not diagnosed and appropriate interventions are not implemented.

COMMUNITY CARE 23–2

The Child With Sickle Cell Disease in School or Daycare

Children with sickle cell disease will participate in school and daycare in both public and private settings. It is important for the child's teachers and caregivers to know that they have sickle cell disease. Also, staff should know the guidelines that have been established to prevent and manage crisis events, and to promote normal growth and development in children with sickle cell disease.

The nurse may assist the child's family in providing information to the staff. Outcome objectives for the child's caregivers include the following:

- Describe sickle cell disease, in general, and how it affects the child who will be cared for at the daycare center, in particular.
- State factors that may precipitate crisis events in the child with sickle cell disease, such as humidity, heat, cold, and excessive physical activity.
- Describe common types of crisis events associated with sickle cell disease:
 - Vaso-occlusive crises
 - Infections
 - Acute splenic sequestration
 - Aplastic crises
- Discuss common signs and symptoms associated with "crisis" events:
 - Pain
 - Fever
 - Pale color
 - Difficulty breathing
 - Enlarged abdomen
 - Vomiting, diarrhea
 - Refusal to eat or drink
 - Irritability
 - Increased somnolence
 - Weakness or numbness of arms or legs
 - Swelling of hands or feet
- Discuss the need for prompt medical care for "crisis" events associated with sickle cell disease.
- Discuss the importance of the child receiving extra fluids and pausing for rest periods during times of physical activity. Daycare center personnel should be informed of any activities in which the child is not to participate, such as swimming in cold water.
- Relate the child's more frequent use of restroom facilities to the effect of sickle cell disease on kidney function.
- Describe the significance of treating the child as other children are treated. Although there is a need to be aware of sickle cell disease and what to do if a crisis event occurs, the school or daycare center staff should not focus on it or single the child out for special attention or privileges.

In addition, some children inherit a gene for hemoglobin S from one parent and a gene for beta thalassemia from the other parent. This inheritance results in sickle beta thalassemia. The severity of this disorder depends on the extent to which the beta thalassemia gene contributes to production of hemoglobin A. When no hemoglobin A is present in the red blood cells, the disorder tends to be severe. When some hemoglobin A is present in the red blood cells, the disorder is usually milder.

WORLDVIEW: Beta thalassemia is most common among people of Mediterranean descent. Also, it affects a substantial number of those whose ancestral roots are in the Middle East, India and Southeast Asia, and Africa. Screening programs are common in Europe and Asia, where the incidence of thalassemia is greater. In the United States, hemoglobin electrophoresis is recommended for at-risk populations to identify those with thalassemia and thalassemia trait.

Beta thalassemia is classified in terms of its clinical intensity as

- *Thalassemia minima*, referred to as “silent” because it causes no clinically important hematologic abnormalities
- *Thalassemia minor*, associated with some abnormal hematologic findings but most are asymptomatic on physical examination
- *Thalassemia intermedia*, becoming apparent during early childhood with hematologic abnormalities in conjunction with classic findings of hyperbilirubinemia, splenomegaly, hepatomegaly, delayed growth and sexual maturation, and abnormal facial appearance
- *Thalassemia major (Cooley anemia)*, the most severe form with symptoms of pallor, fatigue, and weakness; and poor feeding, failure to thrive, and delayed growth and development generally appearing during the first year of life.

The prognosis for beta thalassemia depends on its severity. If untreated, children with thalassemia major die during the first year of life. Children with thalassemia minor generally experience no disease-related health problems, whereas those with thalassemia intermedia experience moderately severe anemia, bone deformities, and splenomegaly.

Pathophysiology

Beta thalassemia stems from a defect in the beta globin gene. The result is inadequate production of the beta globin chains, necessary for hemoglobin A synthesis.

People who are heterozygous for beta thalassemia generate about half the normal quantity of beta globin chains. Those who are homozygous for beta thalassemia are subclassified as having beta⁺ thalassemia and beta⁰ thalassemia. Those in the beta⁺ group synthesize up to one third the normal quantity of beta globin chains, whereas those in the beta⁰ group produce no beta globin chains.

Alpha globin chains, which are also required for the synthesis of hemoglobin A, continue to be produced in their normal quantity. However, the lack of beta globin chains with which they can be paired creates an excess of free alpha globin chains. These free alpha globin chains precipitate and appear as inclusion bodies within developing red blood cells. The inclusion bodies have a destructive effect, leading to the demise of most red blood cells while they are still maturing in the bone marrow.

The red blood cells that enter the peripheral circulation in decreased number are characterized by microcytosis (small size), hypochromia (less color as a result of poor staining properties because of decreased hemoglobin), poikilocytosis (abnormal shape), and the presence of inclusion bodies. Their life span is usually limited to a few hours or days, with damaged cells being removed from circulation by the spleen and liver. Red blood cells that contain a substantial amount of hemoglobin F survive longer. People with thalassemia may produce an increased amount of hemoglobin F to compensate for the deficiency of hemoglobin A.

When severe anemia occurs, the bone marrow greatly expands and produces an increased number of erythroid precursor cells. However, these cells meet an early demise, just like their predecessors, and increased erythropoiesis is negated by hemolysis.

Assessment

The clinical manifestations of beta thalassemia vary considerably, depending on its severity. Typically the child with thalassemia minima and minor will be asymptomatic. However, for the child with thalassemia intermedia and major, observe for facial changes that begin during infancy, including frontal *bossing* (prominence of the frontal bone), prominent cheekbones, depression of the nasal bridge, maxillary overbite, and mandibular prominence. This classic “thalassemic” facies is caused by the expanding bone marrow (Fig. 23–6). In addition, urine may appear dark and tea-colored as a result of red blood cell hemolysis. Extramedullary areas of hematopoiesis occur as compensation for ineffective erythropoiesis. Features of the ineffective erythropoiesis include enlargement of involved anatomic sites, such as the liver, spleen, and lymph nodes. Although the clinical manifestations of beta thalassemia can be severe, they are less frequently seen today because of the use of transfusion therapy.

FIGURE 23–6. Iron overload related to thalassemia leads to bony changes such as frontal bossing and maxillary prominence.

Diagnostic Tests

Diagnosis of beta thalassemia is generally made after the third month of life, when the normal switch from predominantly hemoglobin F to predominantly hemoglobin A fails to occur, and the child becomes anemic (see Tests and Procedures 23–1 earlier in this chapter). The infant with thalassemia is born with only hemoglobin F, or in some cases hemoglobin F and hemoglobin E. Children with beta thalassemia have severe anemia with few reticulocytes (<8%), numerous red cells, and microcytosis. Unconjugated serum bilirubin levels are usually elevated. Other blood chemistry values will appear normal during the early stages of the condition. Elevated serum ferritin levels and Hemoglobin A₂ are present. Radiography is used to assess for bone marrow hyperplasia.

In addition, serum bilirubin levels may be increased as a result of red blood cell hemolysis. Leukocytosis also may be present. A normal white blood cell differential distinguishes this leukocytosis from that associated with infection.

Radiography may detect bone changes such as a thinning of long bone cortices, which makes these bones fragile and prone to pathologic fractures (Salama et al., 2006). They also may detect sites of extramedullary areas of hematopoiesis that develop as the body attempts to compensate for ineffective erythropoiesis in the bone marrow. These sites may appear as masses in the chest, for example.

Nursing Diagnoses and Outcomes

Nursing diagnoses and outcomes for the child with beta thalassemia are described in Nursing Plan of Care 23–1. In addition, the following nursing diagnosis and outcomes apply to the child with beta thalassemia:

Risk for injury related to effects of iron overload

Outcomes: Child and family will demonstrate understanding of the etiology of iron overload.

Child and family will identify the physical changes associated with iron overload, including their life-threatening potential.

Child and family will demonstrate acceptance of the importance of iron chelation therapy in preventing severe iron overload.

Interdisciplinary Interventions

Management of beta thalassemia varies, depending on its severity. Most children with thalassemia minima or thalassemia minor do not require blood transfusion therapy, because they do not tend to have anemia. An exception occurs during pregnancy, when transfusion support may be necessary. Treatment for children with thalassemia intermedia and thalassemia major includes transfusion therapy, iron chelation therapy, and bone marrow transplantation. Current investigations for new treatment modalities include the use of medications to stimulate increased synthesis of hemoglobin F, as well as the development of curative gene transfer therapy.

Transfusions and Iron Chelation Therapy

The primary intervention for beta thalassemia is a chronic transfusion program of PRBCs with iron chelation. Such a

program facilitates adequate oxygenation of body tissues and practically eliminates all symptoms of thalassemia.

WORLDVIEW: In some countries, limited blood supply and the risk of transfusion-transmitted viral infections may make it difficult to effectively provide beta thalassemia patients with the PRBCs they need for treatment. In such cases, newer treatments are being investigated, such as hydroxyurea, which is an oral agent widely used in the treatment of myeloproliferative disorders. Hydroxyurea has been shown to help reduce the transfusion requirements of these patients and thereby lengthen the time intervals between when transfusions are necessary (Anasari et al., 2007).

Transfusions of PRBCs are generally required every 2 to 4 weeks. Management of the condition by numerous transfusions results in excess iron in the body (transfusional hemosiderosis). Removal of the excess iron is necessary to prevent damage to major organs. Iron chelation therapy is used to remove the excessive iron. Deferoxamines is most commonly used to chelate the iron, allowing excretion in the urine and stool. Side effects include nausea, joint pain, stomachache, and low white blood cell counts (Roberts et al., 2007).

Children with minima or minor types of beta thalassemia, who do not require ongoing transfusion, may need supportive transfusions during times of infection and other events that trigger hemolytic or aplastic crises. Oral folic acid supplements may be prescribed to maintain adequate folate stores.

Bone Marrow Transplantation

A newer mode of treatment for beta thalassemia intermedia and major is allogenic bone marrow transplantation (see Chapter 22). This procedure has been shown to be most effective in children younger than 15 years old without excessive iron stores and hepatomegaly (DeBaun & Vichinsky, 2007). When successful, it offers the hope of cure. Although it is not an option for every child with severe beta thalassemia, bone marrow transplantation may be recommended when a suitable donor (preferably a human leukocyte antigen-matched sibling) or stem cells are available.

Community Care

Interdisciplinary management of beta thalassemia requires ongoing physical assessment and laboratory studies to monitor for anemia and its sequelae. Although children in a transfusion program often lead nearly normal lives, they need regular follow-up assessment for iron overload and its associated physical alterations. The psychosocial interventions for children with beta thalassemia and their families are similar to those described in the section on sickle cell disease.

The nurse and other members of the healthcare team play a major role in beta thalassemia. In addition to family-centered patient care and education, they provide community education about the disorder and its management, and genetic counseling about the probability of having a child with heterozygous or homozygous beta thalassemia. The Cooley's Anemia Foundation is an additional source of information (see [thePoint](#) for Organizations).

See [thePoint](#) for a summary of Key Concepts.

The Child With an Infectious Disease

Case History

Remember Ashley Tran from Chapter 7? Ashley is occasionally having unplanned and unprotected intercourse with her boyfriend. Ashley is experiencing frequent urination and a burning sensation when she urinates. She has also

noticed an increase in vaginal discharge with an unusual odor. She is worried that she may have a sexually transmitted infection. She decides to go talk to the school nurse.

CHAPTER OBJECTIVES

1. Discuss interventions that disrupt the chain of infection.
2. Identify assessment findings specific to pediatric infections and the diagnostic criteria used to confirm diagnoses.
3. Discuss nursing interventions to prevent the transmission of disease-causing organisms.
4. Name the diseases that constitute the TORCH syndrome and describe the nursing care for congenitally infected infants.
5. Compare the different herpesviruses and discuss the nursing care for each.
6. Describe at least one key intervention to decrease the risk of transmission of human immunodeficiency virus from a pregnant female to her fetus.
7. Identify the symptoms of at least three tick-borne fevers and teaching needed to reduce transmission of tick-borne fevers.
8. Name two sexually transmitted diseases and interventions to prevent transmission.
9. Identify two infectious diseases that should be reported to the local health department for follow-up contact tracing.

See [thePoint](#) for a list of Key Terms.

Microorganisms are as ancient as life itself. They are essential to life. Yet, they can be a great nemesis worthy of annihilation. Some organisms cause devastating disease and acute illness. Others live quietly in a symbiotic relationship with the body, benefiting the organism and the human host. Disease-producing microorganisms, such as bacteria, viruses, fungi, and parasites, are often called **infectious**

agents (see [thePoint](#), Supplemental Information: Summary of Infectious Agents and Disease-Producing Characteristics). This chapter explores these infectious agents and the diseases they produce, their periods of communicability (**incubation period**), and their assessment and related nursing interventions.

DEVELOPMENTAL AND BIOLOGIC VARIANCES

Every healthy child is born with an innate (natural) immune system. This system enables the body to recognize that it is being invaded by foreign microorganisms and to quickly respond to the invasion before healthy body tissue cells are destroyed. It also includes the first line of defense for preventing diseases from entering the body: the skin and mucous membranes.

Children also receive passive immunity from their mothers, either transplacentally or through the breast milk. This immunity varies, based on the diseases to which the mother has been exposed and the antibodies she has developed. The antibodies passed to the infant offer only temporary protection, typically for the first year of life.

The adaptive, or active, immune system develops throughout the life span and is a response to the diseases to which we are exposed or against which we are immunized with vaccines. Children, especially infants and young children, experience higher incidences of infections than adults because of physiologic and immunologic immaturity (Fig. 24–1). It is not unusual for a child, especially one who attends daycare, to have six to nine infections a year during the first 2 years of life.

Some infections are particularly prevalent in specific age groups:

Chronic itching, fatigue, and malaise may result in poor school performance.

Infants and young children frequently mouth objects. This facilitates spreads of organisms through saliva, nasal secretions.

Moveable, non-tender lymphnodes often are palpable in normal infants and children; lymph tissue grows rapidly until about 11 years old. Then it slowly involutes.

Immunity to many infections occurs only after exposure or immunization. An infant's immature immune system is unable to respond to many pathogens.

Infants and young children may have 8 colds per year. During middle childhood children may have 6 colds per year. Adolescents may have 4 colds per year.

Infants and young children often swallow sputum and have an ineffective cough. Therefore they are not very infectious when they have TB.

Young children cannot articulate not feeling well. Disease may be advanced before it is detected. Contagious children may unknowingly expose other children at daycare or school before symptoms occur.

Diapered children in daycare easily spread enteric pathogens by leaky, sagging diapers.

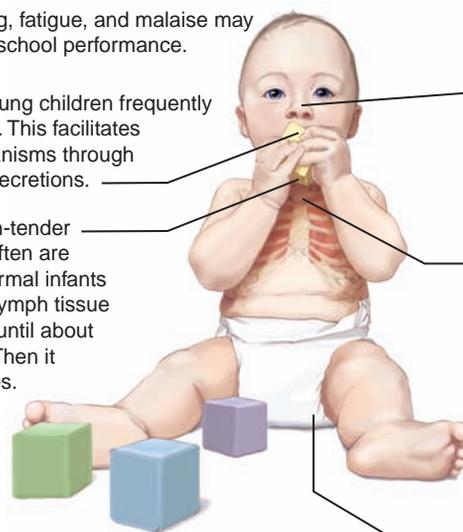

FIGURE 24–1. Developmental and biologic variances: infection in children.

- **Infancy:** Upper respiratory infections, enteric infections, vaccine-preventable diseases such as pertussis (because of incomplete immunity), gastroenteritis, and other diseases transmitted by the oral–fecal route
- **Early Childhood:** Upper respiratory infections, enteric infections (in those not toilet trained), communicable diseases transmitted by adults and other caregivers, soil-borne diseases (parasites), food-borne illnesses
- **Middle Childhood:** Ectoparasites (lice), food-borne illnesses, upper respiratory illnesses, pharyngitis
- **Adolescence:** Sexually transmitted diseases, mononucleosis (“kissing disease”)

The fetus is also at risk. TORCH (*toxoplasmosis, other, rubella, cytomegalovirus, herpes simplex virus*) is the acronym used for some of the chronic congenital infection syndromes that can affect the fetus and cause developmental and physical damage. In most cases, the infant fails to thrive and exhibits physical disorders such as blindness, hydrocephalus, and intellectual disabilities. To rule out a TORCH infection in infants, a careful maternal history must be obtained along with a serologic blood panel of tests for toxoplasmosis, rubella, cytomegalovirus (CMV), and herpes. A Venereal Disease Research Laboratory (VDRL) test is useful for syphilis, and a hepatitis profile can rule out hepatitis B. These conditions are discussed later in this chapter.

QUESTION: Ashley goes to see the school nurse. What aspects would be most important for the school nurse to address during the health history and physical assessment?

ASSESSMENT OF THE CHILD WITH AN INFECTIOUS DISEASE

It is difficult to focus on one system when discussing infectious diseases. The infection may be localized to one system or it may be systemic. Infections may have a rapid onset or occur long after exposure to the infectious agent. Infections may also mimic other diseases. Thus, the nurse needs astute questioning and assessment skills (see [thePoint](#), Supplemental Information: Features of Immunodeficiency).

History of response to previous infections and of the current illness, as well as meticulous documentation of physical findings, is essential for the healthcare team to diagnose the child accurately and to decide on effective therapy. Depending on the causative organism and resulting disease, infectious illness may manifest in different ways. The first sign may be a deviation from normal behavior, such as altered sleep pattern, irritability, or increasing lethargy. Inflammation, fever, rash, or some combination may also be seen as general signs. More system-specific signs of infection include rhinitis, cough, diarrhea, and jaundice.

Focused Health History

Infectious disease processes cover such a wide range of health concerns that the nurse must start with a broad systems approach when obtaining a health history. Use responses to general questions to focus the assessment (Focused Health History 24–1).

Start with general questions regarding the presenting symptoms of illness, such as fever, rash, enlarged lymph nodes, and cough. Obtain information regarding the child’s recent illness exposures, daycare or school exposures, environmental exposures, exposures to animals, and any travel history. Document immunization status and any history of past infections. This information often provides valuable clues that can lead to the diagnosis of the child’s illness.

WORLDVIEW: Different infectious agents are prevalent in different parts of the world. To uncover clues about the causative agent, ask about recent immigration, travel within the country or abroad, and exposure to people who have traveled or immigrated recently.

Augment the focused health history with specific questions about the presenting illness. For example, if the child presents with failure to thrive and esophageal thrush, focus the health history on maternal and birth history to determine the risks of serious illness such as human immunodeficiency virus (HIV) infection. Similarly, a child presenting with severe bloody diarrhea and cramping would need a detailed nutritional assessment focusing on the names and locations of restaurants or social gatherings where the child has eaten or the name of the child’s infant formula and the methods used to prepare formula in the home.

Use the history to try to determine whether the child has features suggestive of impaired host defense. The practitioner should determine whether the child has infections that are too frequent, too severe, or rare in the child’s demographic group. For example, five to six upper respiratory infections each year can be expected during the early and middle childhood years. However, more than one episode of pneumonia during a 5-year period would be unusual in children without asthma, cystic fibrosis, or another underlying pulmonary pathology. Also, the time required to clear infections may be prolonged in children with compromised immune function.

A history of infection with an unusual pathogen (e.g., *Aspergillus*, *Serratia*, or *Pneumocystis* species) suggests a defect in immune surveillance. The site of infection may also imply specific immune deficits. For example, children with neutropenia may experience frequent dermatologic infections, and children with antibody deficiency syndromes usually experience recurrent upper and lower respiratory infections. Equally important, ascertain whether infections resolve completely between episodes.

Focused Physical Assessment

After a thorough history, examine the child, carefully reviewing each major system. Assess growth parameters.

FOCUSED HEALTH HISTORY 24–1

The Child With an Infectious Disease*

Current history	<p>Known infectious contacts; their symptoms (and diagnosis, if known) Presence, timing, and site of onset, and home management of</p> <ul style="list-style-type: none"> • Neuromuscular symptoms: headache, stiff neck, ataxia, muscle pain or weakness, joint pain, swelling, or erythema (describe) • Eyes, ear, nose, throat, neck: change in vision, drainage, conjunctivitis, ear pain or discharge, otitis media, rhinitis (describe), mouth sores or lesions, sore throat, difficulty swallowing • Lymph nodes: swollen or painful lymph nodes • Chest: cough (productive or nonproductive), shortness of breath or difficulty breathing, new murmur • Skin: rash (describe), pruritus (describe), pain • Gastrointestinal symptoms: vomiting, diarrhea (frequency, appearance), abdominal pain • Genitourinary symptoms: discharge (describe), flank pain or pain on urination, rash or lesions (describe), generalized edema or recent weight change • Fever: describe fever extremes and pattern, diaphoresis, chills, rigors • Change in level of consciousness or behavior (e.g., lethargy, irritability, weakness), headaches, seizures
Past medical history	<p>Prenatal/Neonatal History Birth history: maternal infectious disease history, delivery method, prematurity, neonatal illnesses, skin lesions noted at birth, postnatal exposures, method of infant feeding</p> <p>Previous Health Challenges Recurrent or chronic illness, prior hospitalizations, transfusion, surgery, evidence of complete resolution of infection between episodes Childhood illnesses: previous communicable diseases, recent exposure to disease Immunizations: immunizations received, dates, any rashes, unusual responses to live vaccines Allergies: allergic reactions to drugs, antibiotics, food, or plants or products (describe reaction)</p>
Nutritional assessment	Recent changes in food or fluids consumed; recent weight change; formula preparation (describe); ingestion of honey, raw or undercooked meats, seafood, or restaurant food
Family medical history	Family history of early infant mortality, immunodeficiency, autoimmune disease, or malignancy History of child's presenting illness in other family members or close contacts (describe)
Social and environmental history	Recent changes in family lifestyle, daycare or school attendance (name and location), living arrangements (home, apartment, homeless, number of family and extended family living there), living location (rural, urban, suburban), drinking water source, family pets (list), exposure to farm or exotic animals, travel history (domestic and foreign), exposure to foreign-born individuals General hygiene, hand hygiene routines of child and caregivers, bathing History of pica; animal or insect bites or scratches; living or playing near or recent visit in wooded area, pond, lake, or farm
Growth and development	Child's growth plotted along own height and weight growth curves, head circumference in children younger than 3 years Body mass index Achievement of age-appropriate developmental milestones

*This a history is focused on infectious disease. See Chapter 8 for a comprehensive format.

Children with severe immunodeficiency often have growth failure, which can be an important indicator of disease severity. Weight is typically impaired first, so low weight for height may be an early indicator of failure to thrive.

In children with competent immune systems, the infectious process may be localized to one system but often has systemic effects (Focused Physical Assessment 24–1).

caREminder

If one child in the family has symptoms of an infection, assess the siblings for infection as well.

In contrast to the typical appearance of some diseases in adults, such as tuberculosis (TB), clinical findings in children may be few. Most children cannot produce sputum or mucus when they cough, and what little is produced is usually swallowed. Therefore, children with TB rarely present with a coughing illness. Jaundice is rare in childhood hepatitis. In many cases of hepatitis, the child does not even look ill.

ANSWER: Key aspects of the health history would include identification of the onset of Ashley's symptoms as well as any other overall complaints, her sexual history and current sexual activity, and information to determine whether her boyfriend is experiencing any symptoms. Physical assessment would focus on identifying any fever, evaluation of her urinary complaints and appearance of urine to rule out possible urinary tract infection, and evaluation of the appearance of her vaginal discharge, such as color, amount, characteristics, and odor.

Diagnostic Criteria for Evaluating Pediatric Infections

Numerous methods can be used to analyze immune system function and to identify causative organisms of infectious diseases (Tests and Procedures 24–1). Prudent use of laboratory tests requires that they be selected on the basis of history and physical examination findings. Rapid and accurate identification of causative organisms facilitates initiation of appropriate therapy and improves outcomes.

TREATMENT MODALITIES

The key to controlling infectious diseases is prevention. Childhood immunization is the primary intervention to prevent disease. Immunizations not only prevent disease in the child, but they also protect unvaccinated individuals who come into contact with them. Immunizations are responsible for preventing and controlling many of the once-common and often fatal childhood diseases. See Chapter 8 for more about immunization. Breast-feeding also can reduce the incidence of infection (Tradition or Science 24–1).

Regardless of the agent causing the infection, use standard precautions (see Siegel, Rhinehart, Jackson, et al. [2007] for guidelines). Care for all children as if they may have a communicable infection to prevent the spread of infection throughout the hospital or community.

Alert! Follow standard precautions at all times to prevent infection transmission.

Most communicable diseases must be reported to the local health department. Check local regulations; they vary in terms of which communicable diseases are reported.

Individual treatment of the child depends on the disease process. Prophylactic antibiotics are often used in children with immunodeficiencies to prevent serious infections. A variety of other treatments may be used, depending on the specific immunodeficiency. These modalities include intravenous (IV) gamma globulin, enzyme replacement, gene therapy, interleukin 2 infusions, and bone marrow transplantation. Refer to Chapter 31 for more about managing fever.

QUESTION: Which nursing diagnosis from Nursing Plan of Care 24–1 would be most appropriate for Ashley?

NURSING PLAN OF CARE FOR THE CHILD WITH AN INFECTIOUS DISEASE

The history and physical assessment should identify health issues that need to be addressed. Applicable nursing diagnoses depend on specific assessment findings. Chapter 11 identifies nursing diagnoses commonly applicable to the psychosocial needs of the acutely ill child. Nursing diagnoses and care generally applicable to a child with an infection are identified in Nursing Plan of Care 24–1. More specific diagnoses depend on the specific pathology and its effect on the child's health.

ANSWER: Appropriate nursing diagnoses may include deficient knowledge about the infection, transmission, and ways to reduce the risk of transmission; and non-compliance related to Ashley's current stage of development (being an adolescent).

PEDIATRIC INFECTIONS

Infectious diseases are generally classified into five major categories on the basis of causative agents: bacteria, viruses, fungi, parasites, and rickettsiae. Sepsis results when the body is overwhelmed by infection, and may be caused by various infectious agents. Infections may occur when the immune system does not function properly; thus, persistent infection despite treatment, or infection

FOCUSED PHYSICAL ASSESSMENT 24-1

Infectious Disease

Assessment Parameter	Alterations/Clinical Significance
General appearance	Deviation from normal behavior, lethargy, irritability, disinterest in environment, or assuming specific position may indicate infectious process.
Integumentary system (skin, hair, nails)	Color: erythema (on cheeks: fifth disease, scarlet fever); jaundice (hepatitis); pallor (generalized in some chronic infections, such as intestinal parasites; circumoral scarlet fever) Rash: appearance—macular (rubella, rubeola), papular, vesicular, pustular (varicella), crusts (impetigo), hives, blanches with light pressure (roseola), petechial (meningococemia) Location and distribution on trunk, extremities, or face (e.g., varicella starts on trunk and spreads to face and extremities); eczema may be present in immunodeficiency syndrome; lymphadenopathy often present during infection. Nails: clubbing, embolic lesions (endocarditis); thickened, discolored (fungal infection) Hair: hair loss (tinea), thinning (chronic infection)
Head and neck	Head: normocephalic (microcephaly could indicate neonatal infection) Neck: stiff neck, painful or swollen lymph nodes (many infections)
Eyes	Eyes: conjunctivitis (rubella, rubeola, adenovirus), jaundice (hepatitis)
Ears	Ears and neck: earache, parotid swelling and tenderness (mumps)
Face, nose, and oral cavity	Face: facial tenderness or headache (sinusitis, cellulitis) Nose: congestion, rhinorrhea, excoriation (cold, sinusitis) Throat and mouth: swollen tonsils, if present (tonsillitis); oral ulcers; adherent white patches on tongue, palate, inner cheeks (candidiasis); membrane in pharynx, adherent, gray-white (diphtheria, scarlet fever); Koplik's spots on buccal mucosa opposite molars (rubeola); vesicles (HSV), white strawberry tongue (white coat on tongue with red, edematous papillae projecting through) or later red strawberry tongue (white coat desquamates leaving red, edematous papillae projecting [scarlet fever])
Thorax and lungs	Cough (rubeola, TB, pertussis); note whether cough is productive, associated with cyanosis, vomiting (pertussis) Oxygen saturation less than 97% (respiratory infection) Presence of rales or rhonchi, use of accessory muscles to breathe (respiratory infection)
Neuromuscular	Change in level of consciousness, sluggish pupillary response (meningitis, encephalitis), Brudzinski's or Kernig's sign (meningitis) Limited range of motion: arthritis, arthralgia (rheumatic fever, fifth disease, Lyme disease) Muscle pain or weakness (influenza)
Cardiovascular system	Tachycardia above expected for fever (especially with diphtheria, scarlet fever, rheumatic fever) New-onset murmur (endocarditis)
Vasculature	Swollen or painful vessels associated with IV lines (infection, phlebitis)
Abdomen	Appearance: distention (intestinal parasites), pain with palpation, hepatomegaly (hepatitis, visceral larva migrans, mononucleosis, congestive heart failure resulting from rheumatic heart disease), splenomegaly (mononucleosis)
Lymphatic system	Multiple, scattered, swollen, and tender lymph nodes (EBV)
External genitalia and breasts (includes anus)	Vaginal or urethral discharge (sexually transmitted diseases)
Musculoskeletal system	Painful, swollen, or tender joints (<i>Staphylococcus</i> infection, malaria)
Neurologic system	Peripheral weakness or ataxic gait, hyper- or hyporeflexia, sluggish or asymmetric pupillary response, disorientation (meningitis, encephalitis)

Tests and Procedures 24–1 For Evaluating the Child With an Infection

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
Complete blood count with differential	To compare the status of specific blood elements. Detailed evaluation of the white blood cell count and morphology may help to detect infection.	<p>Values outside age-appropriate laboratory reference ranges indicate how the body is responding to the infection and adequacy of response.</p> <p>Infection usually causes leukocytosis.</p> <p>Neutropenia in a neonate often indicates sepsis.</p> <p>Neutrophilia after the neonatal period indicates an infectious process.</p> <p>An increase in bands (immature neutrophils) may indicate bacterial infection.</p> <p>Immunocompromised patients may not be able to mount a response that is reflected in an increased white blood cell count or change in the differential.</p>	<p>Provide psychosocial support.</p> <p>Obtain specimen, label appropriately, and send to laboratory.</p> <p>Obtain results, notify healthcare prescriber.</p>
Serum C-Reactive Protein (CRP)	To detect elevated levels of CRP, a nonspecific measure of inflammation in the body. CRP is normally present in trace amounts; production is increased after tissue injury or destruction.	<p>Levels of 10 to 19 mg/L suggest viral infection or non-invasive bacterial infection.</p> <p>Levels more than 20 mg/L suggest invasive bacterial infection or fungal septicemia.</p> <p>In neonates, levels more than 10 mg/L suggest sepsis or meningitis.</p>	<p>Provide psychosocial support.</p> <p>Obtain specimen, label appropriately, and send to laboratory.</p> <p>Obtain results, notify healthcare prescriber.</p>
Erythrocyte sedimentation rate (ESR)	A screening procedure to identify children who may have an infectious or inflammatory process	An elevated ESR is generally indicative of the presence of infection or an inflammatory process; it is nonspecific (not diagnostic for any particular pathology).	<p>Provide psychosocial support.</p> <p>Obtain specimen, label appropriately, and send to laboratory.</p> <p>Obtain results, notify healthcare prescriber.</p>
Urine culture	<p>To diagnose a urinary tract infection</p> <p>To monitor microbial colonization after urinary catheter insertion</p>	<p>Cultures are reported as “no growth” if urine is sterile (no infection).</p> <p>Bacterial count of more than 100,000 organisms/mL of a single species is indicative of infection.</p> <p>Bacterial count of 10,000 to 100,000 organisms/mL of a single species from a catheterized specimen may indicate infection.</p> <p>Counts less than 10,000 organisms/mL or multiple organisms indicate contamination.</p>	<p>Use gloves when handling all specimens.</p> <p>Obtain a sterile catheterized specimen (preferred) or a clean-catch specimen from continent children and adolescents.</p> <p>Collect at least 3 mL urine and send to the laboratory immediately or store in a specimen refrigerator until transport to the laboratory.</p>

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
Stool culture	To identify pathogenic bacteria	Normal fecal flora consists of gram-negative aerobic and anaerobic bacteria. Pathogenic bacteria include <i>Salmonella</i> , <i>Shigella</i> , <i>Campylobacter</i> , <i>Escherichia coli</i> O157:H7, <i>Clostridium difficile</i> , <i>C. botulinum</i> , <i>Yersinia</i> , and <i>Vibrio</i> .	Send a fresh specimen collected from a bedpan or diaper. Use a tongue blade to transfer it to a sterile container. If a rectal swab is used, insert the swab into the anus just past the anal sphincter. Rotate the swab gently. Withdraw it and place it in a transport tube.
Sputum culture	To identify the cause of pulmonary infection	Expectorated sputum has normal flora (alpha streptococci and <i>Neisseria</i>) and is Gram's stained before processing to determine the quality of the specimen. The presence of the following organisms usually indicates infection: <i>Mycobacterium tuberculosis</i> , <i>Haemophilus influenzae</i> , <i>Klebsiella</i> spp., <i>Staphylococcus aureus</i> , <i>Pseudomonas</i> spp.	Send early morning specimen (before eating breakfast) for TB. Have the child rinse or gargle with water and then cough deeply into a sterile container. Transport specimen to laboratory within 2 hours. Small children may not be able to produce sputum. Consider using gastric lavage as an alternative.
Blood culture	To confirm sepsis To identify the microorganism in bacteremia and sepsis	The presence of any organism usually indicates infection. Common skin contaminants (coagulase-negative <i>Staphylococcus</i> , <i>Bacillus</i> , <i>Corynebacterium</i>) isolated from a single bottle frequently represent contamination.	Disinfect blood culture bottles (two in a set) with appropriate disinfectant. Clean venipuncture site with appropriate disinfectant. Allow to dry. For endocarditis, send two specimen sets taken from two sites at least 2 hours apart.
Gastric lavage	To identify TB in a child when bronchoscopy cannot be performed Often gives better results than bronchoscopy in children	The presence of TB in the specimen by acid-fast staining and culture techniques indicates infection.	In the early morning, before eating, introduce a nasogastric tube. Withdraw a sample and place in a sterile container. Lavage 20 to 30 mL sterile water if unable to spontaneously withdraw gastric fluid. Transport to the laboratory within 15 minutes at room temperature.
Enzyme-linked immunosorbent assay (ELISA)	Direct detection of viral antigens in body fluids	Specific viral antigens are tested and are either positive or negative.	Obtain a blood specimen for most tests. Obtain a nasal wash for respiratory syncytial virus or influenza testing. Stool or urine can also be tested.
Nucleic acid probes (GYNProbe, GENProbe), PCR	Diagnostic and screening test that can detect specific viral or bacterial DNA or RNA	If sample is positive for the presence of specific organisms (e.g., <i>Neisseria gonorrhoeae</i> , <i>Chlamydia</i> , various strains of <i>Mycobacterium</i>), infection with the organism is indicated.	Send throat, urogenital, or rectal swabs to the laboratory. Other specimen sources include blood, CSF, urine, and bone marrow.

(Continued)

Tests and Procedures 24–1 For Evaluating the Child With an Infection (Continued)

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
Direct fluorescent antibody (DFA)	<p>Detects specific enzyme-labeled antibodies</p> <p>Usually used for respiratory viruses, herpes, rabies, some respiratory bacteria (pertussis)</p>	If positive, results are virus and bacteria specific.	<p>Send sputum samples or throat swabs to the laboratory on transport medium.</p> <p>Lesion scrapings should be sent on DFA slides.</p>
Western blot	<p>Lysate of concentrated virions is placed on specialized gel. Viral proteins separate by molecular weight.</p> <p>Used as a confirmatory test with ELISA for HIV but can be specific for other viruses.</p>	<p>Positive results are reported as bands. The specimen has bands in specific molecular weight ranges for the virus being tested. For example, HIV has p24, gp120, and so on.</p>	<p>Send a blood specimen.</p> <p>If a patient has a positive ELISA for HIV, perform a confirmatory Western blot test before explaining the results to the patient.</p>
Rapid antigen extraction	To test rapidly for the presence of group A streptococci (antigen), or influenza A and B	Result is positive if group A streptococci, flu A or B are present. For GAS, negative tests require a 24-hour incubation for conventional growth on agar.	<p>Send a throat swab to the laboratory. Swab both tonsillar pillars.</p> <p>Have the child take a deep breath to reduce gagging.</p>
Delayed hypersensitivity skin testing	<p>To test for certain diseases (e.g., coccidioidomycosis, TB)</p> <p>To serve as a positive control when conducting these tests, one or more antigens (e.g., <i>Trichophyton</i>, tetanus, <i>Candida</i>, mumps) are injected intradermally at the same time; if the child responds to any of them, it demonstrates effective T-cell function and results of the others can be considered valid.</p> <p>Sometimes used to test T cell-mediated immunity, although it has limited value in the HIV era.</p>	<p>A positive reaction (induration at site) to the antigens indicates the body has mounted a T cell-mediated immune response.</p> <p>Findings depend on antigens injected. All children older than 1 year should demonstrate a reaction to <i>Candida</i>, which is ubiquitous, as well as tetanus, mumps, and diphtheria, to which they have been exposed via routine immunizations. A positive reaction to purified protein derivative indicates a history of infection with TB.</p> <p>Immunocompromised or chronically ill children or those with severe nutritional deficiencies may not demonstrate a response (anergy).</p>	<p>Review the child's history for hypersensitivity to the test antigens.</p> <p>Observe the child for signs of anaphylaxis.</p> <p>Each antigen is injected intradermally to the forearm using a separate needle for each antigen; a control antigen must be used in chronically ill children.</p> <p>Use a pen to circle each site and label appropriately.</p> <p>Teach the child and family that the test involves injecting small doses of antigens under the skin; that the area needs to be monitored at 24, 48, and 72 hours after the test; and that the circles should not be washed off until the test has been completed.</p> <p>A negative reaction may require placement of additional or stronger antigens.</p> <p>When reading the test, record erythema and induration in millimeters.</p>

TRADITION OR SCIENCE 24–1

Does breast-feeding during early infancy decrease the risk of infection during infancy?

EVIDENCE-BASED PRACTICE

Multiple studies have demonstrated that human milk feeding decreases gastrointestinal (Arifeen, Black, Antelman, et al., 2001; Dewey, Heinig, & Nommsen-Rivers, 1995; Howie, Forsyth, Ogston, et al., 1990; Lopez-Alarcon, Villalpando, & Fajardo, 1997; Quigley, Kelly, & Sacker, 2007) and respiratory infections (Arifeen et al., 2001; Bachrach, Schwartz, & Bachrach, 2003; Blaymore Bier, Oliver, Ferguson, et al., 2002; Gdalevich, Mimouni, & Mimouni, 2001; Quigley et al., 2007). Delaying complementary feeding until after 3 months of age was associated with reduced risk for respiratory infection and improved growth (Kalanda, Verhoeff, & Brabin, 2006). Compared with exclusive breast-feeding for only 4 to 6 months, exclusive breast-feeding for 6 months or longer decreased morbidity from respiratory infections and otitis media (Chantry, Howard, & Auinger, 2006) and did not negatively affect growth (Khadivzadeh & Parsai, 2004; Kramer & Kakuma, 2002; Onayade, Abiona, Abayomi, et al., 2004). Many health professionals, including the AAP (Gartner, Morton, Lawrence, et al., 2005) and the WHO (2003a), recommend breast-feeding exclusively for the first six months of life. See Tradition or Science 24–2.

Evidence regarding the infection-reducing properties of human milk feedings for premature infants is weaker. A number of studies have noted decreased infection rates with human milk compared with formula (Blaymore Bier, et al., 2002; el-Mohandes, Picard, Simmens, et al., 1997; Hylander, Strobino, & Dhanireddy, 1998; Narayanan, Prakash, Murth, et al., 1984), but the studies were flawed by small sample sizes, inadequate operational definitions of variables, and failure to consider confounding variables. Therefore, a systematic review concluded that the evidence regarding the infection-protecting properties of human milk require further inquiry with larger, more controlled studies (de Silva, Jones, & Spencer, 2004).

with an unusual pathogen, may signal an underlying immunodeficiency (see [thePoint](#); Supplemental Information: Summary of Infectious Agents).

SEPSIS

Sepsis is the presence of systemic inflammatory response with infection (Goldstein, Giroir, Randolph, et al., 2005). Systemic inflammatory response is diagnosed in the presence of at least two of the following features (one of which must be abnormal temperature or leukocyte count) (Goldstein et al. 2005):

- Core temperature (measured via rectal, oral, bladder, or central catheter) more than 101 °F (38.5 °C) or less than 96 °F (36 °C)

- Tachycardia (mean heart rate greater than two standard deviations above normal for age not caused by external stimuli) *or*, in children younger than 1 year of age, bradycardia (mean heart rate less than 10th percentile for age) not caused by external agents or congenital heart disease
- Mean respiratory rate more than two standard deviations above age norms
- Leukocyte count depressed or elevated for age or more than 10% immature neutrophils

The incidence of sepsis in children is 0.56 in 1,000, with infants having the highest incidence at 5.6 in 1,000 (Watson, Carcillo, Linde-Zwirble, et al., 2003). Overall mortality is 10% (Dellinger, Levy, Carlet, et al., 2008). Neonates and young infants have immature immune systems and can rapidly become critically ill with infection, resulting in overwhelming sepsis. These infants are commonly admitted to the hospital with an acute febrile illness in which the source of the fever is unknown, even after a careful history and physical examination. The management of acute febrile illness in young infants is challenging because the risk of serious overwhelming bacterial illness in this age group is high. During the initial assessment, distinguishing bacterial or fungal infections from other often less serious viral infections is nearly impossible.

Children with skin defects, such as aplasia cutis, epidermolysis bullosa, or ichthyosis, often have breaks in the skin that provide an opening for bacteria to invade, causing a secondary bloodstream infection. Defects in skin closure, as with gastroschisis or exstrophy of the bladder, expose underlying tissues and organs to outside microbial contamination and invasion, resulting in sepsis. Children who are immunocompromised (e.g., because of chemotherapy, steroid therapy, asplenia, or immune cell dysfunction) or who have invasive devices such as indwelling lines are also at increased risk for sepsis.

Low-birth-weight infants, infants with certain congenital or acquired defects, and those with maternal perinatal risk factors, such as maternal infection or prolonged rupture of membranes, are at particular risk for sepsis (Gerdes, 2004). Neonatal sepsis can be caused by viruses such as herpes simplex or enteroviruses and by protozoa (e.g., *Toxoplasma gondii*). However, bacteria are typically the culprits. Infants are infected during the birthing process or by transplacental transmission. Events such as prolonged rupture of the membranes (longer than 18 hours) and amnionitis contribute to contamination at birth or ascending infections. Hospitalized neonates, especially premature infants, run an extremely high risk for sepsis because of invasive devices, endotracheal tubes, and central venous catheters. Fungi also play a role in sepsis, particularly in the hospitalized neonate. Multiple antibiotics may be used in the hospitalized infant, killing the infant's normal flora and leaving the infant susceptible to opportunistic organisms such as fungi. Common skin fungi, such as *Candida* spp., are often important causes of sepsis.

Assessment

Evaluate the child's temperature, heart and respiratory rates, and laboratory values in light of the definition of

NURSING PLAN OF CARE 24–1 FOR THE CHILD WITH AN INFECTIOUS DISEASE

Nursing Diagnosis: Hyperthermia related to effects of pathogen

Interventions/Rationale

- Institute cooling measures as indicated (see **thePoint**, Procedures: Cooling Measures).
- Monitor temperature trends.
Fever is a result of endotoxin effects on the hypothalamus. Monitoring helps detect changes early.
- Assess for the presence of the contributing factors such as dehydration, environmental warmth, and exercise.
May identify the source of contributing risk factors.

Expected Outcome

- Child will report or evidence minimal discomfort related to fever.

Nursing Diagnosis: Imbalanced nutrition: Less than body requirements related to effects of decreased intake and increased metabolic demands

Interventions/Rationale

- Weigh daily.
Assess adequacy of nutritional absorption and utilization.
- Auscultate bowel sounds.
Decreased gastric motility can interfere with absorption.
- Palpate peripheral pulses.
Weak pulses are indicative of hypovolemia.
- Observe for increased fatigue, abdominal pain, nausea.
May indicate fluid and electrolyte deficits.
- Monitor complete blood count (i.e., white blood cells, red blood cells, hematocrit, hemoglobin) and electrolytes (i.e., potassium, sodium, calcium, blood urea nitrogen, creatinine).
Assesses level of hydration and cellular breakdown, and reflects fluid shifts, indicating fluid losses, dehydration.
- Monitor intake and output and evaluate fluid balance. Monitor urine specific gravity.
Helps identify risk of dehydration and balance of fluids. Decreasing urine output may indicate hypovolemia. Increased intake with decreased output may indicate third spacing and tissue edema.
- Establish hourly intake schedule; instruct child to drink and eat slowly.
Reduces risk of dehydration and may increase ability to tolerate intake.
- Discuss/identify food preferences; encourage choosing meals from available menus.
May enhance intake and promote sense of participation and control.
- Refer child to dietitian.

May assist in planning a diet that meets nutritional needs.

- Administer vitamin supplements, IV fluids as ordered.

Supplements may be needed to ensure adequate intake and assist in healing and fighting infection.

Expected Outcome

- Child will maintain adequate calorie and nutrient intake (oral, enteral, or IV) to meet maintenance and growth needs.

Nursing Diagnosis: Deficient diversional activity related to effects of isolation, fatigue

Interventions/Rationale

- Encourage family members and support system to mobilize around child.
Family knows the child best and can provide social interaction targeted to the child's needs and temperament.
- Encourage one-on-one social interaction with the child.
Allows child to concentrate on social interaction without excessive disruption.
- Provide periods of rest.
Fatigue can discourage social interaction.
- Determine favorite play activities and hobbies prior to illness. Encourage child to play at developmental level; have parents bring in toys, favored objects (e.g., doll, blanket) from home.
Play helps children process and cope with events in their world; familiar objects and routines provide security, comfort, and a sense of control.
- Encourage participation in a variety of activities (e.g., music, crafts, games, social interactions), as developmentally appropriate.
Varying activities provides different mechanisms with which to cope and helps the child to master different skills.
- Refer to occupational therapist, play therapist.
Can introduce and design new programs for stimulation.
- Increase activity levels as tolerated.
Promotes gradual return to normal activity level and improves stamina. Increases self-esteem and sense of control.

Expected Outcomes

- Child will engage in situationally and developmentally appropriate activities.
- Child, if fatigued, will engage in sedentary activities such as painting, reading, or watching television.
- If pruritic rash is present, caregivers will distract child from scratching.

Nursing Diagnosis: Deficient knowledge: Disease process

Interventions/Rational

- Assess child's and family's understanding of the disease process.
Provides baseline of family knowledge. Allows for clarification of misinformation.
- Encourage expression and acknowledge feelings.
Provides an open line of communication and safe environment for children to express themselves.
- Reinforce accurate knowledge and provide accurate information at current level of understanding.
May reduce misconceptions and fears.
- Educate the child and family on the child's needs; provide written instruction.
Provides reinforcement and a source of reference.
- Identify, review, and reinforce current therapeutic regimen.
Provides a continuous progression of recovery and prevents complications.
- Identify signs and symptoms of individual risks, side effects, and self-care needs.
Recognizing problems provides opportunities for prompt and ongoing evaluation and intervention.
- Identify individual roles of child and family members.
Identifies responsibilities and roles to assist family with coping.
- Encourage family members to participate in care of the child.
Facilitates communication and provides a sense of control for family.
- Identify community resources, social worker, support groups for family.
Provides additional assistance to family as the need arises.

Expected Outcome

- Child and family will demonstrate an accurate understanding of the infection and describe its signs and symptoms, transmission, isolation, treatment, and complications.

Nursing Diagnosis: Risk for infection related to potential for exposure

Interventions/Rationale

- Maintain standard precautions. Perform hand hygiene after each care activity.
Reduces the risk of cross-contamination.
- Place the child in a private room or cohort with others, as appropriate, who have the same condition. Encourage parents to keep sick children home from school and activities.
Reduces risk of transmitting infection.
- Limit visitors as indicated; screen visitors for infection.
Reduces risk of exposure for compromised host.

- Assess signs and symptoms of infection (e.g., fever, chills, pain, productive cough), history of exposure to infectious diseases, and presence of wounds, nutritional deficiency.

