Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner; the clinical treatments described and recommended may not be considered absolute and universal recommendations.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with the current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the healthcare provider to ascertain the FDA status of each drug or device planned for use in his or her clinical practice.

Dedication

*A mother,
There to support you,
And hold you up whenever you need her.
—Laurel Stephens*

*To our mothers, June Clark and Barbara Smith, we dedicate this second edition of the book.
You have given us strength, courage, and confidence to help us follow our dreams.*

Acknowledgments

This second edition of *Children and Their Families* represents the combined assistance of contributors, Lippincott Williams & Wilkins editors, friends, and family members to support our efforts to update and enhance this text. The book has evolved and contains not just the words of the most recent contributors, but the cumulative expertise of many nursing colleagues, who provided thoughtful insights on ways to improve the text. We are grateful to our colleagues and students, especially those at Azusa Pacific University and California State University, Fullerton, who provided us with information to ensure the content was relevant, practical, and current. Special recognition goes to Margaret Brady, PhD, RN, and Linda Tirabassi, MN, RN—two of our most helpful and wise colleagues. They answered every e-mail and request for help and consultation.

To Danielle DiPalma, our much appreciated editor at Lippincott Williams & Wilkins, thank you for your talents as an editor and your vision for the book. Working with you is a joy.

At the end of the day, and some very long working sessions, there is always the blessing of friends and family. Our children, Christian and Matthew Bowden and Erin, Jordan and Daniel Greenberg, are no longer awed and amazed that we spend the time doing this work; they simply accept that the writing is part of what we do and who we are. They step in to help, allow themselves to be photo models, and give us some quiet time to work. Special gratitude and appreciation to our husbands Greg Bowden and Jay Greenberg who have helped to keep our lives balanced and who remind us that a simple dinner with the family is a wonderful way to renew the mind and spirit. Lastly we are grateful for each other; working together has always been a blessing. Our friendship and appreciation for one another continues to grow, even when challenged by book deadlines, job changes, and the daily stressors of life. We love doing this work; how blessed to share that love with a sister of the heart.

Preface

Children and Their Families: The Continuum of Care is a comprehensive textbook about children's healthcare that can be used by both students and nurses in a variety of clinical practice settings. In developing this textbook, our goal was to provide the student and practicing nurse with the knowledge base that would enable them to make critical assessments and judgments regarding the child and his or her family in a variety of settings across the continuum of care. Today's pediatric nurse must be well versed in the numerous social, psychological, spiritual, and physical challenges facing youth, and experts in managing complex acute and chronic conditions unique to children and adolescents.

CONTINUUM OF CARE

Nurses caring for children do so in a continuum of care that encompasses ambulatory care, hospital care, primary care, rehabilitative services, case management, school health services, and community health services. Nursing faculty have recognized the extension of healthcare services to a multitude of community-based settings and have intentionally changed the nursing curriculum to reflect the need to broaden the scope of student learning experiences to encompass all arenas in which the child's health needs may emerge. This text reflects this focus, addressing the care of children in a variety of settings, from the home to schools to the medical center. In addition, the text thoroughly covers health promotion, surveillance, and maintenance needs of children from infancy through adolescence. It is recognized that every encounter between the nurse and the family is a teaching encounter. The duration of the nurse–family relationship provides many opportunities for the nurse to equip the family with strategies to address their current healthcare needs. In addition, the nurse can act in a proactive manner to give anticipatory guidance that can assist family members as they work to promote their child's growth and development.

FOCUS ON NURSING CARE

This book's interdisciplinary perspective highlights the role of the nurse working with all members of the healthcare team to meet the needs of children and their families. Nurses have a primary responsibility to oversee and coordinate the multiplicity of healthcare services provided to the child and family.

The dynamics of who implements a specific intervention is influenced by nursing practice acts and by the guidelines established by individual healthcare organizations. In the context of the interdisciplinary team approach, this text highlights the unique role of the nurse by articulating the Nursing Plan of Care. These charts summarize the nursing diagnoses, as approved by the North American Nursing Diagnosis Association, and outcomes that are consistently applicable to defined populations of children with specific health challenges. In addition, specific nursing interventions are featured in charts throughout the text. Nineteen nursing interventions classifications (NICs) have been incorporated into the text to further delineate the definitive nursing activities that have been identified in research and practice as essential in helping the child and family address or resolve the child's actual or potential healthcare problem.

ORGANIZATION OF THE TEXT

The text has been divided into three units:

- Unit I Family-Centered Care Throughout the Family Life Cycle
- Unit II Maintaining Health Across the Continuum of Care
- Unit III Managing Health Challenges

The first two units contain chapters 1 through 13. These chapters present theories, developmental concepts, and principles of pediatric nursing practice that are germane to each encounter with a child and their family, regardless of their specific healthcare concern. These chapters provide a wealth of current knowledge that the student or nurse can use to identify and analyze the needs of a child and his or her family, and to provide targeted anticipatory guidance.

Unit III builds on the content developed in the first two units to present the healthcare challenges most commonly encountered in the pediatric population. A deliberate effort was made to present the healthcare challenges that reflect pathologies of a particular body system in a single chapter. Thus, the reader looking for information about a specific disease or condition is able to locate the content in an efficient and logical manner.

The content in Chapters 14 to 31 is presented in a consistent format to assist the reader in reviewing the assessment, diagnostic, and treatment interventions

specific to a particular body system. These chapters are structured as follows:

- Developmental and Biologic Variances
- Assessment of the Child With an Alteration in _____
- Focused Health History
- Focused Physical Assessment
- Diagnostic Criteria for Evaluating Alterations in _____
- Treatment Modalities
- Nursing Plan of Care for the Child with Altered _____

Each chapter begins with a review of important developmental and biologic variances that explain the differences seen in children compared with adults. The assessment section discusses the focused health history, the focused physical assessment, and the diagnostic tests and procedures that help the clinician determine the presence of an alteration in a particular body system. Also included is a summary of the common treatment modalities used by the interdisciplinary team to manage children facing these health challenges. The nursing plan of care draws upon the information from the assessment and treatment modalities sections to articulate the relevant nursing diagnoses, targeted interventions, and expected outcomes that will help the child and the child's family deal with the condition or situation.

Following this introductory content, the specific conditions—or “health challenges”—commonly seen in children are presented. The discussion of each condition begins with information on incidence, etiology, and pathophysiology. Assessment data, diagnostic test results, and nursing diagnoses unique to the particular condition under discussion are presented. As needed, the reader should refer back to the chapter's introductory section to augment his or her understanding of the general assessment and diagnostic criteria for conditions of the subject body system. The discussion of each condition concludes with presentation of the interdisciplinary care considerations specific to community settings such as the home, school, and daycare facility.

RECURRING FEATURES

A variety of pedagogic features have been incorporated into the text to highlight key aspects of care and to aid in identifying key information. In addition, more than 500 color photographs and drawings are included to illustrate key points.

Nursing Plan of Care

These charts summarize the nursing diagnoses that are consistently applicable to defined populations of children with specific health challenges. Interventions to address the identified nursing diagnoses and expected outcomes of care are identified. If a clinical condition presents with a unique challenge that has not been adequately defined in the Nursing Diagnoses and Outcomes chart, then more specific nursing diagnoses and outcomes for that particular area of concern are listed where appropriate.

Tradition or Science

This feature explores various areas in healthcare to determine whether current practice is based on tradition, historical patterns of care, or science, or the best available credible evidence. This feature poses a clinical question (e.g., Why are vital signs taken every 4 hours?) and then provides a response.

Nursing Interventions

To categorize and describe specific nursing activities in more detail, 19 nursing intervention classifications (NICs) relevant to the pediatric population have been selected from Bulechek, Butcher, and Dochterman's *Nursing Interventions Classification (5th ed.)* (Mosby–Year Book, 2008).