Intervention can be implemented to control related factors; early identification leads to prompt intervention. Chills frequently precede temperature spikes in presence of generalized infection.

- Obtain specimens (e.g., urine, blood, sputum, wound, invasive lines) as indicated for culture and sensitivity.
May reflect inappropriate or inadequate antibiotic therapy or an overgrowth of resistant or opportunistic organisms.
- Monitor laboratory studies (e.g., white blood cells, neutrophils, bands).
Reflects success of the body's attempts to respond to infection.
- Monitor for changes in physiologic functions (e.g., headaches/confusion, flushed skin, fatigue, loss of appetite).
Changes may indicate worsening of child's condition.
- Educate child and family regarding methods of transmission of infection.
Provides a baseline of knowledge.
- Evaluate child's hygiene habits. Educate on appropriate hygiene habits; demonstrate hand hygiene techniques.
Hygiene, especially hand hygiene, is key in preventing nosocomial infection.
- Encourage changes in position, deep breathing.
May provide good pulmonary toilet and reduce respiratory compromise.
- Discuss the influence of nutrition in preventing infection; encourage and maintain adequate nutrition (caloric and protein intake).
Adequate intake of calories and protein can boost the immune system and provide necessary elements for tissue repair.
- Assess for adequate immunizations against childhood diseases. Educate parents regarding the benefits of immunization.
May reduce susceptibility to infection.
- Educate child and family on signs and symptoms of infection.
Provides a baseline of knowledge.
- Educate child and family on methods to avoid infection, including protection from insects, animals, and the environment (e.g., wear shoes when parasites or sharp objects are present in soil), and proper food preparation.
Provides knowledge base to initiate preventive measures.
- Collaborate with local health department when disease outbreaks are noted.
Helps identify and prevent infection; helps identify the mode of transmission.

NURSING PLAN OF CARE 24–1 FOR THE CHILD WITH AN INFECTIOUS DISEASE (CONTINUED)

Expected Outcomes

- Child and siblings will have age-appropriate immunizations.
- Family will be educated regarding the importance of immunizations.
- Child will not expose others to the disease and will not contract another infection.

Nursing Diagnosis: Noncompliance (drug regimen)

Interventions/Rationale

- Create a trusting environment by listening to concerns and being available to child and family.
Respect and rapport must be established before child will take part in the learning process.
- Use a variety of teaching strategies.
Promotes retention of material.
- Explore child's and family's feelings regarding drug regime.
May improve communication; may clear up misconceptions. Includes child in the decision-making process.
- Discuss essential information needed for the plan of treatment.
Provides a knowledge base for the child to make informed decisions.
- Discuss side effects and preventive measures.
Promotes adherence and strategies to deal with side effects.
- Discuss dietary plan to increase adherence, and limit nausea, vomiting, and side effects from medications.
Dietary planning improves nutrition, which may improve adherence to medication regimen.

- Discuss importance of follow-up care and appointments, and explore potential barriers to accomplishing these goals.
Helps to continue follow-up of disease process. Discussing potential barriers may aid in meeting treatment needs.
- Have child self-monitor (e.g., on a calendar, chart) drug regimen on a daily basis.
Places a sense of responsibility on the child for making sure the plan is followed.
- Review signs and symptoms that require medical evaluation, intervention, or both.
May promote prompt intervention to prevent serious complications or nonadherence.
- Discuss stress management strategies (e.g., relaxation, deep breathing, visualization).
Promotes relaxation and stress control.
- Discuss ways in which the child can participate in self-care.
Increases self-control and self-confidence.
- Discuss potential conflicts between parents and child.
May decrease issues of control and improve adherence.
- Refer to social services and support groups.
Provides additional resources for child and family.

Expected Outcome

- Child (and family, if applicable) will complete prescribed course of medication and will verbalize the importance of continuing to take medications even after symptoms disappear.

systemic inflammatory response and sepsis. Look for risk factors and maintain a high index of suspicion for sepsis in any infant who is ill during the first 90 days of life. Infants with sepsis may present with nonspecific symptoms (Chart 24–1). Measure temperature rectally and remember that the magnitude of the fever may not reflect the seriousness of the illness (Henker & Carlson, 2007).

Children with suspected sepsis should have a complete blood count with differential, blood culture, and urine culture. A lumbar puncture should be performed in infants and should be considered in older children with neurologic symptoms. Those with respiratory symptoms should also have a chest radiograph.

Nursing Diagnoses and Outcomes

Common nursing diagnoses and outcomes for the child with an infection are identified in Nursing Plan of Care 24–1 (see also [thePoint](#), Care Paths: An Interdisciplinary Plan of Care for the Child With AIDS Pneumonia).

Interdisciplinary Interventions

Because of the high morbidity and mortality associated with severe sepsis, aggressive treatment must begin immediately. Institute interventions to support and maintain circulation and tissue oxygenation (see Chapter 31). Identify the source of infection and initiate antibiotic therapy within the first hour after sepsis is recognized (Melendez & Bachur, 2006). Empiric treatment typically consists of ampicillin plus an aminoglycoside or cefotaxime, depending on the neonate's risk factors. Vancomycin or ceftazidime may be added to reduce risk of nosocomial infection or provide coverage for infection by methicillin-resistant *Staphylococcus aureus* (MRSA) or *Pseudomonas*. Amphotericin should be added if fungal infection is suspected. Acyclovir should be added if herpes infection is suspected. Antimicrobial therapy can be tailored after a causative organism has been identified (see [thePoint](#), Medications: Summary of Antimicrobial Therapy for Sepsis).

CHART 24-1 SYMPTOMS OF NEONATAL SEPSIS**General**

Temperature instability
 Hypothermia (more common) or fever
 Decreased activity levels
 Irritability, lethargy, or coma
 Decreased urine output
 Floppiness (hypotonia)
 Poor feeding, vomiting, diarrhea
 Hypoglycemia
 Seizures

Cardiac

Bradycardia or tachycardia
 Mottling or pallor
 Poor capillary refill
 Hypotension
 Cyanosis

Pulmonary

Apnea or tachypnea
 Sternal retractions
 Grunting
 Nasal flaring
 Irregular respirations

Maintain aseptic technique and good nutrition, and decrease stress for the child, which may help promote immunocompetence, thus bolstering the ability to resist infection. Closely observe the child for subtle changes in vital signs, behavior, feeding tolerance, and physical assessment to promptly detect signs of sepsis (Clinical Judgment 24-1). When sepsis is suspected, IV antibiotic therapy is necessary (see [thePoint](#), Care Path: An Interdisciplinary Plan of Care for the Child With AIDS Pneumonia).

Community Care

Maternal screening for group B streptococcus (GBS) and prophylactic intrapartum antibiotics can greatly reduce the risk of neonatal GBS sepsis.

Educate parents regarding signs of disease in their infant and advise them when to rapidly seek care for any behaviors that are not typical for their child. This education could be the key to preventing overwhelming sepsis in the young infant. Also educate parents that timely immunization of the child can provide some immunity to serious infectious diseases such as hepatitis and pertussis.

BACTERIAL INFECTIONS

Although vaccination programs have virtually eliminated many of the serious bacterial diseases in developed countries, no vaccines are yet available for most bacterial infections. Therefore, prompt identification and treatment are key in preventing overwhelming bacterial infection.

Mycobacterial Infections

Mycobacteria cause both non-TB and TB disease. Non-TB mycobacterial infections are not spread person to person, whereas TB is.

Nontuberculous Mycobacterial Infections (NTM)

Nontuberculous mycobacteria (NTM) species are found everywhere in nature: soil, food, water, and animals. A few of these species cause infection in children, especially immunocompromised children such as those with HIV or cystic fibrosis. Reliable estimates of the incidence of infection are limited. NTM may also be known as atypical mycobacterial infections or *Mycobacterium avium* complex.

Assessment

Although NTM may cause disseminated disease in the immunocompromised child, the most common presentation in children is cervical lymphadenitis that does not respond to typical antibiotic therapy (American Academy of Pediatrics [AAP], 2006o). An otherwise healthy child typically presents with cervical lymph nodes that are usually firm, mobile, and nontender. The history shows that the lymph node has continued to enlarge over time, and the overlying skin has turned a bluish purple color.

A TB skin test (TST or Mantoux test) may be ordered to assist in the diagnosis of NTM. NTM and TB share many of the same antigens, which may cause the TST to react (AAP, 2006o), but in NTM, the induration (reaction) is usually less than 10 mm. If the TST is reactive, a chest radiograph should be obtained to rule out TB. NTM can be cultured in the laboratory and can be easily grown from excised lymph tissue. Polymerase chain reaction (PCR) testing is available in some reference laboratories.

Interdisciplinary Interventions

Excision of affected lymph nodes is considered a curative treatment for NTM cervical lymphadenitis (Mandell, Bennett, & Dolin, 2005). Antimicrobial therapy is very complex and typically is not successful. Because antibiotic resistance is common, drug therapy involves the use of two or three drugs over a 6- to 12-month period.

Children with HIV should receive antibiotic prophylaxis for NTM.

Tuberculosis (TB)

TB is caused by an infection with *M. tuberculosis*. TB is spread person to person in respiratory droplets. In

CLINICAL JUDGMENT 24–1

An Infant With Sepsis

Melissa is a 4-day-old infant who was admitted to the pediatric intensive care unit after an episode of cyanosis and difficulty breathing. Her mother states that she has not been “doing well.” The mother describes Melissa as fussy, irritable, and not nursing well. Admitting vital signs showed tachycardia and tachypnea with grunting and sternal retractions. She was intubated, given mechanical ventilation, and was placed on a cardiac monitor. Baseline laboratory tests included blood cultures, complete blood count with differential, arterial blood gas, and spinal fluid for cultures and cell counts.

Questions

1. During your assessment, what other information would it be important to have concerning Melissa’s current illness?
2. What is the current problem?
3. What is the best way to support the family during this crisis?
4. Why was Melissa having difficulty feeding?
5. What nursing consultations might be considered?

Answers

1. The birth history is always important, along with information concerning other sick family mem-

bers or siblings. If she was born at your facility, request that the old medical record be sent to the nursing unit.

2. Respiratory distress, behavioral changes, and poor feeding, which are signs of sepsis. Melissa is admitted with a diagnosis of suspected sepsis. The culture results reveal GBS as the causative organism.
3. Keep the family informed. Explain all tests and procedures. Provide paper and pencils so that the parents can write down questions for the nurses or the physicians. Offer to call the hospital-based clergy for support.
4. Melissa has a respiratory infection resulting in blocked nares and tachypnea. Neonates are obligate nose breathers, and feeding is difficult when they cannot breathe through their noses. To suckle, an infant must coordinate breathing with sucking and swallowing, which is difficult when the infant is tachypneic.
5. Consult a lactation specialist to help the mother express milk during the current crisis and assist with any problems when the infant begins to breast-feed again.

children and adolescents, most TB infections are asymptomatic. This type of infection is called *latent TB infection* (LTBI). LTBI is defined as infection in an asymptomatic person with a positive TST, no clinical findings of disease, and a normal chest radiograph (AAP, 2006z).

TB rates are highest in urban, low-income areas and in nonwhite racial and ethnic groups. Foreign-born children account for 25% of all diagnosed cases in children younger than the age of 14 years. The homeless, residents of correctional facilities, people with immune suppression, immigrants, international adoptees, refugees, and travelers to and from endemic regions (Asia, Africa, Latin America, and the former Soviet Union) are at high risk for LTBI and active TB (AAP, 2006z). The risk of disease progression and dissemination is higher among children than among adults.

During the early 1990s, outbreaks of a strain of TB that was resistant to many familiar antitubercular drugs were documented (Centers for Disease Control and Prevention [CDC], 2006a). These resistant strains of TB, called *multidrug-resistant TB*, are resistant to the main first-line TB drugs, isoniazid and rifampin. Multidrug-resistant TB continues to be an increasing problem because of nonadherence to completing TB drug regimens as ordered and decreased funding for public health clinics

used for TB control, which includes distributing TB drugs, monitoring TB patients, and tracking exposures.

In 2006, a new highly resistant TB strain was identified that, to date, has been virtually untreatable. This strain, known as extremely drug-resistant TB, is resistant to the first-line TB drugs and to many of the second-line TB drugs as well. Although both multidrug-resistant TB and extremely drug-resistant TB may initially result from treatment mismanagement that selects for multiresistant strains, once acquired, they can spread from person to person, posing a potential global health threat (CDC, 2006a).

Assessment

In children, TB presents a great diagnostic challenge. Unlike adults, children, especially young ones, are usually asymptomatic even when the TST is positive. History of exposure is often the most vital piece of information obtained. Chest radiograph are seldom positive. When TB infection progresses to disease, clinical findings usually occur within the first 6 months of exposure; however, many years may elapse before infection progresses to disease.

Up to 50% of children with TB are asymptomatic. Notable exceptions include children with HIV infection and infants. Children also may manifest TB in forms other than the traditional pulmonary symptoms (Mandalakas & Starke, 2005). Assess for nonspecific symptoms such as fever, growth delay or weight loss, persistent cough, fatigue, and night sweats (rare). Radiographic findings range from normal to pulmonary and extrapulmonary abnormalities. Nonremitting cough of more than 2 weeks' duration, documented weight loss during the preceding 3 months, and fatigue provide good diagnostic accuracy in HIV-free children 3 years of age or older (Marais, Gie, Hesselning et al., 2006).

The first obvious signs and symptoms of TB after an asymptomatic pulmonary infection may be extrapulmonary (TB that occurs outside the lungs), most commonly cervical lymphadenitis (Marais & Pai, 2007), meningitis, bone infection, and miliary TB. In infants and some children, the lymph nodes continue to enlarge to the point that bronchial obstruction results (Mandalakas & Starke, 2005). Miliary TB, a form of extrapulmonary TB, is also more common in childhood TB. In miliary TB, massive numbers of tubercle bacilli are released into the bloodstream and then disseminate to other organs. Central nervous system (CNS) involvement, TB meningitis, is a serious and often fatal complication seen almost exclusively in children younger than age 4 (see Chapter 21). TB meningitis usually develops gradually, 3 to 6 months after the primary infection. Older children complain of headache, irritability, and insomnia. Infants and younger children lose developmental milestones.

Alert! In children exposed to TB, assess neurologic signs frequently and notify the healthcare provider of changes. An abrupt onset of lethargy, convulsions, and nuchal rigidity precedes the development of hydrocephalus and increasing intracranial pressure. Coma and irregular pulse and respiration may follow, culminating in death.

Diagnostic Tests The TST (or Mantoux test) is the primary method used for determining TB exposure. Intradermal administration of purified protein derivative is the most accurate and reliable test method. Creating a 6- to 10-mm wheal is crucial for accurate testing (AAP, 2006z). The skin test must be read in 48 to 72 hours by measuring the size of the reaction (induration). Control tests may be performed at the same time as the purified protein derivative test in patients who are immunocompromised. The control skin tests are usually *Candida*, or tetanus. One or two controls are chosen and administered on the opposite forearm. Because most children have been exposed to *Candida* in the environment and to tetanus through immunization, the control test should be positive. A nonreactive control test indicates that the child is anergic. **Anergy** is a condition in which the immune system is so deficient that it cannot mount a reaction to the skin tests. Thus, TB cannot be ruled out in a child with a negative TST and nonreactive control tests.

Chest radiographs may be of little diagnostic value because they usually appear normal. Children also have

great difficulty in producing sufficient sputum and coughing productively. They often swallow their secretions. Obtaining a sputum specimen for an acid-fast bacteriologic culture and smear from a young child may be difficult; therefore, gastric washings are recommended rather than sputum samples. The tubercle bacilli pass through the digestive system completely intact and unharmed by stomach acid and other digestive processes. Hence, sputum smears may be negative for TB, but gastric washings may be positive.

The standard for diagnosis is still a positive culture for *M. tuberculosis*. Acid-fast smears are helpful but cannot be specific for *M. tuberculosis*.

Interdisciplinary Interventions

Because *M. tuberculosis* takes up to 6 weeks to grow in the laboratory, therapy is started on the basis of a positive smear or strong clinical evidence of pulmonary, meningeal, or extrapulmonary infection. Standard drug therapy consists of isoniazid, rifampin, and pyrazinamide given for 2 months, followed by isoniazid and rifampin for 4 months. However, specific drug therapy is based on the organism's drug sensitivity. For more detailed information on the treatment of TB, refer to American Thoracic Society et al. (2003).

Preventive therapy is given to children with positive skin tests (purified protein derivative) and no clinical evidence of disease (i.e., LTBI). Treatment consists of isoniazid for 9 months. For children with HIV infection, preventive therapy may be extended to 12 months. Rifampin is given as preventive therapy in cases of known exposure to multidrug-resistant TB.

Nursing care of children with known or suspected pulmonary TB must be individualized (Fig. 24–2). Because young children are often asymptomatic, their relative infectiousness varies. If hospitalized, most children do not need airborne precautions in a **negative-pressure isolation** room (room in which air flows into the room from the hallway and is removed by a separate, filtered exhaust to the outside); only those with significant pulmonary infection should be in this isolation. Infants and small children with pulmonary TB rarely cough up phlegm. What little sputum they do manage to cough up contains few tubercle bacilli, because their cavitory lung lesions have few bacilli. Therefore, as these cavitory lesions break open, few or no bacilli escape into the bronchi to be coughed up.

As children mature, the ability to cough and infect others increases, especially during adolescence. Place adolescents and children with positive sputum smears in a negative-pressure room. Wear an N95 respirator or a high-efficiency particulate air respirator in the room.

Frequently, the TB source for the child is a parent or close relative. Thus, the child in isolation may not pose an infection risk, but the parents or visitors may. Refer relatives and close family contacts to the local health department (Community Care 24–1) for testing and treatment. Children need their parents, especially when they are ill and in the strange surroundings of a hospital.

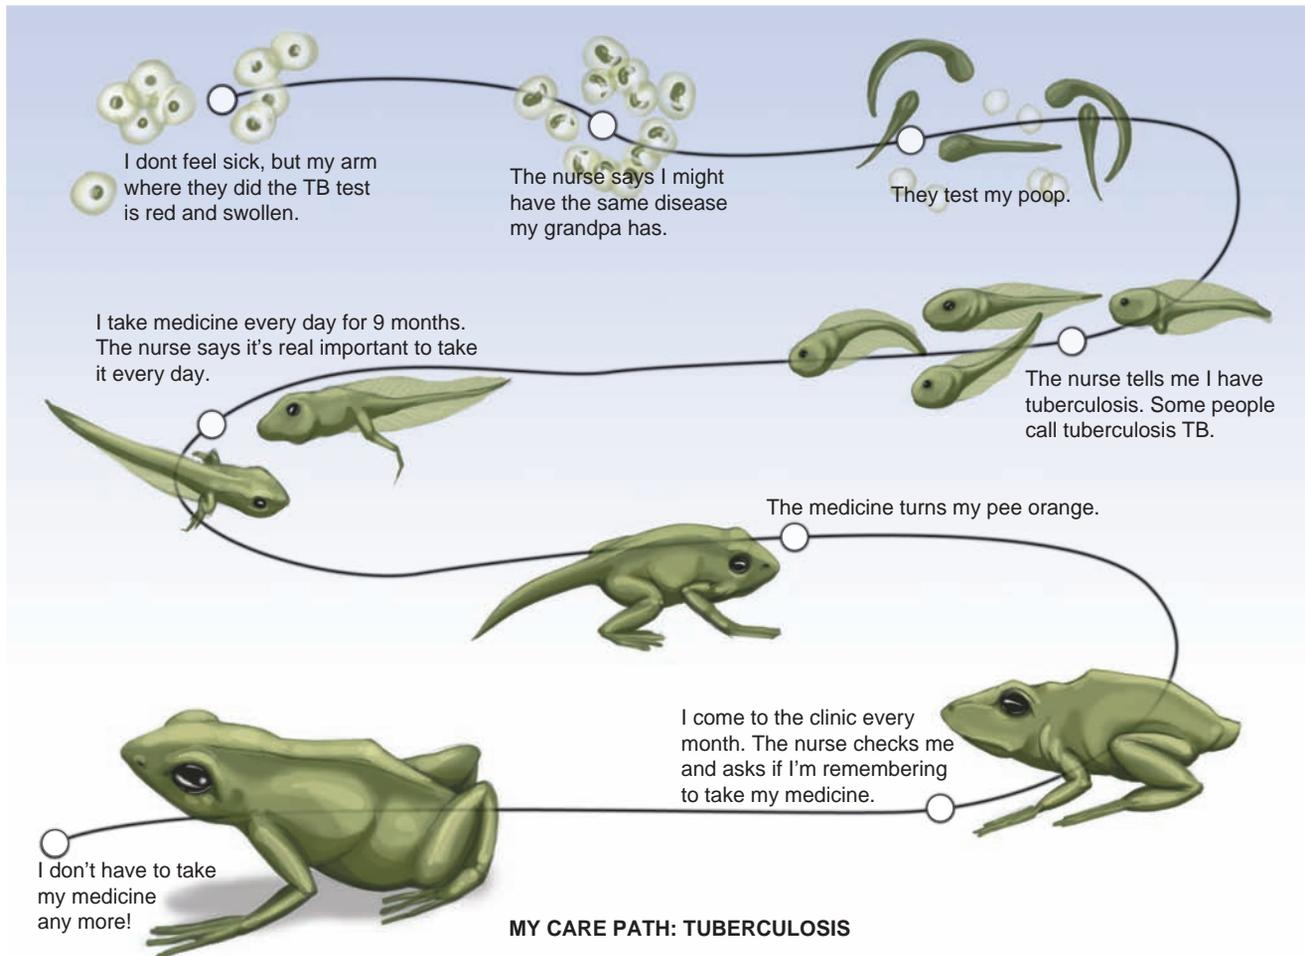

FIGURE 24-2. A care path for a child with TB.

Parents or close relatives with pulmonary TB can wear a mask to and from the isolation room when visiting. Other accommodating strategies can also be arranged, including having food trays for the parents delivered to the child's room.

Community Care

Long-term follow-up of the child with TB is particularly important because of the potential for nonadherence in completing the typically lengthy treatment regimen.

COMMUNITY CARE 24-1

Tuberculosis Follow-up

The healthcare provider, diagnosing laboratory, and treating institution (clinic, hospital, or private physician's office) are legally responsible for informing the local health department of all cases of TB. The local health department then initiates contact investigations. Contacts are persons exposed to the child with pulmonary TB and could be in many locations, such as church, school, or daycare center. The health department

- Determines who in the community has been exposed to the child

- Performs screening tests (skin tests) on exposed individuals, such as family members, neighbors, and schoolmates
- Provides preventive drug therapy (isoniazid)
- Provides drug treatment and follow-up laboratory work and radiographic evaluation
- Provides for directly observed therapy to families who may be nonadherent because of homelessness, parental drug abuse, or other reason
- Assists with arranging temporary placement in halfway housing or other state-run facilities

Strains of TB that are resistant to common antitubercular drugs arise as a result of partial treatment. Monitor the child for the presence of drug side effects (Nursing Interventions 24–1) and adherence to therapy. If nonadherence is an issue, directly observed therapy may be implemented. In this approach, the medication is taken in the presence of the nurse.

Assess nutritional status and provide diet counseling, if needed, to prevent poor healing stemming from inadequate nutrition, which affects immune function. Refer the child to social services if poor intake is related to inadequate finances.

Pertussis

Pertussis, also known as *whooping cough*, begins as an upper respiratory illness and progresses to a persistent cough characterized by an inspiratory whoop. Pertussis is endemic worldwide. Even in countries with high rates of vaccination coverage, a resurgence of pertussis has been noted (Edwards & Freeman, 2006).

Pertussis disease occurs in 3- to 4-year cycles. An estimated 20 to 40 million cases of pertussis occur globally each year, most in developing countries, causing 400,000 deaths, primarily in infants (Tan, Trindade, & Skowronski, 2005). Vaccine-induced immunity to pertussis wanes after 5 to 10 years, leaving adolescents and adults susceptible and an important reservoir for infection. Adolescents and adults play a critical role in the spread of pertussis.

Pertussis is caused by the bacterium *Bordetella pertussis* and is transmitted by respiratory droplets that are coughed or sneezed by the child in the **catarrhal** (characterized by inflamed mucous membranes) and early **paroxysmal** (occurring with a sudden onset) stages of the illness. This infectious period can last for 6 weeks or longer (AAP, 2006q). Common comorbidities associated with pertussis include pneumonia, seizures, and encephalopathy.

Assessment

The incubation period for pertussis is 7 to 10 days, during which the child is most contagious. The *catarrhal phase* occurs during this initial incubation period, producing coldlike symptoms (runny nose, scratchy throat, and mild cough). This stage is followed by the *paroxysmal phase*, characterized by periods of paroxysmal coughing, during which the child coughs violently, vomits, has apneic spells, and becomes cyanotic. At the end of the coughing attack, the patient gasps (whoops) for air. Infants younger than 6 months may not exhibit classic whooping. These intense spells of coughing often interfere with feeding and sleep. The paroxysmal phase lasts 2 to 6 weeks and is followed by a *convalescent stage* characterized by a persistent (but not paroxysmal) cough.

Nasopharyngeal swab samples, obtained using Dacron or calcium alginate swabs, are sent to the laboratory for pertussis culture. These samples are plated on special media and must incubate for 7 days. The laboratory must be informed of the potential diagnosis so that the swab is handled appropriately. A positive culture is diagnostic for pertussis, but the organism is not likely to grow if obtained 2 weeks or longer after the onset of coughing or if antibiotics have already been started.

DNA amplification (PCR) testing is increasingly being used in preference to culture because of its increased sensitivity and shorter turnaround time. The use of PCR testing and single-serum serology is recommended to confirm the diagnosis of cases that meet the clinical definition of pertussis (Cherry, Grimprel, Guiso, et al., 2005).

Nursing Diagnoses and Outcomes

Common nursing diagnoses and outcomes for the child with an infection are identified in Nursing Plan of Care 24–1. Additional nursing diagnoses and outcomes for infants with pertussis may include the following:

NURSING INTERVENTIONS 24–1

For the Child Receiving Antitubercular Drugs

Drug/Route	Nursing Interventions
Isoniazid (INH) PO Rifampin (Rif) PO	Potential liver toxicity. Monitor liver function tests and assess for jaundice. Orange discoloration of secretions or urine. Could stain contact lenses. Teach family about discoloration.
Pyrazinamide (PZA) PO Streptomycin IM	Potential liver toxicity. Monitor liver function tests. Usually given only in meningitis because of ototoxicity. Conduct hearing screens at initiation of therapy, midway, and at the end of therapy. Observe for skin rashes. Rotate injection site, use pain reduction techniques, provide psychosocial support.
Ethambutol (EMB) PO	Use for older children only. Can cause reversible optic neuritis. Assess visual acuity, visual fields, and red/green color discrimination daily.

IM, intramuscular; PO, per os (oral).

Ineffective tissue perfusion: Cardiopulmonary and cerebral related to effects of prolonged coughing attacks

Outcome: Child will maintain adequate tissue perfusion, evidenced by capillary refill less than 2 seconds and no alteration in level of consciousness, and oxygenation, evidenced by an oxygen saturation of 97% to 99%.

Sleep disturbance related to effects of coughing spells interrupting rest

Outcome: Child will obtain adequate sleep and resume previous sleep patterns.

Interdisciplinary Interventions

Infants younger than 6 months may require hospitalization for supportive care to manage apnea, hypoxia, or feeding difficulties. The macrolides (erythromycin, azithromycin, and clarithromycin) are the drugs of choice for pertussis in children 6 months of age or older. Azithromycin and clarithromycin are not Food and Drug Administration approved for use in infants younger than 6 months; however, infants younger than 1 month old should be treated with azithromycin because erythromycin is associated with increased risk of infantile hypertrophic pyloric stenosis. Trimethoprim-sulfamethoxazole is an alternative antibiotic for children who cannot tolerate erythromycin. Antibiotics given during the catarrhal phase of the illness may halt disease progression. Unfortunately, pertussis is often not suspected until the more characteristic symptoms (especially paroxysmal coughing) develop. Antibiotics given at the paroxysmal stage or later usually have little or no effect on the outcome of the illness but are used to limit the spread of pertussis to others.

Use droplet precautions until 5 days after antibiotic therapy has been started or until 3 weeks after the onset of paroxysmal coughing. Offer macrolide chemoprophylaxis for a 5-day course to all close contacts of the child.

caREminder

In the ambulatory setting, place a child suspected of having pertussis in a private examination room as soon as he or she enters the clinic or office. Advise personnel who enter the room to observe standard precautions and wear a mask.

During the paroxysmal phase, the child can have up to 20 coughing attacks a day and may vomit after the attacks. Avoid stimulating the child, which may precipitate a coughing paroxysm. Maintain a calm manner while supporting the child and parents during coughing paroxysms, which are quite frightening. Such coughing also disturbs sleep and nutrition. Focus nursing care on keeping the child adequately hydrated and nourished, and alleviating coughing episodes with antitussives. Gentle suctioning after coughing may be needed to maintain a patent airway. The nursing and respiratory care staff must make it a priority to maintain ventilatory support (see Chapter 16).

To prevent pertussis, universal immunization with pertussis vaccine is recommended for all children younger than 7 years old and for adolescents (11–18 years).

Pneumococcal Disease

Pneumococcal infections are common in the extremes of life—the very young and the very old. Before routine use of the childhood pneumococcal conjugate vaccine, *Streptococcus pneumoniae* was the most common bacterial cause of otitis media, pneumonia, and sepsis in young children (AAP, 2006s). Pneumococcus is also a common cause of meningitis.

Many children and adults are colonized with pneumococcus in the upper respiratory tract. Transmission is person to person by respiratory droplets. The progression from pneumococcal colonization to invasive disease is multifactorial. Preceding viral infections lower resistance to disease and may contribute to invasive disease. Agents and diseases that decrease the normal self-cleaning functions of the respiratory system, such as bronchial obstruction, irritants, or allergens that decrease ciliary function can also push colonization toward invasive disease. Errors in immune response in such conditions as HIV, splenectomy, agammaglobulinemia, leukemia, and sickle cell disease inhibit the body's natural defenses and lead to invasive disease (Table 24–1). Epidemics of pneumococcal pneumonia occur most frequently in the winter in overcrowded situations. Infants, with their immature immune systems, are particularly prone to develop invasive disease.

Pneumococcal disease occurs in many forms, including meningitis, sinusitis, otitis media, occult bacteremia, and pneumonia. Because pneumococci commonly colonize the upper respiratory tract, pneumonia, otitis media, sinusitis, and mastoiditis are a direct result of this colonization.

Pneumococcal meningitis usually results from the bacteria crossing the blood–brain barrier into the CNS and seeding the meninges. Invasion may happen as the result of a pneumococcal infection of the bloodstream or by direct extension from a pneumococcal infection in the mastoid or paranasal sinuses to the meninges.

Children younger than 2 years and those with congenital immunodeficiencies, asplenia, sickle cell disease, and HIV infection are at increased risk for pneumococcal disease, as are Native Americans, Native Alaskans, and African Americans.

Assessment

Pneumococcal pneumonia often occurs abruptly, with the child exhibiting a temperature of 102 to 103 °F (38.9–39.4 °C), chills, productive cough, and otitis media. Listen for rales on auscultation of the lungs and dullness to percussion. Assess the sinuses by pressing the fingers along the sinus tracts of the face; the child may complain of pressure or pain. Children with bacteremia or meningitis may exhibit fever and irritability. In cases of meningitis, nuchal rigidity (neck stiffness) may occur.

TABLE 24-1

Risk for Pneumococcal Disease Associated With Altered Immune Function

Immune Defect	Reason for Increased Risk	Interventions
Immature immune system (premature infant or term neonate) response	Decreased phagocytic activity Varying levels of protective maternal antibodies (IgG) Decreased response to polysaccharide antigen	Antibiotic therapy Proper nutrition to increase infant's response to infection Hand hygiene in hospitals, clinics, daycare centers, and other child care settings
Asplenic infants, children, adolescents	Diminished or absent neutrophil function	Pneumococcal vaccine for all children Daily prophylaxis with oral penicillin until adulthood
Acquired or congenital immunodeficiency (such as in HIV infection or agammaglobulinemia)	Dysfunctional immune system Increased respiratory infections	Antibiotic therapy Pneumococcal vaccine for all children
Sickle cell disease	Decreased immune function related to functional asplenia	Daily prophylaxis with oral penicillin starting at age 4 months Pneumococcal vaccine

caREminder

Ask the child to try to touch the chin to the chest. If pain prevents the child from doing this, it may be from nuchal rigidity caused by inflamed meninges.

In pneumococcal pneumonia, chest radiographs reveal subsegmental lobar consolidation. Bacteriologic cultures of blood, spinal fluid, and other body fluids are commonly collected and Gram's stained to reveal pneumococci. Elevated white blood cell counts are helpful in diagnosis but are not conclusive. Rapid antigen tests can detect pneumococcal capsular antigen in urine, spinal fluid, pleural fluid, and blood. These tests are of limited value, however, because they lack sensitivity and specificity.

Nursing Diagnoses and Outcomes

Common nursing diagnoses and outcomes for the child experiencing an infection are identified in Nursing Plan of Care 24-1. The following nursing diagnosis and outcome may also apply to a child with pneumococcal disease:

Ineffective airway clearance related to effects of excessive mucus production

Outcome: Child's airway will remain patent.

Interdisciplinary Interventions

Penicillin and cephalosporins are the drugs of choice for treating *S. pneumoniae* infection. Because resistant pneumococcal strains are increasingly common, vancomycin plus ceftriaxone or cefotaxime may be used as an alternative to treat serious infections, such as meningitis or bacteremia. High-dose amoxicillin or amoxicillin-clavulanate is effective treatment for mild to moderate infections, such as otitis media. Extended-spectrum cep-

alosporins, such as cefdinir, cefuroxime, and ceftriaxone are also useful, especially in cases of penicillin allergy. As with any antibiotic, teach the family to complete the full course exactly as prescribed.

Community Care

Standard precautions are recommended for children with pneumococcal infections, including those caused by penicillin-resistant strains. The primary goal is to prevent invasive pneumococcal disease. Teach parents the importance of immunization. Two pneumococcal vaccines are available against pneumococcal disease (see Chapter 8). Children at high risk of developing invasive pneumococcal disease should also be offered prophylactic low-dose antibiotics for preventive therapy. Refer to the specific disease forms caused by pneumococcus for other nursing care (e.g., otitis media, see Chapter 28).

Staphylococcal Infections

Staphylococcus aureus and *S. epidermidis* are normal flora of the skin. Infection results when staphylococci enter normally sterile body fluids or sites. *S. aureus* produces localized and invasive infections as well as three toxin-mediated illnesses: toxic shock syndrome (hypotension, skin desquamation, fever, and multisystem involvement), scaled skin syndrome (blistering and peeling), and food poisoning.

Staphylococci are the cause of 40% of all skin and wound infections, 23% of all lower respiratory tract infections, 22% of all bloodstream infections, and 15% of all other infections (urinary tract, brain, abdominal) in infants and children (Mandell et al., 2005). *S. aureus* is the leading cause of nosocomial infections and is responsible for 50% to 70% of community-acquired osteomyelitis.

Furuncles, cellulitis, lymphatitis, impetigo, and wound infections are common childhood staphylococcal infections (see also Chapter 25).

Toxic shock syndrome gained national attention during the late 1980s, when women who used superabsorbent tampons became quite ill with fever, vomiting, a desquamating rash, and hypotension. Later, a toxic shocklike syndrome was observed in nonmenstruating women and children who had one thing in common: positive cultures for *S. aureus*.

Pathophysiology

Staphylococci can infect the blood, the pulmonary system (pneumonia), bones, joints, skin and soft tissue, and surgical wounds; meningitis is rare. A major complication of a staphylococcal blood infection is endocarditis. Although staphylococcal endocarditis is most common in IV drug abusers, children with congenital heart disease or those with artificial heart valves, grafts, and patches can also develop this infection. The lesions formed by a staphylococcus infection may break off to form septic emboli in other locations, such as the brain or lungs.

MRSA is common in large hospitals and is responsible for 50% of health-care associated infections (AAP, 2006u). MRSA is also increasingly responsible for community-associated infections. The major reservoir for MRSA is the lower part of the nose (anterior nares). Hands become contaminated by touching or rubbing the nose. Then healthcare workers, colonized with MRSA in their nose, spread the organism unwittingly from patient to patient on their hands. Children can easily become colonized with MRSA if they frequently encounter healthcare workers or spend time in community settings such as daycare or schools. Children can also develop MRSA as a result of antibiotic therapy for persistent infections, such as chronic otitis media or lung infections.

Coagulase-negative staphylococci, common flora of the skin and mucus membranes, are frequently seen in hospital-associated infections, in infections of medical devices, and in urinary tract infections.

Assessment

Species of staphylococci that produce exfoliating toxins can cause scalded skin syndrome. In this syndrome, assess for skin bullae that evolve into generalized desquamation. The child's skin can be painful to the touch, and even the slightest touch can lead to skin peeling.

Bone and joint infections resulting in septic arthritis or osteomyelitis often begin as a bloodstream infection. These infections often begin in the metaphyseal portions of the long bones. Assess for refusal to move the limb, painful joints, crepitus, and heat. Soft-tissue swelling is evident either on physical examination or radiograph.

Surgical wound infections and device-related infections produce yellow, foul-smelling pus at the operative site or device insertion site. The wound becomes red, inflamed, and hot to touch. Pus oozes from the suture line or can be expressed by applying gentle pressure along the sides of the suture line. Areas of fluctuance are often palpable.

Diagnosis is confirmed by Gram's stain of the infected body fluids. Cultures determine whether the gram-positive cocci in clusters are coagulase-positive or coagulase-negative staphylococci. Microbiologic evaluation of the cultures further identifies the organism and its susceptibility pattern.

Nursing Diagnoses and Outcomes

Nursing diagnoses and outcomes for the child with an infection are identified in Nursing Plan of Care 24–1. Additional nursing diagnoses and outcomes most commonly associated with staphylococcal infections include the following:

Activity intolerance related to effects of joint pain in septic arthritis

Outcome: Child will report or evidence adequate pain control and will participate in age-appropriate activities.

Impaired skin integrity related to effects of staphylococcus causing desquamation

Outcomes: Child will not develop secondary infection.

Child's skin integrity will be restored.

Interdisciplinary Interventions

Many staphylococci are resistant to penicillin. Vancomycin is the drug of choice for serious infections involving multi-drug-resistant strains. However, sensitive strains respond to most antibiotics, including oxacillin, nafcillin, methicillin, most cephalosporins, erythromycin, and clindamycin. Most community-acquired MRSA infections can be treated on an outpatient basis with trimethoprim-sulfasoxazole or clindamycin.

Maintain scrupulous hand hygiene when caring for patients with staphylococcal infections. *Staphylococcus* is present in the normal flora on the child's and nurse's skin. Provide wound care wearing gloves. Wear a gown if there is any risk that your clothing may become soiled.

Implement contact precautions for children with MRSA infections or those who are colonized with MRSA. Continue contact precautions until antibiotic therapy is discontinued and repeated cultures are negative.

During outbreaks of MRSA infection, cultures may be taken of healthcare workers' anterior nares, axilla, and groins as part of an epidemiologic workup. The infection control practitioner can use the results to determine a common source of the outbreak. Individuals found to be positive may undergo CDC-recommended decolonization by taking daily showers with chlorhexidine gluconate, applying mupirocin ointment to the anterior nares, or taking a prolonged course of oral trimethoprim-sulfamethoxazole.

Community Care

Educate daycare and school staff regarding hand hygiene for all staff and students to reduce the spread of community-acquired MRSA. Because emergence of community-acquired MRSA has been documented among sports and athletic teams during the past several years, educating team leaders and members is particularly important (Turbeville,

Cowan, & Greenfield, 2006). To prevent the spread of MRSA among family members, teach the family to keep fingernails short, not to share washcloths and towels, and to change sleepwear and underwear daily (Kaplan, 2005).

Streptococcal Infections

Two types of streptococci cause disease: group A and group B.

Group A Streptococcal Infections (GAS)

GAS disease is one of the most common diseases of childhood, causing a variety of cutaneous and systemic infections and complications with variable severity and prognosis (Table 24–2). Invasive GAS disease has received media attention as “flesh-eating” bacteria. Because GAS disease is so common and not reportable to the health department, estimating the true incidence of the disease is impossible. Globally, approximately 1.7 million new cases of serious GAS disease occur each year, with an estimated 500,000 deaths (Steer, Danchin, & Carapetis, 2007). Mortality from GAS toxic shock syndrome is 5% to 10% in children, much lower than the 30% to 80% for adults (Chuang, Huang, & Lin, 2005). The severity of GAS disease is determined in part by the susceptibility of the host and the serotype of the group A streptococci.

Pathophysiology

Streptococci inhabit the upper respiratory tract in 15% to 50% of asymptomatic children. Pharyngitis is spread primarily through droplets as the infected child coughs or sneezes. In daycare centers and nursery schools, hand-to-hand-to-mouth transmission may occur, especially among young children. Food can be a mode of transmission if handled by an infected or colonized individual. The incubation period is 2 to 5 days for streptococcal pharyngitis and 7 to 10 days for impetigo (AAP, 2006v).

Before the antibiotic era, scarlet fever, rheumatic fever, and glomerulonephritis were common complications of GAS disease. The incidence of all three complications has decreased since World War II. They are now relatively preventable with appropriate antibiotic therapy. Rheumatic fever typically occurs a week after the onset of pharyngitis, with the development of fever, polyarthritides, and carditis. Nephritis is more common after streptococcal skin infections than after pharyngitis, but long-term renal sequelae are seldom seen in children.

Assessment

GAS pharyngitis typically presents as fever, malaise, and a sore throat. Lymph nodes in the neck are palpable. Examine the tongue, which at first appears white, then within 2 days becomes red (strawberry tongue). If GAS pharyngitis progresses to scarlet fever, the rash appears

TABLE 24–2

Types of Group A Streptococcal Infections

Infection	Clinical Manifestations	Complications
Streptococcal pharyngitis	Sore throat, malaise, fever, enlarged tonsils studded with gray-white exudate, enlarged lymph nodes	Peritonsillar abscess Scarlet fever Rheumatic fever Damage to mitral valve may necessitate replacement in midlife
Erysipelas	Red, edematous, warm, raised lesions with sharply demarcated margins Edema that advances rapidly	Bullae can leave open weeping lesions that may develop secondary infection
Streptococcal impetigo	Fragile vesicles that evolve into pustules Pustules that enlarge and erode	Secondary bacterial infection Streptococcal toxic shock Glomerulonephritis
Streptococcal cellulitis	Warm, erythematous, painful, edematous lesion with ill-defined margins that rapidly spreads History of trauma, varicella lesions, burns, or surgery	Invasion of lymph nodes and bloodstream Streptococcal toxic shock
Necrotizing fasciitis (invasive GAS disease)	Within 24 hours of trauma, site swelling and cellulitis that spreads to surrounding tissue Deep infection of subcutaneous tissue that destroys fascia and fat Frank gangrene that develops by 4 to 5 days	Life-threatening infection Need for surgical drainage or amputation

about 12 hours after onset of the disease. The rash follows an ordered progression and has been compared with a “sunburn with goose pimples” (Figs. 24–3 and 24–4).

Invasive GAS disease begins as a mild infection such as strep throat and rapidly progresses to a severe illness. Be alert for signs of bacteremia (blood infection), a toxic shocklike syndrome, multisystem organ failure, a rapid decrease in blood pressure, and necrotizing fasciitis, which destroys muscle, fat, and underlying tissue.

A positive throat culture for GAS disease makes the definitive diagnosis for streptococcal pharyngitis. However, rapid antigen tests have proved useful in diagnosing patients quickly to begin antibiotic therapy. Because these tests are not as sensitive as a throat culture, a negative test must be confirmed by a culture.

Common serologic tests used for diagnosis include antistreptolysin O and a latex agglutination test (Streptozyme). These serologic tests are frequently used to diagnose rheumatic fever. Expect a positive result if group A streptococci are present.

Skin infections are usually diagnosed by skin or wound cultures. Invasive GAS infections are diagnosed by positive cultures of CSF or synovial, peritoneal, or pleural fluid. Tissue biopsies may be performed in cases of suspected gangrene.

Nursing Diagnoses and Outcomes

In addition to those identified in Nursing Plan of Care 24–1, the following nursing diagnoses and outcomes may apply to the child with GAS pharyngitis:

Impaired swallowing related to painful sore throat

Outcomes: Child will experience minimal throat pain.

Child will maintain adequate fluid and nutritional intake.

The following nursing diagnosis and outcome may apply to the child with invasive GAS disease:

Impaired tissue integrity related to effects of pathogen

Outcomes: Child will experience minimal tissue damage.

Child will not develop secondary infection related to effects of cellulitis or necrotizing fasciitis.

Interdisciplinary Interventions

The agent of choice is penicillin, which is the cheapest effective therapy available for treating streptococcal infections (Bisno et al., 2002). Cephalosporins, the macrolides, and clindamycin are also effective but should be reserved for children with penicillin allergy. In necrotizing fasciitis, drainage and debridement are often necessary. In severe cases of gangrene, fasciotomy or amputation may be necessary.

For hospitalized children with GAS pharyngitis or pneumonia, maintain droplet precautions until antibiotic therapy has been given for 24 hours (AAP, 2006v). Unfortunately, this regimen excludes the child from the playroom or other group activities. Provide psychosocial support as indicated to help the child adjust to body image changes and to activity limitations.

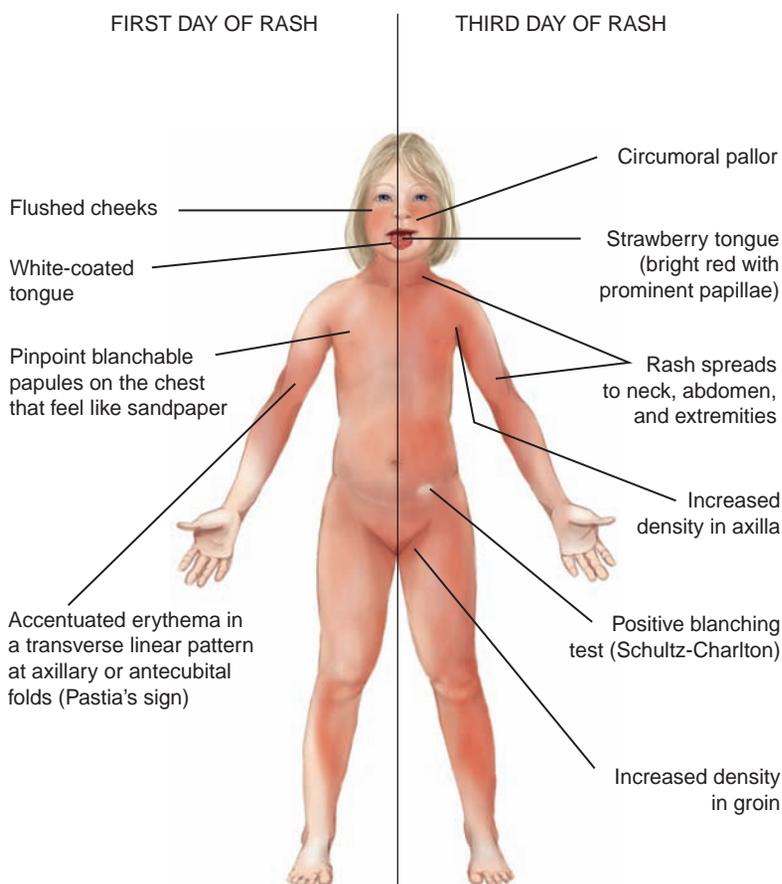

FIGURE 24–3. Progression of rash in scarlet fever.

FIGURE 24–4. During the convalescent phase of scarlet fever, the skin of the palms and soles frequently peel.

Community Care

Nurses should advise parents of nonhospitalized children with group A pharyngitis to exclude the child from day-care or school until after 24 hours of effective therapy.

caREminder

Instruct parents of the child with group A pharyngitis to discard the child's toothbrush. The organism can survive on the toothbrush and reinfect the child after antibiotic therapy is completed.

Observe strict hand hygiene between patients and adhere to aseptic techniques to prevent nosocomial spread of infection. In outbreaks, group the patients with GAS infection into a cohort and have the same nurse or nurses care exclusively for these infected patients.