The text also includes nursing intervention charts developed by the authors to provide a more in-depth description of particular nursing care activities. These charts delineate specific nursing care responsibilities that can be initiated to ensure the child with a specific condition receives optimal care whether in an acute or community care setting.

TIP

The Teaching Intervention Plans present an interdisciplinary plan focused on an aspect of care involving patient and/or family education. In each TIP, nursing diagnoses and child and family outcomes define the problem and the desired goals.

Developmental Considerations

Appearing throughout the text where appropriate, these charts highlight important psychosocial, teaching, physiologic, or pathophysiologic differences between children and adults or between children of various age groups.

Clinical Judgment

This feature provides a self-check for the reader in evaluating her or his critical thinking skills. Each begins with a clinical situation, or vignette, followed by five questions that include

1. Question regarding an assessment of the situation
2. Question in which the student must classify or group related data into patterns
3. Question in which the student must draw a conclusion or differentiate information
4. Question regarding the interventions that should now be carried out based on the answers to the three previous questions
5. Question regarding evaluating the outcomes, evaluating what they should see as outcomes, or, if they do not see certain outcomes, then what referrals or further action should be taken

These questions are then answered based on the preceding vignette.

Community Care

These charts present special teaching or clinical information to assist the nurse working with the family in community settings.

International Content

Evidence-based practice guidelines that have been developed and accepted by the international health care community are presented throughout the text. Computer healthcare resources that can be accessed by all national and international readers are presented on [thePoint](#).

Developmental and Biologic Variances Drawing

Throughout Chapters 14 to 31, this feature highlights important developmental and biologic variances to further refine the reader's knowledge of age-appropriate assessment and intervention criteria.

Focused Health History Chart

Throughout Chapters 14 to 31, this chart summarizes specific health history information the nurse needs to know to assess disorders in a particular body system.

Focused Physical Assessment Chart

Throughout Chapters 14 to 31, these charts highlight or summarize assessment findings, identifying what would be considered abnormal findings.

Tests and Procedures Table

Throughout Chapters 14 to 31, these tables describe the tests and procedures used most often in the assessment and diagnosis of conditions affecting a particular system or diagnostic group. Each one highlights the healthcare responsibilities associated with assisting the child in undergoing the test or procedure.

In-Text Highlights

In addition to the aforementioned special features, four in-text features highlight key information:

1. **KidKare** provides ideas for directing care to meet a child's unique needs.
2. **Alert!** highlights indicators of imminent emergencies or factors to consider that indicate the need for immediate action by the healthcare provider.
3. **Worldviews** indicate how cultural, ethnic, or religious practices may influence the perception of a condition, the course of the condition, or the treatment plan.
4. **caREminder** is a brief reminder of an aspect of care that is especially important for the nurse to remember to ensure safe care.

RESOURCES FOR STUDENTS

Valuable learning tools for students are available both on [thePoint](#) and on the free Student Resource CD-ROM bound in this book.

Watch and Learns

A special icon  throughout the book directs students to the free video clips that demonstrate important concepts related to child health nursing. These clips can be viewed on [thePoint](#) and on the Student Resource CD.

NCLEX-Style Review Questions

NCLEX-style review questions that correspond with each book chapter help students review important concepts and practices for the NCLEX. These are provided on [thePoint](#) and on the Student Resource CD.

Key Terms

A list of terms considered essential to the chapter's understanding is presented on [thePoint](#). Each term appears in the text in boldface type, with the definition included in text.

Summary of Key Concepts

Key concepts provide a quick review of essential chapter elements. Presented on [thePoint](#), these bulleted lists help the student focus on important aspects of the chapter.

Resources and Bibliography

A list of resources that includes organizations, hotlines, and computer resources are provided on [thePoint](#). These lists enable the reader to access additional sources of information and explore topics of interest. The bibliography also offers articles and texts for more extensive review.

Care Paths

Care Paths were selected as the clinical tool to present the interdisciplinary plan of care for children with selected diseases and conditions discussed in the text. Although we recognize the need for students to learn and articulate the traditional nursing care plan, we also recognize that in the healthcare arena, the focus is on interdisciplinary collaboration. This agenda is articulated in a plan of care that reflects all of the components of the care for a "typical" child with a particular diagnosis. Nursing diagnoses are incorporated in each care path to establish

the areas of concern that need to be addressed by the healthcare team. For each nursing diagnosis, patient outcomes are identified as goals to be achieved over a defined time period. The care categories delineate the healthcare interventions to be performed in each identified time interval to enable achievement of the patient outcomes.

The student using this text is likely to already have benefited from the concepts presented in a nursing fundamentals course and a medical–surgical nursing course. This text aims to build on that knowledge and further the student’s understanding of collaborative practice and the clinical tools that have been adapted in practice settings to reflect the interdisciplinary care. Through the use of these tools, the student has the opportunity to gain more knowledge about achieving patient outcomes, which in turn will have an effect on the child’s length of stay and the optimal use of resources. These issues are defining the delivery of healthcare and thus must be vital components of any education program for the health professional.

Medication Administration

Medication administration tables are presented on [thePoint](#). These tables summarize information about commonly used medications.

Procedures

Step-by-step instructions are presented on [thePoint](#) in a clear, concise format to facilitate performance of selected procedures that are commonly encountered when caring for children. Procedures are based on the best credible evidence available.

Supplemental Information

Additional information, including disease coverage or specific nursing care information, is also provided on [thePoint](#) when appropriate.

Spanish–English Glossary

A Spanish–English Glossary lists words commonly encountered or needed in the nurse’s practice.

RESOURCES FOR INSTRUCTORS

Tools to assist you with teaching your course are available on [thePoint](#) at <http://thepoint.lww.com/Bowden2e>:

- An extensive collection of materials is provided for each book chapter: Prelecture Quizzes and Answers, which are quick, knowledge-based assessments that allow you to check students’ reading; PowerPoint presentations, which provide an easy way for you to integrate the textbook with your students’ classroom experience, either via slide shows or handouts; Guided Lecture Notes that walk you through the chapters, objective by objective, and provide you with corresponding PowerPoint slide numbers; Discussion Topics (and suggested answers), which can be used as conversation starters and are organized by learning objective; and Assignments (and suggested answers), which include group, written, clinical, and Web assignments.
- An Image Bank lets you use the photographs and illustrations from this textbook in your PowerPoint slides or as you see fit in your course.
- A sample syllabus provides guidance for structuring your pediatric nursing course.
- The Test Generator lets you put together exclusive new tests from a bank containing more than 550 questions to help you in assessing your students’ understanding of the material. These questions are formatted to match the NCLEX, so your students can have practice in preparing for this important examination.

UNIT II
Maintaining Health Across the
Continuum of Care 255

8 Health Assessment and Well-Child Care 257

Levels of Prevention 258

Primary Prevention	258
Secondary Prevention	258
Tertiary Prevention	259
Nurse's Role	259
Immunization	259
Recommended Childhood Immunization Schedule	259
Considerations, Contraindications, and Precautions for Immunization	265
Strategies for Improving Immunization Status	266
Health Assessment From Infancy Through Adolescence	267
Communication Skills	267
Health History	268
Physical Examination	275
Database and Interpretation	298
Health Surveillance Visits	298
Anticipatory Guidance	300

9 Pharmacologic Management 303

Developmental Considerations in Pharmacokinetics and Pharmacodynamics	304
Pharmacokinetics	304
Pharmacodynamics	305
The Six Rights	306
The Right Medication	306
The Right Dose	306
The Right Patient	308
The Right Route	309
The Right Time	309
The Right Approach	309
Avoiding Common Errors in Medication Administration	310
Prescribing and Transcription Errors	310
Dispensing and Administration Errors	310
Reporting Adverse Drug Reactions and Medication Errors	313
Administering Medication to Children	313
Routes of Administration	313
Education About Pharmacologic Agents	321
Administering Medication in School, Camp, or Childcare Settings	321
Verbal Orders	321
Resources for Safe Medication Practices	321