Group B Streptococcal Infections (GBS)

GBS is a leading cause of neonatal sepsis and death. Group B streptococci are gram-positive, aerobic diplo-

cocci that are divided into nine serotypes. Serotype III is the primary cause of GBS meningitis and most late-onset GBS disease (Fluegge, Supper, Siedler, et al., 2005).

Pathophysiology

Colonization of the lower genitourinary tract occurs in approximately 15% to 40% of pregnant women (AAP, 2006v). Group B streptococci may ascend the birth canal to infect infants, or infants may acquire the bacteria as they descend through the birth canal. The implementation of maternal GBS screening and the initiation of intrapartum antibiotic prophylaxis has substantially decreased the incidence of GBS early-onset disease, but not late-onset disease (Pettersson, 2007).

Assessment

Early-onset GBS disease often begins as an overwhelming systemic infection within the first few days of life. Early-onset GBS is characterized by respiratory distress, apnea, shock, pneumonia, and (less often) meningitis. Watch for signs and symptoms of sepsis. Late-onset GBS disease typically occurs at 1 to 3 months of age and often presents with meningitis, osteomyelitis, septic arthritis, or cellulitis.

A positive culture from the infant with gram-positive cocci in chains can provide a presumptive diagnosis of GBS infection. Positive maternal cultures and the signs and symptoms of sepsis in the neonate are also evidence of infection. Cultures of GBS from any sterile body site, such as blood, spinal, or pleural fluid, or from an area of focal infection are diagnostic. Rapid antigen tests, which test for the presence of GBS in cerebrospinal fluid (CSF), blood, or urine, are available but are not recommended because of their poor specificity.

Nursing Diagnoses and Outcomes

Common nursing diagnoses and outcomes for the child with an infection are identified in Nursing Plan of Care 24-1 (see also [thePoint](#), Care Path: An Interdisciplinary Plan of Care for the Child With AIDS Pneumonia).

Interdisciplinary Interventions

Treatment for GBS disease requires penicillin or ampicillin plus an aminoglycoside. This combination of antibiotics is often used to treat suspected bacterial infections empirically when the organism has not yet been identified.

The length of hospitalization for an infant admitted with GBS sepsis can vary from 3 to 5 days to 1 to 3 weeks. The length of treatment for GBS ranges from 10 days for sepsis to 2 to 3 weeks for meningitis. GBS osteomyelitis or endocarditis may require 4 to 6 weeks of IV antibiotic therapy. The infant may be sent home with IV antibiotics. Instruct the parents how to give IV antibiotics and care for the IV access line, and emphasize the importance of finishing all the medication (see earlier discussion of sepsis). Also teach parents the signs of infection and which ones should trigger a call to their healthcare provider.

Isolation is not necessary for GBS disease, but may be needed for outbreaks of GBS in nurseries. Frequent updates to the family of a sick infant are appreciated and

critical in communicating information that may be difficult for laypeople to understand.

VIRAL INFECTIONS

Viral infections account for most upper respiratory tract infections. They are caused by such viruses as respiratory syncytial virus, parainfluenza virus, influenza virus, coronavirus, various enteroviruses, rhinovirus, and adenovirus. See Chapter 16 for information on respiratory syncytial virus infection and influenza. Vaccines have been developed for many common and easily transmissible viral infections. Many new antiviral agents are also available to treat specific viral infections.

Adenovirus Infection

Adenovirus commonly infects the upper respiratory tract in infants and young children during the late winter, spring, and early summer months. Adenovirus typically presents with symptoms of the common cold, sore throat, tonsillitis, and otitis media. It is also commonly associated with fever and conjunctivitis. Adenovirus may also cause other disorders, including hemorrhagic conjunctivitis; severe respiratory infections such as croup, bronchiolitis, or a pertussislike syndrome; and hemorrhagic cystitis. A few adenoviruses infect the gastrointestinal tract and cause gastroenteritis. Enteric adenovirus infection occurs year-round and usually affects children younger than 4 years. Serious life-threatening infection such as pneumonia, meningitis, or encephalitis can occur in infants and immunosuppressed children (AAP, 2006a).

Pathophysiology

Adenovirus infection is common in all pediatric age groups. Respiratory infections are transmitted by direct contact through exposure to respiratory secretions (as in coughing or sneezing). Enteric strains are transmitted by the oral–fecal route. Eye infections may result from swimming in pools that are not properly chlorinated, from direct contact with the conjunctiva with contaminated fingers, or from ophthalmologic equipment that has not been properly disinfected. Nosocomial infection can result from contact with infected healthcare workers or contaminated equipment. The incubation period for adenovirus is 2 to 14 days. Children are most contagious during the first few days of illness but may continue to shed adenovirus up to several months. Asymptomatic infection is common, and reinfection may occur.

Assessment

Respiratory tract infections can present as pharyngitis, bronchiolitis, croup, or severe pneumonia (see Chapter 16 for specific signs and symptoms of these respiratory disorders). The pharyngitis is typically exudative and is often confused with streptococcal pharyngitis. The nurse can differentiate adenoviral pharyngitis from GAS pharyngitis if conjunctivitis is present, because conjunctivitis

suggests a viral etiology. Adenoviral upper respiratory tract infections often mimic pertussis, with prolonged episodes of paroxysmal coughing.

Suspect adenoviral eye infection (epidemic keratoconjunctivitis) when the conjunctiva appear red and granular, with clear drainage, and the child has frequent tearing and photophobia. Eye irritation and redness can last for 1 to 2 weeks. Superficial erosion of the cornea and subepithelial corneal infiltrates can be seen by ophthalmologic examination.

caREminder

Adenovirus is not inactivated by ethanol, commonly used in eye clinics to disinfect equipment. Immerse contaminated instruments in 1% sodium hypochlorite for 10 minutes or steam autoclave.

Gastroenteritis infections caused by enteric strains of adenovirus are second only to rotavirus in frequency. Symptoms include diarrhea that lasts for 6 to 9 days, accompanied by vomiting.

Hemorrhagic cystitis caused by adenovirus occurs more often in males than in females. The child excretes grossly bloody urine for 1 to 2 weeks.

Diagnostic Tests

Viral cultures of samples from pharyngeal swabs or rectal swabs, urine, or eye drainage all yield adenovirus. Serologic tests by complement fixation can detect adenovirus if acute and convalescent sera are used. PCR testing is available to rapidly detect adenovirus.

Nursing Diagnoses and Outcomes

In addition to those identified in Nursing Plan of Care 24–1, the following nursing diagnosis and outcome may apply to the child with epidemic keratoconjunctivitis:

Acute pain related to effects of conjunctivitis

Outcome: Child will report or evidence only minimal discomfort.

The following nursing diagnoses and outcomes may apply to the child with adenovirus gastroenteritis:

Impaired skin integrity related to effects of diarrheal stool in contact with perianal skin

Outcome: Child's perianal skin integrity will be restored.

Deficient fluid volume related to excessive diarrheal output and decreased intake

Outcome: Child will maintain adequate fluid volume and tissue perfusion evidenced by urine output of 1 mL/kg and capillary refill less than 2 seconds.

Interdisciplinary Interventions

No effective antiviral therapy exists for adenovirus. Treatment is supportive care.

If soothing saline eye drops are used for conjunctivitis, instruct the parents to wash their own hands after instilling

the drops, to avoid infecting themselves. Thorough hand hygiene after diapering an infant with diarrhea is essential to prevent further spread in the family.

Children with croup seem to benefit from cool-mist humidifiers. During acute exacerbations, it is often helpful for the child to breathe the water vapor created by running hot water in the shower or the cool night air (see Chapter 16).

Healthcare workers with adenoviral infection should avoid direct patient care for 14 days after onset of illness.

Community Care

Children in daycare centers are at increased risk for respiratory and enteric infections with adenovirus. Encourage parents to exclude their child from daycare if the child has diarrhea, conjunctivitis, or respiratory infection symptoms or if children at the center exhibit these symptoms.

Enterovirus (Nonpoliovirus) Infections

Enteroviruses, classified as group A and B coxsackieviruses, echoviruses, and enteroviruses, are frequently responsible for asymptomatic, mild, and widespread illnesses in infants and children. Children with enteroviruses may present with the following signs and symptoms:

- Respiratory: Coldlike symptoms, sore throat, herpangina, stomatitis, pneumonia
- Skin: Rashes
- Neurologic: Aseptic (viral) meningitis, encephalitis
- Gastrointestinal: Nausea, vomiting, diarrhea, abdominal pain
- Eye: Conjunctivitis
- Heart: Myopericarditis

Children with immune deficiencies may have persistent infection lasting for months (AAP, 2006f).

Pathophysiology

Enteroviruses are spread by respiratory droplets, by the fecal–oral route, and from mother to infant during the peripartum period. They also live for long periods on surfaces, allowing transmission by fomites. Infections occur most commonly in the summer and fall, except in tropical climates, where infections occur year-round. Respiratory viral shedding typically lasts 1 week; however, fecal viral shedding may last for several weeks. The incubation period is usually 3 to 6 days.

Assessment

Enterovirus infection most commonly presents as a non-specific febrile illness. Because they cause a variety of illnesses, enterovirus infections may manifest in diverse ways; assess for the signs noted here.

Group B coxsackieviruses and echoviruses can cause serious disseminated disease in the newborn, which can be fatal. These infections may be transmitted either

transplacentally or from mother to infant during the newborn period.

Enteroviruses commonly cause febrile illnesses in infants and young children. Many of the enteroviruses also cause rashes, particularly the coxsackieviruses and echoviruses. Hand-foot-and-mouth disease is a common enterovirus illness characterized by fever, a vesicular rash on the buccal mucosa and tongue, and a maculopapular rash on the hands and feet, which may also become vesicular.

The enteroviruses commonly cause viral meningitis (Lee & Davies, 2007); assess for characteristic signs of fever, headache, malaise, and signs of meningeal irritation. This illness is self-limited, and most children have minimal morbidity (Lee, Chawla, Langley, et al., 2006a). Children with immune deficiencies who develop enterovirus CNS infections may have an infection that persists for years. These children may have frequent recurrent symptoms of meningitis, encephalitis, or progressive deterioration of the CNS.

Enterovirus type 70 and coxsackievirus A24 cause subconjunctival hemorrhage with swelling, redness, congestion, tearing, and pain. Patients usually recover fully in 1 week.

Herpangina is usually caused by group A coxsackieviruses and is characterized by tiny vesicles on the tonsils, uvula, posterior pharynx, and soft palate. The illness is also accompanied by high fever, sore throat, loss of appetite, and difficulty swallowing. Some children may also experience vomiting. Herpangina typically occurs in the summer and fall, and may occur in epidemics.

Group B coxsackieviruses and echoviruses cause myocarditis or pericarditis in older children. Illness ranges from a mild, self-limited pericarditis to severe chronic or even fatal myocardial disease. The enteroviruses have also been implicated as the cause of some viral cardiomyopathies.

Diagnostic Tests

The enteroviruses can be cultured from stool, rectal swab, throat specimens, urine, blood, and CSF; however, many group A coxsackieviruses do not grow well in culture. PCR is available to rapidly detect enterovirus RNA, but it cannot characterize the type of enterovirus.

Interdisciplinary Interventions

No specific therapy is available for enterovirus. IV immunoglobulin (Ig) has been used in immunodeficient patients with CNS infection, in infants with life-threatening disseminated infection, and for viral myocarditis. Provide supportive care as indicated.

Community Care

Use contact precautions for infants and young children during their illness. Educate caregivers to pay particular attention to hand hygiene when changing diapers. Also educate caregivers, particularly child care providers, to clean contaminated surfaces with soap and water and then disinfect them with a chlorine bleach solution

($\frac{1}{4}$ cup bleach to 1 gallon water), which inactivates the virus.

Herpesvirus Infections

Seven herpesviruses produce clinically important infection in humans:

1. Cytomegalovirus (CMV)
2. Epstein-Barr virus (EBV)
3. Herpes simplex virus type 1 (HSV1)
4. Herpes simplex virus type 2 (HSV2)
5. Human herpesvirus type 6
6. Human herpesvirus type 7
7. Varicella zoster virus (VZV)

All herpesviruses can remain dormant in the body after the primary infection has subsided, producing periodic, recurrent, or latent infections. Recurrent infections are usually not as severe as the primary infection but may be life threatening in the immunocompromised host.

Cytomegalovirus Infections (CMV)

Like all herpesviruses, CMV can be reactivated after primary infection. Almost everyone encounters CMV eventually. However, the infection is usually asymptomatic and of little consequence. An infectious mononucleosislike syndrome may occur in adolescents and adults. CMV can cause pneumonia, colitis, and retinitis in immunosuppressed individuals, such as those undergoing organ transplantation, receiving chemotherapy, or infected with HIV.

CMV congenital infection also occurs and is typically asymptomatic. Approximately 10% of infants with congenital CMV infection present with serious illness, however, such as growth retardation, jaundice, purpura, microcephaly, intracranial calcifications, and retinitis. Between 10% and 20% of congenitally infected infants are diagnosed with mental retardation or sensorineural deafness in childhood (AAP, 2006d).

Transmission of CMV is by direct contact with virus-containing secretions, such as urine or saliva. This contact can occur in daycare centers or nurseries when drooling, teething babies share toys that they bite or gum. Adolescents may acquire CMV through sexual intercourse and kissing (saliva). Transmission from an infected mother to her infant may occur by transplacental passage of the virus in utero, passage of the neonate through an infected birth canal, or ingestion of infected breast milk. Other modes of transmission include blood transfusions and solid organ transplants.

Reactivation of CMV after transplantation could contribute to organ rejection. It is believed that CMV is in itself immunosuppressive, suppressing the activity of natural killer cells and contributing to immunosuppression in children with HIV infection and other infections.

Assessment

Most CMV infections are asymptomatic. A few individuals may exhibit a vague mononucleosislike illness with fatigue, fever, and mild hepatitis. Immunocompromised children

may experience pneumonia, gastritis, colitis, arthralgia, arthritis, encephalopathy, retinitis, fever, and lymphadenopathy. AIDS patients with reactivated CMV, if untreated, may develop vision loss caused by CMV retinitis.

Most infants with congenital CMV infection are asymptomatic, but about 11% manifest fetal damage at birth (Kenneson & Cannon, 2007), as summarized in Chart 24–2. Long-term sequelae such as hearing loss or cognitive or neurologic impairment occur more often, and are more severe, in symptomatic infants than in asymptomatic infants (40%–58% vs. 13.5%) (Dollard, Grosse, and Ross, 2007).

Despite the physical signs with which a symptomatic newborn typically presents and even if cerebral calcifications are evidenced on radiographs viral culture or serologic testing is still needed to confirm the diagnosis. Viral culture specimens can be obtained from urine or from pharyngeal or cervical secretions. CMV can also be isolated from human milk, semen, and leukocytes. In addition, the presence of IgG CMV antibodies in cord blood can identify congenitally infected infants. The shell vial assay is the standard rapid culture method for detecting CMV infections. Newer methods for CMV detection include a CMV antigenemia assay, which detects a viral protein in the infant's white cells, and PCR, which detects CMV DNA.

Nursing Diagnoses and Outcomes

In addition to those listed in Nursing Plan of Care 24–1, the following nursing diagnosis and outcomes may apply to the infant affected with congenital CMV:

Interrupted family processes related to reaction to extremely ill infant

Outcome: Parents will express concerns regarding the infant's treatments and prognosis.

Family will visit the newborn frequently, maintain mutual support, and seek external resources as needed.

Parents will be involved in the infant's care.

Interdisciplinary Interventions

Treatment for CMV, especially retinitis, is with ganciclovir or foscarnet. Antiviral drugs are given by induction therapy (doses that gradually increase over 3 weeks to the therapeutic dosage). Limited studies show that ganciclovir

CHART 24–2 EFFECTS OF CONGENITAL CYTOMEGALOVIRUS INFECTION

- Intrauterine growth retardation
- Jaundice, hepatitis, hepatosplenomegaly
- Anemia, thrombocytopenia
- "Blueberry muffin" rash (deep, bluish, purpuric lesions)
- "Celery stalking" (radiographic lines in the long bones)
- Chorioretinitis
- Cerebral calcifications, mental retardation, microcephaly, seizures, hearing loss

vir is beneficial in children (Biron, 2006). However, more studies are needed to verify its safety and effectiveness in children (AAP, 2006d). After therapeutic levels are reached, some HIV-infected children and bone marrow transplant recipients are given 6 to 12 weeks of maintenance therapy with reduced dosages. Even with reduced dosages, ganciclovir and foscarnet are highly toxic. Ganciclovir may induce bone marrow toxicity, and foscarnet can trigger renal tubular dysfunction.

Focus nursing care of infants or children who may have congenital CMV syndrome or who may be shedding CMV on supportive care and good hand hygiene. The risk of acquiring CMV infection during pregnancy can provoke anxiety among healthcare workers who are pregnant or planning to become pregnant, because of the risk of congenital CMV syndrome.

However, the common notion that nurses and other healthcare workers are at increased risk for acquiring CMV from pediatric or neonatal patients is a misconception. Many studies of CMV transmission in healthcare settings have concluded that healthcare workers acquire CMV at the same rate as the general population (Balcarek, Bagley, Cloud, et al., 1990; Morgan, el-Ghany, Khalifa, et al., 2003). Standard precautions are important, however, because any patient could reactivate CMV at any time because of stress, and could shed the virus in the urine, saliva, and other body fluids. Neonates can also shed CMV. Therefore, infants and children who have not been identified as infected may pose a greater risk to others, especially if standard precautions are not followed.

caREminder

The CDC does not recommend isolating infants with congenital CMV infection (Siegel et al., 2007). Instead, it recommends using standard precautions and educating healthcare workers (especially pregnant ones) about hand hygiene.

Epstein-Barr Virus Infection

EBV, the causative agent in mononucleosis, infects up to 90% of the population (Adams, Deboer, Jeffrey, et al., 2006). Also known as the *kissing disease*, mononucleosis is transmitted primarily by oral-salivary spread in young children and close intimate contact (kissing) in adolescents and young adults. Illnesses with EBV range from asymptomatic to fulminant lymphoproliferative disease (AAP, 2006e). EBV is also associated with malignancies such as Burkitt's lymphoma, nasopharyngeal cancer, Hodgkin's disease, and some autoimmune disorders, such as Sjögren's syndrome.

EBV is a member of the herpes family of viruses and, like all herpesviruses, can be reactivated after primary infection.

Assessment

Symptoms of mononucleosis present as a triad: sore throat (exudative pharyngitis), fever, and lymphadenopathy. Ask about other common symptoms, which include

fatigue, headache, and an enlarged liver or spleen. Jaundice is uncommon, occurring in only 5% of cases (Adams et al., 2006). Although a rash is not typical, a central rash may occur during the first few days of the illness.

The disease can begin insidiously over 30 to 50 days after the 4- to 6-week incubation period, or it may begin abruptly after the incubation period. In general, symptoms are more pronounced in adolescents than in children, who may be asymptomatic. Co-infection with group A strep pharyngitis is common and could mask the symptoms of EBV, leading the healthcare practitioner to overlook the diagnosis of mononucleosis during the early stages of illness (Fig. 24-5).

Diagnostic Tests The total number of atypical lymphocytes in the blood characteristically increases, along with a high titer of heterophil antibody. Monocytes constitute 50% of the total white cell count. The overall leukocytosis that is present early in the disease can be so elevated that leukemia is suspected.

Diagnosis is based on a blood count showing lymphocytosis and at least 10% atypical lymphocyte formation, symptoms, and testing for heterophil antibody. In young children, the heterophil antibody test is usually negative.

Viral cultures can be obtained from saliva, blood, or lymph tissue, but can take up to 8 weeks to cultivate. EBV-specific antibody tests are most commonly used to diagnose EBV. During the course of mononucleosis, EBV produces an initial antiviral capsid antigen immunoglobulin M (anti-VCA IgM). This VCA IgM declines to barely detectable levels over time. As VCA IgM starts to decline, there is a detectable increase in anti-VCA IgG. Antibodies to EBV nuclear antigen appear during the recovery phase of infection. EBV VCA IgG and EBV nuclear antigen persist for life.

PCR testing is also useful in determining the presence of EBV DNA. A positive test is indicative of infection but must be quantitated to differentiate acute infection from past infection.

FIGURE 24-5. Appearance of tonsils in a child with infectious mononucleosis. Note the degree of erythema, enlargement, and purulent covering. Copyright Dr. P. Marazzi/SPL/Science Source/Photo researchers. Reprinted with permission.

Nursing Diagnoses and Outcomes

In addition to those listed in Nursing Plan of Care 24–1, the following nursing diagnosis and outcome may apply to the child with EBV:

Fatigue related to effects of disease process

Outcome: Child will obtain adequate rest and perform age-appropriate quiet activities as tolerated.

Interdisciplinary Interventions

In general, no therapy is currently recommended for EBV. Steroids should be used only to control life-threatening complications such as enlarged tonsils blocking the airway, fulminant hepatitis, or hemolytic anemia. Ganciclovir is used to treat EBV infection in the immunosuppressed population.

caREminder

Avoid ampicillin if concomitant streptococcal pharyngitis is present. Use of ampicillin causes a rash in most individuals with mononucleosis.

No isolation precautions are recommended for the hospitalized patient. Most otherwise healthy children and adolescents recover with no sequelae. Provide supportive nursing care and educate the family regarding comfort techniques such as antipyretics for fever reduction and pain relief (e.g., medications; dark, quiet room).

Suggest a soft or liquid diet for children with throat pain. Encourage enough liquids to prevent dehydration. Because of their chronic fatigue, children and adolescents usually self-limit their activity; thus, forced bed rest is not necessary. Recommend home teachers for children with prolonged fatigue who cannot attend school. Teach children and parents to notify the health-care provider if abdominal pain, especially in the left upper quadrant, or left shoulder pain occurs (may indicate splenic rupture).

KidKare ■ Advise children with an enlarged spleen to limit activity until they are cleared by their healthcare providers. No activity more than walking is recommended until splenomegaly resolves (about 1–2 months), and contact sports should be avoided for about 6 months or until the radiograph is normal (Stephenson & DuBois, 2007).

Herpes Simplex Virus Infections (HSV)

HSV1 and HSV2 produce similar clinical syndromes. Generally, HSV1 is associated with oral lesions (above the waist) and HSV2 is associated with genital lesions (below the waist). However, HSV1 infections can occur in the genital area, and HSV2 infections can occur orally.

The appearance of HSV1 and HSV2 lesions is identical: vesicular lesions on an erythematous base.

Transmission and acquisition of HSV infection is most often asymptomatic, which has contributed to a worldwide epidemic. In the United States, more than 50% of young adults are estimated to have been infected with HSV1, and 20% to 30% are infected with HSV2 (AAP, 2006j).

The most devastating HSV infection occurs when HSV is passed to the fetus or neonate by maternal genital HSV infection. Because most genital HSV infections are asymptomatic, the mother is often unaware of her infection or the risk to the infant. Maternal transmission to the fetus occurs during passage through an infected birth canal or as an ascending infection with prolonged (longer than 6 hours) rupture of amniotic membranes (Kimberlin, 2007). Occasionally, during a primary maternal infection, the virus crosses the placenta during the maternal viremic phase, when a high volume of virus is circulating in the maternal blood.

The incidence of neonatal HSV infection ranges from 1 in 3,000 live births to 1 in 20,000 live births. The greatest risk of infection is in infants born to mothers with primary infection (33%–50%). The risk is much lower in infants of mothers with recurrent infection (<5%). The presence of maternal HSV antibodies from past recurrent infection can serve to protect the infant during pregnancy. Neonatal HSV infection is caused by HSV2 at least 75% of the time (AAP, 2006j).

Children with dermatitis are at increased risk of developing eczema herpeticum, a disseminated HSV infection of the skin. Teach the family to use caution to avoid exposing the skin of children with dermatitis to cold sores whenever possible.

Prognosis

Untreated infants with disseminated disease soon develop respiratory and circulatory collapse, with death following. Even with antiviral treatment, the mortality rate among neonates with disseminated disease is 25%. Surviving infants often face the lifelong sequelae of neurologic impairment, blindness, and recurrent skin lesions. Although most infants with isolated CNS involvement survive, almost all sustain considerable neurologic sequelae. The best outcome is in infants with disease limited to the skin, eyes, and mouth (Kimberlin, 2007).

QUESTION: Based on Ashley's complaints, would the school nurse suspect a genital herpes infection?

Assessment

Primary genital infections often involve painful labial and cervical lesions in females or penile lesions in males; assess for such lesions. Inguinal lymphadenopathy may be present. Systemic illness including fever, muscle aches, and malaise lasting about a week may also occur with primary infection. Recurrent infections are generally less severe and, in females, may be limited to the cervix,

which has few nerve endings for pain. Thus, many recurrent infections are asymptomatic. For these reasons, monitor pregnant females for signs of primary genital herpes infection. HSV2 infections typically are acquired from sexual activity; evaluate for sexual molestation when the infection is present in nonneonates.

Neonatal herpes presents in three distinct groups: disseminated disease; isolated CNS involvement; and localized infection of the skin, eyes, and mucous membranes. However, infants with CNS involvement can also have localized disease as well. Neonatal HSV infection manifests within the first 3 weeks of life, typically 7 to 10 days after birth (Chart 24–3).

Oral HSV infections range from mild “cold sores” to gingivostomatitis. Shedding of herpesvirus occurs in the saliva. Monitor for dehydration, because the mouth becomes intolerably sore with severe gingivostomatitis resulting in decreased intake (see Chapter 22 for interventions). Illness usually begins with a fever, sore mouth, and anorexia. Lesions can extend to the entire mouth area, tongue, gums, and inside of the cheek (buccal mucosa). Infants or children who suck their thumbs or fingers can develop herpetic whitlow (herpetic lesions appearing on the fingers or thumb).

Primary infections begin with an “aura” or tingling sensation; note this when obtaining a history. Then, 24 to 48 hours later, painful vesicular lesions with an erythematous base erupt. The lesions typically last 10 to 14 days (Fig. 24–6).

HSV1 infection has been transmitted during athletic competitions that involve close physical contact and frequent skin abrasions (AAP, 2006j). Wrestling and rugby are the sports most commonly associated with the transmission of HSV1. Transmission may occur through active lesions or asymptomatic viral shedding. Teach coaches and athletes to clean mats and sports equipment with a bleach solution between matches to limit or prevent the spread of HSV.

CHART 24–3 EFFECTS OF CONGENITAL HERPES SIMPLEX VIRUS INFECTION

- Nonspecific symptoms: irritability, fever, poor feeding, lethargy
- Intrauterine growth retardation
- Jaundice, hepatitis, hepatosplenomegaly
- Anemia, thrombocytopenia (characterized as blueberry muffin purpura), disseminated intravascular coagulopathy
- Vesicular lesions on the infant’s skin, eyes, or mucous membranes
- Chorioretinitis
- Meningoencephalitis, cerebral calcifications, mental retardation, microcephaly, seizures
- Pneumonitis

FIGURE 24–6. Lesions in herpes simplex.

Diagnostic Tests HSV is easily cultured from skin lesions; 1 to 3 days are required for viral detection. Rapid diagnosis is made with detection of HSV antigens in lesion swabs using commercially available enzyme-linked immunosorbent assay (ELISA) kits. Commercially available ELISA antibody blood test kits can be used to identify recent (IgM) or past (IgG) HSV infection. A Western blot for HSV can distinguish between HSV1 and HSV2. PCR testing rapidly detects HSV DNA in CSF and blood.

ANSWER The school nurse might suspect a genital herpes infection because it is a sexually transmitted infection. However, genital herpes infection would involve painful labial and cervical lesions. Ashley has complained of burning on urination and increased vaginal discharge, but no pain in the genital area.

Nursing Diagnoses and Outcomes

The common nursing diagnoses and outcomes discussed in Nursing Plan of Care 24–1 apply to the infant with congenital herpes simplex infection. Depending on the disease manifestations, other diagnoses may also be appropriate. For the child with acquired herpes simplex disease, the following nursing diagnosis and outcomes may apply:

Impaired oral mucous membrane related to effects of herpesvirus

Outcomes: Child will ingest sufficient fluid to prevent dehydration.

Child and family will implement interventions to minimize discomfort and speed healing.

Interdisciplinary Interventions

Treatment for congenital infection is with IV acyclovir. Disseminated and CNS disease should be treated for a minimum of 21 days, and localized (skin, eyes, or mucous membrane) disease should be treated for 14 days. Topical treatment for eye involvement is usually with trifluridine, idoxuridine, or vidarabine. The pregnant mother or the adolescent with genital HSV infection can be treated

with oral acyclovir, valacyclovir, or famciclovir to decrease viral shedding and encourage faster resolution of the lesions. Suppressive therapy may be offered to patients with more than six outbreaks a year. Because the lesions of varicella and herpes simplex resemble each other, varicella infection is considered in the differential diagnosis for an infant who may have a congenital herpes infection.

Educate postpartum women with active herpes lesions on the value of hand hygiene. Transmission of HSV to the infant can occur if the mother touches the baby with contaminated hands. HSV transmitted to the mother's hands after postpartum pericare can be washed off with soap and water. Mothers, fathers, grandparents, or any visitor who has active oral HSV lesions should not kiss the infant, because they can transmit their virus to the infant.

Use contact precautions with the infant with congenital herpes simplex infection. Advise parents to exclude their child with HSV mouth sores from daycare only if the child *cannot* control oral secretions (drooling). Ensure that healthcare workers with active oral lesions wear surgical masks to cover the lesions, avoid touching the lesions, and pay scrupulous attention to hand hygiene.

Human Herpesvirus Type 6 and Type 7 Infections

Infection with human herpesvirus type 6 or type 7, also known as *roseola*, is a common childhood rash disease. Roseola is typically characterized by a high fever that is followed by a rash and may lead to febrile convulsions. The virus is thought to be transmitted primarily through the respiratory secretions of infected children. Infection seldom occurs before the age of 6 months, and nearly all children are infected by 2 to 3 years of age. Viral shedding continues after the rash and fever subside. The incubation period is approximately 9 days (Dyer, 2007).

Assessment

Suspect roseola in a child who does not appear ill despite 3 to 5 days of high fever (103–104 °F [39.4–40 °C]); typically, the child is quite playful. A rash appears briefly after the fever subsides. The rash begins centrally (on the trunk) and then spreads to the neck, arms, and legs. The rash is rose colored and blanches under pressure. It can disappear within hours of its initial appearance.

The diagnosis of roseola is based on the clinical presentation. PCR testing is available, but standardized interpretation has not been established. Some research virology laboratories may be able to isolate the virus from blood.

Nursing Diagnoses and Outcomes

In addition to those listed in Nursing Plan of Care 24–1, the following nursing diagnosis and outcomes may apply to the child with roseola:

Risk for injury related to the effects of the fever (febrile seizures)

Outcomes: Child will experience no sequelae of the fever.

Parents will implement fever management inter-ventions.

Interdisciplinary Interventions

Isolating the infant is not necessary if the infant is hospitalized. Nursing care consists of standard precautions and supportive care. Acetaminophen or ibuprofen is given to reduce fever. Implement seizure precautions and anticonvulsants, such as phenobarbital, as ordered for children with a history of febrile convulsions (AAP, 2006k). Tepid baths can be given to augment the effects of antipyretic agents (see [thePoint](#). Procedures: Cooling Measures).

Varicella Zoster Virus Infection (VZV)

Primary VZV infection is commonly known as *chickenpox*; the recurrent form is known as *shingles*. Varicella is a common, relatively benign childhood illness; however, complications of varicella are increasingly common. They include secondary bacterial infections of the skin, pneumonia, and encephalitis. Varicella tends to be more severe in adolescents and adults, and the immunocompromised are at risk for more serious complications, including disseminated disease or even death.

Varicella is transmitted by direct contact with the vesicles and by the airborne route (AAP, 2006aa). As the child talks, coughs, and sneezes, viral particles can become airborne. Although 95% of all adults are immune to varicella because of a history of the disease, maternal varicella can occur, leading to fetal infection. Fetal infection during the first or second trimester can cause limb atrophy, scarring of the arms and legs, and eye and CNS disorders or fetal death.

Once a person is infected with varicella, the virus remains in the body hidden among the dorsal root and trigeminal nerve ganglia. Reactivation of varicella causes shingles, which can occur years to decades later and can produce painful lesions along the ganglia (nerve pathways). Reactivation is triggered by exposure to a stressor, such as excessive sunlight, extreme cold, labor, the loss of a loved one, job loss, chemotherapy, or other forms of immune suppression.

Assessment

After an incubation period of 10 to 21 days, the illness begins with a low-grade fever and malaise. Assess for the vesicular lesions that characterize the disease, which usually begin as superficial vesicular lesions that resemble dewdrops on the skin. A red base develops, followed by pustules. The rash is extremely pruritic. The lesions appear in successive crops over several days and affect the trunk, scalp, face, and extremities. Lesions can appear on the mucous membranes of the eyes, vaginal mucosa, rectal mucosa, mouth, and throat. Sunburned skin and diapered areas have significantly more lesions, but they are often smaller than in other areas. Between 5 to 7 days after onset, the lesions begin to crust (Fig. 24–7).

FIGURE 24–7. A soothing oatmeal bath can help relieve the pruritus associated with chickenpox.

The VZV PCR test is the method of choice for quickly diagnosing VZV. ELISA is the most common antibody test used to determine immunity. Paired sera for acute and convalescent antibodies can be used to determine acute infection. Collecting the virus using skin scrapings and then staining with immunofluorescent monoclonal antibodies can rule out herpes simplex. Because the tests are specific for VZV, test results are positive for an infected child.

Interdisciplinary Interventions

As with all vaccine-preventable illnesses, prevention is the best management (see Chapter 8 for discussion of the varicella vaccine). Varicella zoster immune globulin (VZIG) is given to immunosuppressed children immediately after exposure to someone with varicella. VZIG is given in the hope of preventing varicella, because varicella infection in an immunosuppressed child can be life threatening. VZIG decreases the infection's effects on the already weakened immune system. For hospitalized children who receive VZIG prophylactically, use airborne isolation precautions from day 10 to day 28 after the exposure occurs.

Treatment for immunocompromised patients and pregnant patients with severe complications involves administration of IV acyclovir.

Children with active varicella are rarely hospitalized. If a child with varicella is hospitalized, maintain isolation precautions. Place the child in a private room, preferably a negative-pressure room. If the child must leave the room for tests or procedures, ensure that the child wears a mask. Examine the child's skin for new lesions daily. When lesions have begun to crust and no new lesions appear, isolation precautions can be discontinued after 5 more days. To relieve the child's boredom of being confined in an isolation room, ask the child life specialist to bring washable toys, videotapes, DVDs, or games into the room.

The most common complication of varicella is secondary bacterial infection caused by the child scratching the

lesions. Teach the child and parents interventions that promote comfort and prevent infection or scarring caused by scratching the lesions (TIP 24–1).

Parents may sometimes need to bring a child with active varicella to the pediatrician's or family practitioner's office. Teach parents to alert the office staff about the child's potential diagnosis. Many physicians' offices have an alternative entrance for contagious children.

Community Care

Varicella has a large effect on families where both parents work and the child attends daycare. Because the child is highly contagious, a parent must often stay home with the sick child. Nurses can encourage parents to explore alternative baby-sitting arrangements with agencies that accommodate sick children.

Human Immunodeficiency Virus (HIV) and Acquired Immune Deficiency Syndrome (AIDS)

HIV is a retrovirus that attacks the immune system by destroying T lymphocytes (cells that are critical to fighting infection and developing immunity). Untreated, HIV infection renders the immune system useless, and the child is unable to fight even the most benign infection. HIV infection leads to AIDS. There are two types of HIV, HIV type 1 and HIV type 2 (most commonly found in Africa).

Globally, approximately 2.5 million children younger than 15 years were living with HIV in 2007; this constitutes almost 17% of those newly infected (UNAIDS et al., 2007). In the United States, an estimated 7.4 and 2.7 children per 100,000 younger than the age of 13 are living with HIV and AIDS, respectively (CDC, 2007a).

Three chief modes of transmission exist for HIV (Chart 24–4). Blood transfusions and administration of clotting factors are rarely modes of transmission because donated blood is tested, and clotting factors are heat treated. Mother-to-child transmission accounts for almost all new HIV infections in the preadolescent population (AAP, 2006l). In developed countries, the total number of children with AIDS has dropped dramatically during the past decade, thanks to routine use of antiretroviral therapy in HIV-infected women. Mother-to-child transmission rates are less than 2% in developed countries, but 25% to 40% in developing countries (Prendergast, Tudor-Williams, Jeena, et al., 2007).

Several maternal factors determine the likelihood of HIV transmission to the infant (see Chart 24–4). The main goal in prenatal care of the pregnant woman with AIDS is to decrease her viral load by giving her highly active antiretroviral therapy (HAART) during the pregnancy (Thorne & Newell, 2007). Prolonged rupture of the membranes in a mother with a detectable viral load increases the risk of transmission of HIV to her infant. In these cases, cesarean section may lessen the risk of HIV

TIP 24–1 A Teaching Intervention Plan for the Child With Varicella

Nursing diagnoses and outcomes

- Risk for impaired skin integrity related to effects of pruritic skin lesions
- Risk for infection related to effects of scratching

Outcomes

- Child will not develop secondary infection.
- Child will experience minimal discomfort from pruritus.

Teach the child/family

Managing discomfort and rash

- The best treatment for skin discomfort is a cool bath with soothing colloidal oatmeal (e.g., Aveeno) every 3 to 4 hours for the first few days. Calamine lotion may help decrease itching. If the itching becomes severe or interferes with sleep, give the child a nonprescription antihistamine (diphenhydramine hydrochloride [Benadryl]).
- Keep fingernails short. Wash child's hands frequently with antibacterial soap to reduce bacterial colonization.
- Remind child not to scratch lesions. If young child scratches at lesion, consider applying mittens or cotton socks over hands.

- If urination becomes painful, apply some 2.5% lidocaine (Xylocaine) or 1% dibucaine (Nupercainal) ointment (nonprescription) to the genital lesions every 2 to 3 hours to relieve pain.
- Administer acetaminophen for fever. Aspirin should be avoided in children and adolescents with varicella because of the link with Reye syndrome.
- If child is uncomfortable because of oral lesions, offer cool fluids, ice pops, or soft, bland food. Avoid citrus, spicy, or salty foods. If mouth ulcers become troublesome, have the child gargle or swallow 1 tsp to 1 tbl of an antacid solution four times a day after meals.

Contact Healthcare Provider if:

- Red, tender areas are noted on skin, or a speckled, fine rash develops
- Child seems very sick or develops the following: difficulty awakening, stiff neck, trouble walking, difficulty breathing or rapid breathing, or vomiting more than three times
- Scabs become soft and drain pus
- Fever lasts more than 4 days

transmission. Diagnosing and promptly treating occult sexually transmitted infections (STIs) is necessary.

Babies born to HIV-positive women may test positive for HIV antibody. This result is actually a measure of maternal antibody and not indicative of true infection. Usually, 13% to 39% (one in four) babies born to untreated HIV-positive mothers are actually infected (AAP, 2006). Infants may remain HIV antibody positive for as long as 18 months because of the slow rate of decay of maternal HIV antibody. Therefore, true infections in infants must be confirmed by detecting HIV in culture, or by PCR testing for HIV DNA or RNA.

HIV can be transmitted postnatally through breastfeeding. Although this risk of transmission is low in the United States, worldwide HIV is thought to be transmitted by breast-feeding in one third to one half of cases (Tradition or Science 24–2).

The rate of HIV infection continues to increase in the adolescent population, primarily through sexual exposure. Adolescents account for approximately 50% of new HIV cases each year (AAP, 2006). Most HIV-infected adolescents are asymptomatic.

caREminder

Routinely offer HIV testing to all pregnant adolescents. Administration of HAART significantly decreases (from 25% to 8%) the likelihood of perinatal transmission.

Pathophysiology

The sole purpose of HIV is to replicate or make copies of itself. It enters a cell, basically takes over the DNA, and commandeers the cell to make copies of HIV. Although HIV selects T4 lymphocytes as the preferred cells, it invades many other cells as well. However, T4 cell invasion is important because T4 lymphocytes defend the body against invading pathogens. HIV either renders T4 cells dysfunctional or creates “holes” in the membranes of T4 cells, resulting in osmotic pressure differences between the outside and the inside of the cell, that cause the cells to literally destroy themselves. Thus, T4 cells are depleted in number and cannot signal B cells to form protective antibodies to fight off the invading virus. In short, HIV targets the immune system to leave the body defenseless.

Prognosis

The prognosis for an HIV-infected child who has the first AIDS-defining illness (Chart 24–5) during the first year of life is usually grim, especially if the first illness is *Pneumocystis jiroveci* pneumonia (PCP). Children who can fend off the first AIDS-defining illness have the best prognosis. The use of early HAART and adjunctive therapies, including PCP prophylaxis, has substantially improved survival rates among children with HIV infection (Nesheim, Kapogiannis, Soe, et al., 2007).

CHART 24-4 TRANSMISSION OF HUMAN IMMUNODEFICIENCY VIRUS

Modes of Transmission

- Sexual contact (both homosexual and heterosexual)
- Percutaneous or mucous membrane exposure to needles or other sharp instruments contaminated with blood or bloody body fluids
- Mother-to-infant transmission before or around the time of birth

Timing of Transmission

- Intrauterine: HIV can be detected in aborted fetal tissue as early as 8 weeks.
- Intrapartum: In twin pregnancies, the incidence of infection is higher among the first twins born.
- Postpartum: HIV-positive mother breast-feeds the infant, and the infant acquires HIV infection from the breast milk.

Maternal Factors That Determine Transmission of HIV

- Low maternal CD4⁺ lymphocyte counts (<100): advanced HIV disease
- High maternal viral load
- Presence of sexually transmitted diseases, such as syphilis, which tax the immune system and cause placental inflammation, compromising the placental barrier
- Zidovudine therapy during pregnancy: reduces transmission of HIV to the baby by 67%

Assessment

Most children infected with HIV develop symptoms within the first the first year of life. The remainder become symptomatic sometime before age 5. HIV-infected children typically present with generalized lymphadenopathy, enlarged liver and spleen, failure to thrive, thrush, diarrhea, growth and developmental delays, and frequent recurrent infections.

Examine the history carefully. Untreated, children, with their immature immune systems, may have recurrent opportunistic infections (see Chart 24-5). PCP is one of the most common AIDS-defining diseases in children. Along with PCP, children may experience at least two serious bacterial infections in 2 years. These infections are typically sepsis, otitis media, chronic sinusitis, meningitis, gastroenteritis, and pneumonia (see also [thePoint](#), Care Path: An Interdisciplinary Plan of Care for the Child With AIDS Pneumonia). The causative organism varies, although *S. pneumoniae* is a common cause.

Differential diagnosis in children with HIV is often difficult. Many conditions mimic HIV and the failure to thrive that it causes (Chart 24-6). For example, children born with congenital heart defects often fail to thrive because of the severity of their lesions. Inborn errors

TRADITION OR SCIENCE 24-2

Should HIV-positive mothers breast-feed their infants?

EVIDENCE-BASED PRACTICE

Because HIV is transmitted in breast milk, the AAP recommends that HIV-positive mothers do not breast-feed (Read et al., 2003). However, because lack of breast-feeding increases morbidity and mortality when overall survival (not just avoiding HIV infection) is considered, breast-feeding may be indicated in nonoptimal situations. In a randomized clinical trial that studied HIV-infected women in Botswana, breast-feeding (compared with formula feeding) reduced infant morbidity and mortality from diarrheal and respiratory illnesses (Thior, Lockman, Smeaton, et al., 2006). The immunologic integrity of the breast milk of HIV-infected women has been demonstrated to be intact, and discontinuing breast-feeding puts the infant at higher risk for morbidity (Shapiro, Lockman, Kim, et al., 2007). Exclusive breast-feeding by HIV-positive women significantly decreased infant mortality when compared with mixed or no breast-feeding (Taha, Kumwenda, Hoover, et al., 2006) and reduced risk of postnatal HIV transmission (Coutsoudis, Pillay, Spooner, et al., 1999; Iliff, Piwoz, Tavengwa, et al., 2005; Coovadia, Rollins, Bland, et al., 2007). Duration of breast-feeding affects transmission risk, however; the risk was 3.8% at age 4 months and increased to 17.9% by age 24 months (Fawzi, Msamanga, Spiegelman, et al., 2002). WHO (2003b) recommends that HIV-positive women avoid breast-feeding only if replacement feeding is acceptable, feasible, affordable, sustainable, and safe—a situation often not present in developing countries. If these criteria are not met, WHO recommends that HIV-positive mothers breast-feed exclusively for the first few months of life, but discontinue it as soon as feasible (WHO, 2003b). Because early weaning is associated with high morbidity and mortality from infections other than HIV, newer research indicates that the benefits of breast-feeding exclusively until 6 months of age, and possibly even as long as 24 months, may outweigh the harms (Ellis, 2007; Kuhn, Kasonde, Sinkala, et al., 2005; Ross & Labbok, 2004). Further research is needed to determine the optimal duration of breast-feeding to balance these risks.

of metabolism and genetic causes of immunodeficiency must also be ruled out. Typical TORCH infections could be opportunistic infections in the HIV-infected child.

Diagnostic Tests

During infancy, diagnosis of HIV requires detection of HIV by culture or of HIV DNA or RNA by PCR, because ELISA and Western blot tests for HIV antibody may be positive from the presence of maternal antibody.

CHART 24–5 AIDS-DEFINING ILLNESSES IN CHILDREN WITH HIV INFECTION

Candidiasis: esophagus, trachea, bronchi, or lungs
 Coccidioidomycosis: disseminated or extrapulmonary
 Cryptococcoses: extrapulmonary
 Cryptosporidiosis: chronic intestinal
 Cytomegalovirus (CMV) disease: (other than liver, spleen, lymph nodes) in children older than 1 month
 CMV retinitis: loss of vision
 Chronic herpes simplex: ulcer (longer than 1 month), pneumonitis, esophagitis in children older than 1 month
 Histoplasmosis: disseminated or extrapulmonary
 HIV encephalopathy
 Isosporosis: chronic (longer than 1 month)
 Kaposi's sarcoma: rare in young children
 Lymphoid interstitial pneumonitis
 Lymphoma, primary brain
 Lymphoma (Burkitt's or immunoblastic sarcoma)
Mycobacterium avium complex or *M. kansasii* (disseminated or extrapulmonary)
M. tuberculosis: disseminated or extrapulmonary
Pneumocystis jiroveci pneumonia
 Progressive multifocal leukoencephalopathy
 Toxoplasmosis of brain: onset in child older than 1 month
 Wasting syndrome caused by HIV

A presumptive diagnosis of HIV can be made on the basis of a single positive HIV culture or PCR; however, two negative tests are required to rule out HIV infection. Routine ELISA and Western blot tests for HIV antibody may be used to diagnose HIV in children after the age of 12 to 18 months.

Interdisciplinary Interventions

Maternal treatment consists of oral zidovudine during the pregnancy and intravenously during delivery. Zidovudine reduces the likelihood of transmission without harming the fetus. The newborn also receives zidovudine for 6 weeks after birth (AAP, 2006).

The goal of treatment is to keep the child as healthy as possible for as long as possible. Zidovudine effectively interferes with HIV replication but can cause bone marrow suppression and nausea. If it fails, or the child cannot tolerate it, the physician may select another antiretroviral drug.

CHART 24–6 CONDITIONS THAT MIMIC PEDIATRIC AIDS

Condition: Description

Cardiac syndrome: poor contractility, myocarditis, heart failure

Chronic pneumonitis: lymphoid interstitial pneumonitis, pulmonary lymphoid hyperplasia

Encephalopathy or myelopathy: progressive encephalopathy, subcortical dementia, impaired brain growth, neoplasm, stroke

Hematologic syndrome: idiopathic thrombocytopenic purpura, lymphadenopathy

Hepatitis syndrome: hepatosplenomegaly, hyperbilirubinemia

Malignancies: lymphoreticular tumors, Burkitt's lymphoma, leiomyosarcomas

Opportunistic infections: *Pneumocystis jiroveci* pneumonia

Renal syndrome: progressive glomerulopathy

Wasting syndrome: failure to thrive, wasting

PCP prophylaxis with trimethoprim–sulfamethoxazole (Septra or Bactrim) should begin at 4 to 6 weeks of age and continue through the first year of life. After 1 year of age, PCP prophylaxis should be started when CD4 cell counts start to decrease. Age-appropriate immunizations are given on schedule as long as CD4 counts are normal. Live-virus vaccines should be held if CD4 counts are low or the child is severely immunocompromised.