10 Pain Management 324

Neurophysiology of Pain	325
Nociceptive and Neuropathic Pain	325
Developmental Patterns	325
Factors That Influence the Pain Experience	326
Type of Pain Experience	326
Child Characteristics	328
Parental Influence	331
Influence of Healthcare Professionals and Systems	332
Assessing Pain in Children	332

Self-Report Strategies	334
Behavioral Observations	334
Physiologic Parameters	336
Developmental Factors in Pain Assessment	338
Managing Pain in Children	343
Pharmacologic Pain Management	347
Biobehavioral Strategies (Nonpharmacologic) and Comfort Interventions	353
Management of Special Pain Situations	362
Ensuring Effective Outcomes of Pain Management	369
The Interdisciplinary Pain Team	369
Nurse's Role in Pain Management	370
Documentation	370

11 Acute Illness as a Challenge to Health Maintenance 377

The Acute Care Experience	378
The Acute Care Environment	379
Nursing Care of the Child and Family During the Admission Process	381
Preparing the Child and Family for Admission: Hospital Tours	381
Conducting an Admission Assessment	382
Nursing Care of the Child and Family During Hospitalization	384
Promoting Activities of Daily Living	384
Maintaining Safety	387
Performing Routine Procedures	393
Maintaining Infection Control	394
Educating the Child and Family	397
Promoting Coping: The Child	397
Promoting Coping: The Family	408
Nursing Care of the Child Going Undergoing Surgery	415
Preoperative Care	415
Postanesthesia Care	419
Same-Day Surgery	421
Preparing for Discharge From an Acute Care Setting	421
Prolonged Hospitalization	424
Effect on the Child	424
Effect on Parenting	425
Care Conferences	426
Discharge	426

12 Chronic Conditions as a Challenge to Health Maintenance 429

Terminology Related to Chronicity	430
Chronic Condition Versus Chronic Illness	430
Person-First Language	430
Disability and Other Related Terms	430
The Spectrum of Chronic Conditions	432
The Prevalence of Chronic Conditions	433
Psychological Adjustment to a Child With a Chronic Condition	433
The Period Prior to a Diagnosis Being Made	433

<i>The Time of Diagnosis</i>	434
<i>The Period of Adjusting to and Coping With the Ongoing Demands of Having a Child With a Chronic Condition</i>	438
<i>The Time of Exacerbation or Deterioration Requiring Hospitalization</i>	446
Impact of a Chronic Condition on a Child/Adolescent	447

Family-Centered Care Throughout the Family Life Cycle

C H A P T E R

1

The Child Developing Within the Family

Case History

The Tran family consists of Tung Tran, the father; Loan Pham, the mother; Ashley Tran, a 16-year-old daughter; and George, a 14-year-old son. They have just moved to a new home in the same section of town where they had been living for the past 17 years. Prior to the move, the family had been living with Loan's mother and father after immigrating to the United States from Vietnam. Loan's mother died 3 years ago and Loan's father died last year. Loan's youngest sister, Ha, also lived in the home. Loan has two other sisters. Both are married and live down the street.

The family moved so they could open a Vietnamese restaurant. The new home is above the restaurant. Tung speaks English fairly well, but Loan only speaks a few words. The family members communicate with each other in Vietnamese in the home. At home, Ashley is called Chi Lon, which means "oldest sister."

The family is strict Roman Catholic and attends church every Sunday as a group. The religious influence is apparent in their home, with crucifixes, statues, and pictures of religious figures throughout the home.

The Tran children were born in the United States.