Antiretroviral therapy is indicated for most children and adolescents with HIV; however, in asymptomatic patients with normal CD4 counts, antiretroviral therapy may not be started right away. Combination antiretroviral therapy (HAART) is more effective than monotherapy, preferably with three drugs when possible (U.S. Department of Health and Human Services, 2006).

Nursing care of HIV-positive infants and children involves using standard precautions. Because these children have many needs, and the mothers of HIV-positive infants may not have health insurance because of homelessness, IV drug abuse, or unemployment, involve social services as soon as possible. Refer mothers and infants to the dietitian for counseling to prevent the general decline in nutritional status of HIV-positive children. In developed countries, teach mothers with HIV not to breast-feed (Gartner, Morton, Lawrence et al., 2005; Hawkins, Blott, Clayden, et al., 2005). In developing countries, the risk of infant mortality from nutritional deficiency and other infectious diseases outweighs the risk of HIV transmission (Coovadia, Rollins, Bland, et al., 2007). Explain

all current medications, especially antiviral drugs, and PCP prophylaxis to the primary caregiver. HIV disease is a chronic condition (Plowfield, 2007). Encourage children to practice healthy lifestyles and lead well-rounded lives. Discuss discipline and family standards with parents (see Chapter 12).

Community Care

Many educators and government officials believe that education and prevention are the best ways to manage HIV disease. Recommend safer sex practices. Although the only 100% safe sex practice is abstinence, safer sex can be achieved through using latex condoms, having a monogamous relationship, and avoiding substances such as drugs and alcohol that cloud judgment.

Children cope with the diagnosis of AIDS in different ways at different ages (Developmental Considerations 24–1). Assist the family by listening to their concerns and

making appropriate referrals to the various agencies and organizations that can offer both social and financial support.

Measles

Measles is a serious disease that is highly communicable.

Incidence and Etiology

Measles is an acute viral illness characterized by fever, cough, **coryza** (acute rhinitis), conjunctivitis, rash, and Koplik’s spots. Measles complications include otitis media, pneumonia, and encephalitis. Acute encephalitis resulting in permanent brain damage occurs in approximately 1 out of every 1,000 cases in the United States (AAP, 2006m). Measles can be fatal in children younger than 5 years, immunocompromised children, and those with severe malnutrition.

DEVELOPMENTAL CONSIDERATIONS 24–1

Psychosocial Issues Related to Pediatric HIV Infection

Children

Infancy

Unable to grasp concept of illness and death. Infants and toddler have immediate concern about physical trauma and parent separation.

Early Childhood

Begin to conceptualize death process involving physical harm. Concerns center around medical tests and procedures.

Middle Childhood

Children begin to understand “something is wrong.” By age 10 or 11, understand death is permanent and universal. Fear of ostracism and rejection. Guilt regarding origin of illness.

Adolescence

Diagnosis often produces denial, fear, withdrawal, and fear of being rejected by peers. There is a disruption in forming relationships outside the family. Anxieties may lead to poor school performance, depression, isolation, and acting-out behavior.

Families

Trauma of diagnosis falls on the caregiver. Biologic mother may have found out her status upon diagnosis of child. Guilt: Regardless of mode of acquisition, all parents experience some degree of guilt. Anger: Against medical system if contracted through a transfusion, against themselves if prenatal. Families tend to move past this phase when reassured of ongoing comprehensive family care. Task overload, whether from scarce resources, lack of support, or burden of secrecy. Caring for a child with HIV infection is overwhelming. Isolation: Most parents unwilling to share child’s diagnosis. Therefore, the traditional supports available to families of a child with a life-threatening illness are not available from friends, community, and clergy. Medical home may be only source of support for these families. Depression: Reactive depression may result from facing HIV infection in the family, and parents may also have chronic depressive state that is a result of the coexistence of multiple problems. Fears of multiple losses: Parents begin to mourn alienation from other family members, loss of lifestyle, trust of friends, self-esteem.

The routine use of the measles vaccine has dramatically decreased the incidence of measles (see Chapter 8 for a discussion of vaccines). In 2000, measles was declared eliminated from the United States, but cases of measles continue to occur when the virus is imported from other countries (CDC, 2008b). There were an average of 63 cases per year from 2000 to 2007; in 2008, there were 131 cases (CDC, 2008b).

WORLDVIEW: Underimmunized populations, especially in large urban areas, are at risk for measles. Immigrants, members of religious groups that prohibit vaccination, and homeless or impoverished people are frequently unvaccinated. Some have limited access to healthcare; others lack adequate knowledge of the healthcare system.

Pathophysiology

Measles is a seasonal disease. Outbreaks peak during the winter and spring. It is highly contagious and is transmitted by the airborne route. It can be spread directly by coughing or sneezing or indirectly by airborne-suspended droplets. The child harbors the virus in nasopharyngeal secretions during the acute stage of the illness. The typical incubation period is 8 to 12 days. Children are contagious from 1 to 2 days before the rash appears until 4 days after the onset of the rash. The cycle of illness typically lasts 10 days; therefore, this illness is often called the *10-day measles*.

Occasional complications include otitis media, mastoiditis, pneumonia, encephalomyelitis, and (rarely) subacute sclerosing panencephalitis. Subacute sclerosing panencephalitis is a degenerative CNS process associated with progressive behavioral and intellectual deterioration followed by convulsions, coma, and death. Measles vaccination programs have reduced the incidence of subacute sclerosing panencephalitis to nearly zero.

Assessment

The hallmark of measles is the appearance of Koplik's spots. Look for them first appearing as red spots along the inside of the cheek (Fig. 24–8). They evolve over time to form pinpoint white papules on a rose-red base. Two days after the appearance of Koplik's spots, a red maculopapular rash appears with fever. The rash first appears on the face and neck, and then progresses down the body.

Other typical symptoms include fever, conjunctivitis, coryza, and a cough. Symptoms peak between the second and third days. The rash generally begins to fade by the third day. By the fourth day, symptoms begin to resolve, with the fever decreasing and conjunctiva clearing.

Diagnosis is typically made by the presenting clinical features. The measles virus can be isolated in tissue culture from nasopharyngeal secretions, blood, urine, and conjunctival fluid. Viral cultures are generally not used, however, because most laboratories are not equipped to cultivate the viruses.

FIGURE 24–8. The rashes of measles. Koplik's spots appear as red spots along the inside of the cheek. Sources: SPL/Custom Medical Stock Photo. Reprinted with permission.

The most useful antibody test is a paired sera test comparing the difference in titers between an acute specimen and a convalescent specimen taken 2 to 4 weeks later. Measles IgM antibodies can be detected in a single specimen if it is collected after the second day of the rash but before 30 days after the onset of illness.

Nursing Diagnoses and Outcomes

In addition to those identified in Nursing Plan of Care 24–1, the following nursing diagnoses and outcomes may apply to the child with measles:

Disturbed sensory perception: Visual related to effects of measles photophobia

Outcome: Child will undergo interventions to decrease the discomfort associated with photophobia.

Hyperthermia related to effects of measles

Outcome: Child will experience minimal discomfort and no injury associated with fever.

Interdisciplinary Interventions

No specific antiviral treatment is available. Uncomplicated measles is self-limiting and usually requires only supportive care.

If the child is hospitalized with measles, use airborne precautions for the duration of the illness. Provide care that includes supportive therapy and fluids. Coughs are sometimes difficult to control, and common cough suppressants seem inadequate. Therefore, encourage fluid intake to lubricate the mucous membranes. Do not treat associated conjunctivitis with antibacterial drops or ointments. The virus is unaffected by the antibacterial medication. If photophobia is present, dim the lights. However, avoid completely darkening the room, because it may be depressing to a child whose activity is already curtailed. Provide quiet, diversionary activities.

Alert! As with all viral illnesses, avoid aspirin products because of the increased risk of Reye syndrome.

Community Care

Susceptible persons exposed to measles may be given the measles vaccine to prevent disease. Prevention after exposure is possible because the body's immune response to the measles vaccine is elicited in 7 days, whereas the incubation period of natural measles is 8 to 12 days. Vaccination is certainly the method of choice in outbreaks in schools or daycare centers. For outbreaks in daycare centers, the vaccination age may be lowered to 6 months. These children can then resume the normal vaccination schedule, with the first immunization at 15 months and the next before school entry or at age 11 or 12, depending on local school requirements. Pregnancy is a contraindication for the measles vaccine (measles, mumps, rubella vaccine [MMRV]), because it is a live-virus vaccine. However, measles is not known to cause congenital birth defects. Administration of MMRV is not harmful if it is given to a person who is already immune to one or more of the viruses.

Mumps

Before a vaccine was developed, mumps was a common childhood disease.

Incidence and Etiology

Mumps is a vaccine-preventable disease that occasionally occurs in outbreaks in undervaccinated populations (see Chapter 8 for a discussion of vaccines). Known as *infectious parotitis*, it is a systemic disease characterized by acute inflammation of the salivary glands, particularly the parotid glands. It is seasonal in its occurrence, with most cases arising during late winter and spring.

The incidence of mumps in developed countries has been low during the postvaccine era (e.g., 200–300 cases per year in the United States from 2001 to 2005 [CDC, 2008a]), but some recent outbreaks have involved mainly older youths and young adults (age 15–26 years) in developed countries such as the United States (CDC, 2008a), the United Kingdom (CDC, 2006b), Canada (Watson-Creed, Saunders, Scott, et al., 2006), and Korea (Park, Nam, Kim, et al., 2007). These outbreaks highlight the importance of immunizations. Globally, more than 440,000 cases of mumps occurred in 2006 (World Health Organization [WHO], 2008).

Pathophysiology

Complications of mumps are rare. Occasionally, adolescent or adult males experience orchitis (inflammation of the testis), but sterility rarely occurs. Mumps during pregnancy is not known to result in birth defects. However, pregnancy is a contraindication for the mumps vaccine or MMRV because of the theoretic risks (AAP, 2006n).

Assessment

Swelling of the salivary glands is the hallmark of mumps (Fig. 24–9). In the classic illness, the child complains of an earache made worse by chewing. Fever, headache, and generalized malaise are often accompanying symptoms. The healthcare team will rule out other causes of parotid swelling. Such causes include stones that block Stensen's ducts, cytomegalovirus, coxsackievirus, parainfluenza virus infections, and various tumors, hemangiomas, and lymphangiomas of the parotid gland.

Mumps can be diagnosed by isolating the mumps virus from throat swabs, urine, and spinal fluid. Mumps-specific IgM antibody or mumps virus by PCR can be detected in serum. Specific mumps serologic tests include mumps hemagglutination inhibition test, complement fixation, and enzyme immunoassay.

Nursing Diagnoses and Outcomes

See Nursing Plan of Care 24–1 for pertinent nursing diagnoses and outcomes. The diagnosis of Imbalanced nutrition: Less than body requirements may be especially applicable for a child with mumps because of pain associated with chewing.

Interdisciplinary Interventions

No antiviral therapies are available to treat mumps, so supportive care is indicated. Children with mumps are seldom hospitalized. Mumps vaccine may be helpful in controlling outbreaks.

FIGURE 24–9. In mumps, the parotid glands swell and obscure the angle of the jaw. Copyright Morris Huberland/Science Source/Photo Researchers. Reprinted with permission.

When a child with mumps is hospitalized, place the child in a private room with droplet precautions until 9 days after the onset of swelling. In an outbreak, when two or more children with mumps are admitted, they may share a room.

Community Care

In the home, educate the family to keep the child with mumps out of attend school or daycare until 9 days after the onset of swelling. Assist the family to arrange for home teachers for school-aged children.

Nursing care of children with mumps is supportive. Swollen parotid glands may cause discomfort while eating. Because the child often complains of increased pain upon chewing, recommend a soft diet. Educate the child to avoid citrus foods and some sour candies or foods that may elicit pain and increased salivation.

Parvovirus B19 Infection

Parvovirus B19 infection is also known as *erythema infectiosum* or *fifth disease*. It is called *fifth disease*, because it was the fifth childhood disease recognized to cause a rashlike illness in children. The other four diseases are measles, rubella, varicella, and scarlet fever. The mode of transmission is through respiratory secretions. It is contagious upon close contact with the infected individual. Outbreaks among elementary and middle school classmates are often demonstrated; secondary transmission among family members accounts for 50% of new cases (AAP, 2006p). The incubation period is 4 to 14 days. Complications are rare in children.

Assessment

In children with the well-known “slapped cheek” facial appearance, look for a lacelike rash on the abdomen and extremities (Fig. 24–10). The lacelike rash increases in color with heat, such as after a warm bath, and may last for several weeks.

The unique rash and facial appearance in children with parvovirus B19 are diagnostic. However, acute infection can be confirmed with the serologic test that measures parvovirus B19-specific IgM antibody. The presence of parvovirus B19 IgG antibody indicates past infection and immunity. Parvovirus B19 antigens can be detected by radioimmunoassay or by enzyme assay. Viral detection by PCR is also available, but the parvovirus DNA must be quantitated to distinguish acute infection from past infection.

Interdisciplinary Interventions

Treatment for parvovirus B19 infection is generally supportive. Because parvovirus B19 infections can trigger an aplastic crisis in patients with hemolytic anemias such as sickle cell disease, provide supportive care, such as oxygen and transfusion with red cells, for these patients as

FIGURE 24–10. Rashes of parvovirus B19. (A) The hallmark sign is the “slapped cheek” appearance of the face. (B) The lacelike rash (source: CDC). Reprinted with permission.

indicated. IV Ig is helpful for the immunocompromised patient.

By the time the rash appears, most children are no longer infectious, so isolation is unnecessary. However, in the immunodeficient child and those with sickle cell disease or other chronic hemolytic conditions, parvovirus B19 infection may cause aplastic crisis, rendering them infectious during the entire course of the illness. For these individuals, implement droplet precautions. Because only about half the population has had parvovirus B19, healthcare personnel could be susceptible. Fetal infection can result in fatal nonimmune hydrops. Thus, pregnant employees and visitors must observe droplet precautions. For children managed with droplet precautions, arrange for play therapy, video games, and other diversions, because trips to the playroom are not possible.

Rubella

Rubella, also known as *German measles*, is a vaccine-preventable rash disease. It is also called *3-day measles*,

because it produces a rash that lasts approximately 3 days. Rubella has an incubation period of 14 to 21 days.

Pathophysiology

Rubella is a relatively mild disease in children but is important in nonimmune pregnant females. If maternal infection occurs during the first trimester, transplacental infection can have disastrous effects on the fetus. Rubella is part of the TORCH syndrome of infections that affect fetal development. In the pregnant woman, rubella is a relatively mild disease. In 25% to 50% of the cases, the woman has no symptoms at all. The rash occurs as an immune response to viral invasion, which occurs at the end of the incubation period. Much of the fetal damage occurs during the viremic stage, when the viable virus is circulating in the maternal blood. The risk of congenital abnormalities is 80% if rubella is acquired during the first 12 weeks of pregnancy (Best, 2007). The risk of fetal damage from rubella declines as the pregnancy progresses.

Assessment

In children with acquired rubella, a fine rash appears. A slight fever and generalized lymphadenopathy, particularly in the suboccipital, postauricular, and cervical areas may be found. In infants with congenital rubella, skin lesions, such as a “blueberry muffin” rash, and major organ system defects (Chart 24–7) are the hallmarks.

Most virology laboratories can perform serologic tests that isolate rubella virus from blood, urine, throat, and spinal fluid. Observing a fourfold increase in antibody titer in paired sera (acute and convalescent) is a common test for distinguishing between immunity and acute infection. Detection of rubella-specific IgM and IgG antibodies is especially useful for confirming congenital infection.

CHART 24–7 EFFECTS OF CONGENITAL RUBELLA

- Intrauterine growth retardation
- Hepatosplenomegaly
- Thrombocytopenia
- “Blueberry muffin” rash
- “Celery stalking” (Radiographic lines through long bones)
- Cataracts, salt-and-pepper retinopathy, glaucoma, microphthalmia
- Mental retardation, microcephaly, encephalitis, seizures, hearing loss
- Pneumonitis
- Ventricular septal defect, valvular stenosis, myocardial stenosis

Nursing Diagnoses and Outcomes

In addition to those identified in Nursing Plan of Care 24–1, the following nursing diagnosis and outcome may apply to the child with congenital rubella:

Disturbed sensory perception: Visual and auditory related to effects of rubella

Outcome: Child’s sensory–perceptual deficits will be recognized early, and interventions will be implemented to minimize their deleterious effects on growth and development.

Interdisciplinary Interventions

Rubella immune globulin is available for postexposure prophylaxis for pregnant women in whom pregnancy termination is not an option. It may prevent or limit the disease in these women.

Nursing care of children with rubella is largely supportive. Maintain contact precautions for 7 days after the onset of the rash or, for a child with congenital infection, for the duration of the hospital stay. Teach parents to maintain these precautions. Provide specific care related to the number and type of defects the child exhibits. Discharge planning along with parent teaching eases the transition from the hospital to the home.

All healthcare personnel should be vaccinated with rubella vaccine (MMRV) or demonstrate immunity by titer. Most individuals born before 1957 have had rubella, ensuring immunity. Those born after 1957 need a second MMRV to guard against waning immunity.

Community Care

Infants with congenital rubella can shed rubella virus in urine and nasopharyngeal secretions for a year or longer. Educate parents that congenitally infected infants must be excluded for this period from large groups, such as daycare and church nurseries. Passive maternal antibodies wane after 4 to 6 months. Because the MMRV is usually given at ages 12 to 15 months, all infants between the ages of 6 to 12 months are susceptible.

Viral Hepatitis

The hepatitis group of viruses (hepatitis A, hepatitis B, hepatitis C, hepatitis D or delta, and hepatitis E) are related in name only. For example, hepatitis A virus is an RNA virus and hepatitis B virus is a DNA virus, but they share a common pathology: infection of the liver. Hepatitis can cause liver inflammation, jaundice, an increase in liver enzymes, and liver failure. Hepatitis A and B are the most common hepatitis infections in infants and children, and are covered in this section.

Incidence and Etiology

Hepatitis A viral infection (HAV) (also known as *infectious hepatitis*) is commonly transmitted from person to person

by fecal–oral contamination. Infected children shed HAV in the stool. Transmission can occur between children and caregivers in the home and in daycare centers. For example, a daycare worker could change the diaper of an infant who is shedding HAV, then the worker might prepare food without proper hand hygiene. Although prolonged or relapsing hepatitis A infection can occur, chronic infection does not (AAP, 2006i).

In recent years, HAV has affected more adolescents and young adults than in the past, when most infections occurred among young children. This shift is likely the result of the introduction of routine hepatitis A immunization.

Hepatitis B virus (HBV) is transmitted by exposure to blood and body fluids. People with chronic HBV infection are the primary reservoirs for infection. Transmission commonly occurs through sharing unclean needles, needle sticks, sexual contact, and perinatal exposure to an infected mother. However, young children can be at great risk for HBV infection from household child-to-child transmission or transmission from inanimate objects, such as washcloths and toothbrushes. Children in institutions, or those who are immunosuppressed or on dialysis, are also at high risk for HBV infection. Sexually active adolescents are at high risk for HBV infection as well as for other STIs. Chronic infection can occur, resulting (rarely) in fulminant hepatitis. This highly fatal complication of HBV infection may lead to hepatic coma and death unless a liver transplantation occurs. The implementation of routine childhood immunization for hepatitis B has dramatically reduced the number of infections in infants and children.

Assessment

Hepatitis A typically presents with fever, malaise, and nausea. Younger children are often asymptomatic and without jaundice, whereas older children are typically symptomatic, with infection lasting several weeks and accompanied by jaundice 70% of the time.

Hepatitis B may present in a variety of ways. Signs and symptoms range from nonspecific illness such as anorexia, nausea, or malaise, to hepatitis with jaundice or, rarely, fulminant liver failure. Generally, children have mild symptoms without jaundice or are asymptomatic. Symptoms in children without jaundice are characterized by headache, malaise, anorexia, nausea, vomiting, and abdominal pain. Symptoms in children with jaundice are characterized by dark urine, clay-colored (light) stools, and jaundiced skin and sclera.

Diagnostic Tests

Serologic testing for hepatitis A IgM and IgG is available. HAV IgM is present at the onset of illness and typically disappears by 4 to 6 months. HAV IgG may be detected shortly after the appearance of IgM and persists after IgM disappears, indicating past infection and immunity.

A variety of serologic tests are available to detect hepatitis B; PCR testing can detect HBV DNA. Serologic tests for specific hepatitis viruses and their corresponding

IgM and IgG antibodies confirm the diagnosis. In acute hepatitis, hepatitis IgM antibodies are present. Later in the infection, hepatitis IgG antibodies are present. The presence of IgG antibodies alone suggests that hepatitis occurred sometime in the past and that the patient is no longer infectious.

Serologic tests for hepatitis B can help confirm the diagnosis. Generally, the presence of any hepatitis B *antigen* always indicates that circulating virus is present and that the child's blood and body fluids are infectious. The presence of hepatitis B *antibody* means that the body is responding to the infection and that immunity is beginning. Those with chronic infection have circulating hepatitis B antigen and core antibody.

In hepatitis, liver enzymes are elevated, including lactate dehydrogenase, serum glutamic-oxaloacetic transaminase, and serum glutamic-pyruvic transaminase.

Nursing Diagnoses and Outcomes

In addition to those identified in Nursing Plan of Care 24–1, the following nursing diagnosis and outcome may apply to the older child with hepatitis:

Activity intolerance related to fatigue

Outcome: Child will be increasingly able to tolerate activity and maintain school requirements.

Interdisciplinary Interventions

No treatment or cure exists for acute hepatitis infection. Vaccines have been developed for some of the hepatitis viruses, and routine childhood immunization for hepatitis A and B is recommended (see Chapter 8).

Antiviral therapy is available for chronic HBV infection, including interferon-alfa, lamivudine, adefovir, or entecavir therapy.

caREminder

Liver transplantation has been used as a treatment for end-stage liver disease resulting from hepatitis B infection. However, because other body tissues still harbor HBV, the new liver may also become infected.

Focus nursing care for children with hepatitis A infection on teaching preventive measures, good sanitation, and careful hand hygiene. Through family hygiene instruction, nurses can help prevent outbreaks in families. Educate that hand hygiene after toileting or diaper changing is essential to hygiene, but specific in preventing HAV infection. Teach family members about proper food handling. Counsel that HAV-infected infants or food handlers should be excluded from daycare or work for 1 week after the onset of illness.

Educate adolescents about sexual activity during the acute phase of HBV infection, when transmission may be likely. Healthcare workers should advise abstinence or the use of condoms.

Focus nursing care of an infant born to a hepatitis B antigen-positive mother on standard precautions such as

wearing gloves when handling the infant after delivery and until all amniotic fluid is wiped off. Because hepatitis B has a long incubation period (up to 6 months), the infant of a chronic carrier or a woman with active HBV infection should receive hepatitis B immune globulin (HBIG). Active immunization with hepatitis B vaccine is also initiated. Giving hepatitis B vaccine to the child along with HBIG can prevent disease in 95% of infants (AAP, 2006i).

Community Care

Routine testing of *all* pregnant women for hepatitis B surface antigen (HBsAg) is recommended (CDC, 2005). Without intervention, approximately 90% of infants born to women who are positive for both HBsAg and Hepatitis B e Antigen (HBeAg) will develop chronic hepatitis B infection (Chang, 2007). Hepatitis B infection is preventable in infants of HBsAg mothers with the administration of HBIG and hepatitis B vaccine (Lee, Gong, Brok et al., 2006b).

caREminder

Pregnant women should ideally be tested for hepatitis B early during pregnancy and before delivery (in patients at high risk) to identify infants who need immediate prophylaxis at birth.

Routine immunization for hepatitis A and B is recommended for all infants and children. In general, preventing and controlling viral hepatitis transmission include hand hygiene after toileting or diapering infants, giving immunoprophylaxis after exposure (immune globulin), and active immunization. Limiting environmental contamination and sanitizing water can decrease the potential for exposure to hepatitis A. The inability to identify children who are infected, because they lack symptoms, emphasizes the importance of routine infection control procedures such as hand hygiene, sterilization of medical equipment, and standard precautions.

SEXUALLY TRANSMITTED INFECTIONS (STIs)

STIs typically affect adults or sexually active teenagers. An STI in a child (other than a newborn) suggests sexual abuse, which the healthcare team must report to the appropriate authorities. In STIs, females usually exhibit vaginitis; males, urethritis. In infants and young children some forms of vulvovaginitis result from chemical irritation rather than infection. For example, vulvar irritation can be induced by ammonia (from wet diapers), and allergic or chemical irritation of the vulva can result from the use of harsh soaps or bubble baths.

The classic STIs, gonorrhea and syphilis, have been joined by such entities as chlamydia, human papilloma virus, genital herpes, hepatitis B and C, and HIV infection.

Herpes, hepatitis B, and HIV infection have been previously discussed in this chapter. Venereal warts are caused by human papillomavirus and are discussed in Chapter 25. Syphilis, gonorrhea, and chlamydia are discussed in this section.

The sexual activity leading to infection includes genital–genital, oral–genital, oral–anal, and genital–anal contact between heterosexuals or homosexuals. Approximately 19 million new cases of STIs are reported in the United States each year, with more than 50% of these infections occurring in the adolescent or young adult population (CDC, 2006c).

Syphilis

Acquired syphilis is an STI that occurs in three stages: primary, secondary, and tertiary.

Incidence and Etiology

Syphilis is a disease caused by a motile spirochete, *Treponema pallidum*. Congenital syphilis occurs when transplacental transmission of *T. pallidum* occurs any time during pregnancy or at birth. Transmission from an infected, untreated mother occurs 70% to 100% of the time in primary syphilis; the risk decreases with progression of maternal disease (Chakraborty & Luck, 2007). The incidence of acquired syphilis has declined in developed nations since the 1990s; however, rates remain high in large urban areas, the southern United States, among men who have sex with men, and in HIV infection (AAP, 2006w). Some European countries have seen a resurgence of congenital syphilis, and it remains an important issue globally, with an estimated prevalence of more than 700,000 to 1.5 million (Simms & Brouet, 2008).

Pathophysiology

The incubation period of syphilis is typically 3 weeks, but ranges from 10 to 90 days after exposure. *T. pallidum* is a sexually transmitted organism acquired by direct contact with the highly infectious ulcerative skin lesions or mucous membranes or through transplacental transmission from an infected mother to her fetus.

Prognosis

An infected person who does not get treatment may infect others during the first two stages. Untreated syphilis in the tertiary stage, although not contagious, can cause serious heart abnormalities, mental disorders, blindness, other neurologic problems, and death.

Syphilis is a treatable disease, even in pregnancy. In untreated active maternal infection, adverse outcomes occur in up to 80% of births, including stillbirth (40%), perinatal fetal death (20%), and serious neonatal infection (20%) (Schmid, Stoner, Hawkes, et al., 2007). Lack of treatment or late treatment during pregnancy often results in hydrops fetalis or preterm birth. Infants born

with congenital syphilis may have many body systems affected.

Assessment

Infants with congenital infection may present with illness at birth, or symptoms may develop within the first 4 to 8 weeks of life (Chart 24–8). If untreated, infants may go on to develop late disease, which typically involves the CNS, bones and joints, teeth, eyes, and skin.

The spirochete can be visualized using darkfield microscopy or with direct fluorescent antibody tests of lesion fluid, the placenta, or the umbilical cord. Serologic tests include nontreponemal and treponemal tests. The nontreponemal test is the VDRL slide test or the rapid plasma reagin test. Treponemal tests include the fluorescent treponemal antibody absorption test and the *T. pallidum* particle agglutination test. All women seeking prenatal care are screened for syphilis with a VDRL or rapid plasma reagin test early during pregnancy and again at delivery. The fluorescent treponemal antibody absorption or the *T. pallidum* particle agglutination test is used as a confirmatory test and remains positive for life.

Diagnosis in the newborn is confirmed by persistent or increasing VDRL titers or a titer that is fourfold greater

than the maternal titer. Radiographs of long bones in the legs and arms may show metaphysitis (inflammation of the growing end of the bone). Spinal fluid of the newborn is also sent for a VDRL test. A positive result is indicative of infection (see [thePoint](#), Diagnostic Tests: Stages of Syphilis for review of the clinical characteristics of the three stages of acquired syphilis).

Interdisciplinary Interventions

Maternal treatment consists of intramuscular or IV penicillin G, even in individuals who are allergic to it. Women with penicillin allergy are desensitized to penicillin and then receive penicillin therapy. Desensitization is accomplished while the woman is hospitalized to ensure adequate emergency care is available should a severe reaction occur. Alternatives to penicillin are less effective. IV crystalline penicillin G is the treatment of choice for the infant.

Community Care

Nursing care for the infant with congenital syphilis consists of hand hygiene and careful handling of all secretions, particularly nasal secretions. Observe contact precautions for at least 24 hours after antimicrobial therapy has started.

Report syphilis and congenital syphilis to the local health department. For pregnant women with syphilis, offer testing for HIV and other STIs.

For infants with congenital syphilis, recheck the VDRL or rapid plasma reagin test at 2 to 4, 6, and 12 months after treatment or until the test is negative. Educate parents on the need for intensive follow-up health-care visits for their infant during the first year of life.

Congenital syphilis is preventable. Consistent prenatal care and education are essential.

CHART 24–8 EFFECTS OF CONGENITAL SYPHILIS

Early

Intrauterine growth retardation

Snuffles (persistent, sometimes bloody rhinitis containing *T. pallidum*), associated with hoarse cry

Hepatosplenomegaly, jaundice, lymphadenopathy, thrombocytopenia, anemia

Macropapular rash on palms and soles followed by desquamation

Osteochondritis, periostitis

Late (Appearing After Age 2 Years)

Saber shins (long bones at lower leg are broad at the knee and narrow at the ankle, resembling a saber)

Perforated hard palate, saddle nose (cartilage in the nose is deformed so that it has a saddlelike appearance)

Mulberry molars (molars are deformed and take on the appearance of a cluster of mulberries), Hutchinson's teeth (teeth are malformed and small, resembling shoe-peg corn)

Interstitial keratitis, iridocyclitis, and chorioretinitis

Neurosyphilis: hearing loss

Localized rash, nodules and gummas (granulomatouslike lesions)

Gonococcal Infections

Gonorrhea is one of the oldest STIs described.

Incidence and Etiology

Gonorrhea is caused by a gram-negative diplococcus, *Neisseria gonorrhoeae*. Like its cousin, *N. meningitidis*, *N. gonorrhoeae* is a fragile organism with strict growth requirements. It rapidly dies on inanimate objects, such as toilets. Transmission occurs during vaginal, anal, or oral intercourse. Transmission to the neonate (neonatal eye infection) occurs when the infant descends through an infected birth canal. The incubation period is usually 2 to 7 days. The incidence of infection in the United States is highest in females age 14 to 19 years, and more than 300,000 cases of infection are reported annually (Datta, Sternberg, Johnson, et al., 2007).

Assessment

Gonorrhea infections occur in three distinct age groups: neonates, adolescents, and adults (AAP, 2006h). Neonates

typically develop an eye infection (ophthalmia neonatorum), which formerly was a leading cause of neonatal blindness. Young girls may exhibit vulvovaginitis as a result of sexual abuse by an infected individual.

Sexually active adolescent girls tend to exhibit vaginitis, which may progress to pelvic inflammatory disease. Some infected persons, such as those with rectal or pharyngeal infections, remain asymptomatic. Assess for hallmark symptoms of gonorrhea, which include a thick yellow or white vaginal or urethral discharge, painful or burning urination, and, in females, abdominal cramping or pain. Infection could extend beyond vulvovaginitis to include abscesses of Bartholin's glands, salpingitis, and perihepatitis.

In males, the infection is often limited to urethritis. A thick yellow or white penile discharge or painful urination may be present. However, some males exhibit acute epididymitis and prostatitis. In all cases, the organism could gain access to the circulatory system, causing sepsis, arthritis, endocarditis, and meningitis.

Diagnostic Tests

The standard for diagnosis is a culture of eye drainage, cervical secretions, urethral discharge, or a rectal or throat swab sample that is positive for *N. gonorrhoeae*. Smears with Gram's stains of these fluids that are positive for gram-negative diplococci can also be helpful in making the diagnosis. Nucleic acid amplification testing is available for urethral or endocervical swabs and urine. These tests are highly sensitive and specific.

caREminder

Notify the laboratory of the possible diagnosis of gonorrhea pharyngitis when throat swabs are submitted. A throat swab in most laboratories is evaluated for group A streptococcus only; additional methods are needed to isolate gonorrhea.

The laboratory should differentiate the gonococci from other *Neisseria* species, especially meningococci. Both appear as gram-negative diplococci. Individuals with disseminated gonorrhea often appear clinically as if they have infection with *N. meningitidis*.

Nursing Diagnoses and Outcomes

Refer to Nursing Plan of Care 24–1 for general nursing diagnoses and outcomes for the child with an infection. Nursing diagnoses and outcomes for the child with gonorrhea depend on how the child or adolescent acquired the infection and clinical manifestations. If rape was involved, the following nursing diagnosis and outcome may apply:

Rape trauma syndrome related to forced sexual activity

Outcome: Child will verbalize feelings, and interventions will be implemented to assist the child with coping.

If pelvic inflammatory disease is present, the following nursing diagnoses and outcomes may apply:

Acute pain related to effects of disease

Outcome: Child will experience minimal discomfort.

Deficient knowledge: STI prevention

Outcome: Adolescent will state and implement methods for preventing STIs (e.g., abstinence, condoms).

Interdisciplinary Interventions

Gonorrhea is often treated in the emergency room or ambulatory setting. Single-dose therapy with an extended-spectrum cephalosporin is recommended and generally effective. Implement pain management (e.g., topical analgesia, distraction) for intramuscular injections. On occasion, the infection spreads to the cervix and fallopian tubes. Pelvic inflammatory disease ensues, requiring parenteral antibiotic therapy that includes an extended cephalosporin and doxycycline regimen, followed by oral doxycycline. Conditions such as appendicitis, cystitis, and pyelonephritis must be ruled out in the differential diagnosis. Disseminated infection should be treated with 7 to 14 days of IV cefotaxime. Gonorrhea continues to develop drug resistance over time; therefore, consult CDC STI guidelines before starting treatment (CDC, 2007b).

The current practice of applying prophylactic eye drops (silver nitrate, tetracycline, or erythromycin) at birth decreases the incidence of ophthalmia neonatorum drastically. Ceftriaxone is the drug therapy of choice for gonococcal ophthalmia neonatorum. Patients should be empirically treated simultaneously for chlamydia, because these two infections frequently occur together.

Community Care

Educate adolescents that abstinence or the use of condoms effectively prevents transmission of gonorrhea and most other STIs. Report gonorrhea to the local health department to initiate contact tracing and treatment. Report gonorrhea in children older than 1 month to the local Department of Health and Human Services, because of suspicion of sexual abuse.

QUESTION: Ashley is diagnosed with a chlamydia infection. For what other sexually transmitted infection would the school nurse need to assess?

Chlamydia

Chlamydia has become a serious public health issue.

Incidence and Etiology

Chlamydia trachomatis is caused by an intracellular bacterial agent that has multiple serotypes. Trachoma is usually caused by serotypes A through C, whereas genital

and perinatal infections are caused by B and D through *K. C. trachomatis* is the most common STI worldwide, with high rates among sexually active adolescents and young adults (Kučinskienė, Šutaitė, Valiukevičienė, et al., 2006; Public Health Agency of Canada, 2007). The CDC record nearly 1 million cases of chlamydia in the United States annually; however, the true incidence is estimated at closer to 3 million cases (CDC, 2006c).

Pathophysiology

Genital infection is transmitted sexually. *C. trachomatis* and gonorrhea are often co-infections, so treatment for both is recommended if either is confirmed. Neonatal infection is acquired as the infant passes through an infected birth canal. Infection occurs in 50% of infants born to untreated mothers (AAP, 2006c). Conjunctivitis and pneumonia are of the greatest risk to these infants. The incubation period varies but is at least 1 week.

ANSWER: Because Ashley has chlamydia the nurse also needs to assess for gonorrhea, because these two infections often occur together.

Assessment

Be alert for signs of chlamydia. This STI can be asymptomatic or can produce urethritis in both sexes, vaginitis in girls, cervicitis in adolescent girls, and epididymitis in boys. In girls, the infection may ascend the vaginal tract and progress to pelvic inflammatory disease that may ultimately lead to infertility or increase risk for ectopic pregnancy. Signs in girls may be abnormal vaginal discharge or bleeding, painful urination, abdominal pain, fever, or nausea. Signs in boys may be watery, white, or yellow penile discharge or painful urination.

Infants may acquire neonatal chlamydial conjunctivitis or pneumonia. The conjunctivitis appears as a keratoconjunctivitis with purulent discharge. The risk of chlamydial conjunctivitis in the exposed neonate is 25% to 50%. The infant may also have an asymptomatic infection of the pharynx, rectum, or vagina that can persist for 2 years (AAP, 2006c). The risk of pneumonia in the neonate is 20%. The symptoms of pneumonia include a staccato cough without fever and hyperinflation of the chest as seen on radiographic evaluation.

C. trachomatis, the causative agent, can be grown in tissue culture cells. Rapid antigen detection includes direct fluorescent antibody, enzyme immunoassay, and genetic probe testing. The DNA probe methods can rapidly and accurately test for the presence of both gonorrhea and chlamydia.

Nursing Diagnoses and Outcomes

Nursing diagnoses and outcomes for adolescents with sexually transmitted chlamydial infections are similar to

those for gonorrhea. For the infant or child with chlamydial pneumonia, the following nursing diagnoses and outcomes may apply:

Ineffective breathing pattern related to effects of disease

Outcome: The child will be assisted to maintain an effective breathing pattern and tissue oxygenation.

Sleep deprivation related to coughing

Outcome: The child's cough will be controlled to obtain adequate sleep.

QUESTION: Ashley has a trusting relationship with the school nurse. What interventions would be the priority for Ashley and how might the school nurse promote Ashley's compliance with the treatment regimen?

Interdisciplinary Interventions

Treatment of chlamydial infection in adolescents usually involves doxycycline for 7 days or a one-time dose of azithromycin. Sexual partners should also be treated. Conjunctivitis in the newborn is treated with oral erythromycin to ensure that asymptomatic carriage is eradicated; topical application of erythromycin eye drops is ineffective. Pneumonia can be treated with oral azithromycin or erythromycin.

Oral erythromycin in infants younger than 6 weeks of age has been associated with infantile hypertrophic pyloric stenosis; however, it continues to be the drug of choice for chlamydia.

Nurses who work with adolescents may have the opportunity to discuss STI prevention with adolescents who have already been infected or are sexually active. If so, explain abstinence and the use of latex condoms as ways to prevent transmission. Teaching must include instructions on finishing the prescribed dose of medication completely and returning for follow-up care as needed.

ANSWER: Priorities for Ashley would include antibiotic treatment for her and her boyfriend, and an emphasis on the need to adhere to the medication therapy regimen to ensure that the infection completely resolves. As an adolescent, it might be more helpful for her and her boyfriend to receive the one-time dose of azithromycin rather than a 7-day regimen of doxycycline for chlamydia treatment. Both also would need simultaneous treatment for gonorrhea (a single-dose, broad-spectrum cephalosporin). In addition, both would need instruction on safe sex practices, including the use of condoms to prevent transmission. Then nurse also needs to emphasize that the infection does not always cause symptoms, so adhering to safe sex practices reduces the risk of transmission and recurrence of the infection, which could ultimately lead to problems in the future.

FUNGAL INFECTIONS

Fungal infections often occur when the child's immune system has been suppressed because of chemotherapy, radiation, illness, or transplantation. Fungi are opportunists that take advantage of a vacated ecologic niche. When antibiotics are used to kill pathogenic strains of bacteria, they often kill useful bacteria (normal flora) as well. These useful bacteria normally keep fungi in check, and when they are gone, fungi can take over and cause serious infections. (See [thePoint](#) Supplemental Information: Fungal Infections for a discussion of aspergillosis, coccidioidomycosis, histoplasmosis, and *Malassezia furfur* infections.)

PARASITE AND VECTOR-BORNE INFECTIONS

Parasites have infested humans worldwide throughout the centuries. Parasites can range in size from the microscopic *Plasmodium* spp. that cause malaria to the guinea worm, which can measure up to 3 m. Parasites have one aspect in common: they are free-living organisms. In many instances, humans are merely incidental hosts. In other cases, humans are a vital part of an elaborate life cycle that could include other animals or insects. Of all the infectious and parasitic diseases, few cause more distress to nursing staff than lice and scabies. These parasites are discussed in detail in Chapter 25.

Many bacteria or viruses must rely on vectors such as mosquitoes, ticks, or other arthropods to transmit diseases to humans and other mammals. These diseases are known as *vector-borne infections* (see [thePoint](#) Supplemental Information: Malaria).

Giardiasis

Giardia lamblia (also called *Giardia intestinalis*) is a protozoal organism that lives in freshwater streams. It infects both humans and wildlife. *G. lamblia* is the most common disease-causing parasite in the United States (AAP, 2006g). It exists as a trophozoite and as a cyst. The cyst form is infectious. Transmission is through ingestion of cyst-contaminated water or direct hand-to-mouth inoculation from cyst-contaminated hands; transmission by infected food is rare. Infection with this organism causes giardiasis. Infections range from asymptomatic to severe, life-threatening diarrhea.

Assessment

Suspect giardiasis in a child who has acute watery, foul-smelling diarrhea with abdominal pain, particularly if they have recently been camping or hiking. Watery stools are often accompanied by flatulence and abdominal distention. Anorexia is often seen, leading to weight loss and failure to thrive. Infections may last from a few days to years.

Identification of trophozoites or cysts in a direct stool smear is diagnostic. These smears can be observed

directly (wet mount) or after being stained with iodine. Enzyme immunoassay tests for *Giardia* are commercially available.

Interdisciplinary Interventions

The treatment of choice is a 5- to 7-day course of metronidazole or a 3-day course of nitazoxanide. Therapy may be repeated if relapse occurs. Treatment of asymptomatic carriers is not recommended.

Community Care

Because outbreaks of giardiasis have occurred in daycare centers, instruct the parents to withdraw their infected child from daycare until the diarrhea resolves. If more than one child is involved, notify local health department officials. Instruct family members and caregivers to wash their hands carefully after diapering infants and toileting to avoid infection.

Advise families who camp and hike that the pristine appearance of cool mountain water may be deceiving. Beavers and other wildlife can harbor *Giardia* cysts and contaminate streams. Therefore, advise families who enjoy camping to boil all water and avoid drinking from streams.

Pinworm Infestation

Because it is caused by worms, pinworm infestation is often troubling to families. The causative agent of pinworm infestation (enterobiasis) is *Enterobius vermicularis*. Pinworm infestation occurs frequently in early and middle childhood, children who attend daycare centers, and primary caregivers of infested children. Up to 50% of these populations in the United States may be infested with pinworm (AAP, 2006r). Clusters of infestation are also known to occur in families.

Pathophysiology

The mode of transmission is oral-fecal. The gravid female pinworm lays eggs at the child's perianal region at night. It usually dies after depositing the eggs. Rectal itching leads to scratching. Autoinoculation results if the child scratches the rectal area and then puts the hand in his or her mouth (e.g., thumb sucking). Eggs can remain viable and infective on inanimate objects for 2 to 3 weeks. Eggs are swallowed and then hatched in the duodenum. The larvae live and grow, then slowly make their way toward the colon. Molting twice, adults mature in 1 to 1½ months. Then gravid females once again migrate to the anus to lay eggs.

Assessment

Suspect pinworm infestation in a child with perianal itching and localized irritation. Children heavily infested have been reported to exhibit sleeplessness, hyperactivity, weight loss, tooth grinding, abdominal pain, and vomiting, although a causal relationship has not been documented.

Aberrant migration of gravid female worms to the vagina may cause vaginitis. Subsequent aberrant migration from the perineum can contribute to salpingitis and pelvic peritonitis in female children (AAP, 2006r).

Diagnosis is confirmed by direct visualization of worms by the parents or by microscopy. Tell parents to view the child's anus with a flashlight 2 to 3 hours after the child is asleep. The worm is white, thin, and about a half-inch long, and it moves. A simple technique, the cellophane tape slide method, is used to capture worms and eggs. Transparent adhesive tape is lightly touched to the anus and then applied to a slide. The tape is examined under low power for worms and eggs. The best specimens are obtained as the child awakens, before toileting or bathing.

Nursing Diagnoses and Outcomes

In addition to those identified in Nursing Plan of Care 24–1, the following nursing diagnosis and outcomes may apply to the child with pinworm infestation:

Impaired skin integrity related to scratching perianal region from pruritus caused by pinworm

Outcomes: Child will receive treatment to eradicate pinworm, thus pruritus.

Child's skin integrity will be restored.

Interdisciplinary Interventions

Treatment is with a single dose of mebendazole, albendazole, or pyrantel pamoate, repeated 2 weeks later. Retreatment is often necessary. Entire families or daycare groups may need to be treated simultaneously.

Children infested with pinworms are rarely hospitalized. Nursing care centers on teaching parents and children appropriate eradication techniques. Linens and bedclothes can harbor eggs that remain infective. Therefore, emphasize rigorous hand hygiene after contact with the child, linens, or clothes. Teach parents to wash all linens and contaminated clothing, using the hot cycle of the washing machine. Personal hygiene measures such as good hand hygiene and avoiding scratching of the perianal region may prevent transmission.

Community Care

Educating family members, schools, and daycare centers that recurrence is common can reduce some anxiety. Controlling infestations in schools and daycare centers can be difficult. Keeping fingernails clipped short and emphasizing handwashing seem to help.

Roundworm Infestation

Ascaris lumbricoides, a helminth, is the most common cause of human roundworm infestations (ascariasis). Roundworm infestations most frequently affect young children, particularly those from developing nations who are living in poverty (Bethony, Brooker, Albonico, et al., 2006). Infestation occurs after ingestion of soil contaminated by infective eggs. Larvae hatch in the small intestine

and are transported to the liver, then to the lungs, from which they ascend to the pharynx and are swallowed back into the intestine, where they mature. The adult worm lives in the lumen of the intestine, and the female can produce 200,000 eggs a day, which are excreted into the stool. Adult worms can live for 12 to 18 months if untreated (AAP, 2006b).

Roundworm infestations are more common in warm climates, in areas of poor sanitation, or where human feces are used as fertilizer. Globally, an estimated 807 million people are infested with roundworms (Bethony et al., 2006). The incubation period (from ingestion of egg to adult worm) is 8 weeks. Person-to-person transmission does not occur.

Assessment

Most infestations are asymptomatic; however, nonspecific gastrointestinal symptoms may occur. During the larval migration phase, the child may present with fever, cough, congestion, and shortness of breath. The eosinophil count is often high, and allergic symptoms such as itching and wheezing may occur with recurrent infestations. Children may complain of vague abdominal pain with nausea, vomiting, and anorexia. Partial obstruction of the intestine may occur. Worms may occasionally emerge through the nose or mouth, so ask parents if they have observed this. The child's history may reflect impaired growth, poor fitness, and poor cognitive and school performance (Bethony et al., 2006; Ezeamama, Friedman, Acosta, et al., 2005).

Ova can be detected by direct microscopic examination of the stool. Adult worms can be identified if they are passed from the rectum, nose, or mouth.

Interdisciplinary Interventions

Deworming campaigns using antihelminthic drugs have helped to reduce worm burden in endemic countries (WHO, 2005). Albendazole or ivermectin in a single dose or mebendazole for 3 days is the recommended treatment for roundworm infestation.

Community Care

Educate parents that roundworm infestation can be prevented by sanitary disposal of human feces away from children's play areas and vegetable gardens. Household bleach is ineffective in killing roundworms.

Toxocariasis

Toxocariasis (infestation with *Toxocara*, a group of roundworms) causes two conditions in children: visceral larva migrans and ocular larva migrans. Toxocariasis is caused by second-stage larval migration of roundworms to the liver, lungs, CNS, and eyes of humans, usually children. The adult worms are commonly found in dogs (*T. canis*) and cats (*T. cati*). Young children become accidental hosts when they ingest soil contaminated by infective eggs,

which can exist in the soil for years, or play with infested puppies. Many puppies younger than 10 weeks are congenitally infested with *T. canis* and excrete eggs in their feces.

Pathophysiology

A child ingests the eggs. The incubation period in humans is unknown. The eggs hatch in the intestine, and the larvae penetrate the intestinal wall. Using the intestinal capillary system, the larvae gain access to the bloodstream and migrate to the liver. Most of the larvae remain in the liver, but some pass on to the lungs, CNS, and eyes. Eventually, the larvae gravitate to a single location (either the liver or the eyes).

Assessment

A history of exposure to puppies or a history of **pica** (eating nonfood items such as dirt) is useful in establishing the diagnosis. The degree of symptoms depends on the number of eggs ingested. Most infestations are asymptomatic. Fever, increased white blood cell count, persistent eosinophilia, hypergammaglobulinemia, and hepatomegaly are typical. Malaise, anemia, and cough are sometimes present. Rare manifestations include myocarditis, encephalitis, and pneumonia.

Ocular manifestations occur as a visual decrease or even total vision loss in one eye. The retinal damage may go unnoticed until adolescence and may be noted only when the child applies for a driver's license and fails the eye examination.

Diagnostic Tests

Eosinophilia and hypergammaglobulinemia, along with high titers of isohemagglutinin to the A and B blood groups, are suggestive of *Toxocara* infection. Antibody titers for *Toxocara* are positive in infected children.

Liver biopsies and retinal examinations can reveal larvae, either by histologic preparation and staining of biopsy specimens or by direct visualization of the larvae in the eye. Other eye damage, such as retinal detachment, can also be directly observed.

Nursing Diagnoses and Outcomes

In addition to those identified in Nursing Plan of Care 24-1, the following nursing diagnosis and outcome may apply to the child with ocular larva migrans:

Disturbed sensory perception: Vision related to effects of eye infestation

Outcome: Child will obtain corrective visual aids as applicable.

Interdisciplinary Interventions

Treatment is with corticosteroids to reduce the allergic, inflammatory reaction and with antihelminthic drugs, such as albendazole or mebendazole, to destroy the parasite. Anthelmintic drugs may not successfully treat ocular larva migrans, and steroids may be indicated (AAP, 2006x).

Community Care

Toxocariasis infestation is preventable. Instruct parents to cover sandboxes when not in use, to keep cats from using them as litter boxes. Instruct them also to keep children's play areas free of dog and cat feces, and to have puppies dewormed at age 2, 4, 6, and 8 weeks.

Parents may need to administer eye drops to a child with ocular larva migrans. Because some types of drops are administered hourly, the parents of a school-aged child may need to discuss eye drop administration with the school nurse. Parents may need to arrange for a home teacher if their child's school does not have a school nurse.

Toxoplasmosis

Toxoplasma gondii is one of the world's most common parasites. Toxoplasmosis is caused by *T. gondii*, a protozoan that lives in the intestinal tract of many animals, including domestic cats. The parasite occurs in three forms: tachyzoites (an amebalike form), bradyzoites (a cast form), and highly infectious oocysts. Transmission occurs by eating foods contaminated with *T. gondii* cysts or inhaling dust that contains oocysts from cat feces. Eating fruits or vegetables harvested in countries that use fecal fertilizer sprays; drinking unpasteurized milk; and eating unfrozen or undercooked lamb, pork, or beef are the principal ways in which transmission occurs. The immunosuppressed and those with HIV are at increased risk for toxoplasmosis. A pregnant woman who empties cat litter boxes can inhale oocysts from the litter dust, develop toxoplasmosis, and transmit the parasite to her fetus. The incidence of fetal infection is 1 in 1,000 live births (AAP, 2006y).

Congenital toxoplasmosis occurs when a woman contracts toxoplasmosis for the first time during pregnancy. The organism can cross the placenta and infect the fetus. The risk of transmission to the fetus increases from 6% at 13 weeks to 72% at 36 weeks gestation (Dunn, Wallon, Peyron, et al., 1999). Damage to the fetus depends on the trimester in which the infection occurs. Maternal infection during the first trimester causes the most fetal damage; infection during the last trimester may cause little apparent damage.

Assessment

Acquired toxoplasmosis in otherwise healthy children is usually asymptomatic. The signs and symptoms of congenital toxoplasmosis are summarized in Chart 24-9. Maternal symptoms are vague, usually consisting of fatigue. Most neonates are asymptomatic, but without treatment, congenital toxoplasmosis has adverse neurologic, intellectual, visual, and audiologic outcomes (McLeod, Boyer, Karrison, et al., 2006; Wilson, Remington, Stagno et al., 1980).

Ocular *Toxoplasma* infection can result from congenital or acquired infection. It can cause tissue necrosis in the retina, vitreitis, iridocyclitis, and cataracts. Undetected and

CHART 24–9 EFFECTS OF CONGENITAL TOXOPLASMOSIS

- Intrauterine growth retardation
- Jaundice, hepatitis, hepatosplenomegaly
- Anemia, thrombocytopenia, disseminated intravascular coagulopathy
- “Blueberry muffin” rash
- Chorioretinitis, microphthalmia, optic atrophy, blindness
- Intracranial calcifications, seizures, hydrocephalus, microcephaly, severe retardation, developmental delay

therefore untreated congenital infections usually manifest during adolescence as ocular disease (chorioretinitis).

Diagnostic Tests

A positive result for maternal IgM antibody to *T. gondii* is diagnostic. Fetal blood samples can be tested for the presence of IgM-specific antibodies. A PCR specific for *T. gondii* is becoming available to more laboratories; it can be performed on blood from the fetus, infant, or mother.

Fetal ultrasonography can show the presence of cerebral calcifications. After birth, ophthalmologic and neurologic examinations of the infant can be performed to look for chorioretinitis, hydrocephalus, microcephaly, and meningoencephalitis. Computed tomography or magnetic resonance imaging of the infant’s head can show calcified brain lesions indicative of congenital toxoplasmosis.

Nursing Diagnoses and Outcomes

In addition to those identified in Nursing Plan of Care 24–1, the following nursing diagnosis and outcome is applicable to a severely affected infant who may be in the neonatal intensive care unit and requires mechanical ventilation:

Ineffective breathing pattern related to effects of disease process

Outcome: Child will maintain adequate tissue oxygenation, evidenced by an oxygenation saturation of 97% to 99%.

Interdisciplinary Interventions

Treatment for maternal infection and for infected children is with pyrimethamine and sulfadiazine. These two agents act together (synergistically) and, along with leucovorin (folinic acid), serve as standard therapy. Pyrimethamine may cause severe depression of bone marrow function; leucovorin is given to counteract the suppression. Infants with congenital disease are treated for 12 months (McLeod et al., 2006).

Because the infection cannot be transmitted from human to human, no special isolation precautions are

observed. Explain the necessary ophthalmologic examinations and diagnostic laboratory tests (e.g., TORCH titers) and provide emotional support to the parents to help them cope with this adverse outcome of pregnancy.

Preconception and prenatal teaching includes washing all fruits and vegetables, and freezing all meats, then cooking them thoroughly before consuming them. Avoid steak tartar and other raw meat pâtés. Encourage cat owners to have someone other than the pregnant woman empty the cat litter box daily. It takes 1 to 5 days before the oocyst can turn into the highly infectious spore form; thus, daily attention to the litter box is a must. Teach families to use disposable plastic litter box liners or disinfect the box with boiling water for 5 minutes.

Arboviral Infections

Arboviruses are spread by mosquitos, ticks, sandflies, and other biting arthropods and can cause central nervous system disease, fever with rash and headache, joint pain, and occasionally hemorrhagic fever with hepatitis. Illnesses range from a self-limited febrile illness with headache to aseptic meningitis or acute encephalitis resulting in seizures, coma, or even death. Arboviral infections commonly seen in the United States include LaCrosse encephalitis, eastern equine encephalitis, western equine encephalitis, Powassan encephalitis, and St. Louis encephalitis.

Birds and small mammals are the primary reservoir for most arboviruses. Humans and domestic animals are infected incidentally when an arthropod bites an infected animal, picks up the virus, and then bites a person or pet. Person-to-person transmission does not occur except through blood transfusions, intrauterine transmission, and possibly through human breast milk.

Definitive diagnosis is made by viral isolation from serum or CSF. Virus-specific antibody tests for IgG and IgM are also available. The presence of antibody in the serum or CSF of a patient with CNS symptoms is evidence of recent infection. A fourfold increase in antibodies 2 to 4 weeks apart confirms the diagnosis. PCR testing is available in reference laboratories. No specific treatment or immunizations are available. Treatment is supportive. The primary intervention is to prevent infection by such measures as using insect repellents containing DEET, wearing protective clothing, and implementing mosquito-control programs.

West Nile Virus (WNV)

WNV is transmitted to humans primarily through the bite of infected mosquitoes. The *Culex* mosquito, which feeds at dawn and dusk and breeds in standing water, is the primary vector of WNV. The mosquito acquires the virus by feeding on infected birds and then transmits the virus to humans and other mammals.

WNV can also be transmitted through blood transfusions and organ transplantation. Intrauterine transmission and transmission in human milk have been described, but such cases are rare, and transmission in human milk has

not been confirmed (Truemper & Romero, 2007). Some concern exists that aerosolized transmission can also occur. In the United States, WNV occurs during the late spring, summer, and early fall.

About 80% of WNV infections are asymptomatic, 20% of all infected patients develop West Nile fever, and fewer than 1% develop WNV neuroinvasive disease (Truemper & Romero, 2007). Children younger than 18 years old have a reduced incidence of morbidity and mortality associated with WNV and WNV neuroinvasive disease (LaBeaud, Lisgaris, King, et al., 2006), which occurs primarily in the elderly or immunocompromised (Truemper & Romero).

Assessment

Children with West Nile fever typically present with a sudden onset of fever, headache, muscle aches, and weakness. They may also often have abdominal pain with nausea, vomiting, or diarrhea. Some patients also have a rash. This phase of the illness lasts several days; however, the fatigue and weakness may linger for weeks.

Those with central nervous system disease present with typical signs of meningitis or encephalitis. Flaccid paraly-

sis can also be part of this syndrome or can occur in isolation, without fever or other signs.

Although most women known to have had WNV infection during pregnancy have delivered infants without signs of infection or clinical abnormalities, evaluate these infants for signs of infection (Truemper & Romero, 2007).

Consider WNV in any child with a febrile illness or CNS disease who has had recent exposure to mosquitoes. Virus-specific antibody tests for WNV IgG and IgM are available for serum and CSF. The presence of antibody in the serum or CSF of a patient with CNS symptoms is evidence of recent infection. A fourfold increase in antibodies 2 to 4 weeks apart confirms the diagnosis. PCR testing is available in reference laboratories.

Interdisciplinary Interventions

Treatment for WNV infection is supportive, and standard precautions are recommended. Prevention is key. Educate families to take steps to avoid being bitten by infected mosquitoes. Teach them to stay indoors during dawn and dusk, when mosquitoes are active; to wear long-sleeved shirts, pants, and socks; and to apply insect repellents. See TIP 24-2 for a

TIP 24-2 A Teaching Intervention Plan to Avoid Tick-Borne Disease

Nursing diagnosis and outcomes

- Risk for injury related to environmental conditions (tick-infested areas)

Outcomes

- Child and family will describe and implement preventive measures to avoid tick attachment. Child will not become infected with rickettsial disease.

Teach the child/family

Preventive Measures to Avoid Tick Attachment

- Spray clothing with permethrin and exposed skin with tick repellent containing DEET; follow label directions for use. For young children, use products containing DEET sparingly; do not use on children younger than 2 months of age. Do not use products with more than 30% DEET. Do not put DEET on eyes or mouth and use sparingly around ears, do not apply to a young child's hands (to prevent getting the product in the mouth or eyes). Do not apply to skin with wounds, sunburn, or irritated skin (where it is absorbed more readily). Length of protection from DEET products is concentration dependent (e.g., 6.5% lasts about 2 hours, 24% provides about 5 hours). Wash repellent off skin with soap and water after child comes indoors. Do not use combination insect repellent and sunscreen products, because sunscreen products must be applied more frequently, thus risking

overuse of DEET. Apply regular sunscreen first, then insect repellent.

- Wear light colors and long sleeves, long pants, socks, and shoes. Tuck shirt or blouse into pants and pants into socks.
- Check skin and scalp for ticks every 2 to 3 hours, when leaving infested areas, after playing with outdoor pets, and when coming indoors. Ticks can be as small as a pinhead.
- Inspect pets daily for ticks.

Tick Removal Techniques

- Inspect and detect promptly; ticks are easier to pull off when not firmly attached.
- Grasp the tick as close to the head and as close to the skin as possible with fine-tipped tweezers.
- Apply steady upward pull. Do not twist or exert enough pressure to crush the tick.
- If the head remains in the skin, leave it and wash the site with soap; attempts to remove it may cause tissue damage, and leaving it does not increase the risk of disease.
- Wash the site and your hands with soap and water.

Contact Healthcare Provider if:

- Tick cannot be removed
- Child develops redness, swelling, a rash or fever the week after the bite

discussion of DEET and permethrin; picaridin or lemon eucalyptus oil may be alternatives to DEET (Kendrick, 2006).

Tick-Borne Infections

Many organisms produce tick-borne infections in humans. Most organisms belong to the *Rickettsiaceae* family of bacteria. Because Rocky Mountain spotted fever (RMSF), human monocytotropic ehrlichiosis (HME), and Lyme disease are the most common tick-borne infections, they are described in this section. In the United States, the incidence of tick-borne disease follows the seasonal pattern of tick exposures; the incidence is generally highest in the spring and summer. Most cases of tick-borne infections occur in children between ages 2 and 15, because children play outdoors in tick-infested areas. Most ticks live in grasses and plants, especially in heavily wooded areas. As a child brushes past the grass or plant, the tick crawls onto the child and attaches. Unattached ticks on a family pet may climb onto a child who is playing with or grooming the animal. As the tick ingests blood, the warmth of that blood activates the bacteria. After the tick feeds for 6 to 10 hours, the organisms are released from the tick's salivary glands.

Not every tick is infected. The total number of organisms in infected ticks varies, and the severity of the resulting disease is dose related.

Treated early, prognosis of tick-borne disease is generally good; delaying treatment increases morbidity and mortality (Flicek, 2007). Complications of untreated

RMSF and HME can lead to death. Mortality from RMSF is highest in children younger than 4 years and adults older than 60 years: 3% to 4% and 4% to 9%, respectively (Rim & Eppes, 2007). Mortality associated with HME is 3%, most commonly seen in severely immunocompromised patients (Flicek). Mortality is rare with Lyme disease, typically involving cardiac disease if it occurs (Rim & Eppes).

Assessment

Obtain a thorough history and physical examination. Thoroughness is important, because symptoms may be vague in all three of these tick-borne diseases (Table 24-3). Ask whether the child or parents have found a tick or remember an insect bite.

The rickettsiae in the spotted fever group of diseases cause a vasculitis that involves the skin (as a rash; Fig. 24-11) and major organ systems. Untreated cases with high numbers of organisms can present as overwhelming meningitis, multisystem organ failure, and disseminated intravascular coagulopathy.

HME symptomatically resembles RMSF. Some patients with Lyme disease are completely asymptomatic. During the early, localized stage, which occurs 3 to 30 days after the tick bite, a distinctive rash known as *erythema migrans* appears (Fig. 24-12). Early treatment of erythema migrans should prevent other manifestations, including later stages of the disease.

Diagnosis is based primarily on a history of a tick bite (especially one with an attached tick) and specific

TABLE 24-3

Clinical Features of Selected Tick-Borne Diseases

Disease	Bacterial Agent and Vector	Clinical Manifestations
Rocky Mountain spotted fever (RMSF)	<i>Rickettsia rickettsii</i> Dog tick Lone star tick Wood tick	Fever, headache, malaise, myalgia, nausea, vomiting Rash: occurs before sixth day of illness; begins on wrists and ankles, spreads centrally and to palms and soles; 10% to 15% of cases have no rash (spotless fever) Severe cases: disseminated intravascular coagulopathy, organ failure, and death
Ehrlichiosis	<i>Ehrlichia chaffeensis</i> Deer tick	Fever, headache, chills, malaise; rarely rash, which may help differentiate from RMSF Severe cases: renal failure, meningitis, encephalopathy, respiratory failure
Lyme disease	<i>Borrelia burgdorferi</i> Deer tick	Early localized stage: erythema migrans (erythematous macule or papule with central clearing) at site of tick bite, fever, arthralgia, myalgia Early disseminated stage: headache, fever, chills, malaise, multiple erythema migrans smaller than the original lesion, hepatosplenomegaly, sore throat with a nonproductive cough, conjunctivitis, lymphadenopathy, meningitis, carditis Late disseminated: seizures, ataxia, chronic fatigue, numerous ocular lesions (panuveitis, retinal vasculitis), chronic arthritis

FIGURE 24-11. The rash of Rocky Mountain spotted fever begins on the wrists and ankles then spreads to become more generalized. Courtesy of Stuart Starr, MD, The Children's Hospital of Philadelphia. Reprinted with permission.

serologic tests for each of the three organisms. Acute and convalescent antibody titers for RMSF, ehrlichiosis, and Lyme disease show a fourfold increase in the indirect fluorescent antibody test. These titers are usually accurate 7 to 10 days after the onset of the illness and are diagnostic at 1:64 (AAP, 2006t). IgM and IgG antibodies for each of the specific organisms can be measured by enzyme immunoassay.

Interdisciplinary Interventions

Treatment usually begins empirically while waiting for the test results. For a child who requires hospitalization, the treatment of choice for RMSF is doxycycline. Fluoroquinolones are alternative treatments. Doxycycline may be given orally during convalescence or in less severe cases. The course of therapy is 7 to 10 days.

Alert! Administration of tetracyclines to children younger than 9 years is typically avoided because of the risk of permanently staining developing teeth. However, some experts consider doxycycline to be the drug of choice at any age in acute life-threatening cases of rickettsial infection (AAP, 2006t).

For ehrlichiosis, doxycycline is also the drug of choice. The treatment for Lyme erythema migrans and early disease is oral doxycycline. This drug should be given to children older than 8 years; children younger than 8 years should receive amoxicillin (Wormser, Dattwyler, Shapiro et al., 2006). Cefuroxime is the alternative for children younger than 9 who are allergic to penicillin. Early Lyme disease is treated for 14 to 21 days. For early disseminated or late Lyme disease, IV penicillin or ceftriaxone is used for 14 to 28 days.

Community Care

Children with tick-borne illnesses are not contagious and therefore do not need isolation. Prevention is paramount;

FIGURE 24-12. The erythema migrans of Lyme disease begins as a small circular, reddened area and then expands with a central zone of clearing. Copyright Larry Mulvehill/Science Source/Photo Researchers. Reprinted with permission.

teach the family how to avoid tick attachment and remove ticks safely (see TIP 24-2). Agents other than DEET (e.g., picaridin, lemon eucalyptus oil, IR3535) have been suggested as effective insect repellents (Cilek, Petersen, & Hallmon, 2004; Kendrick, 2006), but their effectiveness against ticks has not been determined.

Report all tick-borne infections to the state and local health departments. Although the child is not contagious, suggest to parents that they notify the school nurse when the child is being treated, to dispel unwarranted fear among classmates.

See [thePoint](#) for a Summary of Key Concepts.

The Child With Altered Skin Integrity

Case History

Nick Currccio, Joey's 13-year-old brother (Chapter 21), is a soccer player and Boy Scout. He is attending Boy Scout camp this summer between seventh grade and eighth grade. Unfortunately, he has returned home early from camp with an extensive rash. Nick has an olive complexion, he tans easily, and he is not prone to skin-related problems. He has seasonal allergies, ragweed in particular.

On Wednesday, pink patches began to appear on Nick's arms and neck. On Friday, the rash was continuing to spread, and Nick was sent home from camp. When his mother picked him up, his rash appeared as raised, pink blisters in patches across both forearms, on the inner aspect of the upper arms, on his torso where his arms came in contact with his torso, and on his neck up to the jaw line. Some of the blisters are still intact; many are ruptured and leaking fluid. Approximately one third of his skin above the waist is affected by the rash. Nick complains that he itches all the time and he can't sleep.

His mother takes him to their family physician, who diagnoses this rash as a bad case

of poison ivy. Nick has only had a rash from poison ivy

once and it consisted of a spot about the size of a half dollar on the back of his hand. He asks the office nurse why it is so different this time. The nurse explains that like many other allergic reactions, the reaction is greater with subsequent exposure. It is the oils of the plant that cause the reaction. Because Nick did not realize he had come into contact with the plant, the oils on his shirt and arms continued to touch new areas of skin. He also did not shower that day or night.

The physician sends them home with a methylprednisolone dose pack, the recommendation to take an antihistamine at night, and instructions for topical care of the rash. Topical care includes using hydrocortisone cream or calamine lotion to help control itching. Cool compresses and tub soaks with colloidal oatmeal or baking soda may also help relieve itching. In addition, his mother should wash all the clothes that Nick brought home, including anything thrown in the duffle bag with the dirty clothes Nick wore in the woods.

CHAPTER OBJECTIVES

1. Identify characteristics of the child's skin that make the child especially susceptible to injury.
2. Perform a health history and physical examination that include a complete evaluation of the skin, hair, and nails.
3. Select nursing diagnoses that articulate the needs of the child, family, and community for the child who has a skin condition.
4. Describe the presenting signs and symptoms of skin conditions frequently seen in the pediatric population.
5. Use strategies to prevent further spread of a skin condition or further damage to tissue that has altered skin integrity.
6. Discuss therapies that are effective in treating conditions of the skin.

See [thePoint](#) for a list Key Terms.

The skin is an undervalued organ. Despite constant exposure to a changing environment, it provides an effective defense against disease and promotes homeostasis. To perform these functions, however, the skin must remain intact. Skin disorders are extremely common in infants, children, and adolescents, and in many pediatric healthcare practices constitute the most frequent significant complaint for an office visit. Skin disorders can affect the daily life of the child by excluding them from school or daycare (Mancini, 2005; Popovich & McAlhany, 2007). Skin conditions are, by their nature, visible. Children with altered skin integrity have the same needs as all other children but must also cope with the ways their condition affects their lives and the perceptions of others. Healthcare providers must understand the basic principles of skin and wound diseases and appropriate interventions. This chapter explores various disorders that breach the skin's defense system, including infections, noninfectious conditions, and trauma.

DEVELOPMENTAL AND BIOLOGIC VARIANCES

The integumentary system begins to develop by the eighth week of gestation and continues to undergo many metamorphic events throughout the course of the individual's life. Skin, hair, and nail cells are constantly moving through stages of growth, replication, and maturation. The infant's fragile skin transforms during the first 3 years of life into a barrier of protection against a young child's many falls. During adolescence, hormonal changes trigger changes in skin appearance, contour, and smell. In addition, biologic variances such as color are more pronounced in the integumentary system than in most other body systems.

Neonates and Infants

The skin of the newborn serves a pivotal role in the transition from the "wet" (aqueous) intrauterine environment to the "dry" extrauterine environment. The skin, hair,

and nails develop early in gestation. At less than 8 weeks of fetal life, the epidermis begins to form. Between the 14th and 16th weeks of gestation nail and hair formation is established. A unique skin characteristic of the fetus is that the embryo and the early-gestation fetus (during the second and third trimesters) have the ability to heal a potentially scarring injury without developing scar formation. Although the exact processes of fetal wound healing are not fully understood, it is known that epithelial and mesenchymal tissues are regenerated to restore the tissues (Valencia, Falabella, & Schachner, 2001).

Lanugo (fine, soft, lightly pigmented hair) covers most of the fetal skin. During the early neonatal period, vellus hair (also fine, short, soft, and lightly pigmented) replaces lanugo. Over time, terminal hair growth replaces vellus hair on the scalp, arms, and legs. Many other body areas continue to be covered with vellus hair until puberty (Fig. 25–1). Immediately after birth, vernix caseosa (a white, cheeselike substance produced in utero by the sebaceous glands) clings to the neonate's skin, especially on the neck, groin, and genital regions. This substance, which begins to form after the 20th week of gestation, protects the delicate fetal skin from abrasions, chapping, and hardening as a result of continuous exposure to amniotic fluid.

After birth, environmental and behavioral factors (e.g., ambient temperature, surface moisture, intermittent friction from clothing and blankets, and even being held) can affect skin structure and functions. Pigmentation is not well developed; the neonate's nail beds, ears, and scrotal areas are generally darker than the rest of the skin. **Milia** (white papules) caused by blocked sebaceous ducts appear over the nose, cheeks, and chin, but disappear within a few weeks after birth. Because the vasomotor control of the skin in neonates is immature, a mottled appearance (*cutis marmorata*) may be observed in response to cooling, and the hands and feet may show acrocyanosis transiently. Prolonged cyanosis must be investigated.

The structure of the term newborn's skin is similar to that of an older child, and about 40% to 60% thinner than that of an adult (Eichenfeld, Frieden, & Esterly, 2008). The neonate's vascular and integument structures are immature, and melanin production and eccrine gland function are reduced; therefore, the skin has yet to develop all of its protective, metabolic, and interactive functions. Skin pH is more alkaline during the first few weeks of life, making it a better host for harboring microorganisms. As the pH becomes more acidic, the skin's capacity to fight infection improves.

The premature infant's skin reveals many unique features, based on the degree of prematurity. The epidermis is very thin, transparent, permeable, and friable, and is not equipped to handle the demands of thermoregulation, homeostasis, and protection (Developmental Considerations 25–1). In comparison, the skin of postmature and small neonates is thicker, appears dry and cracked, and may be meconium stained.

Skin functions in premature infants are primarily protective, one of the foremost being the regulation of water loss and intake. Permeability barrier immaturity in these infants has many consequences, primarily increased

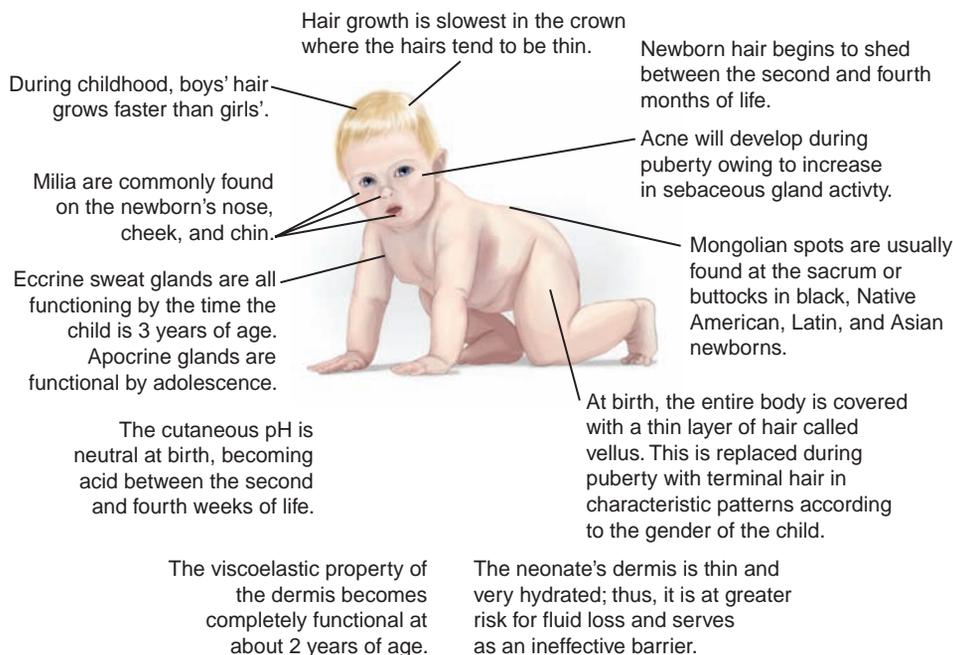

FIGURE 25-1. Developmental and biologic variances: the skin and hair.

evaporative loss of free water from the skin surface, which could lead to energy loss through loss of heat by evaporation. This process can result in transepidermal water loss (evaporation of water from the skin). Numerous interventions are available to reduce the potential for fluid loss in premature newborns (see Chapter 14 for a complete discussion of these interventions).

The skin of term infants exhibits excellent barrier properties; in fact, its barrier function as measured by transepidermal water loss is superior to that of adult skin. The full-term neonate has well-developed brown fat stores—some internal (e.g., on the neck, behind the sternum) and some found over the scapular area in the connective tissue. The skin of the newborn has a greater ratio of body surface area to body weight than that of the older child or adult. As a result, chemicals placed on newborn skin can be absorbed systemically at higher doses than might be desired.

caREminder

Maintaining and replacing fluid, and preventing fluid loss through evaporation, are vitally important, priority care issues in managing preterm and term infants.

Young Children

As the child grows, both physical and developmental changes are manifested in the skin, hair, and nails. The skin thickens, hair grows at a faster rate, and sebaceous glands provide sebum, which lubricates the skin. Pigmentation darkens. The skin of the well-nourished child is elastic. The skin of young children and infants who eat an abundance of yellow vegetables, such as carrots and squash, may take on a yellowish cast (carotenemia) and is generally considered harmless.

Older Children and Adolescents

As the child matures, substantial skin changes occur in both boys and girls. Most of these changes represent the onset of puberty. The apocrine and sebaceous glands increase in activity, causing more pronounced body odor and oily skin.

Secondary sex characteristics appear in response to hormonal release, which also stimulates integumentary alterations. For example, in the male, the pubic, axillary, and facial hair start to grow and darken. In the female, the areola of the breast darkens and enlarges, and pubic and axillary hair appears. Hair on the trunk and limbs increases during and after puberty, most noticeably in males. These changes occur as vellus hair converts to terminal hair in specific body regions. Concurrently, in the occipital and bifrontal areas of the male's scalp, some terminal hair converts back to vellus hair, resulting in a receding hair line. These changes in body function can generate problems with self-image in teenagers.

Racial Variations

Differences in the hair and skin pigmentation of children can be seen in persons of different races. For example, considerable variation exists in the hair of African Americans, which ranges from long and straight to thick, curly, and fragile. Asians and Native Americans generally have straight, silky hair, but not in all cases.

Skin eruptions are not generally associated with specific racial differences. The most commonly cited biologic difference is in the appearance of mongolian spots in African American, Native American, Latin, and Asian newborns. Identifying skin lesions and assessing the degree of redness, jaundice, cyanosis, or pallor may be more challenging in children with darker skin tones. In

DEVELOPMENTAL CONSIDERATIONS 25–1

Characteristics of the Premature Infant's Skin

Thin, transparent, permeable, and poorly keratinized epidermis
 The stratum corneum is not fully mature until about 34 weeks' gestation
 Epidermal layer consisting of only a few layers of stratum corneum during first 3 weeks of life
 Diminished cohesion between less cohesive epidermal and dermal layers
 Dearth of sebaceous lubrication after first few weeks of life
 Immature acid mantle
 Enhanced permeability of the skin
 Little subcutaneous fat
 Wrinkled, gelatinous skin hanging loosely over limbs
 Lanugo covering the body and increased vernix caseosa at birth
 Increased loss of transepidermal water, leading to difficulty in fluid balance evaporation of water from the skin (called *transepidermal water loss*), which leads to difficulty in maintaining fluid balance
 Nonfunctional apocrine sweat glands

Implications for Care

Neonate is prone to hypothermia. Keep the baby warm using an incubator

Minimize the number of times healthcare providers enter the isolette, thus changing the ambient temperature.
 During bathing or procedures in which the neonate is out of the isolette, use heat lamps to keep the child warm.
 Neonate is prone to skin breakdown, tearing, and blistering. Turn the neonate frequently to prevent skin breakdown.
 Minimize use of adhesive-based products on the skin. Use pectin-based barrier products to protect the skin. Remove adhesives with water and diluted soap. Do not bathe the neonate on a frequent basis. Prevent IV catheter infiltration.
 Neonate is at risk for fluid and electrolyte losses. Monitor fluid and electrolyte status diligently. Provide fluid and electrolytes as needed via IV administration.
 Neonate is at risk for potentially lethal topical absorption of chemicals (percutaneous toxicity). Minimize use of pharmacologic and cleansing compounds to the skin, such as neomycin, soap compounds, and lotions.

Sources: Larson & Dinulos (2005), Lund (1999), Lund et al. (2001b), and Spray & Siegfried (2001).

these cases, observing for color changes in the mucous membranes, earlobes, conjunctivae, nails, and palms; the abdomen and trunk (two areas less exposed to sunlight) may be the best indicator of systemic problems.

ASSESSMENT OF THE CHILD WITH ALTERED SKIN INTEGRITY

The health history and physical assessment serve as the clinician's tools to evaluate threats to the function, integrity, and cosmetic appearance of the skin, hair, and nails. Numerous environmental risks to the skin are inherent during childhood. Chemically and biologically contaminated air, water, soil, and foods present special risks to children's health. These environmental factors, which have a profound effect on adult health, affect children differently and perhaps more intensely. Children have "windows of vulnerability" while they are developing, during which their target organs and immune system may be more susceptible to environmental risks than an adult's. In addition, children spend their time in different physical locations than adults. For example, infants and young children spend lots of time on the floor; children, because

of their height, inhale in a different breathing zone than adults. All these factors must be considered when managing wounds and other skin alterations in children.

Focused Health History

QUESTION: What information provided in the case study is pertinent in obtaining a focused health history on Nick?

The purpose of the health history is to collect data about the skin changes reported by the child or parent and to successfully elicit information that indicates the primary source of the skin eruption. This assessment should provide clues to the diagnosis, management, and nursing care of the underlying issue. Careful observation and meticulous descriptions should cover the following areas: (1) history of the patient's skin condition, (2) physical assessment of the entire child as well as the specific skin condition, and (3) assessment of the child's and care providers' knowledge about the condition. Clinical findings from skin rashes, lesions, and infestations often lack

specificity, and the etiologic agents may be elusive. Skin problems can be a source of acute embarrassment, yet assessment requires complete openness from the family. To ensure that all potentially affected individuals are identified and notified to limit further spread of the disorder, the parent must approach such situations with sensitivity.

Focused Health History 25–1 specifies the dimensions of the health history specific to identifying skin disorders. Because the skin yields rich information about the child's general health, hygiene practices, and nutritional status, incorporating components of the skin assessment into all health interviews is essential. The skin also reveals many complex systemic pathologic processes. In these situations, the skin history may serve as the preliminary screen pointing to the need for a more in-depth review of a particular system.

The child's age and ethnicity are important data. For instance, distinguishing a bruise from a birthmark, such as a mongolian spot, is easier if the patient is a 7-day-old dark-skinned child compared to a 7 year old child with very dark skin. Interview questions should also elicit descriptions of attempts at self-remedy to assess typical health promotion practices in the home.

Take the history from an individual who can describe the evolution of the eruption, potentially related factors, and measures taken to relieve the condition. Older children can provide their own histories, although they may be unable to provide information regarding immunization status, childhood illnesses, and family medical history.

Focus on the course, characteristics, and related systemic problems of the current skin condition. Ask the parent or child to describe the lesions and to identify contacts with other children.

caREminder

Based on parental permission, note the name of the child's school or daycare center, because communication with the teacher may be necessary if the child's diagnosis proves to be contagious.

The medical history elicits information about events occurring during the prenatal, natal, and neonatal periods. In all children, changes in medication, diet, environment, and lifestyle can be causative factors. Brief encounters with animals, insects, plants, and other children can be key elements in explaining the source of the skin condition.

ANSWER: It is pertinent that Nick developed a rash in a new and different environment. It is relevant that rashes are unusual for Nick and that he does suffer from allergies.

Focused Physical Assessment

QUESTION: What are the characteristics of Nick's rash that you would observe and document?

As the child develops, the skin, hair, and nails will change in appearance as a result of exposure to environmental elements and natural changes associated with human development.

Skin

Physical assessment of the skin involves two basic techniques: inspection and palpation. Focused Physical Assessment 25–1 summarizes the key data to assess during the examination. The ideal environment for the physical assessment is a well-lit room with white walls. Bright white fluorescent ceiling lighting is optimal, because it does not cast a yellow hue on the skin.

caREminder

*Gloves are not necessarily required for skin assessment. However, if you suspect a contagious disorder, if body fluids are present on the skin, or if lesions are moist, then you must wear gloves. Use vinyl gloves if any possibility exists that the child may have a latex allergy. Touching the skin of an allergic child with latex may precipitate **urticaria** and **airway edema**.*

Place the child in a warm room, wearing an examination gown to provide easy access to all areas of the skin. The infant's diaper should be removed to inspect and palpate the genital area.

Allow the child and the adolescent to wear underclothes during most of the examination, to prevent any undue embarrassment and to protect the child's emerging sense of modesty.

Begin the assessment with a general inspection of the total skin surface and then proceed to a focused assessment of the specific lesions noted during the health history. This method enables you to assess the general fitness of the skin. These observations can guide the health promotion and disease prevention discussions that conclude the health visit.

The child's pigmentation should be consistent with genetic background and age. Among the members of any population, a significant range of skin colors and hair types exists. Healthcare professionals must be able to recognize anomalies in children with deeply pigmented skin. For example, lesions that appear red or brown in children with white skin may appear black or purple in pigmented skin. Newborns may present with bluish nail beds, hands, feet, and sometimes circumoral (around the mouth) for up to 10 days after birth, especially noted during episodes of intense crying, breath holding, or exposure to colder environments. This process is referred to as **acrocyanosis**, which results from vascular insufficiency and resolves as the newborn adapts to extrauterine life; it is considered normal. In general, the white infant is usually pink to red, the Hispanic newborn may have an olive tint or slightly yellow hue, black infants may appear pinkish or even yellowish brown, and Asian newborns may be a rosy or yellowish tan. Freckles and moles appear in young children as a function of aging. Many birthmarks, such as

*This history is focused on the skin, hair, and nails. See Chapter 8 for a comprehensive format.

mongolian spots, fade as melanocytes in the dermis mature. Inborn variations in skin color must be differentiated from transient changes (associated with crying, acne, or sunburn) and from reflections of pathologic processes (see Focused Physical Assessment 25–1).

During inspection, use your sense of smell to detect skin odors. Sweat odors can be caused by hormonal changes and, depending on the child's age, may be a sign of poor hygiene. Intense odors can also signify infection. Throughout the assessment process, integrate the child's verbal and nonverbal cues into the examination findings. These can add important data to your assessment. For example, consistent scratching, persistent pulling at clothes, and attempts to discreetly cover certain body areas can indicate a skin condition. Allowing the child to verbalize freely during the physical examination can yield pertinent information.

Inspection and palpation yield information regarding skin moisture, color, thickness, temperature, and texture. Touching the child's skin provides valuable clinical information about skin texture, turgor, and temperature. Note the shape, color, size, consistency, character (e.g., redness, scaling, or excoriation), and distribution of any lesions or birthmarks. Many skin disorders have characteristic patterns of distribution. For example, candidiasis is usually found in the moist, dark intertriginous folds of the groin, axillae, and neck; warts and herpes lesions are most often located on mucous membranes. Eruptions that appear on previously healthy skin as a response to disease or trauma are called **primary lesions** (Table 25–1). **Secondary lesions** result from changes over time in the primary lesion, usually related to the progression of the disease process, scratching, or secondary infection (Table 25–2). Skin lesions can have characteristic shapes that clearly differentiate the diagnosis (see [thePoint](#) Supplemental Information: Common Configurations of Skin Lesions). For example, the skin lesions of ringworm (tinea corporis) are annular (circular). Contact dermatitis usually forms in cluster shapes, whereas chicken pox appears as distinct, individual lesions.

Risk assessment is an important factor in preventing pressure sores; therefore, when a child is admitted to the hospital, document baseline skin integrity. Pressure ulcer development is an important issue with children as well

as with adults. Although the majority of recommendations for skin assessment and care of children have been modified from adult practice guidelines, evidence-based guidelines specific to children and neonates are being developed (Tradition or Science 25–1).

ANSWER: It is important to note the distribution of the rash, the shape of the lesions (patches), and their color and character. The character of Nick's rash is that it comprises vesicles, small blisters, and bulla (larger blisters). It is also important to note that some of the blisters are intact and many others are not, thus increasing the risk of an infection.

Hair and Nails

Focused Physical Assessment 25–1 summarizes normal and abnormal findings of hair and nail examination. Hair that is matted and dirty or nail beds that contain dirt may signify poor hygienic practices. Further inspection of the hair and scalp may detect the presence of lice or other parasites. Dry, brittle, or depigmented hair and brittle nails can signal nutritional deficits. Children coping with a great deal of stress may exhibit chronic nail biting or pulling of the hair (trichotillomania). Diseases of the scalp and nails are not common in children, except in cases of infestations (e.g., lice and scabies), which spread easily in home, school, and daycare environments.

Diagnostic Criteria for Evaluating Alterations in Skin Integrity

QUESTION: Is there a diagnostic test or procedure identified here that is effective in differentiating a rash caused by poison ivy?

A limited number of methods are available to confirm a diagnosis generated by a skin health history and physical examination. These include laboratory analysis by

FOCUSED PHYSICAL ASSESSMENT 25–1

Skin, Hair, and Nails

Assessment Parameter	Alterations/Clinical Significance
General appearance of the skin and mucous membranes	<p>Generalized color and condition of the skin versus local changes in skin color: pallor, cyanosis, jaundice, erythema</p> <ul style="list-style-type: none"> • Yellow or jaundiced: liver disease, hemolytic disease, renal failure, myxedema, anorexia nervosa • Red or red-blue: alcoholism, local inflammatory process, fever, venous stasis • Blue: heart conditions, lung disease, disorder of hemoglobin, disorder of circulation • Pallor or loss of color: syncope, albinism, vitiligo, tinea versicolor, anemia, nephrosis, arterial insufficiency, anxiety states • Hyperpigmentation: mongolian spot, café-au-lait spots, port-wine stain <p>Complexion: over- or underexposure to sun; pallor may indicate presence of illness, shock; blue-tinged complexion indicates cardiac or respiratory problems</p> <p>Turgor and mobility: dehydration, edema, swelling, presence of underlying mass</p> <p>Moisture: dryness found in dermatitis conditions; excessive moisture may indicate fever or hyperhidrosis (excessive sweating)</p> <p>Temperature: hypothermia, hyperthermia</p> <p>Odor, dry skin, presence of dirt may indicate poor hygienic practices</p> <p>Texture: previous scarring, sites of dermatitis outbreaks</p> <p>Vascular changes: telangiectasia, hemangiomas</p> <p>Evidence of scratching, such as erythema, scaling, or excoriated areas: atopic dermatitis (AD), scabies, lice, rash associated with infectious conditions</p> <p>Rash: environmental exposure, allergic reaction, infectious condition</p> <p>Plaques: AD</p> <p>Scaling: seborrheic dermatitis</p> <p>Macules, papules, vesicles: burns, SJS, ETN, impetigo, AD, acne, milia, candidiasis, allergic contact dermatitis, CSD, hand-foot-mouth disease, seborrhea; poison ivy, oak, sumac; sunburn</p>
General appearance of the hair	<p>Healthy scalp hair is shiny, silky, and strong; may be straight, curly, or kinky</p> <p>Normal distribution: light hair on all other body surfaces except palms, soles, inner labial surfaces (girls), and prepuce and glans penis (boys)</p> <p>Hair distribution appropriate to gender and Tanner staging of child: inappropriate distribution may indicate metabolic problems</p> <p>Quantity and areas of hair loss (alopecia) or balding that may be related to medical treatments (chemotherapy) or chronic hair pulling/tugging</p> <p>Texture: dry, brittle, or depigmented hair as seen in metabolic disorders</p> <p>Scalp condition and hygiene: lesions or scaling may indicate seborrheic dermatitis</p> <p>Presence of white eggs (nits) on hair shaft indicative of lice</p>
General appearance of the nails	<p>Healthy nail surface is slightly curved or flat (spoon shaped in newborn–3 years of age); may appear translucent in infants; edges are smooth, rounded, and clean; nails are clipped and clean, suggesting good hygiene practices</p> <p>Signs of nail biting may indicate stress</p> <p>Clubbing present with cardiac and chronic conditions; thickening may indicate fungal infection</p> <p>Color: discoloration of the nail or nail bed such as cyanosis suggests insufficient oxygenation or yellowing suggests fungal infection</p> <p>Slow capillary refill indicates problems with circulation</p> <p>Presence of hangnail</p> <p>Tender nail beds, swollen cutaneous area, pus or blood underneath the nail indicates infection, nail biting</p>
Other systems	<p>Evaluate as indicated by types of lesions, e.g., burns will have systemic involvement secondary to fluid and electrolyte loss and damage to underlying tissue; periorbital cellulitis will affect vision and sinuses</p>

scrutiny of skin scrapings and culture, skin lesion biopsy, skin testing, and the use of special equipment, such as in **Wood's lamp** examination (Fig. 25–2 and Tests and Procedures 25–1).

Laboratory analysis of skin scrapings and cultures can provide excellent diagnostic assistance. For example, scabies, tinea, dermatophytes (ringworm), and candidal infection can be diagnosed with the use of superficial

TABLE 25-1
Primary Skin Lesions

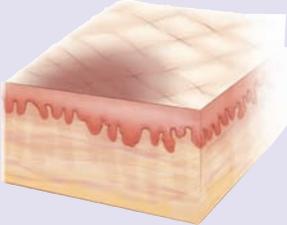

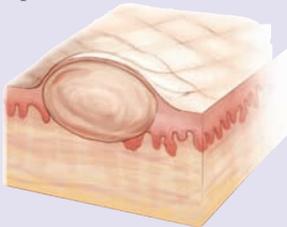

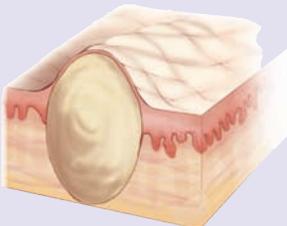

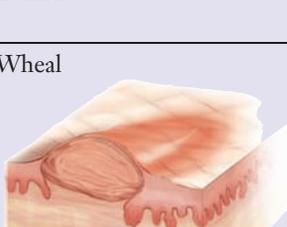

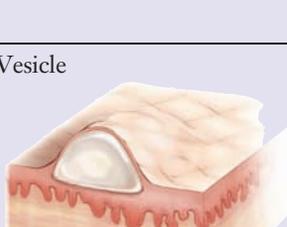

Type	Description	Example
Macule 	Circumscribed change in skin color without elevation or depression, less than 1 cm	Freckle Petechia Flat nevi Measles Scarlet fever
Papule 	Solid, elevated, circumscribed area, less than 1 cm	Mole Wart Lichen planus
Nodule 	Solid, elevated, hard or soft lesion in the dermal or subcutaneous tissue, larger than 1 cm	Fibroma Intra-dermal nevi
Tumor 	Solid, raised mass; firm or soft; benign or malignant; larger than 1 to 2 cm	Hemangioma Osteosarcoma
Wheal 	Superficial raised area of localized skin edema, irregular, transient, and erythematous	Mosquito bite Allergic reaction Hive
Vesicle 	Circumscribed elevated lesion containing serous fluid, less than 1 cm	Herpes simplex Early varicella (chicken pox) Contact dermatitis

Cyst	Encapsulated, fluid-filled cavity of dermis or subcutaneous layer	Sebaceous cyst Epidermal cyst

Source: Bickley (2008)

shavings or scrapings from the epidermis, and the **nits** or eggs from lice can be seen under the microscope. Cultures of the skin lesion or wound may identify bacteria and fungi. Skin biopsies can establish whether lesions are malignant or benign. Some minor biopsies can be completed in outpatient settings. Biopsy of the skin by excision is rarely required for diagnosis in children.

Skin testing is helpful in detecting the cause of an allergic contact dermatitis (ACD). It is performed in one of three ways: intracutaneous, scratch, or patch testing.

ANSWER: No diagnostic criteria are effective here in differentiating a rash caused by poison ivy. Poison ivy must be diagnosed by the history and the physical appearance of the rash.

TREATMENT MODALITIES

QUESTION: Which of the following treatment modalities would be helpful to Nick? What is your rationale?

Skin and wound care has numerous objectives, principally, to preserve the integrity of normal skin. Care should incorporate these underlying concepts: First, the

skin is a barrier that must be maintained; second, any insult that removes water, lipids, or protein from the epidermis alters the integrity of this barrier and compromises its function; and third, the normal epidermal barrier can be restored with the use of mild products, soaps, and appropriate emollient creams and lotions.