Tung and Loan have very high expectations of their children. Both children are expected to maintain an A average in school. Ashley is a B to B+ average student. The parents are upset with the amount of time that Ashley spends socializing with her friends, most of whom are not Vietnamese. Her parents also are concerned about how Ashley dresses and the amount of makeup she wears. Ashley is upset because she feels that her parents don't understand. Ashley also never uses her Vietnamese name when she is with her friends.

George maintains an A average and is very interested in mathematics, hoping to become an engineer in the future. George has several friends, many of whom are Vietnamese and share his interest in mathematics.

George is brought to the emergency department after sustaining first- and second-degree burns to his hands and forearms while helping out his father in the restaurant kitchen. Loan, Ashley, and Loan's sister Ha have accompanied George.

CHAPTER OBJECTIVES

1. Select strategies to integrate elements of family-centered care into patient care practices.
2. Discuss selected family theories, describing their strengths, limitations, and application to nursing practice.
3. Explain the family life cycle model as a framework for viewing family development across the life span.
4. Describe different family structures.
5. Describe the functions and roles of family members within the family.
6. Examine the impact of selected family issues on the family system.
7. Examine the cultural and religious influences that can affect child healthcare.

See **thePoint** for a list of Key Terms.

An African proverb states: “It takes a village to raise a child.” These few, simple words emphasize the significant role of the community, in addition to the family, in the child-rearing process. The community that surrounds the child affects every aspect of the child’s health and general welfare. The quality of life within this community has the greatest effect on the child’s ability to achieve developmental tasks and to become a functional member of society. For some children, this community is a close-knit group that consists of one or both parents, step-parents, and siblings. For others, the community constellation may include an extended multigenerational familial group of grandparents, aunts, uncles, and cousins. In

some societies, the family unit extends well beyond the child’s biologic parents to include friends and family members bound closely together as a group that fosters communal or tribal living and joint accountability for the rearing of children. Variances in the structure of the family reflect changes in societal values and an openness and appreciation for greater diversity in the family structure.

QUESTION: Using the U.S. Census terminology, how would you describe the Tran family?

The multiplicity of family configurations in today’s society creates a challenge in adhering to a single definition of the term *family*. In the most recent U.S. Census, terminology was used to define both family and nonfamily households to provide mechanisms to ensure inclusiveness in the population count (Table 1–1). The traditional description of a nuclear family is no longer representative of the family units in our society. Because of the many different family configurations, it is no longer possible to define the family in strict terms of the composition of its members or within the context of its previously defined functions. Therefore, broader definitions have been used to conceptualize the family without the boundaries previously respected by the law and by societal sanctions (Chart 1–1). Bozett (1987) suggested that the most workable definition of the family is this: The family is who the patient says it is. This definition frees the nurse from value judgments about the importance of certain familial ties within a given family and allows practices and policies to be instituted that are in the best interest of the child.

TABLE 1 – 1
U.S. Census Bureau Definitions of the Family

Type	Definition
Household	Consists of all the people who occupy a housing unit. A household includes the related family members and all the unrelated people, if any, such as lodgers, foster children, wards, or employees who share the housing unit. A person living alone in a housing unit, or a group of unrelated people sharing a housing unit, such as partners or roomers, is also counted as a household. The person who owns or rents the residence is designated as the <i>householder</i> .
Family household	Household that has at least two members related by birth, marriage, or adoption, one of whom is the householder. Family households are maintained by married couples or by a man or woman living with other relatives. Children may or may not be present.
Nonfamily household	Can be either a person living alone or a householder who shares the housing unit only with his or her nonrelatives (e.g., boarders or roommates). The nonrelatives of the householder may be related to each other.
Children	Include sons and daughters by birth, stepchildren, and adopted children of the householder regardless of the child’s age or marital status.