The nurse is responsible for completing skin surveillance measures to monitor skin condition and to implement actions that maintain skin integrity. These measures include completing a thorough assessment of the skin (see Focused Physical Assessment 25-1), identifying children at risk for skin breakdown, and instituting measures to prevent further deterioration (e.g., overlay mattresses, frequent repositioning). In addition, the nurse is responsible for teaching children and their family hygienic practices that promote healthy skin and hair, and that help prevent the spread of a contagion (Community Care 25-1, Tradition or Science 25-2). Remember that the child with a skin condition may be in pain. Managing the pain, whether transient, chronic, or acute, is a nursing intervention that can be as simple as wiping away some tears or as complex as implementing patient-controlled analgesia (see Chapter 10).

Providing optimal skin care is an interdisciplinary effort. Many institutions have enterostomal therapists, and wound, ostomy, and incontinence specialists. These expanded practice nurses provide a valuable resource. Collaboration with the dietitian is also extremely vital to proper healing of the child's skin.

TABLE 25-2

Secondary Skin Lesions

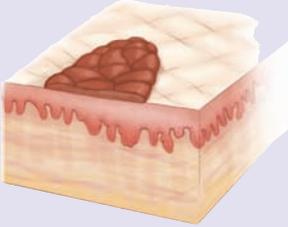

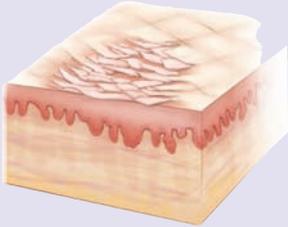

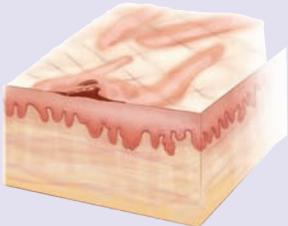

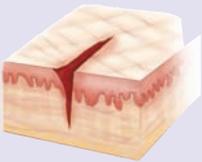

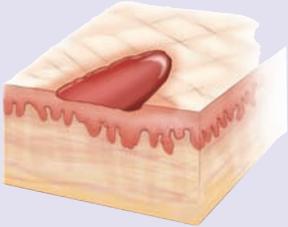

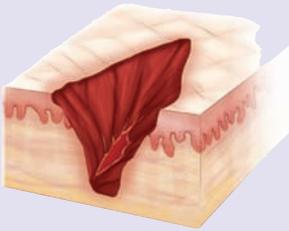

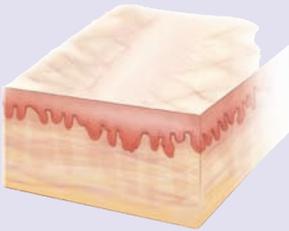

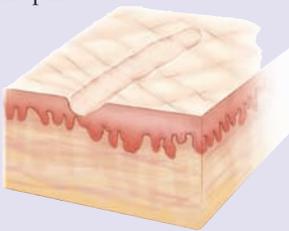

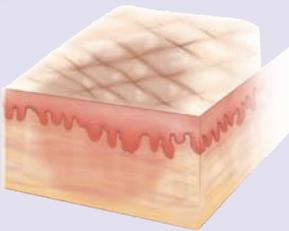

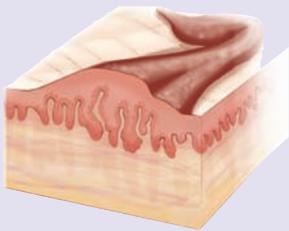

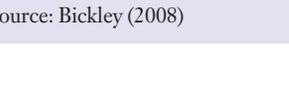

Type	Description	Example
Crust 	Thickened, dried-out area formed when serum, blood, or purulent exudate dries on the skin	Impetigo Scab formed after abrasion
Scale 	Thin, dry, or greasy flakes of skin; silvery or white in color	Psoriasis Drug reaction Seborrheic dermatitis Eczema Dry skin
Excoriation 	Superficial, self-inflicted abrasion or a scratch from intense itching	Insect bites Poison ivy Scabies Chicken pox
Fissure 	Linear crack with abrupt edges, extends into the dermis	Athlete's foot
Erosion 	Moist, circumscribed, depressed lesion that does not extend into dermis	Ruptured varicella lesion

TABLE 25-2

Secondary Skin Lesions (Continued)

Type	Description	Example
Ulcer 	Deep depression that extends into the dermis, irregular shape, may bleed	Pressure sore Chancre
Scar 	Fibrotic change resulting from the wound-healing process, normal tissue replaced with connective tissue (collagen)	Healed incision site or injury site Acne
Atrophic scar 	Thinning of the epidermis, which results in skin-level depression	Striae associated with pregnancy or weight gain
Lichenification 	Thickened skin area resulting from prolonged, intense scratching	Eczema
Keloid 	Hypertrophic scar area that has built up tissue far greater than the size of the original injury	Site of multiple injuries or incisions
Petechia 	Small, flat, nonblanchable vascular lesions caused by capillary hemorrhage	Rash evident with meningococcal meningitis Soft-tissue injury
Ecchymosis 	Large areas of hemorrhage that change in color over time	Bruise caused by a fall or abuse

Source: Bickley (2008)

TRADITION OR SCIENCE 25–1

Are valid scales available to assess skin integrity in the pediatric population?

MORE INQUIRY NEEDED

Several valid and reliable skin assessment scales exist to assess adult patients. However, it is recognized that the factors that contribute to skin breakdown in children and premature infants differ from those for adult populations, making development of a pediatric risk assessment tool critical to determining the quality of pediatric skin care (Suddaby, Barnett, & Facticeau, 2005). Currently there are more than 10 published scales for assessing the risk of skin breakdown in children. Reliability and validity testing of these instruments is ongoing, thus they have yet to establish the same level of credibility as tools used in the adult population. The pediatric scales have been primarily tested in the pediatric or neonatal intensive care settings, and lack testing on general pediatric hospital populations and nonhospital populations (Baharestani & Ratliff, 2007). The most widely used scale is the Braden Q Scale, based on the Braden scale for adults. This scale is for pressure ulcer risk identification in children age 21 days to 8 years (Curley, Razmus, Roberts et al. 2002; Loman, 2000; Quigley & Curley, 1996). The Neonatal Risk Assessment Scale, modeled after the Braden Scale, measures skin issues in the neonate population and is based on gestational age (Gray, 2004; Huffiness & Lodgson, 1997). The Starkid Skin Scale shows promise as a measure of risk of skin breakdown in the pediatric population (Suddaby, Barnett, & Facticeau, 2005). This one-page tool is based upon the Braden Q scale and is self-explanatory and easy to use. Further research is needed to determine which assessment tools should be used for specific pediatric populations and to better identify what are the cutoff scores for identifying risk. In addition, research can help determine when risk assessments should be performed and when reassessments should be completed (Baharestani & Ratliff, 2007).

The physical therapist plays a role in skin care if physical mobility has become restricted, and may provide alternative forms of treatment to enhance wound healing and facilitate elasticity of the affected area. Depending on the cause of the child's skin condition, a social worker consult and visits by a home care nurse may ensure continuity of care in the home setting, and provide social support and educational resources for family members.

Amid the many interventions of the healthcare team, the psychological and cognitive needs of the child must be met. Approaches to skin care should account for the child's developmental stage and associated perception of the events surrounding the encounter with the healthcare team (Developmental Considerations 25–2).

Measures to Promote Skin Hydration

Bathing and environmental considerations affect general skin hydration; moisturizers and lubricants can help to maintain or improve it.

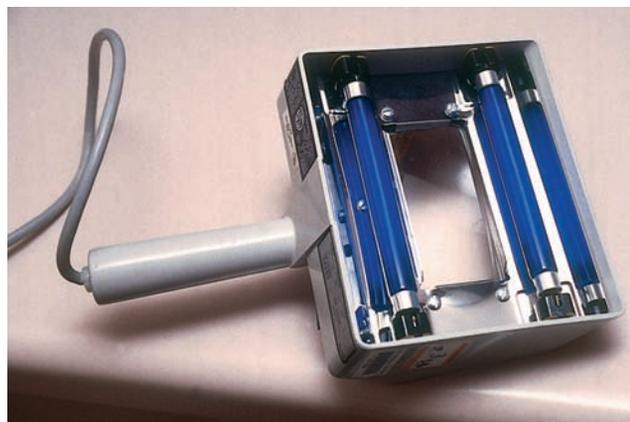

FIGURE 25–2. A Wood's lamp uses ultraviolet light to fluoresce specific skin lesions.

Bathing

Bathing is also often recommended to enhance hydration of the skin in dry climates or if the child has a condition in which the skin is very dry. Bathing in lukewarm (not hot) water can promote comfort and reduce itching (see TIP 24–1). The bath should not last long enough for the skin to become supersaturated. Soaps and oils may be used during the bath to cleanse and moisturize the skin. Mild soaps that can be used on the child's skin include Dove, Aveeno, and Neutrogena. Bath oils include Alpha Keri and Domol. Aveeno is an acceptable colloidal oatmeal bath. The child with a skin condition should avoid bubble baths because they can further irritate the skin. After the bath, the child should be gently dried. Children with skin conditions such as atopic dermatitis (AD) should immediately apply an emollient to the skin to maintain the skin's hydration.

Environmental Considerations

Environmental humidity affects skin hydration. Excessive humidity (>90%) or deficient humidity (<10%) can lead to alterations in skin integrity. Children with dry skin are especially susceptible to discomfort when the humidity is low. Use of a vaporizer, humidifier, and humidified heating during the winter months may help relieve itching. In warmer weather, air conditioning may help alleviate discomfort and itching.

Skin hydration is also affected by the child's fluid intake. To promote good skin hydration, the child should be encouraged to drink plenty of fluids.

Moisturizers and Lubricants

Many moisturizers and lubricants are composed of petrolatum or a mixture of petrolatum and lanolin (skin care products used in the perineal area [i.e., those that will "repel" urine and stool]). These agents, which assist the child's skin to retain water, are most effective when applied to wet skin. They are used for children, such as those with AD, whose skin appears very dry or is unable to maintain hydration.

Tests and Procedures 25-1 Evaluating Alterations of the Skin, Hair, and Nails

Test or Procedure	Purpose	Healthcare Provider Considerations
Cultures <ul style="list-style-type: none"> • Skin • Wound • Nails • Hair 	Samples of exudate, scales, and crusts are cultured to identify the bacterial, viral, or fungal causes of redness, irritation, or visible lesions.	Skin <ul style="list-style-type: none"> • Use polyester-tipped swabs to collect all skin and wound cultures. Cotton-tipped swabs are unsatisfactory because they may be treated with bacteriostatic solutions. • Wash affected site with 70% isopropanol or sterile water, allow to dry, and culture several lesion sites, swabbing the edges of the lesion. Wound <ul style="list-style-type: none"> • All superficial debris adjacent to the lesion and the wound itself must be gently wiped with a 70% isopropanol solution before culture is obtained. • Specimens collected from the wound edge are not very accurate. • Specimens should be delivered to the laboratory immediately so that testing can begin within 60 minutes of collection. Hair <ul style="list-style-type: none"> • Obtain hair and hair stubs or scrapings from areas of hair loss or infection sites without cleansing the scalp. • Both shaft and infected root or suspicious hairs are clipped or plucked with sterile forceps and sent to the laboratory in a Petri dish.
Scrapings for microscopic analysis	Samples of skin scraping, nail clippings, or plucked hairs are stained and evaluated under the microscope to identify the bacterial, viral, or fungal causes of redness, scaling, irritation, or visible lesions.	Same considerations as for cultures.
Potassium hydroxide stain	Identifies fungi or yeast from skin, hair, nails.	Same considerations as for cultures.
Tzanck preparation <ul style="list-style-type: none"> • Giemsa method • Wright's stain 	Examines cells from the base of vesicles or bulla. Smears are useful in diagnosing some viral infections (herpes simplex, varicella, herpes zoster, and eczema herpeticum) and in examining the white cell morphology of pustular disorders (erythema toxicum neonatorum, candidiasis).	Wipe lesion with alcohol and allow to dry for 1 minute. Using a no. 15 blade, either remove crust or unroot the vesicle or pustule, then scrape the base of lesion with edge of blade. Transfer material to a glass slide, where stain is then applied.
Gram stain for bacteria	Identifies bacterial growth from a skin lesion.	Same considerations as for cultures.
Scabies preparation	Identifies presence of scabies.	Scrape intact vesicles, papules, or burrows with a no. 15 blade coated with immersion mineral oil. Sample as many primary lesions as possible to have a greater chance of having a positive scabies preparation.
Skin biopsy <ul style="list-style-type: none"> • Punch biopsy • Shave biopsy 	Determines the histopathologic diagnosis of any skin tumor, palpable purpura, or persistent dermatitis, as well as removal of small lesions.	A local anesthetic using 1% to 2% plain lidocaine should be given prior to biopsy. After the punch biopsy, bleeding may occur at the site. Firm pressure should be applied until bleeding stops. Suturing is optional.

(Continued)

Tests and Procedures 25–1 Evaluating Alterations of the Skin, Hair, and Nails (Continued)

Test or Procedure	Purpose	Healthcare Provider Considerations
Skin testing <ul style="list-style-type: none"> • Intracutaneous • Scratch • Patch 	Identifies the offending allergen, which may be the cause of allergic dermatitis responses.	Conduct the test after the allergic dermatitis has subsided. Testing should be performed by a healthcare provider experienced in the interpretation and potential hazards of the procedures. Allergenic substance is injected under the skin. The skin surface is irritated with a suspected allergic agent. The suspected trigger agent (antigen) is applied to the skin and occluded by hypoallergenic tape. Patches should not be allowed to become wet while taped on the skin. The site is evaluated for a reaction 48 to 72 hours later, using standardized results for interpretation. Tell children to avoid bathing and strenuous activity while the patches are in place. The patches should not be allowed to become wet while taped on the skin.
Wood's lamp	Ultraviolet light is useful in the diagnosis of certain superficial pigmented or infectious skin lesions.	Test must be performed in a darkened room. Procedure is noninvasive. No pain is associated with testing. Infected hair follicles have a grayish appearance in normal light, but exhibit a yellow-green fluorescent appearance under Wood's light.

caREminder

Do not apply moisturizers and lubricants to the infant's or young child's diaper area. These products are likely to promote skin breakdown. They overhydrate the skin and act as a friction agent between the diaper and the baby's skin. Using appropriate ointments, and educating caregivers about their use, is paramount. Avoid products that contain fragrances.

Petrolatum-based agents include Vaseline pure petrolatum jelly and Moisturel. Petrolatum, lanolin, or mineral oil combination agents include Aquaphor ointment, Eucerin cream and lotion, Lubriderm, Keri Crème, Nivea Moisturizing, and Ultra Derm. Popular zinc oxide-based products include Desitin, Balmex, generic zinc oxide, and Calmoseptine (also with calamine lotion).

Topical Medications

Topical medications can be used to treat skin conditions or prevent alterations in skin integrity. A topical medica-

tion consists of an “active” agent contained in a vehicle, or base. In addition, the topical application may contain an “accelerant,” which increases skin permeability, thus enhancing the mechanisms for medication absorption. Topical agents are widely used because of their ability to deliver an optimal concentration of a medication to the exact site where it is needed (Nursing Interventions 25–1). Topical therapies are beneficial to children who have cutaneous infections, because they minimize the risk of systemic drug exposure that can occur with oral or intravenous (IV) medications. In addition, parents often find it easier to use a topical agent rather than convince a child to take an oral medication.

Alert! Topical use does not guarantee safety. Systemic absorption and toxicity, local irritation, chemical burns, contact dermatitis, and poisoning from accidental ingestion can occur if safe administration techniques are not followed.

The nurse applying a skin care agent to the child is responsible for monitoring the skin for effectiveness of the

COMMUNITY CARE 25-1

Measures to Promote Skin Care and Hygiene

Personal Care

Ensure the child is bathed and the hair is washed on a regular basis.

Keep the child's nails trimmed.

Brush the child's teeth and tongue at least twice daily.

Use protective agents such as sunscreen and diaper rash ointments to protect the child's skin from injury.

Clean cuts and scrapes immediately, and cover with an appropriate type of dressing.

Home, Daycare, and School

Introduce new foods gradually and monitor the skin for allergic reactions.

Note the presence of an unusual rash and report this information to a healthcare provider.

Ensure that clothing and other personal items such as hats, toothbrushes, and drinking cups are not shared. Separate children with an unusual rash from other children until the causative agent can be determined.

Ensure that costumes used in play activities are washed frequently in hot water.

Instruct care providers and teachers to wash their hands frequently to prevent spread of infectious agents from one child to another.

Teach care providers to wear gloves when changing diapers, applying topical ointments, or treating wounds.

therapy. The child may have a sensitization to the agent that aggravates rather than relieves the symptoms or that creates new skin problems. Apply the agents following the frequency and dosage requirements recommended by the manufacturer or a pharmacist. Teach the family where and how to apply the agent. Suggest that reapplication of topical agents might be necessary if the child's skin becomes wet. Advise parents to wash their hands after applying the agent, to remove it from their skin.

Systemic Drug Therapy

Many of the skin conditions that occur in the pediatric population are a result of infection or immune responses within the body. In these cases, the primary cause of the skin condition must be treated using some type of systemic therapy. In addition, medications are given to relieve pain and reduce inflammation (see [thePoint](#), Medications and Administration: Systemic Drug Therapy).

If systemic therapy is initiated, assess the family's understanding of the need for this treatment and their ability to continue the course of therapy for the entire treatment. This includes financial ability as it relates to the family's healthcare plan. Some of the products are expensive, and reimbursement may not be adequately covered under the family's healthcare plan. Inform the family of the side effects of the medications. If IV administration is required, hospitalization may be necessary.

Dressings

Wound healing may occur by primary, secondary, or tertiary intention. Primary intention refers to surgical closure, and these wounds generally heal very quickly. In secondary intention, the wounds are left open and allowed to heal by producing connective tissue; many

products are available to use with these wounds, and the choice of product is guided by clinical factors. Most of the wounds described in this chapter, and most seen clinically, close by secondary intention. Tertiary intention closure occurs when there is a delay between the actual injury and closure; an example is a wound purposely left open for drainage but that is later closed.

Various wet, dry, and occlusive dressings may be used to treat a skin condition or wound (see [thePoint](#), Supplemental Information: Dressings for Wound Care). Today's dressings, which may be "dynamic" and "interactive" (e.g., hydrocolloids, calcium alginates, wound gels) or "static" (gauze) serve several functions, such as

- Reducing pain
- Providing a barrier to infection
- Helping clean the wound or lesion by debridement
- Promoting a moist environment conducive to healing
- Absorbing drainage from the wound or lesion
- Providing an aesthetic barrier while maintaining easy access to view the wound or lesion site

Wet Dressings

Wet dressings help moisturize the skin, decrease itching, and remove crusts. The dressing should be wet with lukewarm water and applied for 10 to 20 minutes, four to six times per day for up to 1 week. During the treatment, the dressing should not be allowed to dry, but should be rewetted or replaced with a new wet dressing. Creams or ointments are usually applied after the wet dressing therapy to promote hydration. In some cases, after the application of a cream or ointment, another wet dressing followed by a dry dressing may be applied. For instance, in the treatment regimen for a child with psoriasis, a wet dressing is applied for 20 minutes, followed by application of a moisturizing agent. The body is then covered with a wet sleeper pajama or long johns, which is covered

TRADITION OR SCIENCE 25–2

Is scientific evidence available regarding management strategies for the neonate's skin?

EVIDENCE-BASED PRACTICE

An important evidence-based standard for neonate and infant skin care has been developed by the Association of Women's Health, Obstetric and Neonatal Nurses, and the National Association of Neonatal Nurses (Lund et al., 1999; Lund et al., 2001a; Lund, Osborne, Kuller et al., 2001b). The guidelines were based on a multicenter (51 hospitals) study completed to test the effectiveness of evidence-based clinical practice guidelines for neonatal skin care on selected clinical outcomes for newborns in neonatal intensive care units, special care units, and well-baby nurseries. Skin condition was assessed using the Neonatal Skin Condition Score, based on dryness, erythema, and skin breakdown. Through implementation of these guidelines, neonatal skin improvement was noted as less visible dryness, redness, and breakdown. Furthermore, the study yielded recommendations for using emollients, decreasing frequency of bathing for this population, using pH-neutral cleaners, and using adhesives sparingly. All these recommendations were incorporated into the standard of care.

The guidelines have been updated based on an extensive review and evaluation of skin care-related research published between 2000 and 2007. The revised guidelines include discussions on newborn skin assessment, bathing, cord and circumcision care, disinfectants, diaper dermatitis, adhesives, emollients, transepidermal water loss, skin breakdown, and IV infiltration (Lund et al., 2007).

Although this study provides important direction in skin care, newer studies also conclude that daily prophylactic application of a topical ointment improves skin condition and decreases evaporative water loss, yet can also increase risk for infection, particularly with *Staphylococcus aureus*, in preterm infants (Conner, Soll, & Edwards, 2004). Current recommendations include not using topical ointments routinely on the skin of premature infants.

in turn by a dry sleeper or long johns. The dressing and clothing are changed every 6 hours for a 24- to 72-hour period, or they may be used overnight for 5 to 10 hours.

caREminder

Avoid chilling the child by making sure the room is warm, but not hot. Also make sure a damp dressing remains damp and does not dry out. Change a dry dressing as needed to ensure that it remains dry and to help prevent chilling.

Dry Dressings

Dry dressings are most commonly used to cover a surgical wound or other break in the surface of the skin. A dry dressing may be as simple as a Band-Aid placed over a scraped knee.

Many children do not like bandages placed on their “owwies.” To gain the child's cooperation, allow the child to place the bandage on him- or herself. The use of bandages with cartoon characters on them may make wearing the bandage more acceptable to the child.

Before placing a dressing, cleanse the wound gently with normal saline or other nontoxic wound cleanser. Treat surrounding normal skin in the same gentle fashion as the affected site to protect the healthy area from deterioration. Remove an old dressing carefully; never pull it off forcefully. Wetting the dressing and tape may be necessary to ease removal.

Alert! The neonate's skin has weak intracellular attachments. Rapid removal of tape can separate skin layers (epidermal stripping) and form blisters.

Occlusive Dressings

Occlusive dressings enhance hydration of the skin, promote the absorption of topical medications, and prevent exposure of the area to microorganisms. Occlusive dressings are also effective in preventing epidermal stripping in preterm infants by eliminating the need for tape to be used and in preventing skin irritation by functioning as an artificial barrier (Lund et al., 2001b; Lund et al., 2007). The effectiveness of polyurethane dressings as a barrier to prevent microorganism growth on the excoriated skin of the preterm infant has been questioned. Data remain inconclusive, with some research indicating that high concentrations of bacterial growth under the dressings place the neonate at risk for infection (Strickland, 1997). A trend has also been noted toward increased risk of bacterial infection when occlusive topical ointments are used prophylactically on preterm infants (Conner, Soll, & Edwards, 2004).

Occlusive dressings are used in various ways. For instance, plastic wraps may be placed on the skin after hydrating the skin and applying a moisturizing agent. This type of occlusive dressing is left on for no longer than 8 hours. Occlusive dressings are also used to protect the entry site of a vascular access device, to promote absorption of a topical agent such as EMLA cream, and to protect an open area of the skin from fecal contamination (e.g., in the child with myelomeningocele).

Wound Care

The nurse is responsible for assessment of a wound and the surrounding tissue. These observations are important as baseline data from which the clinician can make judgments about progression of healing and course of treatment (see [thePoint](#), Supplemental Information: Wound Assessment).

Alert! Signs of infection at the wound site may include a red streak running from the wound, a wound that progressively becomes more tender, dehiscing of the wound site, or a suture that comes out too early.

DEVELOPMENTAL CONSIDERATIONS 25-2

Skin Care

Stage Age	Developmental Principles	Nursing Strategies
Infancy	<p>Exploration of the body is occurring. Infants are acutely aware of attitudes portrayed by caregivers.</p> <p>There is high need for comfort by a person who is familiar to the infant.</p> <p>Pain response may be difficult to interpret.</p>	<p>Involve the primary caregiver in the skin care.</p> <p>Distract the infant with toys during the procedure.</p> <p>Ensure that the infant is free from pain during procedures.</p> <p>Decrease the pain caused by frequent dressing changes by using Montgomery straps or protecting the skin with a skin barrier.</p>
Early childhood	<p>Child's thinking is egocentric, magical, and concrete.</p> <p>Child believes that two events contiguous in time are usually related.</p> <p>Child may perceive injury or hospitalization as a result of a misbehavior.</p> <p>Limited experiences make it difficult to understand complicated explanations of events.</p> <p>Child learns about self and environment through play.</p> <p>Child is able to perform simple self-care tasks.</p>	<p>Use diversional play such as clay, crayons, or a favorite video during the procedure.</p> <p>Convey an attitude to the child that skin care is a process performed <i>with</i> them, not to them.</p> <p>Elicit cooperation and assistance when possible from the child; give choices.</p> <p>Provide careful, simple, present-oriented explanations.</p> <p>Use therapeutic play to foster expression of feelings and child's knowledge of the skin care activities. Allow child to perform skin care on a doll.</p>
Middle childhood	<p>Child follows rules or directions given by those in authority.</p> <p>Child is able to apply logical reasoning skills to familiar situations.</p> <p>Child comprehends cause-and-effect relationships.</p> <p>Memory is improved.</p> <p>One of the major fears is loss of control.</p>	<p>Allow child to help with skin care. The child may want to place the bandage on or assist in putting on the tape.</p> <p>Explain that the dressing should not be touched, picked at, pulled off, or gotten wet by the child.</p> <p>Use of rules and limits is important.</p> <p>Explain all aspects of the procedure including the concept of sterile technique and germ transmission.</p> <p>Give specific guidelines regarding the degree of participation by the child and family in skin care.</p> <p>When medicating the child for pain, avoid drugs or doses that may make the child feel a loss of control.</p>
Adolescence	<p>Abstract thought processes develop.</p> <p>Body image is paramount.</p> <p>Privacy is important.</p> <p>Child is developing independence from parents.</p>	<p>Teach the adolescent to manage skin care independently as appropriate.</p> <p>Parents should be included in care for support and as wanted by the adolescent.</p> <p>Address issues about body image in a positive, thorough, and honest manner.</p> <p>Consider the adolescent's body image concerns as important if not more important than the actual skin care.</p>

TIP 25–1 A Teaching Intervention Plan for the Child With Diaper Dermatitis

Nursing diagnoses and outcomes

Impaired skin integrity related to irritation of the diaper area

Outcomes

- Child regains skin integrity.
- Child exhibits no further evidence of skin breakdown.

Deficient knowledge: Prevention and treatment of rash

Outcomes:

- Parents demonstrate skin care techniques to promote healing and to prevent further skin breakdown.
- Parents verbalize measures to prevent diaper dermatitis.

Teach Child/Family

Medications

- If candidal infection is present, topical anticondoidal agent (Nystatin, Lotrimin, Micatin, Nizoral) is applied to diaper area.
- If severe inflammation is present, apply a topical low-potency, nonfluorinated 1% hydrocortisone cream to rash site for 7 to 10 days.
- Children with recurrent diarrhea may be prescribed an oral anticondoidal agent (Nystatin) to sterilize the gastrointestinal tract and to prevent systemic infection.

Diaper Changes

- Change diaper frequently.
- Check diaper every 1 to 2 hours for wetness or soiling, and change wet or soiled diaper immediately.
- Use superabsorbent diapers if affordable. If using cloth diapers, consider placing a stay-dry liner in the diaper.
- With each wet diaper change, wipe the skin gently with a plain water or a diaper wipe (nonallergenic, unscented).
- With each soiled diaper
- Wash the skin with water and a gentle, pH-neutral soap; rinse well
- Pay particular attention to cleaning areas of skin folds
- Pat the baby's bottom dry; do not rub or use a hair dryer to dry.
- Avoid air-tight occlusive diapers or diaper covers.
- Do not use plastic pants.
- Fasten the disposable diaper loosely.
- Brand-name disposable diapers can be altered to breathe better by snipping the elastic bands around the legs in a few places, and cutting a few slits in the plastic diaper cover.
- Leave the baby's bottom exposed to air as much as possible.
- Put a towel or diaper open under the baby during nap time.
- Let the young child be "diaper free" for periods of time.

Creams and Ointments

- Do not use creams and lotions on most babies.

- Apply a layer of protective ointment or barrier cream (such as zinc oxide, petrolatum, or dimethicone base) to the noninfected diaper rash.
- Do not remove the barrier cream with every diaper change as long as a layer of paste remains on the skin, and the skin underneath is clean.
- If the barrier cream must be removed, use a minimal amount of mineral oil to remove it.
- Do not use talcum powder. Cornstarch may be applied to areas where friction might occur. When wet, however, the cornstarch can clump and retain moisture on the skin. There is some controversy regarding cornstarch. Some sources recommend not using it because microorganisms metabolize the cornstarch and aggravate yeast infections.

Nutrition

- If the child has diarrhea, the child should be evaluated for dehydration. Dietary restrictions and hydration measures may be needed to stop the diarrhea and to prevent dehydration.

Nighttime Care

- Apply creams liberally to diaper area before bedtime, making sure to rub the product in completely, then apply a thin layer or coating.
- Avoid plastic pants at night.
- Until rash improves, awaken the child at least once a night to change the diaper.

Cloth Diapers

- Cloth diapers should always be washed in hot water with a combination of mild soap and distilled white vinegar and then double-rinsed. Wash, rinse, let the diaper soak in water with ammonia added for a half hour, then rinse again.
- Do not use fabric softener or antistatic products because they may cause allergic rash. Be aware that some fabric softeners make fabrics nonabsorbent, and thus should not be used.

Prevention

- After the child's bath, let child be "diaper free" for a period of time.
- Change diapers frequently. Never leave a child in a soiled diaper.
- Wash cloth diapers appropriately (see above).
- Use appropriate barrier creams and ointments.

Contact Healthcare Provider if:

- Rash develops big blisters (more than 1 in across), open sores, or boils
- Rash does not look better in 3 days
- Rash becomes solid and bright red
- Rash becomes raw and bleeds
- The child is male and circumcised, and a sore or scab develops at the end of the penis
- Rash causes enough pain to disrupt sleep
- Child develops a temperature more than 100 °F (37.8 °C).

The physician or nurse practitioner can choose to treat the wound either surgically or medically. Surgical interventions may consist of debridement and closure of an open, noninfected wound with sutures or staples (called a *flap*), whereas medical interventions entail the use of medications and special dressings. Research during the late 1950s and early 1960s demonstrated that moisture provides the best microenvironment for both wound regeneration and repair. **Moist wound-healing** methods must be matched to the patient, wound, and setting, and use “dynamic” products (see [thePoint](#), Nursing Interventions: Dressings for Wound Care) as opposed to the traditional “static” gauze dressings. If antiseptics are applied topically to cleanse the wound area, use them only briefly, in low concentrations, and irrigate with normal saline, with the appropriate dressings applied. Normal saline is still considered the best solution to “wash out” wounds, because of its relative isotonicity and minimal effect on tissue regeneration.

Chronic wounds may be managed using sterile, clean, or aseptic techniques. Research evidence is lacking that demonstrates the superiority of one method over another in the management of chronic wounds and that support the use of one technique over another in specific patient care settings (Wooten et al., 2005).

ANSWER: Treatments that decrease itching include bathing in a colloid oatmeal such as Aveeno, keeping cool in air conditioning, and using cool compresses. Topical agents that decrease itching and help dry open blisters include calamine lotion and hydrocortisone ointment. Systemic drugs that are recommended for Nick include antihistamines and glucocorticosteroids. Dressings are not necessary for Nick’s poison ivy rash.

Miscellaneous Treatments

Various physical and surgical interventions can be used to remove skin lesions or alter the appearance of the skin. For instance, camouflage makeup may be used to cover disfiguring birthmarks and scars. Ultraviolet (UV) light therapy is used to treat psoriasis and acne. Repeated laser therapy treatments can remove vascular malformations such as a port-wine stain. Liquid nitrogen is used to remove warts. Disfiguring or irritating lumps or bumps can be removed from the skin surgically. All these therapies require the healthcare team to ensure that the child and family are well acquainted with the treatment options. The treatment options may be painful and may themselves cause some disfigurement between the time of treatment and the complete healing of the skin. Alternative wound strategies include

- Surgical interventions: Skin grafts, skin flaps, muscle flaps
- Negative pressure: Vacuum-assisted closure
- Biologic agents: Human skin equivalents (Dermagraft, Apligraf), growth factors (Regranex)
- Hyperbaric oxygen therapy, topical oxygen therapy

- Electrical stimulation
- Ultrasound therapy
- Free-radical scavengers

Nutritional Management

When managing skin conditions, the importance of nutrition cannot be overlooked. Slow or insufficient wound healing, or the presence of skin disorders (e.g., dermatitis or hair loss) are manifestations of nutritional deficiencies. Protein deficiencies retard the formation of collagen. Vitamins and minerals are necessary for various metabolic processes and for epithelial tissue and collagen formation (Table 25–3). As a result of certain developmentally appropriate behaviors (e.g., food jags), children can challenge the clinician’s ability to provide sufficient nutrition. Metabolic and congenital disorders can also make the challenge of meeting energy requirements difficult. In a severely debilitated child, wound healing is often compromised, because the nutrients crucial to the healing process are not available for metabolic purposes. For example, if albumin levels are below normal, protein depletion and edema impair wound healing. Parenteral protein and nutrients may be needed if the child is unable to ingest and digest foods taken orally.

Nutritional management may also be of concern to the child who has to avoid certain foods that cause a localized or systemic skin reaction. In these cases, consultation with a nutritional specialist is imperative. The specialist can assist the family in identifying all the foods that may contain the allergic substance. In addition, a dietary plan must be established that ensures that, even though certain foods are avoided, a well-balanced diet is maintained (see Chapters 3–7 for information on the nutritional needs of healthy children).

NURSING PLAN OF CARE FOR THE CHILD WITH ALTERED SKIN INTEGRITY

QUESTION: What is an appropriate nursing diagnosis and outcome for Nick and his family?

The data from the focused health history and physical assessment yield information about the child’s skin, hair, and nails. Nursing diagnoses are formulated to direct the interdisciplinary team in a plan that addresses altered skin integrity (Nursing Plan of Care 25–1). Immediate goals for the child include treating the skin condition and relieving pain or itching. If the condition is contagious, measures also must be taken to prevent the illness from spreading to children and adults who have had contact with the affected child. When the condition limits physical mobility or alters body image, the interdisciplinary team must identify these concerns and provide measures to support the child and his or her family. Certain skin lesions are secondary symptoms of primary conditions

NURSING INTERVENTIONS 25–1

Administering Topical Agents

Agent	Purpose	Key Points
Emollients	Lubricate and hydrate skin for dry, scaly skin conditions A bath additive to dry skin A soap substitute, to cleanse the skin in treatment of all the inflammatory dermatoses	Apply with clean hands to avoid contaminating the contents of the container. Each family member should have a separate supply to avoid cross-contamination.
Barrier creams	Protect against irritation or repeated hydration Serve as water-repellent substance	In the diaper area, barrier creams should not be wiped away completely after each wet or dirty diaper. Such actions can cause further skin breakdown. Only clearly dirty or stained areas of cream should be removed. Additional cream may need to be applied with each diaper change.
Antiseptics and astringents	Cleanse skin and wounds	Povidone–iodine and hexachlorophene should not be used in neonates or those with badly burned or excoriated skin because of the risk of toxicity from absorption.
Keratolytics	Remove thickening of the surface of the skin (hyperkeratosis) in conditions with dry, scaling skin, such as ichthyosis, psoriasis, and eczema For acne, to relieve follicular obstruction by promoting peeling of the skin and inhibition of bacteria	The agent may leave a greasy feeling on skin. Generally, the agent needs to be used only every 12 hours.
Corticosteroids	Treat inflammatory conditions of the skin, particularly eczematous disorders	The more potent the steroid, the higher the incidence of side effects, including adrenal suppression and cushingoid effects. Also need to watch for thinning/weakening of the epidermis and regressive changes in the dermal connective tissue. <i>In children, the risk is increased</i> <ul style="list-style-type: none"> • By prolonged application • Under occluded areas, such as those covered by disposable diapers • On areas of thin skin Local side effects include skin atrophy, telangiectasia, purpura, and striae. Topical steroids may mask signs of infection.
Steroid/antibiotic mixtures	Treat inflammatory conditions of the skin, particularly eczematous disorders that have developed a secondary infection	Most steroid-responsive skin diseases do not require a topical antibiotic.
Coal tar	Treats eczema and psoriasis, although the mechanism for its therapeutic effect is unknown	Coal tar can be used alone, in ointment, or paste base. Scalp preparations and shampoos are also available.

Agent	Purpose	Key Points
Antibacterials, antifungals, and antivirals	Treat localized infections Infection prophylaxis in traumatic and surgical wounds	Prolonged use may promote bacterial resistance and sensitization reactions. This treatment should be aimed at minor skin problems for 5 to 7 days only.
Antiparasitic preparations	Treat lice and scabies infestations	Give written instructions to the family to increase the likelihood of observing correct application procedure.
Sunscreens and sunblocks	Protect skin from effects of ultraviolet light	The higher the skin protection factor, the more efficient the preparation is in preventing burning. There is no internationally agreed-on standard of photoprotection.

that affect other organs. In these cases, healthcare must encompass a plan to treat the primary condition. Last, nursing diagnoses must articulate the need for family education to prevent exacerbations of the skin condition

and to manage the child's health needs in the home and at school. Nursing Plan of Care 12-1 provides additional information to assist in planning care for a child with a chronic skin condition.

TABLE 25-3

Nutrients and Wound Healing

Nutrient	Effect on Wound Healing
<i>Carbohydrates</i>	
Glucose	Provides energy for leukocytes and fibroblasts
<i>Protein</i>	
Amino acids	Necessary for neovascularization and fibroblast production, lymphocyte formation, synthesis of collagen, phagocytosis, and wound remodeling
Albumin	Necessary to prevent edema by controlling oncotic pressure
<i>Fats</i>	
Essential fatty acids	Metabolized in prostaglandins and form cell membranes; primary energy source for infants
<i>Vitamins</i>	
Ascorbic acid	Necessary for collagen synthesis; improves immune response to infection
B complex	Cofactor of enzyme system and needed for energy; no direct link to wound healing
A	Promotes epithelialization and collagen synthesis
D	Necessary for calcium metabolism; no direct link to wound healing
E	May protect vitamin A oxidation during digestion; antioxidant; supports immune functions
K	Necessary for synthesis of prothrombin and other clotting factors; "hemostasis"
<i>Minerals</i>	
Zinc	Stabilizes cell membrane, promotes cell mitosis, helps with epithelialization
Iron	Necessary for collagen synthesis, enhances bactericidal action of leukocytes
Copper	Promotes formation of a stable collagen tissue
Magnesium	Important for protein synthesis

NURSING PLAN OF CARE 25–1 CHILD WITH ALTERED SKIN INTEGRITY

Nursing diagnosis: Impaired tissue integrity related to primary break in the skin's surface, or exposure to physical, chemical, or environmental hazards.

Interventions/Rationale

- Obtain baseline and ongoing assessments of skin and mucous membranes for alterations in integrity (see Focused Physical Assessment 25–1).

Baseline assessments provide an index upon which to compare changes. Ongoing assessment enables prompt detection of changes and interventions to address the alteration.

- Assess ongoing nutritional status, including intake and output, weights, calorie count, composition of diet, and serum albumin levels, as indicated by child's condition.

Increased caloric intake may be needed to maintain nutritional intake and promote wound healing. Analyzing composition of the diet ensures that substances are ingested that will enhance wound healing (e.g., calcium, vitamin D). Weight loss or gain may indicate need for alterations in diet. Decreased serum albumin levels (<2.5 g/dL) indicate severe protein depletion and place the child at risk for skin breakdown.

- Assess environmental factors that may compromise skin integrity (e.g., wound drainage, humidity, friction, shear, pressure to bony prominences, immobility, presence of exacerbating agents such as pets, grass, exposure to sun).

Identifying causative environmental agents can assist in prevention and early recognition and treatment of skin conditions.

- Implement measures to treat alterations in tissue integrity or to prevent potential alterations. Evaluate effectiveness of interventions.

Use of topical agents, systemic drug therapy, protective dressings, skin hydration techniques, use of specialty beds, and nutritional support provide mechanisms to treat symptoms and pathology.

- Support parental competence in assessing the child's needs and in caring for the child.

Reinforces new behaviors and bolsters the parents' feelings of competence.

Expected Outcomes

- Child's areas of impaired tissue integrity will heal.
- Child's circulation and nutrients delivered to the wound site or lesion will remain adequate.
- Child and family will follow advised course of therapy to manage the child's skin condition.

Nursing diagnosis: Acute pain related to skin disorder, healing process, diagnostic and treatment measures

Interventions/Rationale

- Assess pain using a reliable and valid method that is appropriate developmentally and for the situation. Elicit parent's assessment of child's pain.

The subjective rating of pain is most reliable but may not be an option in a nonverbal child, (infant, intubated, comatose). Validated tools provide the most accurate assessment. The absence of behaviors indicative of pain does not necessarily mean that the child is not experiencing pain. Parents know their child best and are familiar with typical behaviors.

- Implement pharmacologic and biobehavioral interventions to alleviate the pain (see Chapter 10). Use a preventive approach to keep pain at or below an acceptable level. Involve the family in pain management.

Unrelieved pain has deleterious physiologic effects such as tachycardia, suppressed immune function, and atelectasis, as well as negative psychological effects. Pain is better managed if it is not allowed to escalate. If the family can provide measures, that approach may be more comforting to the child than if measures are provided by nursing staff.

- Reassess pain level and evaluate effectiveness of interventions frequently.

Frequent assessments are required to control the pain; children respond differently to interventions, so what is effective for one may not be for another.

Expected Outcomes

- Child will express a feeling of improved comfort or demonstrate pain relief through playful, smiling, responsive behaviors.
- Child and family will perform measures to relieve pain and comfort child.

Nursing diagnosis: Risk for infection related to wound or open lesion

Interventions/Rationale

- Observe for signs and symptoms of infection (e.g., malodorous wound drainage, elevated leukocyte count, elevated temperature) and signs and symptoms of septicemia (e.g., positive blood cultures, hemodynamic changes).

Loss of the first line of defense (skin) and formation of eschar provides an excellent culture medium for growth of infectious bacteria.

- Obtain culture and sensitivity results from blood, wounds, and lesions as indicated.

Determines the presence of bacteria, fungal, or viral agents that may colonize and cause infection or septicemia. Determines sensitivity of causative agent to indicate most appropriate type of medication to treat the condition.

NURSING PLAN OF CARE 25–1 CHILD WITH ALTERED SKIN INTEGRITY (CONTINUED)

- Use aseptic techniques when managing external lines and tubes, and when providing skin and wound care. Ensure that staff and visitors use universal precautions.

Multiple exogenous factors contribute to the risk of infection (e.g., Foley catheter, IV, central venous catheters) as well as nonadherence to aseptic practices by staff and visitors. Universal precautions will help prevent transmission of child's infection to others.

- Administer antibiotics, topical antimicrobials, and bacteriostatic agents as ordered; evaluate and document effectiveness.

Provides mechanism to treat causative agent and underlying pathology.

Expected Outcomes

- Child's vital signs, temperature, and laboratory values will remain within normal parameters.
- Child's wound or lesion site will remain free of signs and symptoms of infection.

Nursing diagnosis: Disturbed body image related to real or perceived disfigurement caused by a skin condition

Interventions/Rationale

- Convey positive attitude about child; reinforce positive aspects of child's appearance and abilities.

Child may be very self-conscious because of altered appearance related to skin condition. Positive feedback may enhance self-esteem.

- Help child to express feelings about current status, fears for the future; listen actively. Incorporate other healthcare personnel as appropriate.

Fears and concerns may be real or unfounded, but in any case the child will benefit from opportunities to discuss feelings and to develop a repertoire of coping strategies.

- Assist child to find methods to enhance physical appearance, personal comfort, and daily management of skin condition.

Promotes active adaptation to condition, with variety of coping strategies to enhance self-esteem and to promote normalization in daily life.

Expected Outcomes

- Child will verbalize concerns regarding changes in body appearance or function.
- Child will express positive feelings about self.
- Family members will acknowledge variations or changes in child's appearance and verbalize acceptance of child.

- Child and family will institute measures to positively affect child's appearance (makeup, selection of clothing).

Nursing diagnosis: Effective therapeutic regimen management related to demands of healthcare associated with chronic or acute skin condition

Interventions/Rationale

- Encourage participation and cooperation in care; reward all efforts; give choice and control over situation as appropriate.

Minimizes perception of powerlessness. Maximizes personal responsibility of child for daily care.

- Provide predictability for the child (e.g., do procedures/skin care at consistent time and place).

Diminishes fears of unknown. Routine establishes structure and demonstrates how skin care can be incorporated into daily cares of child's life.

- Provide child and family education regarding skin care needs of child. Ensure that opportunities for redemonstration are provided and encourage family involvement in care prior to discharge.

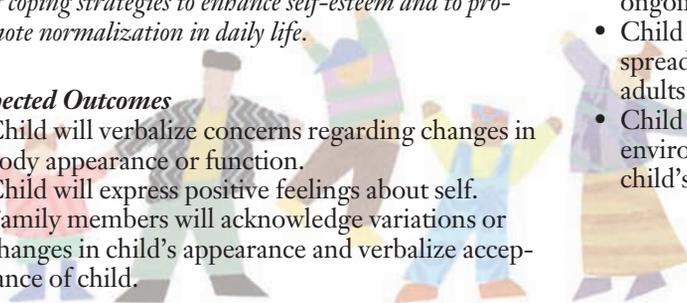

Ensures that child and family are comfortable with providing skin care measures and are capable of managing child when away from the healthcare setting. Validates that family will comply with treatments.

- Develop a plan with the family to prevent or minimize exacerbations of child's skin condition, prevent occurrence of infections, and/or prevent communicable transmission of skin condition.

Identifies modifications in the home and child's social environments that may be required to protect child from recurrence or exacerbation of conditions. Provides concrete measures to protect other children and adults from causative agents.

Expected Outcomes

- Child and family will recognize child's need for ongoing management of skin condition.
- Child and family will take measures to prevent spread of skin condition to other children and adults.
- Child and family will institute measures to alter environmental factors that may exacerbate the child's skin condition.

ANSWER: Several nursing diagnoses are appropriate, including discomfort, risk for infection, and deficient knowledge regarding identification of poison ivy. However, “impaired skin integrity related to exposure to an environmental hazard” is the most comprehensive diagnosis. Appropriate outcomes include, “Child shows improvement in skin integrity.”

ALTERATIONS IN SKIN INTEGRITY

Alterations in skin integrity can result from a variety of sources and have implications for the overall health of the child.

NEONATAL SKIN LESIONS

Skin lesions unique to neonates may be congenital or acquired. Acquired skin disorders include transient skin rashes, infestations, and infections. Acquired lesions usually have a short, benign course, although some neonates may be critically ill if involvement of other body systems is extensive.

Congenital abnormalities, which include hemangiomas, vascular malformations, and disorders of pigmentation, may pose specific problems because of their location on the body, their relation to other associated developmental defects, and their disfiguring appearance.

This section reviews some of the congenital lesions and common transient rashes found in the newborn population. Infestations and infections such as scabies, candidiasis, herpes simplex, and impetigo are discussed in subsequent paragraphs and are not unique to newborns.

Vascular Birthmarks

Vascular malformations are caused by errors in vessel morphogenesis during embryogenesis, are virtually always visible from birth, and modify only slowly, over years or decades (Blei, 2005). Affecting vascular or epidermal tissue, birthmarks can vary in the degree to which they cause more serious physical problems. Vascular lesions in infants and children are broadly classified as hemangiomas and vascular malformations (Table 25-4). Hemangiomas are benign, vascular proliferations that rapidly enlarge during the first year of life, with slowing of growth during the next 5 years (Fig. 25-3). Involution, or natural degeneration of the tissue, occurs by 10 to 15 years of age (Herzog, 2007). Vascular malformations are developmental anomalies of blood or lymphatic vessel formation (Figs. 25-4 and 25-5).