From U.S. Census Bureau. (2004). *Current population survey: Definitions and explanations*. Retrieved February 3, 2008, from <http://www.census.gov/population/www/cps/cpsdef.html>

CHART 1-1 DEFINITIONS OF THE FAMILY

Group of persons united by ties of marriage, blood or adoption, constituting a single household; interacting and communicating with each other in their respective roles of husband and wife, mother and father, son and daughter, brother and sister; and creating and maintaining a common culture (Burgess, Locke, & Thomas, 1963, 7–8).

Two or more people joined together by bonds of sharing and intimacy (Family Service America, 1984).

A self-identified group of two or more individuals whose association is characterized by special terms, who may or may not be related by blood lines or law, but who function in such a way that they consider themselves to be a family (Whall, 1986).

Whoever the patient says it is (Bozett, 1987).

A group of individuals who are bound by strong emotional ties, a sense of belonging, and a passion for being involved in one another's lives (Wright, Watson, & Bell, 1996).

Family refers to two or more individuals who depend on one another for emotional, physical, and economic support. The members of the family are self-defined (Hanson, Gedaly-Duff, & Kaakinev, 2005).

The family is a group of individuals with a continuing legal, genetic, and/or emotional relationship. Society relies on the family group to provide for the economic and protective needs of individuals, especially children and the elderly (American Academy of Family Physicians, 2009).

Group of two or more persons related by blood, marriage, or adoption who are residing together (U.S. Census Bureau, 2004b).

Two or more persons who are related in any way—biologically, legally, or emotionally. Patients and families define their families (Institute of Family Centered Care, 2007).

A family is a primary social group in any society, typically consisting of a man and a woman, or any two individuals who wish to share their lives together in a long-term commitment to one another, bring up offspring, and usually reside in the same dwelling (Maskanian, 2007).

caREminder

Although many definitions of family do not fit those stipulated by the law or many religious institutions, when the health and well-being of a loved one is at risk, legal and religious boundaries cannot serve as the sole inclusion criteria for family-centered healthcare interventions. At the same time, the nurse's actions cannot overlook the familial connections that are legally sanctioned and need to be recognized when the healthcare issues related to a child are in question.

However one chooses to define the child's family, there is no doubt that families in today's society are faced with complex financial, environmental, and interpersonal challenges as they try to nurture, develop, and socialize their children. These challenges can create stress and often a sense of crisis within the family unit. As the family responds to normal concerns and unusual developmental and situational crises, the children learn adaptive and nonadaptive behaviors to cope with the stressors of life. In response, some children may develop physical illnesses, psychological symptoms, destructive and disruptive behaviors, depression, or anxiety, all of which can lead to social and academic difficulties when children are unable to cope with stress successfully.

Yet, for many others, the family can protect children from the negative outcomes associated with stress by teaching them appropriate mechanisms for coping with the challenges related to the transitions and changes that accompany the childhood years. It is within the context of the family that the child learns about relationships and behaviors that promote healthy interactions with others. Therefore, to begin to understand the child, it is important first to understand the family and its functions, roles, and structure. Such an understanding is fundamental to providing quality healthcare.

To this end, this chapter begins with a discussion of family-centered care (FCC). **Family-centered care** is a philosophy of care that permeates all interactions between families and healthcare providers. This philosophy places a high value on the contributions made by the family members in relation to their healthcare needs. As providers of FCC services, it is essential nurses understand the complex structure of the family. This chapter reviews several theories that explain how families develop and interact; describes the types of families most prevalent in today's society; and explores the impact of divorce, remarriage, and single parenting on these families. Family roles, family function, and the healthy family unit are also presented.

ANSWER: The Tran family would be described as a family household (one with at least two members related by birth, marriage, or adoption, one of whom is the householder) and includes children (the sons and daughters by birth, stepchildren, and adopted children of the householder, regardless of the child's age or marital status).