Vascular birthmarks may range from relatively minor conditions, causing little if any disfigurement and pathologic consequences, to severe and potentially life-threatening conditions with visible skin alterations. The child’s self-concept and development of body image may be negatively affected based on how parents and others respond to the child’s condition and how the child perceives he or she is valued by others. Many of the conditions may regress spontane-

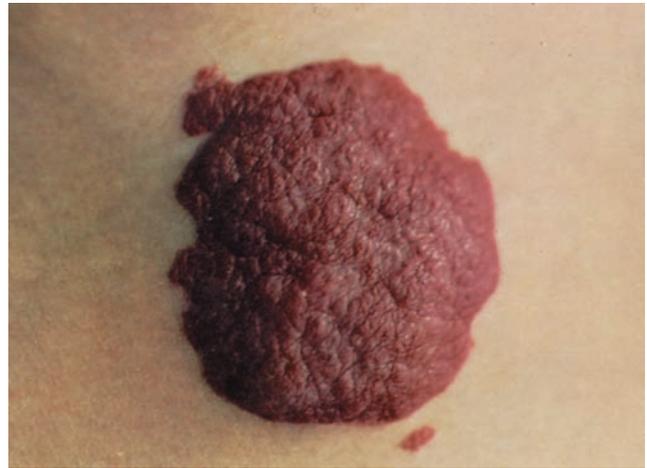

FIGURE 25-3. Strawberry hemangiomas.

FIGURE 25-4. Salmon patch. When located on the nape of the neck (as shown here), these lesions are also referred to as *stork bites*.

FIGURE 25-5. Port-wine stain.

TABLE 25-4

Characteristics of Hemangiomas and Vascular Malformations

Characteristic	Hemangiomas	Vascular Malformations
Types	Classified as <ul style="list-style-type: none"> • Superficial (capillary or strawberry hemangioma) • Mixed (capillary–cavernous) • Deep (cavernous) New classification system <ul style="list-style-type: none"> • Localized • Segmented • Indeterminate • Multifocal 	Capillary (port-wine stain) Telangiectatic (salmon patch) Hypertrophic capillary (angiokeratoma) Venous Arteriovenous Lymphatic Cutis marmorata telangiectatica Mixed
Etiology	Tumor of endothelial cells	Developmental anomaly
Growth	Rapid growth phase lasts several months (up to age 1), followed by spontaneous regression by ages 6 to 9. Lesions usually do not more than double in size.	Slow, stable growth as child grows Does not fade or disappear over time
Incidence	Female predominance ranges 3:1 to 5:1	Ratio of male to female, 1:1
Presence at birth	Only 20% of lesions are seen at birth as blanched or erythematous macules; most appear at about 1 month of age.	Always present at birth, but may not be entirely evident
Clinical presentation	Lesion has a well-demarcated, hypopigmented flat area. Small telangiectatic vessels may course across the lesion. Color may be erythematous or white. During involution, lesion becomes pale centrally with lacy gray regions within the lesion.	Flat, cutaneous vascular lesion, possibly with a subcutaneous component
Associated complications and syndromes	Obstruction of vision Obstruction of respiration Thrombocytopenia Disseminated intravascular coagulation Infection Congestive heart failure Kasabach-Merritt syndrome Diffuse neonatal hemangiomatosis Maffucci's syndrome Gorham syndrome Blue rubber bleb nevus syndrome Bannayan-Riley-Ruvalcaba syndrome	Glaucoma Sturge-Weber syndrome Beckwith-Wiedemann syndrome Klippel-Trenaunay syndrome Parkes-Weber syndrome Cobb syndrome
Treatment	Observation (most regress spontaneously) Corticosteroids (for visual or respiratory obstruction) Interferon alpha Surgical resection Embolization (for arteriovenous complications) Vascular-specific pulsed dye laser therapy	Observation Cosmetics as camouflage Tattooing (with flesh-colored insoluble pigments) Vascular-specific pulsed dye laser therapy

Sources: Chiller, Passaro, & Frieden (2002); Gampper & Morgan (2002); Herzog (2007); and Miller & Frieden (2005).

ously over time. Several treatment measures are available to help remove the lesion and cope with associated complications such as visual impairment and pulmonary obstruction. Nursing interventions include managing pain associated with surgery or laser therapy and assessing for complications of treatments (e.g., scarring, infection, hyperpigmentation). Response to therapy is slow. Assist the child and the parents to learn how to deal with the uncomplimentary comments made by others and with strategies to build the child's self-esteem.

Pigment Abnormalities

The amount and distribution of melanin in the epidermis account for the color of a person's skin. An alteration in melanin production, and the resulting hyper- or hypopigmentation, generally cannot be treated. Other manifestations of the underlying condition may be treated if their sequelae are threatening to the well-being of the child.

Hyperpigmentation

Hyperpigmentation lesions are common at birth and may present during the first few weeks of life. Hyperpigmented lesions include mongolian spots, café-au-lait spots, and freckles (Fig. 25–6). Mongolian spots are blue-black macules or patches commonly located on the lumbosacral area. They are most common in Asian, black, and Hispanic infants. The sacrococcygeal area is most commonly affected, but lesions may occur on the buttocks, dorsal trunk, or extremities. Mongolian spots generally fade by age 2 to 3 years, although some traces of the lesions may persist into adulthood.

Café-au-lait spots are well-circumscribed, light-brown oval macules that may appear anywhere on the body. On black skin, the color of the spots may appear more dark brown. Black infants are more likely to have café-au-lait spots than white infants. The spots persist through childhood and may increase in number. Café-au-lait spots are a feature of several systemic disorders such as polyostotic fibrous dysplasia (large, usually solitary spot) and neurofi-

FIGURE 25–6. Mongolian spots are blue-black macules located on the lumbosacral area. Café-au-lait spots are light-brown oval macules that may appear anywhere on the body.

bromatosis (more than five spots). The significance of café-au-lait spots, therefore, may be as a diagnostic tool to other disorders, because treatment for this actual abnormality is generally unnecessary.

Hypopigmentation

Hypopigmentation occurs in newborns with phenylketonuria. These newborns have blond hair, blue eyes, and light-colored skin. The hypopigmentation is caused by the tight binding of the amino acid phenylalanine to the receptor sites of tyrosinase, which then does not allow the enzyme to oxidize phenylalanine to melanin (Weston et al., 2007).

Pigment loss is also a significant feature of *albinism*, a group of 14 syndromes characterized by congenital pigment loss in the skin, hair, iris, and retina. Nystagmus, strabismus, photophobia, decreased visual acuity, and astigmatism are common ocular findings. Blindness and skin cancer may occur in severe forms of albinism.

Neonatal Acne

Acne that is similar in distribution and appearance to adolescent acne may occur at birth, and usually disappears within the first several weeks of life. However, this acne—small red bumps on the face, trunk and extremities—can last as long as 6 months.

Alert! If blisters or pimples appear on the infant's skin, examine them immediately; the cause may be herpes simplex.

No treatment is usually required because the condition is self-limiting. Antiacne medications are not recommended; however, topical benzoyl peroxide creams, gels, or washes are generally safe and effective. Parents are cautioned not to apply baby oil or other ointments to the skin as a curative measure. The relationship (if any) between severe neonatal acne and severe adolescent acne later in the child's life is unknown.

Milia

Milia are multiple, white or yellow, 1- to 2-mm papules appearing on the infant's cheeks, nose, chin, forehead, and occasionally the upper trunk and limbs. They can also appear on the midline of the palate where they are called *Epstein pearls*. These superficial epidermal cysts are caused by the blockage of the pilosebaceous glands by keratin and sebaceous materials. Although milia that appear on the face and limbs look like pimples, they are not infected.

Milia usually spontaneously disappear at age 1 to 2 months. Advise parents not to apply cream or lotion to the lesion sites and not to squeeze or pick the lesions with a sharp instrument.

Drooling Rash

Transient rashes commonly develop on the chin or cheeks of an infant. Such rashes are similar to those seen in other cases of contact dermatitis, with erythema,

edema, and vesicles likely. Two factors may cause the dermatologic changes. The first may be contact of the child's delicate skin with his or her own vomitus. The young infant is prone to wet burps, in which the food and the acid from the stomach contents may erupt and drool down the chin or, during sleep, may be absorbed into bed linen, resting against the cheeks. Some of this contact between the fluid and the skin may be averted by placing an absorbent diaper under the infant's face during naps and by rinsing the infant's face after feedings.

A drooling rash can also be caused by contact between the infant's cheek and the mother's breast during nursing. Changing the infant's position frequently and placing a cool washcloth on the infant's cheek will help to decrease the incidence of this rash.

Erythema Toxicum Neonatorum (ETN)

Erythema toxicum neonatorum (ETN), or neonatal erythema, is one of the more well-known benign, self-limiting skin eruptions seen during the newborn period. Incidence estimates range from 50% to 70% of all healthy newborns (Marchini et al., 2005). It is virtually never seen in premature infants or those weighing less than 2,500 g. ETN occurs worldwide with no apparent gender, ethnic, racial, or seasonal predisposition (Eichenfield et al., 2008).

Most cases of ETN occur within 24 to 72 hours after birth, although lesions can erupt any time during the first 2 weeks of life. These lesions may wax and wane, usually lasting no longer than a week. The cause of ETN is unknown. Medications and the mode of feeding and skin care do not correlate with the emergence of the condition. It has been postulated that the skin appendages, especially the hair follicles, might act as an entry for microbes. The presence of these microbes then elicits a local and systemic response, leading to the classic skin eruptions (Marchini et al., 2005).

Assessment

Within the first few days after birth, ETN manifests as combinations of erythematous macules, papules with a central vesicle, or pustules, ranging in size from a few millimeters to several centimeters, found anywhere on the body except the soles of the feet and the palms of the hands (Fig. 25-7). The classic eruptions consist of barely elevated yellowish papules or pustules (1-3 mm in diameter) with a macular flare similar to a flea bite. Common locations include the face, trunk, buttocks, and extremities. Lesions are discrete but can become confluent. Lesions that begin as macules often turn into pustules. Individual lesions may appear for a few days and then disappear. The rash usually remits within 1 week, although persistence beyond this period has been seen in some cases. In some cases, however, recurrences may occur within 5 to 11 days after the initial eruption. The secondary eruption is not as extensive as the original rash.

Diagnosis of ETN depends on microscopic examination of the lesions. In the diagnostic test of choice, scrapings of pustules are stained with Wright's solution. If

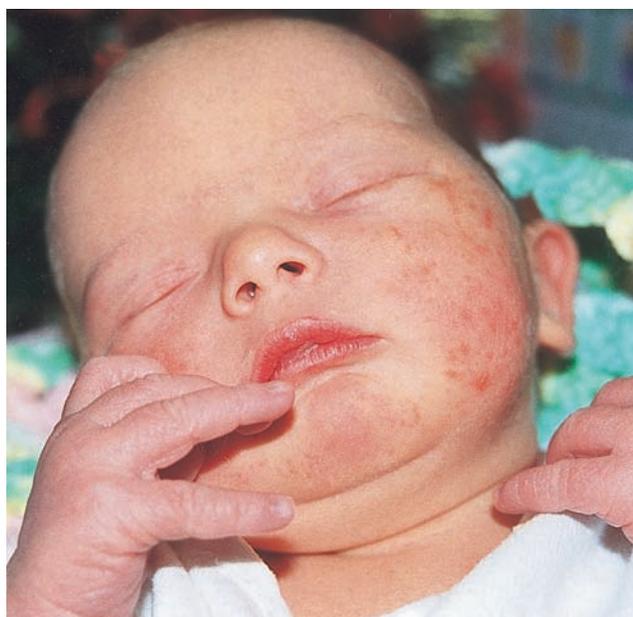

FIGURE 25-7. Erythema toxicum neonatorum.

ETN is present, large numbers of eosinophils are detected. Also, microscopic examination of macules shows an accumulation of eosinophils in the dermis. However, neutrophils are rarely present. Cultures of lesions are sterile. A crucial factor differentiating ETN from other skin disorders is that, aside from eruption of the lesions, the neonate displays no other systemic involvement such as fever, lethargy, or poor feeding.

Interdisciplinary Interventions

Treating ETN is usually unnecessary, and lesions usually fade within 1 week. Monitor the affected neonate to ensure that the rash fades within 1 week. The persistence of lesions beyond this period could indicate the presence of another skin disorder such as transient neonatal pustular melanosis, herpes simplex virus, *Staphylococcus aureus* infections, or candidiasis.

INFLAMMATORY SKIN DISORDERS

Dermatitis is a general term for skin conditions that present with erythema or with erythema accompanied by scaling, vesicles, or crusting. Four common types of dermatitis are discussed: diaper, contact, atopic, and seborrheic. Each type involves different causes, characteristics, and treatment plans.

Diaper Dermatitis

Diaper dermatitis, or *diaper rash*, is one of the most common skin rashes occurring during infancy. Diaper dermatitis is a type of irritant contact dermatitis (ICD). Because of its prevalence and specificity of interventions, the condition is discussed separately from contact dermatitis.

The exact incidence of diaper dermatitis is difficult to specify because less than 10% of episodes are referred for

treatment to a healthcare provider (Bell, 2006). Most children have at least one episode of “diaper rash” during infancy, especially during a bout of gastroenteritis. Diaper dermatitis is most likely to occur within the first 2 years of life, peaking at age 6 to 9 months because of the change in dietary intake (Nield & Kamat, 2006).

Pathophysiology

Prolonged contact with an irritant, most commonly feces, urine, soaps, detergents, alcohol wipes, ointments, or friction, is a major contributing factor in diaper dermatitis (Adalat, Wall & Goodyear, 2007). However, an irritant alone does not cause diaper dermatitis; rather, the problem results from a combination of factors generated by the presence of the diaper. Urinary ammonia was once believed to be the primary etiologic factor for diaper dermatitis, but recent research has indicated that urine itself is not detrimental. It was found that urine and fecal enzymes interact to liberate ammonia and increase pH. Excessive alkalinity makes fecal protease and lipase even more irritating to the infant’s skin, contributing to diaper dermatitis.

Wet skin also plays a role in the pathogenesis of diaper dermatitis. Wet skin is more easily abraded and more permeable, and it has an increased microbial count. This situation can be exacerbated by alkaline soaps used to clean cloth diapers. The wet diaper also increases friction with the wet skin. The average newborn urinates approximately 20 times in one day, creating an environment in which wet skin rubs against a wet diaper.

Irritated, cut, or chapped skin is a contributing factor to diaper dermatitis. Skin breaks that breach the stratum corneum are even more susceptible to the combination of previously mentioned deleterious factors. When lesions or open wounds become infected, candidiasis may be a major culprit. *Candida albicans* can be cultured or recovered from the skin of 40% to 75% of infants with diaper dermatitis. It is rarely found in infants with healthy, unbroken skin (Borkowski, 2004).

Assessment

The affected skin over the diaper area can take various configurations. In general, it is bright red, swollen, and sharply margined; however, it may also have a glazed and wrinkled appearance (Fig. 25–8). There may be papular, vesicular, or bullous lesions, fissures, and erosions. If candidiasis develops, the rash consists of erythematous papular eruptions with satellite lesions. Diaper dermatitis rarely occurs in groin creases.

An infant with diaper dermatitis acts fussy and exhibits trouble sleeping and, in severe cases, even has difficulty with eating. Diaper changes can be extremely painful, especially if commercial diaper wipes are used for cleansing the genital area. Commercial wipes may contain alcohol and allergenic substances that may further irritate the child’s skin.

Interdisciplinary Interventions

If dealt with promptly, diaper dermatitis is usually self-limiting. However, severe cases, indicate the need for fur-

FIGURE 25–8. Diaper dermatitis.

ther assessment and intervention to improve diapering practices and to identify causative agents. Treatment strategies involve differentiating irritant dermatitis versus candidiasis or staphylococcal infections. For mild irritant dermatitis, cleansing the soiled diaper area with a mild cleanser and protecting the skin with a **barrier cream** (e.g., petrolatum, zinc oxide, dimethicone) is sufficient (TIP 25–1). Current practice recommends not using baby powder or talcum powder for many reasons, including possible inhalation into the infant’s lungs, which could precipitate aspiration pneumonia. If a powder is used, one with cornstarch is recommended, with the powder being placed in the hand and then applied to the skin (Tradition or Science 25–3).

caREminder

If the skin underlying the cream is clean, the cream does not have to be completely removed with each diaper change; rather, lightly wiping the area with a washcloth and mild cleanser is sufficient. The ointment prevents maceration and protects the skin from urine and feces. Ensure that the ointment is rubbed well into the skin, so it serves as a true barrier.

Medical therapy is not usually required for diaper dermatitis, unless secondary infections develop.

Alert! If steroid creams are ordered, they should be of a low potency (0.5%–1%), nonfluorinated type. High-potency steroids are rapidly absorbed through the infant’s thin skin and can cause systemic toxicity (Borkowski, 2004). Take special care to avoid using combination products (e.g., antifungals and steroids) without verifying that the steroid is of the low-dose type.

TRADITION OR SCIENCE 25–3

Should “baby powder” be used during diaper changes?

MORE INQUIRY NEEDED

The use of baby powders containing talc (known as talcum powder) can cause accidental aspiration, pneumonia, and death (Brouillette & Weber, 1978; Moss, 1969). Aspiration is predominantly caused when the baby receives a “puff of smoke” when the powder is shaken from the container directly onto the baby’s skin. In addition, the use of talcum powder is abrasive and is considered to contribute to the pathogenesis of diaper dermatitis (Atherton, 2004). Infants generally do not need any powder products on their diaper area. If the parent wants to use a powder, cornstarch is an acceptable alternative to reduce friction in the diaper area. When wet, however, the cornstarch can clump and retain moisture on the skin. There is some controversy regarding cornstarch. Some sources recommend not using it because microorganisms metabolize the cornstarch and aggravate yeast infections (Janniger et al., 2005). If the parent still desires to use talcum powder, it should be applied by shaking it on the parent’s hands first, as far away from the baby’s head as possible. All talcum powder containers should be closed and stored in a safe place, away from curious infants and young children. The parent should not self-administer talcum powder in an infant’s or young child’s presence.

Contact Dermatitis

QUESTION: Is Nick’s rash an irritant contact dermatitis or an allergic dermatitis?

Contact dermatitis is an inflammatory skin condition involving a cutaneous response occurring when human skin is exposed to certain external natural or synthetic substances. Contact dermatitis is classified as either irritant contact dermatitis (ICD) or allergic contact dermatitis (ACD).

In older children and adults, ICD most commonly results from exposure to irritants such as manufacturing processes, insecticides, or hobby supplies. In infants and young children, ICD is most commonly associated with saliva that causes a drooling rash or contact with abrasive soap and irritating detergents (Chart 25–1).

ACD results from a T cell-mediated hypersensitivity reaction. The allergic reaction is commonly caused by exposure to plants (e.g., poison ivy, sumac, oak), nickel (in jewelry, dental appliances, metal fasteners), latex, animal fur, feathers, vegetable oils, synthetic fabrics, cosmetics, and perfumes or scented soaps that contain the offending allergen. As many as 20% of all dermatologic conditions in children are now thought to be ACD (Vozmediano & Hita, 2005). ACD can occur in neonates, because sensitization to an allergen and dermatitis can occur in as few as 10 days. The incidence of ACD is greatly increased

CHART 25-1 COMMON CAUSES OF CONTACT DERMATITIS

Irritant Contact Dermatitis

- Saliva
- Citrus juices
- Bubble bath
- Soaps, detergents, and body lotions with fragrances
- Abrasive materials
- Strong soaps
- Occlusive shoes
- Hobby supplies
- Insecticides
- Manufacturing agents

Allergic Contact Dermatitis

- Poison oak, poison ivy, and poison sumac
- Nickel (jewelry, buckles, clothing snaps)
- Pierced earrings
- Potassium dichromate (shoes, tanning agent)
- Neomycin
- Thimerosal, formaldehyde, and Quaternium 15 (preservatives and topical agents)
- Balsam of Peru (fragrance)
- Wood alcohol (lanolin)
- Colophony (rosin from wood)
- Latex
- Products containing formaldehyde (e.g., specific baby wipes, styling gel, shampoos)

Alert! The increased popularity in body piercing has led to an increase in allergic reactions related to nickel. Sensitization to nickel appears to increase with the number of piercings. For those with a suspected or diagnosed nickel allergy, test kits are available to identify the presence of nickel in a product (Copeland, deBey, & Hutchison, 2007).

after age 8 years. Children at high risk for ACD reactions include those with a personal or family history of hay fever, AD (eczema), and asthma. Other risk factors include preexisting skin diseases, poor personal hygiene, and very dry-hot or dry-cold environmental conditions.

Pathophysiology

In ICD, the irritating substance causes a nonspecific inflammatory reaction in the skin. Individual skin strength, concentration (dose) of the offending substance, and length of contact all contribute to the severity of reaction. Prolonged or repeated exposure to an irritating substance

results in erythema and the potential for skin breakdown and lesions. A detailed health history, evaluation of the involved sites, and the child's age all can provide clues regarding the nature of the irritating substance.

ACD is caused by an allergen that penetrates the epidermis from the skin surface. An interaction between the T-lymphocyte component of the cellular immune system is mediated by antigen-presenting epidermal cells (Langerhans cells). When the antigen penetrates the skin, it is conjugated with a cutaneous protein and transported to the regional lymph nodes by the Langerhans cells. A primary immunologic response occurs locally in the nodes as the sensitized T cells circulate throughout the body. This process is called the *sensitization phase*. The duration of this phase depends on the potency of the allergen. For example, the oil urushiol, the offending agent in poison ivy, penetrates the epidermis, bonds with the dermis, and initiates the immune response usually after only one exposure. (Poison oak, poison ivy, and sumac are discussed in more detail in subsequent paragraphs of this chapter.) After sensitization occurs, children who are exposed to repeated contact by the same antigen experience an inflammatory reaction (ACD) within 8 to 24 hours. Children can remain sensitized to a certain allergen for many years.

Prognosis

The prognosis for contact dermatitis is very good if the offending substance is identified and exposure to the substance is prohibited. If the offending agent is removed, the skin's recuperative powers produce healing without treatment within 1 to 2 weeks. In more severe cases of ACD, the untreated dermatitis persists for 3 to 4 weeks. Any time a child has a break in the skin, risk for secondary infection is present. Therefore, prompt attention to the dermatitis and measures to stop exposure to offending agents should be instituted to prevent further alterations in skin integrity.

ANSWER: Nick's rash is an ACD caused by the body's allergic response to the oil or resin of the plant (urushiol). Poison ivy is unusual in that approximately 85% of the population will have an allergic response (American Academy of Dermatology, 2008).

Assessment

Nurses are often the first to identify contact dermatitis during the history-taking process or physical examination. Contact dermatitis usually occurs in exposed skin areas: the face, neck, hands, forearms, legs, and feet. A characteristic inflamed response varies from erythema to large bullae on a reddened base and edema. The lesions may be well demarcated, exactly resembling the shape and size of the offending substance (e.g., red marks on the abdomen the size and shape of pajama snaps). Itching is intense and constant.

Diagnosis of contact dermatitis depends on a thorough history. Patch testing may be indicated if the etiology is not apparent (see Tests and Procedures 25–1). In addition to testing for the suspected allergen, the child undergoes testing with a standardized tested group of allergens that have been recognized by several medical associations

as the most frequent causes of ACD. The classic positive patch test consists of erythema, edema, and small vesicles that do not extend beyond the border of the patch. Results must be examined within the context of the history and of the physical examination. A positive test does not necessarily mean that the identified allergen is responsible for the child's current dermatitis, although it does indicate that the child has a sensitivity to a particular allergen. Skin cultures and biopsy may be used to rule out herpes simplex virus and staphylococcal infections.

Interdisciplinary Interventions

Untreated ACD slowly resolves over a 3- to 4-week period if contact with the allergen is avoided. Treatment for the itching and edema may include the use of Aveeno baths, calamine lotion, or Burow's solution compresses. Mild- (0.5%–1%) to medium-potency (0.1%–0.2%) topical glucocorticoid may relieve inflammation and hasten the healing process. Oral corticosteroids may be prescribed for more severe reactions. Antihistamines may be ordered to decrease itching. If infected lesions are present, antibiotic therapy is usually initiated.

Community Care

QUESTION: What is the role of the nurse in educating the community about poison ivy?

Teach children and parents ways to prevent contact dermatitis. First, they should remove the irritating and allergy-triggering substance from the home and school environment. Second, the child should wear protective clothing to minimize exposure to irritants, especially with plant allergies and caustic materials. After a contact allergen is confirmed by patch testing, the child must avoid all products or substances containing that allergen. Lists of products that contain the offending agents are usually available from a dermatologist. Teach the family how to read product labels to ensure that the allergen is not present.

Teach children and families proper skin hygiene, and emphasize that using mild antibacterial soaps and moisturizers can help to prevent painful scaling and cracking of the skin that can lead to a secondary infection, such as impetigo. The presence of a skin allergy may necessitate some restrictions of the child's activities to prevent contact with the offending agent. Young children may not understand or tolerate the limitations on their activities. Parents can assist by providing enjoyable play alternatives for the child and by reinforcing the cause-and-effect relationship between the child's exposure to the irritant and the eruption of the skin rash.

ANSWER: Prevention is the most effective approach with poison ivy. Nurses can be instrumental in providing information to individuals, families, and organizations (e.g., Boy Scouts) concerning plant identification, properties of urushiol, strategies to use if one does come in contact with the plant, and products that are available to reduce the impact of contact. For example, when urushiol is transferred to an inanimate object, such as a ball, garden tools, and camping equipment, it can remain potent for months.

Atopic Dermatitis (AD) (Eczema)

AD is a chronic, relapsing inflammation of the dermis and epidermis characterized by itching, edema, papules, erythema, excoriation, serous discharge, and crusting; it is a noncontagious condition that generally begins during infancy or early childhood. The term *atopic* refers to the fact that patients exhibit a heightened reaction to a variety of allergens. To the lay public, the condition is commonly known as *eczema*. The term *eczema* describes the combination of erythema, scaling vesicles, and crusts. Eczemalike lesions occur in several skin diseases; hence, the term *atopic dermatitis* is used in this book. AD is categorized into three stages according to the child's age (Developmental Considerations 25–3).

Incidence

AD is a fairly common health problem. Research has indicated that about 50% of infants who develop AD will do so within the first year of life, and that the prevalence has increased such that 20% to 25% of all 5- to 10-year-old children are affected (Cohen, 2007). Males and females are equally affected, and AD is more common in industrialized cities and in white and Chinese populations. Allergies have been thought to cause AD; however, research has not borne out a definitive association between AD and food allergies (Cohen, 2007).

A number of factors exacerbate AD, including sudden changes and extremes of temperature, irritating fabrics such as wool, excessive exercise that induces sweating, and direct contact with irritants such as detergents and perfumes. AD is also commonly associated with the

ingestion of certain foods, such as dairy foods (Schuerman & Vezeau, 2007).

Etiology

The exact etiology of AD is unknown, and may vary from child to child; however, it is part of the atopy syndrome that includes asthma, hay fever, and rhinitis/allergic rhinitis. Theories that have been proposed to describe the origin of AD include the inborn error of metabolism theory, the psychosomatic theory, and the immunologic theory. The first theory postulates that AD patients have a metabolic skin defect that causes excessive itching. The psychosomatic model holds that AD is caused by underlying stress and psychological dysfunctioning in the life of the child. The immunologic theory postulates that interactions between genes and environment contribute to the development of atopy (Dohil & Eichenfield, 2005; Eichenfield et al., 2008).

WORLDVIEW: The worldwide increase in the incidence of AD, which has paralleled an increase in asthma prevalence, is of great concern to clinicians. An increase in prevalence of both conditions is thought to be attributable to influences of the western lifestyle, urbanization, and development. Industrialized western countries have seen an increasing prevalence of AD during the past 30 years. This prevalence is higher in western countries than in others, higher in industrialized countries with a market economy than in underdeveloped countries, higher in urban areas than in rural areas, and higher among privileged socioeconomic groups and smaller families. Epidemiologists believe that lifestyle changes prevalent in western countries combined with increased environmental exposure to pollutants have influenced the "allergy pandemic" (Cohen, 2007; Eichenfield et al., 2003).

DEVELOPMENTAL CONSIDERATIONS 25–3

Stages of Atopic Dermatitis

Infantile Stage

Age 2 to 6 months, resolving in half of children between ages 2 and 3 years

Characteristics

Pruritus
Erythema
Exudate and crusts
Common sites: cheeks, forehead, scalp, extensor surfaces of arms and legs
Diaper area not usually involved

Childhood Stage

Age 4 to 10 years or following on continuously from infancy stage

Characteristics

Less exudate than the previous stage
Dry, itchy patches of skin
Common sites: wrists, ankles, antecubital and popliteal spaces

Adolescent and Adult Stage

Age 11 years and older

Characteristics

Exudation caused by external irritation or secondary infection
Dry, itchy patches of skin
Common sites: flexor folds, face, neck, back, upper arms, and dorsal aspects of the hands, feet, fingers, and toes

Pathophysiology

Current research indicates that eczema is at least, in part, an allergic disease that manifests as an exaggerated inflammatory response to environmental triggers. Studies indicate that this response is accompanied by an increase in serum immunoglobulin E (IgE) levels and eosinophilia (Eichenfield et al., 2008; Roos et al., 2004; Ross, 2003). In addition to increased IgE levels, patients with AD have other immunologic abnormalities, such as reduced cell-mediated immune responses and slow chemotaxis of both neutrophils and monocytes (Arndt & Hsu, 2006). Numerous theories have been advanced regarding the mechanism of inflammation in AD; they center around excessive T-cell stimulation, increased macrophage and monocyte activity, and cytokine stimulation, and on abnormalities in histamine production, which are increased in the skin (Arndt & Hsu, 2006; Eichenfield et al., 2008).

Prognosis

Prognosis for this condition is optimistic. The condition may resolve spontaneously, especially in those children with milder cases who are able to effectively avoid environmental triggers. In general, the exacerbations become less frequent after adolescence and most of these children can enjoy long periods in which they experience no symptoms. Up to 80% of children with AD will eventually develop allergic rhinitis or asthma later in childhood (Eichenfield et al., 2003).

Assessment

Diagnosis of AD depends on a review of history and dermatologic and behavioral findings, and age. Most children have a family history of allergy (e.g., asthma, allergic rhinitis, food). The infantile form has lesions that are generalized on the trunk, scalp, cheeks, and extremities. The disorder spares the perioral and nasal areas. During childhood, the lesions occur in body creases such as the wrists, ankles, feet, and antecubital, flexural surfaces, and popliteal fossae. In the adolescent form, the face, feet, hands, flexural surfaces, and neck are affected.

The types of AD lesions also vary according to age. In the infantile form of the disorder, they include scaling, crusting, weeping, erythema, vesicles, papules, and oozing. In the childhood form, symmetric distribution of small erythematous papules or patches occurs along with lichenification (hardening of the skin) and hyperpigmentation. In adolescents, the pattern is similar to the childhood form, except that dry, thick plaques are more common.

Other accompanying symptoms that produce the most distressing components of AD including intense itching, drying of the unaffected skin areas, restlessness, irritability, lymphadenopathy, and other signs of allergic response (such as a bluish discoloration under the eyes). Many authorities believe that the intense itching and the resultant scratching (the “itch–scratch” cycle) are the main conditions that generate the lesions. If scratching is controlled, the lesions heal. No laboratory tests are diagnostic for AD, although increased eosinophil counts and serum IgE are common findings.

caREminder

Differentiate between itch and scratch when determining nursing interventions. Itch is the underlying physiologic symptom that results in scratching, which, in AD, can lead to pain, excoriations, and skin breakdown. Scratching is a reflex action that is controlled at the spinal cord level and is, therefore, difficult to prevent in the presence of itch.

Interdisciplinary Interventions

The major goals of therapy are to prevent, alleviate, or control itching; reduce inflammation; hydrate the skin; avoid recurrence; and prevent secondary infection (TIP 25–2). Medical interventions do not cure this condition, but effective palliation can be achieved. Ensure that both child and parents understand that AD is both chronic and recurring. This knowledge can avoid concerns that therapy was withdrawn too soon and may diminish some anxiety when flare-ups occur.

The American Academy of Dermatology has an algorithm for AD treatment (see [thePoint](#), Evidence-Based Practice Guidelines). By carefully controlling or reducing the exacerbations, and by diligently managing inflammation and **pruritus** (itching), the child or adolescent can have a normal lifestyle.

Frequently rehydrating the skin is a key element of the treatment regimen. To maintain healthy skin in the child with AD, hydration practices should be implemented to replace moisture in the stratum corneum and to prevent transdermal water losses. The numerous types of emollient therapies continue to be the cornerstone to successfully managing AD and are continued even in the absence of overt disease. To reduce inflammation, topical *low-dose corticosteroids* are administered to the affected area (Nursing Interventions 25–2). Topical ointments should be considered as treating the current symptom and not curative. In fact, relapse and rebound of the skin disease may occur when treatment is discontinued. Furthermore, the potent anti-inflammatory actions of these medications increase susceptibility to bacterial and fungal infections (Dohil & Eichenfield, 2005; Mancini, 2007; Wong et al., 2003). Systemic corticosteroids are rarely used; consequences include hypopigmentation, acne, secondary infection, and stretch marks.

Newer medications, and those considered as treating the underlying cause, are the topical nonsteroidal creams called *topical calcineurin inhibitors* (e.g., tacrolimus, pimecrolimus) (Dohil & Eichenfield, 2005; Roos et al., 2004). These compounds inhabit inflammatory cytokines within the immune system, which in turn decreases T-cell activation (Connelley & Eichenfield, 2004; Wellington & Noble, 2004). *Tar preparations* can also be applied to the skin. These agents have a slower anti-inflammatory action than corticosteroid therapy and have fewer side effects. The use of *antihistamines*, both first (e.g., Benadryl) and second (e.g., Zyrtec, Allegra, Claritin) generation, may be considered for their antihistamine effect and their ability to help control itching. *Oral anti-infective therapy* may be indicated, because *S. aureus* colonization

TIP 25–2 A Teaching Intervention Plan for the Child With Atopic Dermatitis

Nursing diagnoses and outcomes

Impaired skin integrity related to chronic occurrence of dry skin, intense itching, erythema, and excoriation

Outcomes:

- Child exhibits improved skin integrity.
- Child and family demonstrate skin care regimen.

Risk for infection related to presence of lesions, higher concentration of flora on atopic skin, and decreased integrity of skin barrier

Outcomes:

- Child and family demonstrate measures to prevent infection.
- Child and family identify signs and symptoms of skin infection.
- Child and family verbalize the actions to take if an infection is suspected or confirmed.

Interrupted family processes related to child's discomfort and increased healthcare requirements

Outcomes:

- Child reports increased comfort.
- Child and family correlate precipitating factors with appropriate skin care regimen.
- Child and family verbalize confidence in their ability to manage the child's care.

Teach Child/Family

Skin Care and General Hygiene

- Use a room humidifier or vaporizer to help provide moisture to the skin.
- Cool compresses and colloid bathes can help control itching.
- Bathe child nightly for 15 to 20 minutes.
- Provide creative toys for water play or encourage the older child to read a book while soaking.
- Do not use bath additives such as oatmeal or baking soda, bubble bath, soaps, or bath oils.
- For adolescents with mild symptoms, a daily shower may be sufficient.
- Pat, rather than rub, the skin dry.
- Follow bath with immediate application of occlusive emollient such as Eucerin, Aveeno, or Lubriderm.
- Choose preparations with no artificial fragrance and chemical stabilizer additives that may cause further skin irritation.
- Wet wraps can be used on severely affected skin. Apply after soaking and after applying topical medications.
- For total body wrap, use wet pajamas, long underwear, or tube socks (for hands and feet). Layer dry clothing on top.

- Wet wraps of gauze or Kerlix with stockinette or surginet can be applied to smaller areas.
- Do not allow the wrap to dry.
- Chilling may occur if outer layer becomes wet.
- Use antibacterial soaps for handwashing.
- Keep child's nails clean and cut short. Gloves and cotton stockings may need to be placed on hands and feet to prevent itching.

Medications

Topical Steroids

- Medicine is used to control acute exacerbation.
- The potency of the medication is determined by the body area that it is applied to and the severity of the child's condition. In general, as low a level of potency as possible is used to achieve good effects.
- Side effects include thinning of the skin, hypopigmentation, acne, secondary infection, and stretch marks.

Topical Nonsteroidals (Topical Calcineurin Inhibitors)

- Medicine is used to control acute flare-ups and is believed to control the underlying cause.
- May be used in children as young as 6 months of age (pimecrolimus).
- Indicated for mild/moderate (pimecrolimus) as well as moderate/severe (tacrolimus) eczema.
- Side effects include occasional burning or itching upon application.

Tar Preparations

- Preparations are used to control acute exacerbation; they have a slower inflammatory action than do topical steroids.
- Tar preparations should only be used when symptoms are mild.
- Tar preparations may cause burning and irritation if applied to skin areas with severe symptoms.
- Tar preparations have a bad smell, so many children dislike this treatment.

Antihistamines

- Medicine is used to reduce itching, primarily by causing drowsiness.
- Medicine may be taken at night to aid in comfort while sleeping.

Oral Antibiotics

- Medicine may be ordered if there is widespread skin breakdown or infection.

Phototherapy

- Once weekly treatments, in conjunction with moisturizers and low-potency corticosteroids, can help control skin condition.
- Long-term use not feasible because of adverse effects of radiation exposure.

TIP 25–2 A Teaching Intervention Plan for the Child With Atopic Dermatitis (Continued)

Nutrition

- Identify foods that exacerbate rash, and avoid these foods; utilize the “standard elimination diet.”
- Identify “hidden” ingredients in foods (e.g., eggs in baked goods) that might exacerbate the child’s condition, and avoid these foods.
- Avoid cow’s milk-based formulas; use soy-based or other special formulas such as partial whey.

Safety and Activity

- Outdoor activities are encouraged.
- Child should avoid getting sunburned.
- Swimming is permitted if followed by a shower to remove chlorine from skin, and then occlusive emollient is applied to skin.

Comfort and Support Measures

- Use first-generation antihistamines at night if scratching or rubbing of affected areas inhibits sleep; use second-generation antihistamines as preventive measures.
- Use mittens to prevent scratching during sleep.

- Remove clothing and bedding that increase itching.
- Maintain good skin care at all times to maintain optimal skin integrity and decrease pain.
- Maintain regular sleep/wake schedules, despite disruptions in sleep patterns resulting from discomfort and itching.

Special Considerations

- Avoid known or suspected sensitivities to contact allergens, pets, or other environmental factors.
- Explain the “itch/scratch” cycle.
- If infection occurs
- Use antibiotic creams as ordered.
- Use systemic antibiotics as ordered.
- Continue daily skin care.

Contact Healthcare Provider if:

- Child is in such discomfort that sleep and the ability to concentrate are affected
- Child spikes a temperature of 101.5 °F (38.6 °C) or more
- An area of the child’s skin has a colored discharge, is warm to the touch, or has a foul smell

of the skin is common among children with AD. *Topical and oral antibiotics* are used for secondary infections. Keep the child’s skin clean with tepid baths of nonirritating hydrophilic cleaners. Skin folds and diaper areas need frequent cleaning with plain water.

Phototherapy has demonstrated effectiveness as an adjunctive intervention to control severe, generalized atopic dermatitis. UVA radiation is believed to trigger an immunologic response, mediated through Langerhans cells and eosinophils. UVB radiation is thought to work by immunosuppression, by inhibiting Langerhans cells and altering keratinocyte production (Dohil & Eichenfield, 2005).

Food allergy and other environmental triggers have been linked to AD. Hen’s eggs, cow’s milk, soy, fish, nuts, and wheat account for most of the food allergy triggers seen in children (Findlay, 2007; Werfel & Breuer, 2004). Breast-fed infants may develop AD as a result of sensitization to foods or beverages ingested by the mother. Food-induced eczema should be diagnosed only after a thorough diagnostic evaluation that includes the child’s history, the degree of sensitization, and the clinical relevance of the sensitization. If a food substance is an identified allergen, then it is removed from the diet as in the standard elimination diet, which usually consists of chicken, lamb, rice, banana, apple, and a vegetable from the cruciferous family. This diet is maintained for 2 to 4 weeks; if the child’s symptoms are food related, they will usually disappear within the first 2 weeks. However, the dietitian must reassure the parents that a hypoallergenic diet does not always give immediate relief.

The child’s condition may reach a point of remission, in which case using emollients and avoiding triggers will effectively manage the child’s AD. When a flare-up occurs, acute control of pruritus and inflammation, and managing secondary conditions (e.g., infection) are the prime focus of therapy.

Community Care

AD causes much physical suffering, disability, and anguish for the child and the family. Prolonged discomfort and cosmetic disfigurement disrupt the activities of daily living. The child and the family need intense emotional support and assurance that lesions do not produce scarring unless secondarily infected. Parents need to be taught that feeling overwhelmed by the disorder is a common experience. Poor adherence and maintenance to treatments as well as anxiety about using many of the medications mentioned, are common features seen in families. Nurses can assist parents by allowing them to discuss their frustrations. Parents can alternately feel angry and then guilty about the demands of the child’s care. Parents need to be given emotional support and to be made aware of community sources of help. Older children and teenagers can be badly affected by AD because they are often rejected by peers who are offended by their skin condition.

The personal financial costs of managing this condition can be excessive for the family. In these cases, social workers can provide assistance by interviewing the child

NURSING INTERVENTIONS 25–2

Application of Topical Corticosteroids

Action

Topical corticosteroids are effective anti-inflammatory agents that reduce inflammation of the skin by promoting vasoconstriction of the blood vessels in the skin and by preventing the shedding of inflammatory cells from the bloodstream to tissue sites. These medications reduce redness (erythema) and itching (pruritus) associated with inflammatory and hyperproliferation skin diseases.

Potency

- Potency is determined by the amount of skin blanching (vasoconstriction that correlates with the anti-inflammatory effects of the agent). Four categories exist: low potency, moderate or mid potency, high potency, and highest potency. Steroids are also categorized as **nonfluorinated**, having less potent and fewer side effects, and **fluorinated**, which are rarely used in pediatric practice.
- Potency may be increased by the vehicle (agent) with which the steroid is combined to create a gel or cream form of the medication.
- Corticosteroids are available in several forms: creams, gels, ointments, lotions, powders, aerosols, and tapes.

Administration

- At home, parents should apply corticosteroids for their children.
- A thin layer is applied over the affected area; creams, lotions, and gels are rubbed in until no longer visible.
- Avoid unaffected areas.
- The agent may be applied with bare hands; wash hands thoroughly after application.
- A tongue depressor can be used to scoop the ointment out of a large container.

- On the face and scrotum, only low-potency glucocorticosteroids should be used. The epidermis is thin in these areas and side effects may be severe.
- Occlusive dressings or coverings (plastic pants covering a cloth diaper) should not be placed over an area in which a corticosteroid has been applied because this increases the absorption of the steroid and may lead to toxic side effects.
- The agents should not be used with conditions such as acne, rosacea, and some fungal infections or on severely eroded skin.
- Treatment is usually begun using a low-potency steroid. If lesions do not respond to therapy, the potency may be increased.
- Steroid therapy should be used for as short a time period as possible to achieve the desired effects.

Side Effects

- Striae
- Persistent erythema and telangiectasis
- Increased skin fragility
- Hypopigmentation
- Secondary infection
- Acneform eruption (steroid rosacea)
- Folliculitis, miliaria
- Allergic contact dermatitis
- Steroid addiction syndrome

Systemic Effects

- Cataracts
- Glaucoma
- Glycosuria
- Cushing's syndrome
- Stunted growth in children (rare)

and family, assessing needs, and identifying available community resources. The social worker can help to improve the home environment and lifestyle, especially for impoverished children. If psychotherapy is necessary because of poor self-concept and associated behaviors, social service may be able to generate financial support for the family to receive this therapy.

School performance can be adversely affected by severe AD. Children may be unable to concentrate because of the itching. School nurses can act as a liaison with healthcare personnel to notify parents if they observe that the child's condition is worsening and affecting school performance. The school nurse's office can also be used by children with AD as a place where they can undress to apply moisturizing solutions to the skin. Assist the child with treatments if

needed, assess the status of the condition, and help support a good self-concept. Educate school staff about the nature of the disease and the environmental conditions that need to be considered. For example, physical education (which generates sweating) and art class (exposure to paint and thinning agents) may have to be eliminated if they cause the dermatitis to worsen. Adolescents seeking employment should be guided to find work conditions that do not aggravate or activate their skin condition.

Seborrheic Dermatitis

Seborrheic dermatitis is a common, chronic, noncontagious dermatitis most likely caused by overproduction of

sebum, because it is common in areas with large numbers of sebaceous glands. Characterized by scaling and redness, seborrheic dermatitis lesions usually develop on the face, eyelids, scalp, body folds, external ears, and diaper area. This condition is frequently called *cradle cap* in infants or *dandruff* in older children.

Etiology and Incidence

The incidence of seborrheic dermatitis in the general population is 2% to 5%. Seborrheic dermatitis has been presented as a condition that occurs between the first 2 to 6 weeks of life, with recurrence seen during or after puberty. Most recently, classic seborrheic dermatitis in 2- to 10-year-olds has been noted to be fairly common (Williams et al., 2005). Seasonal fluctuation of the condition occurs, with most cases being reported during the spring and summer when sebaceous gland activity is increased by sweating. However, the child with an existing condition also has more symptoms in colder weather because of the low indoor humidity and lack of sunlight. A seborrhealike dermatitis is also common in children and adolescents infected with the human immunodeficiency virus (HIV).

In contrast to AD, seborrheic dermatitis is not genetically predisposed. The etiologic agents involved in seborrheic dermatitis include the presence of sebum, excessive perspiration, lipase activity, immune function, atmospheric humidity, the *Pityrosporum ovale* yeast organism that grows in hair follicles, poor hygiene, and stress (Arndt & Hsu, 2006; Williams et al., 2005). Occlusion of a skin area (e.g., diaper area), maceration, and moisture may also play distinct exacerbating role.

Pathophysiology

Seborrhea is similar to psoriasis in that white blood cells migrate into the skin plaque. A hyperkeratosing process generates plaque formation (scaling). It may be difficult to distinguish psoriasis from seborrheic dermatitis.

Prognosis

The prognosis for infantile seborrheic dermatitis is excellent. Most cases clear up within 1 month, even without therapy. In the adolescent form, long-term prognosis is good if the treatment plan is adhered to faithfully.

Assessment

Seborrheic dermatitis has different manifestations in various age groups. In infants, yellow, waxy adherent scales occur over the frontal and vertex areas of the scalp (cradle cap), and diaper area. Children age 2 to 10 have been found to exhibit both the “cradle cap” type of scalp scaling, and the nonspecific fine, nongreasy scale commonly termed *dandruff* (Williams et al., 2005). In pubertal and postpubertal children, seborrheic dermatitis manifests as erythematous, oily plaques and patches of vesicles and papules occurring on the forehead, eyebrows, and symmetrically on the nasolabial folds.

Seborrhea may also cause scaling and erythema on the eyelids (blepharitis), on the external ears (otitis externa),

and retroauricular areas. Blepharitis is often accompanied by styes. In severe cases, other affected areas include the intertriginous folds of the trunk, under the breasts in women, and the gluteal cleft.

Mild cases may involve no more than dealing with the nuisance of dandruff. However, severe cases can be extremely deleterious to body image and self-concept. The child can be assured that seborrheic dermatitis does not cause hair loss. Stress can activate an exacerbation in some children. No laboratory test or consistent pattern of laboratory abnormalities is associated with seborrheic dermatitis.

Interdisciplinary Interventions

Infantile seborrheic dermatitis usually responds well to cleansing the scalp with a mild shampoo. The thick, scaling lesions on the child’s scalp can be treated by applying baby oil, salicylic acid in mineral oil, or a corticosteroid gel on the scalp for 10 to 15 minutes. The area is gently massaged with a soft toothbrush; then the scales can be rinsed away. A fine-toothed comb helps rid the hair of scale debris.

In the older child and adolescent, an antiseborrheic shampoo should be used daily to control scaling. Common names for these shampoos include Sebulex, Selsun, and Head & Shoulders. When severe inflammation is present, a low-potency corticosteroid medication (0.5%–1% hydrocortisone) may be administered two to four times a day, or ketoconazole 1% or 2% shampoo (e.g., Nizoral) may be used. Scaling may be so severe that a tar gel preparation (e.g., DHS-T, Seubuton, Zetar) is prescribed that is left on the scalp all night. However, children are usually reluctant to have this medication applied because it is difficult to remove and has an offensive smell.

Teach parents and older children how to prevent seborrheic dermatitis of the scalp. Good scalp hygiene with a mild shampoo and gentle rubbing prevents the situation. If crusts are present, teach parents how to remove the crusts. Generally, topical ointments are not required; but, if they are prescribed, teach the parents how to apply the ointments appropriately. Also teach them to avoid using greasy ointments or creams on the affected child.

Psoriasis

Psoriasis is a chronic proliferative epidermal disease that usually manifests during the third decade of life, but it may develop at any time from birth onward. Characterized by flare-ups and remissions, psoriasis can, therefore, occur at any age.

Etiology and Incidence

Incidence of psoriasis peaks during adolescence and young adulthood, and again during older adulthood. Psoriasis affects 1% to 3% of the population, with 25% to 45% of cases appearing before 10 to 16 years of age (Arndt & Hsu, 2006; Burns et al., 2008). Psoriasis is much more common in white children and is seen twice as often in females.

Although the cause of psoriasis is unknown, a familial predisposition is present in 35% of cases, probably through

polygenic inheritance patterns. Several hereditary and environmental mechanisms have been suggested. These include genetic inheritance, problems in cell division, and alterations in immune response. Other suggested causes are streptococcal and viral infections, hormones, contact with animal skins, increased weight, seasonal change (especially cold), drugs (lithium, indomethacin, and some beta blockers), stress, and inflammatory bowel disease (Burns et al., 2008).

Pathophysiology

The pathogenesis of psoriasis is not fully understood. In psoriasis lesions, basal cell layers reproduce cells too quickly, and these cells move upward in the skin in 3 to 5 days, instead of 2 to 4 weeks. Normally, skin cells die as they move upward; in psoriasis, the quickly migrating cells do not. The partially living skin builds on the skin surface instead of being desquamated. As the heaped-up skin dries, it becomes brittle and cracks. Underlying this hyperactive epidermis is a swollen dermis congested with blood vessels and leukocytes; these conditions form minute abscesses that become pustules.

Prognosis

The course of management for psoriasis is prolonged and unpredictable. Spontaneous clearing is quite rare, but unexplained exacerbation, remission, or improvement is common (Arndt & Hsu, 2006). If psoriasis persists to adolescence, it becomes a lifelong disease. Arthritis can be a noncutaneous complication. Patient outcomes focus on normalizing skin physiology as much as possible and promoting normal activities of daily living.

Assessment

The physical signs of psoriasis are varied. In some children, psoriasis is annoying; in others, it is a debilitating, devastating experience. Sharply demarcated red plaques covered in a silvery white, thick, adherent scale occur at the elbows, knees, scalp, back, genitals, and sacrum.

caREminder

Psoriasis closely resembles AD. Ask the child if the lesions are greasy. Psoriasis scales are erythematous and are not oily.

Facial psoriasis is rare, although facial lesions are more common in children than in adults. Affected skin thickens over the palms of the hands and the soles of the feet. Nail changes include pits, ridges, and brittleness. When the scales are peeled off, pinhead-sized bleeding can be seen (Auspitz sign). As the plaques clear, the skin beneath may show either increased or decreased pigmentation. Another characteristic sign is worsening of the eruptions during the winter.

Interdisciplinary Interventions

Treatment options for children with psoriasis are varied, and are generally based on severity, size of areas involved, type of psoriasis, and the child's response to the initial

therapy (Arndt & Hsu, 2006). The goals of therapy include rehydrating the skin, removing scales, preventing infection, inhibiting the pathologic process and suppressing the immune response, and promoting acceptance of the child's condition (Nursing Interventions 25-3).

Community Care

The care of a child with psoriasis is demanding and emotional. Educate parents that psoriasis is not contagious and that the child should be encouraged to pursue normal activities. Neither overprotecting the child nor ignoring the problem is beneficial. Organizations such as the National Psoriasis Foundation are excellent resources for parents (see [thePoint](#), Organizations). Children and their families may experience a great deal of stress because of the meticulous measures that must be followed, the restrictions on the child's activities, and the unsightly appearance of the lesions. Help the family understand the long-term nature of psoriasis treatment. Lifestyle changes will help minimize recurrence. In addition, the family needs information regarding the side effects of the medications, how to monitor for fluid and electrolyte imbalances and for infection, and how to monitor the status of the skin.

Epidermolysis Bullosa (EB)

Although many skin disorders and infections can generate vesicles and bullae, the phrase "bullous skin disease" is usually reserved for the condition called *epidermolysis bullosa* (EB). EB describes a family of inherited disorders characterized by exceptional skin fragility and the formation of bullae at the site of mechanical trauma. The disorders range in severity from mild (subtle small lesions) to severe (large, mutilating lesions with internal organ involvement). EB affects all races and both genders equally.

Pathophysiology

EB is classified into three major types, depending on the layer of skin in which blistering occurs. *EB simplex* is the most superficial type, in which mechanical trauma causes splitting of the epidermis within the basal layer. The most common forms of EB simplex are autosomal dominant. Although the lesions can be widespread, they occur predominantly on the extremities and heal without scarring. Fingernails may detach, but they grow back. The mucous membranes are not involved. By adolescence, blistering tends to lessen, and the child has the potential for a normal life span.

Junctional epidermolysis bullosa is predominantly an autosomal dominant inherited disease (see Figure 3-3). The condition is characterized by bullae and erosions occurring on mucosal surfaces as a result of splitting within the lamina lucida, which is at the junction of the epidermis and dermis. This is considered a life-threatening condition because the erosions can lead to infection, sepsis, anemia, dehydration, and malnutrition. The mucous membranes of the respiratory, gastrointestinal, and genitourinary systems may all be involved.

NURSING INTERVENTIONS 25–3

Psoriasis Therapy

Goal	Action
Rehydrate epidermis <ul style="list-style-type: none"> • Risk for impaired skin integrity • Deficient fluid volume deficit 	Apply moisturizers several times a day, after bathing and before bedtime. Apply topical emollients. Use soap substitutes. Protect from overexposure to sun. Prevent exposure to psoriasis “triggers (e.g., cold stress, extreme heat, skin trauma) Maintain good fluid intake. Apply keratolytic preparations.
Remove scales <ul style="list-style-type: none"> • Impaired skin integrity Prevent infection <ul style="list-style-type: none"> • Risk for infection 	Protect against injury. Maintain hydrated skin. Use aseptic hand-cleaning techniques. Monitor for infection. Administer systemic and topical antibiotics. Maintain protein-rich diet.
Reduce epidermal cell division and suppress immune response <ul style="list-style-type: none"> • Impaired skin integrity • Ineffective altered tissue perfusion: peripheral 	Administer PUVA, a combination of psoralen medication and ultraviolet light (has serious drawbacks; rarely used for children). Administer retinoid, a vitamin derivative, which can dramatically decrease scaling (has serious side effects). Administer methotrexate, an antimetabolite (serious side effects; rarely used for children). Avoid “triggers”: cold, stress, trauma to skin, infections of skin.
Promote acceptance of the child’s condition <ul style="list-style-type: none"> • Impaired alterations in parenting • Ineffective family coping • Disturbed body image disturbance • Delayed altered growth and development 	Allow family and child to verbalize concerns. Encourage activities that promote child’s self-esteem and achievement of normal growth and developmental milestones. Refer child or family to support services and agencies.

Dystrophic epidermolysis bullosa has both autosomal dominant and recessive types, which are characterized by blistering in the dermis below the lamina densa. At birth, the child has large, dense bullae that heal slowly, leaving scars, fusion of scarred digits, and residual mucosal trauma. Blistering of the oral mucosa and larynx affects the child’s nutritional intake. Protein loss may also occur through the skin, anemia, and chronic constipation. Dystrophic and dermatolytic EB have the poorest prognosis, the greatest degree of scarring, and the most contracture development.

Assessment

Diagnosis of EB is made by evaluating the family history and the child’s clinical course and by completing a skin biopsy. EB usually manifests in neonates when blisters caused by delivery trauma appear. Lesions are clearly related to

areas of handling or occur at sites of pressure or motion. The number and amount of blisters, scarring, and affected sites depend on the type of EB. Specific areas of the body commonly affected include the hands, feet, extremities, nails, and mouth. If the oral mucosa and larynx are involved, as in junctional epidermolysis bullosa, the child may have a hoarse cry. Involvement of other mucosal surfaces of the respiratory, gastrointestinal, and genitourinary tracts can lead to respiratory distress, severe dehydration, anemia, and chronic constipation. Musculoskeletal and eye involvement may result from scar formation.

A special maneuver called the Nikolsky technique is used to aid diagnosis. This procedure involves rubbing or rotating a portion of the child’s skin with the examiner’s fingers. Bullae that develop after this procedure are then sampled for standard light microscopy, transmission electron microscopy, and immunofluorescence mapping. Skin cultures may be assessed to rule out the presence of

herpes simplex. Fetoscopy, a technique in which fetal skin samples are obtained between 18 and 21 weeks' gestation, can be used to elicit a prenatal diagnosis.

Interdisciplinary Interventions

Therapy is supportive and is aimed at optimizing nutrition, growth, and development. To prevent and treat infections, antibacterial baths and soaks, topical antibiotics, and, occasionally, systemic antibiotics may be ordered. Open wounds are treated with nontraumatizing dressings such as hydrogels (e.g., Vigilon), transparent dressings (e.g., OpSite), and petrolatum gauze.

Nursing care minimizes trauma to external skin and internal mucous membrane surfaces. Handle the child very carefully and take measures to avoid rubbing or chafing the skin. A hospital armband may cause enough irritation for blistering to develop. The child should wear loose, soft clothing. Pressure reduction devices such as overlays and special mattresses can be used to reduce skin friction. Wash the skin by soaking rather than by rubbing it with a washcloth.

To provide adequate nutrition, the healthcare team must counter both poor intake and losses caused by leaking of protein and body fluids from the blistering lesions. Breast-feeding is encouraged. If bottle-fed, the infant should have only cool formula with a soft nipple that does not irritate the oral mucosa. If severe nutritional problems exist, gastrostomy tubes can be used to administer feedings. Nasogastric intubation should be avoided to prevent possible irritation of the mucous membranes.

Acne Vulgaris

Acne vulgaris is a chronic, inflammatory process of the pilosebaceous follicles. It is a skin condition affecting as many as 80% of all adolescents (Connelly & Eichenfield, 2004; Rudy, 2003; Vernon, 2003). Although girls often develop acne at a younger age than boys, severe disease affects boys 10 times more frequently (Arndt & Hsu, 2006). Ethnic variations also exist. Acne is more prevalent in white Americans than in either African or Asian Americans.

Acne may develop in children on corticosteroid therapy, anticonvulsant drugs, or antituberculosis drugs. External agents such as suntan oils, heavy makeup bases, or grooming agents can also cause acnelike eruptions. Acne seen in infants is rare and requires no treatment. Other factors that precipitate appearance of the lesions include stress, lack of sleep, and premenstrual hormone activity. Acne tends to be improved in the summer months. In general, food seems to play no specific roles (Connelly & Eichenfield, 2004; Rudy, 2003). Genetic factors also seem to play an important role in the pathogenesis of acne (Rudy, 2003).

Pathophysiology

Acne usually begins 1 to 2 years before the onset of puberty as a result of androgenic stimulation of the sebaceous glands. Increasing androgen levels trigger a hypertrophy of the sebaceous glands, resulting in increased sebum production. In addition, aberrant follicular keratinization of the

pilosebaceous unit and excessive growth of microbial flora occur (Connelly & Eichenfield, 2004; Cotellessa et al., 2004). Inflammation is also added to this process. Overgrowth of certain bacteria on the skin, such as *Propionibacterium acnes* or *S. epidermis*, is thought to produce peptides or enzymes that exacerbate the inflammatory process.

When the normal flow of sebum of the skin is obstructed by the keratinization process, two types of comedones are formed. The open comedone (blackhead) is a firm, noninflammatory lesion filled with keratin and lipid, which block the mouth of the follicle. It has a blackened tip that is the result of oxidized melanin. Blackheads are easily managed except when traumatized or manipulated by the child. Inflammation rarely occurs with blackheads because the contents of the comedone easily escape to the skin surface.

The closed comedone (whitehead) is a semisoft, noninflammatory lesion caused by blockage at the neck of the follicle. It has a microscopic opening that does not allow easy escape of keratin and lipid. Therefore, as these substances build up, they rupture the follicular wall and expel sebum into surrounding dermis tissue. This event begins the inflammatory process that results in the presence of inflammatory papules, pustules, or nodules depending on the location and the extent of the inflammatory reaction.

Prognosis

Prognosis is individual, in that no two children with acne react to treatment identically. Treatment takes time and good self-care. The ultimate goal for all children is the avoidance of the associated scarring.

Assessment

Acne lesions include comedones (blackheads, whiteheads), papules, pustules, nodules, cysts, and scars (Fig. 25–9). Lesions usually occur on the face, back, chest, and shoulders. As the condition resolves, the lesion site may appear red and hyperpigmented. Scar formation can occur. Atrophic scars appear as shallow, broad-based depressions or deep, steep-sided pits with irregular outlines (ice-pick scars). Hypertrophic or **keloid** scars most often appear on the back or chest as elevated, thick fibrotic plaques. Black

FIGURE 25–9. An adolescent with acne vulgaris.

CHART 25–2 GRADING SCALE FOR ACNE SEVERITY

Score	Definition
0	None, skin is clear
1	Few comedones
2	Mild comedones, few papules, minimal erythema
3	Comedones, papules, pustules, erythema
4	Moderate comedones; greater number of papules; pustules extending over wider area of face, chest, shoulders, back; increasing erythema
5	Comedones; increasing number of papules, pustules, nodules with erythema
6	Comedones, papules, pustules, nodules, cysts; scarring may or may not be present with hyperpigmentation

adolescents have a greater propensity for this type of scarring. Facial lesions may extend into the scalp, with scarring alopecia (loss of hair) occurring as a result.

Nursing assessment includes an evaluation of the factors that may exacerbate the onset of acne. Chart 25–2 provides a suggested grading of acne. Routine microbiologic testing is not necessary in the evaluation or management of acne (Strauss et al., 2007).

caREminder

Very young children with acne and other signs of pubertal maturity should be evaluated for precocious puberty.

Question the adolescent regarding his or her use of medications, makeup, and grooming products. In addition, information regarding contact with oils, greases, and waxes should be noted. Affected adolescents may work at gas stations, garages, or restaurants that serve fast foods.

Teenagers may seek help for acne only after trying many home remedies. Question the adolescent about previous treatments, hygiene habits, stress, and diet.

Interdisciplinary Interventions

The child or adolescent with acne may have serious concerns about his or her appearance, which are the usual triggering events for the first healthcare visit. Although the condition is not life threatening, the effect of acne on the adolescent can be great. Taunting by peers can be cruel in severe cases, and sometimes professional psychological help is necessary. Early intervention does not prevent acne, but it does help control scarring.

Pharmacologic Interventions

Treatment usually revolves around medications, both topical and systemic, which are often combined because

no single agent has proved effective against acne. Topical therapy, the preferred method of treatment, has a more rapid effect and few systemic side effects, although it can cause local irritation of the skin (Strauss et al., 2007). Instruct the adolescent to clean the skin with a mild soap before applying the topical agent. Abrasive soaps and astringents should not be used, because these products only serve to cause drying and peeling of the skin, and fail to prevent the lesions from appearing. These over-the-counter products may also interfere with the proper use of known, effective topical agents.

Topical therapy essentially consists of three categories: keratolytic (benzoyl peroxide), retinoid, and antimicrobial (see [thePoint](#); Medications and Administration: Use of Acne Medications) (Rudy, 2003; Stephenson, 2007; Strauss, et al., 2007; Vernon, 2003; Zaenglein & Thiboutot, 2006). *Keratolytic agents* act as bactericides and reverse the formation of follicles. Benzoyl peroxide and combinations of erythromycin or clindamycin have been found to be effective treatments for acne. *Retinoids* are the most potent keratolytic agents available and have also been shown to reduce sebum production. The principal effects of *topical antimicrobials* are to reduce the follicular microbial colonization and decrease the inflammatory response.

Alert! The use of topical antibiotics alone can be associated with the development of bacterial resistance (Strauss et al., 2007).

Oral antibiotics are the most common systemic therapy prescribed. Doxycycline and minocycline are considered more effective than tetracycline (Strauss et al., 2007). The medications must be used for a minimum of 3 to 4 weeks to produce significant results. The systemic agents may produce side effects (see [thePoint](#); Medications and Administration: Use of Acne Medications). The patient should be instructed to stop taking the antibiotic and call the healthcare provider immediately if side effects occur.

Use of *oral contraceptives* may help to treat acne in some girls. Increased oil production can be caused by the body's androgen (male hormone) levels, which can be highest just before menstruation starts. Contraceptives work by decreasing endogenous androgen production.

Nutritional Interventions

Dietary restrictions, although no longer considered crucial to the progress and prognosis of acne care, convey the necessity of a well-balanced diet. Specific food restrictions have not been shown to be beneficial in the treatment of acne (Strauss et al., 2007).

Supportive Interventions

The dermatologist may perform comedone extraction or incision and drainage of cystic lesions. Therapy is targeted at controlling the inflammatory process by altering bacterial flora around the sebaceous glands with antibiotics and topically reducing the obstruction of sebaceous skin glands.

Advise the adolescent not to “pop” pimples, because doing so can cause further inflammation at the site and scarring at sites of larger lesions. If teenagers are compelled to do it anyway, advise them to never open the pimple before it has come to a head. The hands and face should be washed first, and a sterile needle should be used to nick the surface of the yellow pimple. The pimple should not be squeezed, rather the pus should be allowed to run out and then be washed away with soap and water.

Community Care

Nurses often serve as the initial contact for adolescents who are affected by acne and can be instrumental to a teen by helping to decrease the fears of treatment and by offering hope about positive outcomes. Provide counseling related to the many myths (Chart 25–3) about appropriate treatment. Convey to the child that there is no true cure for acne; if untreated, however, it could last for many years, with numerous secondary complications. Teach about general lifestyle, hygiene, and appropriate medication use and realistic expectations of therapy

(Clinical Judgment 25–1). The degree of patient adherence to the intervention plan will determine the effectiveness of therapy, as well as long-term outcomes. Reinforce with teenagers that despite the severity of their acne, it is a temporary condition, and with present-day therapies, it can usually be very well controlled.

PARASITIC INFESTATIONS

Skin infestations in children are a common and growing concern to parents, daycare providers, school officials, and healthcare providers. In the United States, the most common infestations affecting children are pediculosis (lice) and scabies (mites). Often misdiagnosed because of their appearance on healthy, “clean” children, these pesky insects are highly contagious and can be a source of embarrassment to the infected child and family. Eradication is possible when parents closely follow prescribed instructions for treating the lice and mites, clean the home environment, and monitor those who have been in close contact with the infected child.

CHART 25–3 MYTHS ABOUT ACNE

Myth	Reality
Any acne medication works immediately.	It can take at least 8 weeks of a prescribed treatment regimen for the patient to see any improvement. Acne may even get worse before it gets better.
Acne is the result of poor hygiene.	Because of this myth, people tend to overwash their skin, often scrubbing hard with abrasive cleansers. Acne is not caused by dirt or surface oil. Cleaning too often may, in fact, aggravate acne and cause flare-ups. The face should be washed twice per day with a mild soap and lukewarm water, then patted dry, followed by use of appropriate acne treatment.
Washing with abrasive soaps, cleansing granules, astringents, vigorous scrubbing, or a buff puff will clear up acne on the face.	Using fingertips or a soft washcloth is best.
Picking acne will make it go away.	This practice may cause scarring. Acne lesions should never be picked.
Once acne has cleared up, it will be gone forever.	There is no cure for acne. If acne medications are discontinued, acne will most likely flare up.
Stress causes acne.	Stress alone does not cause acne but may exacerbate psychological reaction to the acne. Acne is caused by overactive oil glands stimulated by androgens mixing with dead cells, which is one reason that this condition is seen during the teenage years, when androgen production is at its highest.
Eating chocolate, sugar, or greasy foods, or drinking lots of soda will cause acne.	No evidence supports this belief. Certain foods may make some teenagers’ acne worse, but no specific food has been proved to actually worsen acne. Also, although a balanced diet is important, no particular diet has been shown to be beneficial.
Teenagers are the only ones affected by acne.	Acne, although it predominates during the teenage years, can also affect adults, especially postmenstrual females. Neonates (acne neonatorum) and infants (infantile acne) can also experience acne.

CLINICAL JUDGMENT 25-1

The Adolescent with Acne

Maggie is a 14-year-old who was admitted to the hospital with status asthmaticus. She is being discharged today. As you enter her room, you find her standing near a mirror, squeezing the pimples on her face. When she sees you she says, “I just hate all of these zits. My face looks like frog skin. It is *so* embarrassing. My friend Kim has this neat medicine called ‘Acu-something,’ and when I am at home I use some of that to clear up my face.”

Questions

1. What questions should you ask Maggie regarding the comments she has just made?
2. What data in this scenario illustrate some poor health practices by Maggie?
3. What would be an appropriate nursing diagnosis based on the data you have collected?
4. What should be your plan of action regarding Maggie’s concern about her acne?
5. As you discuss Accutane therapy with Maggie, what outcomes could you tell her can happen if she continues to squeeze her pimples and take her friend’s medication?

Answers

1. Tell me more about this medicine you have been using (how often, how much, how long have you been using this). Have you been having any dry skin and lips; nosebleeds, muscle pain or stiffness, eye irritation, feel that your skin burns easily? Who knows that you are using this medicine?
2. Squeezing her pimples and taking someone else’s medication. Further data would be needed to determine whether current hospital admission was related to poor home management of asthmatic condition.
3. Body image disturbance related to presence of skin lesions, deficient knowledge: skin care and management of acne, risk for injury related to use of friend’s medication
4. Discuss the importance of not squeezing the acne lesions. Discuss some of the treatment options for acne. Discuss the extreme hazards of taking someone else’s medication and the hazards associated with use of Accutane. Tell Maggie you would like to share her concerns with her parents and the doctor so that arrangements might be made for her to see a dermatologist. Tell Maggie’s primary healthcare provider about her use of Accutane. Unmonitored use of this medication places her at risk for injury, especially in light of her asthmatic condition.
5. She may have further inflammation of the facial lesions. Scarring is more likely to occur if she continues to manipulate the lesions. Accutane is a prescription medication, and the person given the medication must be carefully monitored by a physician or nurse practitioner when it is being used. It has several hazardous side effects that could be harmful to Maggie’s general health.

Pediculosis

Pediculosis (lice) infestations have been identified for thousands of years. At one point, lice infestation was thought to be a sign of poor hygiene, with the only known cure being a complete head shave.

Lice have been known to transmit certain diseases, including typhus, trench fever, and relapsing fever. Fortunately, none of these diseases has been transmitted by lice in the United States for decades. Improved hygiene, better ability to wash and change clothes, immunizations, and the development of pediculicides and antibiotics have all played roles in decreasing the threat of disease transference. Lice infestation, however, remains a major community health problem throughout the world.

Etiology

Humans can be infested by two subspecies of lice, each with its own unique set of characteristics and occupying a specific segment of the body: the head and body louse (*Pediculus humanus capitis* or *corporeus*), and the pubic or

crab louse (*Phthirus pubis*). Head lice are the most common type seen in children, although adolescent sexual activity contributes to the incidence of pubic lice in this age population.

Head Lice (*Pediculus humanus capitis*)

A familiar malady in schools and child care centers, head lice infestation occurs in all regions of the United States. Estimates range from 10 to 12 million cases per year (Gray, 2005). Although all socioeconomic groups are affected, lice are most common in school-aged white females, with the peak season occurring from August to November. Head lice are less common in blacks, because lice do not attach easily to tight, curly hair. Head lice can infest both adults and children, but the incidence is greatest in children between ages 5 and 12.

Transmission of head lice occurs by direct contact with an infested person or indirect contact with personal articles. Carpeting, pillows, bed linens, hats, brushes, and ribbons from infested children are all possible sources of transmission.

Pubic Lice (*Phthirus pubis*)

Pubic lice have a more rounded body and prominent pincers than do head lice. These lice generally infest the pubic region, and sometimes the eyebrows, facial hair, and axillary hair. Pubic lice are most commonly transmitted through intimate bodily contact, although they also may be transferred by **fomites** (contaminated objects such as combs, brushes, and clothing). Infestation occurs most commonly in adolescents or adults; infestation in a younger child should raise the suspicion of sexual activity or abuse.

Body Lice (*Pediculus humanus corporis*)

The least common form of pediculosis in the United States is body lice. These lice attach to infested clothing and bedding, living in the seams of these materials. The lice attach to the skin only long enough to feed.

Pathophysiology

Lice are parasitic insects that infest humans and can have an effect on the host. Their bites are relatively painless and may be felt as a slight tickling sensation. The signs and symptoms of pediculosis infestation are caused by the reactions of the host to the saliva or anticoagulants injected by the lice into the dermis. Intense itching may occur on the affected body part or in the scalp. Generally, the severity of symptoms is proportional to the degree of infestation. The adult louse lives only about 48 hours if not in contact with a human host, and the life span of the female is roughly 1 month. Eggs are laid at night, at the junction of a hair shaft and close to the skin; these nits will hatch within 7 to 10 days.

Prognosis

With treatment, these parasites can be eradicated successfully. Most often, resurgence of lice occurs because parents fail to meticulously follow the treatment plan and eradicate the nits in all of the environments in which the child has contact with other carriers or fomites. In addition, no pediculicide is 100% effective or ovicidal, and improper application of the pediculicide and poor nit removal combing techniques can influence the reinfestation rate (Flinders & De Schwenitz, 2004).

Assessment

Parents and clinicians alike often confuse pediculosis with scabies (mites). Both infestations are caused by organisms that primarily choose the scalp as their feeding ground. Lice and scabies may occur in some of the same areas such as the axillary, cubital, popliteal, and inguinal areas. Both lice and mites cause pruritus, although mite infestation is characterized by nocturnal itching as opposed to the continuous pruritus associated with lice. Examination of the affected area and microscopic examination of the lice or nits are the classic discerning methods of analysis. Nits fluoresce white under Wood's light. Mites are not visible using this technique; rather, scrapings from infested skin must be examined under a microscope to discern their presence.

caREminder

The hallmark of pediculosis is intense itching, at all times of the day or night. Any body area, including the scalp, may show signs of the child's intense scratching, such as erythema, scaling, and excoriation of the skin.

Head lice infestation is commonly first suspected when children are observed scratching their heads vigorously. Listlessness or poor school performance may also be clues, indicating the child's high level of distraction. On inspection, the examiner observes whitish to sandy colored eggs (nits) on the hair shafts. Adult lice may be visualized under a microscope or a magnifying glass. They range in color from light beige to black and have six clawlike appendages.

Brown or cream-colored pubic lice nits attach themselves firmly to hair shafts, making removal difficult. As discussed earlier, pubic lice are often seen in the presence of other sexually transmitted diseases, and affected children must be examined for signs of other such diseases, particularly gonorrhea and syphilis.

Interdisciplinary Interventions

Nurses play a crucial role in assessing children for lice and in obtaining a detailed health history. Parents need to be taught the signs of lice infestation. An infested child typically scratches the infested area, most commonly the scalp, ears, and neck. Parents should examine the child's head in natural light near a window. The most readily identifiable sign is the presence of nits. Nits can easily be mistaken for dandruff, but the critical difference is that nits must be picked off to be removed.

When lice are detected, the coordinate care to ensure that treatment of the child and affected family members begins immediately. Treatment for lice involves applying a pediculicidal agent, removing nits, and thoroughly cleaning (delousing) the environment (TIP 25–3). All three steps are crucial to preventing recurrence. All potentially exposed persons should be examined and treated if infested.

Pharmacologic Interventions

Pediculicidal agents include permethrin (preferred agent) and pyrethrins; common brand names include Kwell, Nix, Rid, and Pronto. A 1% lindane shampoo is also used to treat resistant head lice; however, lindane use is now controversial because of concerns about neurotoxicity. None of the currently available pediculicides is 100% ovicidal, and resistance among lice to these more common and popular products has been increasing. Malathion (Ovide) has been shown to kill both nonresistant and resistant lice, and is available by prescription.

Alert! Malathion has a foul odor, is flammable, and may cause respiratory depression if ingested. The agent should not be used on neonates and infants, and its safety in nursing mothers and children younger than 6 years is uncertain (Flinders & De Schwenitz, 2004). Malathion should be considered for use only when other agents have failed.

TIP 25–3 A Teaching Intervention Plan for the Child With Pediculosis or Scabies

Nursing diagnoses and outcomes

Impaired skin integrity related to infestation

Outcomes:

- Child verbalizes a decrease in itching.
- Child maintains minimal integrity.

Health-seeking behaviors regarding prevention of further infestations

Outcomes:

- Family completes home treatment regimen to rid the child of the lice or mites, and to treat itching.
- Family cleans the house to rid the home of all lice and mites.
- Family notifies others in close contact with the child of the contagious nature of the infestation.

Risk for infection related to itching and potential breakdown of the skin

Outcomes:

- Child will remain free from infection.
- Parents notify healthcare provider promptly if lesions appear infected or if a fever develops.

Teach Child/Family

Managing the Child's Condition

Pediculosis (Lice)

- Antilice shampoo
 - Strictly follow manufacturer's directions for application
 - Pour about 2 oz of the antilice shampoo onto the hair, adding warm water to lather. Scrub the hair and scalp for 10 minutes. Rinse the hair thoroughly and dry.
 - Repeat application in 7 to 10 days if live lice are present.
- Removal of nits
 - Divide the child's towel-dried hair (not sopping wet) into four parts and insert the comb at the top of the head first. If nits fall into the lower hair, they will be removed with combing of the inferior areas. Use a fine-toothed comb. This is a time-consuming procedure that may be uncomfortable for the child.
 - Special attention should be given to the area around the ears and the nape of the neck, which are heavy infestation areas.

Scabies

- Have the child bathe or shower.
- Then apply scabies cream or lotion.
 - Apply the cream or lotion to every inch of the child's body from the head down. Pay special

attention to the navel, between the toes, and body folds or creases. Leave some under the fingernails. Eight to 14 hours later, give the child a bath and remove the cream or lotion.

- Unless new lesions develop within 10 days, retreatment is unnecessary.

Cleaning the House

- Wash in hot water all of the child's sheets, blankets, pillowcases, pajamas, underwear, and recently worn clothes. Dry in hot dryer for at least 20 minutes.
- Items that cannot be washed should be set aside in plastic bags for 3 days (for mites) or 23 weeks (for lice/nits) before being used again.
- Vacuum all floors, rugs, play and sleep areas, and furniture of home, school, and daycare facilities.
- For lice, combs and brushes should be soaked for 1 hour in a solution made from antilice shampoo or in a solution of 1½ tbl Lysol and 1 qt water, followed by a hot-water rinse.
- It is not necessary to have the house sprayed or fumigated, because this can be toxic to humans and pets.

Contagiousness

- Children can return to school after one treatment with the shampoo or medicine.
- For pediculosis, check the heads of everyone else in the home and treat any scalp rashes, sores, or itching with the antilice shampoo.
- Sexual partners should be notified of the diagnosis.
- For scabies, everyone living in the house should be treated preventively with one application of the scabies medicine. Close contacts of the infected child (friends, baby-sitter, daycare provider) should also be treated.
- Encourage children not to share hats, coats, combs, and similar personal items.
- The child's school or daycare facility should be notified of the diagnosis, and close contacts should be examined and treated prophylactically.
- Promote good general personal hygiene measures.

Contact Healthcare Provider if:

- Itching interferes with sleep; teach parents that the rash or the itch may continue for 2 to 3 weeks after treatment
- Rash is not cleared within 1 week after treatment
- Rash clears, then returns
- Rash or sores begin to look reddened, warm to the touch, or oozing secretions
- Fever develops
- New nits or burrows appear

Toxic side effects, most often seen with lindane, may include nausea, vomiting, aplastic anemia, hypoplastic bone marrow, convulsions, and death. These serious side effects usually occur after repeated applications. When teaching parents about pediculicide treatment, emphasize that more is not better. Directions for application must be strictly followed. Overuse and misuse may lead to absorption into the bloodstream and the possibility of adverse effects. The child's eyes must be carefully protected, and the parent should wear rubber gloves. Pediculicides cannot be used on eyebrows or eyelashes, because they are irritating. Rather, lice infestation in these areas is treated by applying petrolatum to the lashes and brows three to four times a day for 2 weeks. The petrolatum seems to suffocate the insects. The nits can then be removed with a fine-toothed comb or tweezers.

Systemic agents have shown effectiveness in killing nymphs and lice, but not eggs. An oral dose of ivermectin (Stromectol) has been used to kill newly hatched nymphs. A second dose is administered 7 to 10 days after the first dose. No serious adverse reactions have been reported; however, the medication is not approved for use in children weighing less than 15 kg (33 lb). Trimethoprim-sulfamethoxazole (Bactrim, Septra) has also been used in pediculosis treatment; it acts by killing essential bacterial flora in the insect's gastrointestinal tract (Flinders & De Schwenitz, 2004).

Infestation in infants should never be treated with pediculicidal products. Rather, the lice and nits should be manually removed or hand combed. Pregnant women and persons allergic to pediculicidal agents should never use these agents. Parents should be warned to avoid treating lice infestation with home remedies. Dog shampoo, vinegar, and kerosene have not been clinically proved to be effective against lice.

Community Care

Instruct parents to follow the prescribed intervention plan carefully (see TIP 2-3). They also must be taught how to remove nits properly. The environment must be thoroughly cleaned. Pets are not a host for lice. Transmission occurs from direct contact (body to body, hair to hair) or indirect contact (clothing, brushes, hair apparel). Lice cannot live more than 72 hours off the human body. Therefore, the house should be vacuumed thoroughly, combs and brushes should be soaked in antilice shampoo, and all clothing and sheets should be washed in hot water.

School nurses play an important role in preventing and managing head lice epidemics. A social worker or visiting nurse may need to be called to investigate home conditions if lice infestation becomes recurrent or chronic. The school nurse educates teachers, officials, and parents to

- Have carpeted areas frequently vacuumed
- Discourage body contact and sharing of personal items between children
- Know how to examine for and identify lice
- Notify the nurse if a case is found
- Store naptime supplies in a clean area and send them home for frequent cleaning
- Have student clothes/storage areas (lockers) separated adequately by space and not be shared

Assist schools and daycare facilities to notify parents about prevention, detection, and treatment policies. Infested children should be sent home immediately. In addition, a treated child's hair must be examined on return to school for the presence of residual eggs, which could signal reinfestation. Screening programs for lice should be instituted periodically, with parental notification given in advance. The National Pediculosis Association has free guidelines available for controlling head lice in child care environments and schools (see [thePoint](#) Organizations).

Scabies

A contagious skin condition caused by the human skin mite *Sarcoptes scabiei*, scabies affects children regardless of gender, age, or socioeconomic strata. Scabies occurs worldwide and increasingly in North America, with outbreaks occurring in association with crowded conditions, poor hygiene, and malnutrition. It is transmitted by close personal contact, or shared clothing or linen. The scabies mite cannot survive for more than 3 days away from human skin. Therefore, it is not carried by fomites (combs, brushes, toys) as often as pediculosis, although some cases have been documented.

Pathophysiology

S. scabiei present on an infested person is attracted to the warmth and odor of an uninfested host. Once transmitted to the new host, the mite secretes a fluid that allows it to burrow into the stratum corneum, rarely penetrating through the epidermis. The mite sucks human tissue fluids for nourishment. The female mite lays one to three eggs per day for 15 to 30 days. The larvae mature and hatch in 10 days, emerging on the surface of the skin as eight-legged mites. After mating, the males die and the females begin to burrow under the skin to continue the reproduction cycle. The host's body begins to respond to the secretions of the mite or its feces, which are highly antigenic. This sensitivity response (itching, scratching) usually begins within 3 weeks of infestation, and incubation occurs 1 to 2 months after contact.

Prognosis

The prognosis for eradicating scabies is excellent. The currently available agents are strong scabicides with minimal toxic side effects. Treatment failure, which does occur, may be attributable to inadequate education and improperly applied treatment of the child and the environment. Underlying serious immune suppression (as in acquired immune deficiency syndrome) can delay eradication of the mite infestation.

Assessment

The most common presenting symptom of scabies is pruritus, which is especially profound at night and at naptime. Younger children and infants who cannot scratch effectively respond to the constant itching by crankiness, fitful sleeping, rubbing their feet and hands together, and even refusing to eat. Severe cases can cause significant interference with the mood of the child and with the activities of daily living.

The primary lesion of scabies is the burrow, although vesicles, papules, nodules, and wheals also may appear. The linear, grayish burrows are present in 90% to 95% of all patients with scabies and are easy to find. Difficulty detecting the burrows may occur in the presence of excoriation and secondary infections such as impetigo. Infestation sites differ by age group. In infants and young children, the lesions may be generalized, with distribution on the palms, soles, scalp, face, and axillae being most common. The head and neck may also be affected. In older children, lesions are more often localized, being seen in finger webs, the axillae, body creases, the belt line, genitalia, and nipples.

Scabies is diagnosed by skin scrapings (see Tests and Procedures 25–1). Potassium hydroxide is not used, because it will dissolve the mites, eggs, and feces; rather, a few drops of mineral oil are applied to a burrow, vesicle, or papule, and a dull edge of a scalpel is used to scrape the lesion. Scrapings are best obtained from interdigital areas or from flexor surfaces of the wrist. The burrow ink test, during which a drop of ink or rubbing a washable felt-tipped pen across the suspected burrow, may be done. It may be possible to detect a mite moving in the oil; the ova or feces of the mites may also be visible. Sometimes finding either ova or feces is not possible, leaving the clinician the responsibility of treating the infestation based on the clinical history alone.

Interdisciplinary Interventions

As with pediculosis, treatment of scabies involves not only the affected infant or child but also the family and caregivers. Scabicide agents available include permethrin (Elimite), as well as lindane (Kwell), sulfur 6% in petrolatum, and crotamiton (Eurax). Permethrin 5% in cream is the drug of choice because of its high efficacy and low toxicity (Burns et al., 2008). It may be used in children as young as 2 months of age. It is applied once for 8 to 14 hours and removed, then reapplied 1 week later. Lindane 1% cream is also a good agent, especially for older children (not recommended for children younger than 6 months, with some studies suggesting not younger than 2 years of age; during pregnancy; or when there is a history of seizures). Treatment resistance has been noted with the use of lindane, and neurotoxicity, if the agent is misused, is an adverse effect of major concern (Flinders & De Schwenitz, 2004). Lindane is applied for 8 to 12 hours and is then washed off. A second application is recommended 1 week later.

Topical steroids and antihistamines, such as diphenhydramine (Benadryl), may be administered to help reduce pruritus in older children.

Community Care

Educate the family to apply the scabicide agent, strictly following the manufacturer's directions. Most deleterious side effects result from overzealous application of these agents. Teach parents to apply the agent to the whole body in infants and children (including the scalp and face), with special attention given to the ears, gluteal clefts, and toe and finger webs. Before application, the child should be given a tepid bath and be dried with a

towel. Then the agent should be applied evenly but thinly over the body. In older children, the scabicide agent is applied from the neck down. The parent should wear rubber gloves during application.

Not all lesions clear immediately. Pruritus may persist after treatment, and postscabietic nodules may persist for months, even after the mites are eradicated. The child should not be bathed too aggressively, because the subsequent skin dryness can result in excoriation of the skin. The child with excoriated skin is at risk for secondary infection caused by impetigo.

Teach parents that, because a latent period of 1 month occurs after infestation, there may be other, asymptomatic carriers present in the home or child's school. Instructing the family in good personal hygiene practices, cleaning the environment, and regular bath time checks can help prevent reinfestation (see TIP 25–3).

BACTERIAL SKIN DISORDERS

Infections of the skin are so common that few individuals escape without having had at least one bacterial skin infection during the childhood years. Most of these skin problems are easily handled and are benign in course. However, some can evolve into major illnesses if not promptly diagnosed and treated. Cutaneous bacterial infections are among the most frequent inflammatory skin disorders.

Staphylococcal Scalded Skin Syndrome (SSSS)

Staphylococcal scalded skin syndrome (SSSS) is a disorder that is seen in infants and children, but is rare in adults. In SSSS, infection by a particular strain of *Staphylococcus aureus* causes blistering of the upper layer of skin. Severity can vary from localized blisters to generalized exfoliation affecting the entire body.

Pathophysiology

S. aureus, the causative agent of SSSS, produces an exfoliative toxin. The mechanism by which the bacteria cause this exfoliation remains elusive, although clinical studies are ongoing.

Prognosis

SSSS tends to occur only once and, if treated with antibiotics, usually resolves within a few days. Childhood mortality is approximately 4%. Mortality is associated with extensive skin involvement, overwhelming sepsis, and subsequent fluid and electrolyte imbalances (Patel & Finlay, 2003).

Assessment

The child usually presents with a prodrome of sore throat or conjunctivitis. A culture of the eye drainage is frequently positive for *S. aureus*. Within 48 hours, the child develops fever, malaise, and extremely tender erythematous patches on the face, neck, axilla, and perineum. Flaccid bullae develop within the erythematous areas. Bullae

enlarge and rupture to reveal a moist erythematous base; this process gives rise to the classic scalded appearance (Patel & Finlay, 2003).

Surrounding skin appears normal, and no systemic symptoms are noted. Mucous membranes are not affected. A positive Nikolsky sign is typically elicited by gently rubbing uninvolved or healed skin to produce dislodgment of the superficial epidermis.

Lesion and drainage cultures are essential in identifying the causative organism, especially when infection is present. Blood cultures help to identify the source of the epidermic toxins. Skin biopsies may also assist in diagnosis.

Interdisciplinary Interventions

Healthcare interventions focus on eradicating the causative organism, preventing secondary infection, maintaining systemic support (nutritional, fluid, and electrolyte balances), and ensuring comfort. Prompt initiation of parenteral antistaphylococcal antibiotics (e.g., flucloxacillin) is essential. Fluid and electrolyte loss during the illness is considerable, requiring oral or parenteral replacement. The eroded skin is at risk for secondary infections. Placement in the intensive care unit may occur, and additional antibiotics may be administered, as indicated by the child's condition (Patel & Finlay, 2003).

Thermal dysregulation can occur as a result of the underlying infection, the severity of the illness, and peripheral vasodilation (Patel & Finlay, 2003). Room temperature should be monitored and adjusted to compensate for changes in the child's core temperature.

In addition to monitoring fluid and electrolyte status, vital signs, and ongoing skin assessment, the nurse should attend to the child's pain. Adequate analgesic agents are administered to ensure that the child is comfortable. Opioids may be necessary to manage severe pain.

Blisters are left intact. Ongoing skin care includes covering eroded skin areas with petrolatum-soaked gauze, which helps to further reduce trauma to the skin. Pressure-relieving mattresses are used to reduce development of pressure sores. Diligent skin assessment and collaborative management ensures effective healing and reduces infection. The illness is usually brief, with no residual scarring of the skin.

Impetigo

A common, superficial skin infection that most often occurs on the face, the arms, and the legs, impetigo usually affects children between the ages of 2 and 5 years. Impetigo contagiosa (nonbullous impetigo) and bullous impetigo (staphylococcal impetigo) are the two most common types of impetigo recognized (Table 25-5). Impetigo neonatorum is a form similar to bullous impetigo found specifically in the newborn. Common or secondary impetigo refers to the form that occurs as a complication of a systemic condition or secondary to another dermatologic problem. A child may have the characteristics of more than one type of impetigo at the same time.

Past studies established that the principal etiologic agent responsible for impetigo was group A beta-hemo-

lytic streptococci (GABHS); if *S. aureus* was cultured, it was considered a secondary invader. However, there exists sufficient and compelling evidence to suggest that *S. aureus* is the primary agent in nonbullous and crusted impetigo, and is almost always the exclusive agent in bullous types (McEvoy, 2000). The cause of impetigo and its characteristic appearance is related to the particular type of impetigo present. Impetigo contagiosa is primarily caused by GABHS and *S. aureus* organisms.

Pathophysiology

The causative bacteria are carried in the nasal area and may pass on to the skin. The bacteria invade the superficial skin, most aggressively at areas of broken skin, causing a characteristic vesicular and pustular response and crusting. The infection may be disseminated after scratching an infected site. The infection can also be acquired through contact with other infected children, or through contact with fomites such as combs or toys that come into contact with areas of the skin that have been compromised. Impetigo is more easily spread through crowded conditions, poor hygiene, and play situations in which children have skin-to-skin contact (e.g., contact sports). *S. aureus* is more prevalent in warm, humid climates, whereas GABHS is more prevalent in temperate zones. This disorder is also highly communicable among athletes, and from contaminated equipment used by athletes (Trotto, 2001).

Prognosis

The prognosis for uncomplicated impetigo is usually excellent, because the lesions are shallow and usually heal without scarring (Fig. 25-10). Transient pigmentation changes can occur in children with dark complexions. Lesions usually remain superficial, but organisms may

FIGURE 25-10. A child with impetigo.

TABLE 25-5

Types of Impetigo

Type and Common Sites	Cause	Characteristics of Lesions	Other Symptoms
<p>Impetigo contagiosa (non-bullous impetigo)</p> <p>Sites: skin surfaces exposed to environmental trauma</p> <p>Periorbital area</p> <p>Nares</p> <p>Face</p> <p>Extremities</p>	<p>Group A beta-hemolytic streptococcus</p> <p><i>S. aureus</i></p>	<p>Lesions start with a single 2- to 4-mm erythematous macule that rapidly evolves to a vesicle or pustule.</p> <p>Vesicles are fragile and rupture easily, leaving a typical “honey-colored” yellow, crusted exudate over the superficial erosion.</p> <p>Lesions spread rapidly to adjacent skin.</p> <p>There is often linear distribution, showing how patients scratched themselves.</p>	<p>Mild, localized lymphadenopathy</p>
<p>Bullous impetigo (staphylococcal impetigo)</p> <p>Sites:</p> <ul style="list-style-type: none"> • Buttocks • Trunk • Perineum • Extremities • Neck folds 	<p><i>S. aureus</i></p>	<p>Flaccid and transparent bullae are usually less than 3 cm in diameter on previously untraumatized skin.</p> <p>When the blisters rupture, they leave a “varnish-like” superficial erosion with scant crusting.</p>	<p>Weakness</p> <p>Fever</p> <p>Diarrhea</p>
<p>Impetigo neonatorum</p> <p>Sites: lesions may be few or many, favoring moist surfaces such as the groin, axilla, neck, and umbilicus</p>	<p>Acquired during delivery, from fomites, or from human contact</p> <p><i>S. aureus</i> and <i>Streptococcus</i> most common</p>	<p>Lesions can range from bullous impetigo to the scaled skin syndrome.</p> <p>Bullae are tense, rupture easily, and leave red, glazed, oozing areas.</p> <p>Classic honey-colored crusting may be present.</p> <p>Lesions spread peripherally and clear centrally.</p> <p>Scale and satellite lesions are present.</p>	<p>Fever</p> <p>Adenopathy</p>
<p>Common or secondary impetigo</p> <p>Site: location of primary lesions</p>	<p>Complication of systemic diseases such as diabetes mellitus, acquired immune deficiency syndrome</p> <p>Dermatologic conditions that cause a break in the skin may lead to secondary impetigo (e.g., scabies, pediculosis, herpes simplex, insect bites).</p>	<p>Similar to impetigo contagiosa</p>	<p>Mild lymphadenopathy</p> <p>Symptoms of primary condition</p>

invade deeper areas, causing cellulitis, lymphangitis, and more serious systemic infections including bacterial endocarditis. Acute poststreptococcal glomerulonephritis is a rare complication of impetigo, and early intervention with antimicrobial therapy does not seem to alter the risk.

Assessment

Children with impetigo do not generally appear ill or feverish. Nonbullous impetigo lesions are rarely painful. Thus, the family may delay seeking medical attention. Secondary symptoms, such as regional lymphadenitis, finally bring the child to the healthcare provider's attention. During this time, the infection may have been spread to other members of the household or the child's peers (Clinical Judgment 25–2). Refer to Table 25–5 for descriptions of the lesions.

Laboratory studies often reveal a slight increase in leukocytes in the bloodstream. Gram stains of scrapings from the lesions show gram-positive cocci in clusters, with neutrophils. Cultures and sensitivities are completed to guide therapy, because the number of methicillin- and erythromycin-resistant strains of *S. aureus* is increasing.