WHO WE SERVE: CHILDREN AND THEIR FAMILIES

To understand the role of the pediatric nurse it is important first to clarify both who the nurse serves and the philosophy of care that drives pediatric healthcare practices. Pediatric services are concerned with the health of newborns, infants, children, adolescents, and young adults through 21 years of age (American Academy of Pediatrics, 1998; National Association of Pediatric Nurse Practitioners, 2002). All healthcare professionals are recognizing that care of the child extends to care of the family and its needs in relation to optimizing the growth and

development of the child. The child is an integral entity within the family. The child cannot be viewed as separate and apart from the group of individuals who play such an influential role in molding the child's behavior, emotions, and understanding of the world. Thus, the focus of pediatric nursing is on the child *and* the family. The philosophy of care that has been adopted in pediatric healthcare is aptly called *family-centered care* (Chart 1–2).

Family-Centered Care

FCC is a philosophy of care that acknowledges the importance of the family unit as the fundamental focus of all

CHART 1–2 DEFINITIONS OF FAMILY-CENTERED CARE

The identification of problems and needs of a family and the provision of appropriate service for every family member (Yauger, 1972).

A philosophy, a way of approaching a family, rather than a set of procedures (Atkinson, 1976).

Viewing the family not as a collection of individuals, but as a discrete entity, as the fundamental unit of medical care delivery (Schwenk & Hughes, 1983).

Designing services in response to needs of the total family, including the child with special needs (Friesen, Griesbach, Jacobs, Katz-Leavy, & Olson, 1988).

Recognizing the individual resources and needs of three partners the child, the family, and the service providers in an interactive system (Hanft, 1988).

A philosophy of care based on the belief that all families are deeply caring and want to nurture their child (Edelman, 1991).

True partnership where family members and professionals are of mutual benefit to each other as integral members of the person's care team through the sharing of information from their unique perspectives (Shelton & Stepanek, 1994).

FCC is an approach to healthcare that shapes healthcare policies, programs, facility design, and day-to-day interactions among patients, families, physicians, and other healthcare professionals. FCC in pediatrics is based on the understanding that the family is the child's primary source of strength and support, and that the child's and family's perspectives and information are important in clinical decision making (American Academy of Pediatrics, 2003).

Patient- and family-centered care is an innovative approach to the planning, delivery, and evaluation of healthcare that is grounded in mutually beneficial partnerships among healthcare patients, families, and providers. Patient- and family-centered care applies to patients of all ages, and it may be practiced in any healthcare setting (Institute of Family Centered Care, 2007).

healthcare interventions. This model of care recognizes the *collaborative* relationship between the family and the professional care provider in the pursuit of being responsive to the priorities and needs of families when they seek healthcare (MacKean, Thurston, & Scott, 2005). The concept of FCC is not new; in fact, it is as old as, if not older than, most of the health professions. In days past, healthcare providers were family members. Kin served in the roles of medicine man or woman, nurturer, counselor, and even social worker. However, when healthcare moved to the hospital setting, individuals became separated from the family, and the focus of care concentrated on the individual alone. In addition, as previously stated, societal changes have made it increasingly difficult to define the family. These factors have added to the challenge of moving from a conceptual acceptance of FCC to reality-based methods of providing care that focus on both the child and the family.

Several significant documents have had a great impact on the acceptance of a family-centered approach to healthcare. The concept was introduced with the publication of two documents in 1987 that defined the elements of a family-centered approach to healthcare. The first was a report on children with special needs issued by Surgeon General C. Everett Koop (Department of Health and Human Services, 1987). The second was a document published by the Association for the Care of Children's Health (ACCH), *Family-Centered Care for Children with Special Healthcare Needs* (Shelton, Jeppson, & Johnson, 1987). Since then, federal legislation has supported the principles and practices of family-centered healthcare through such laws as the Individuals with Disabilities Education Act (IDEA), the Disabilities Education Improvement Act, and the Developmental Disabilities Assistance and Bill of Rights Act. In 1992, the Institute for Family-Centered Care was established as an organization to support the integration and development of FCC around the world. Although FCC began as a concept applied to pediatric healthcare, FCC concepts are now being applied to all healthcare arenas and across both pediatric and adult populations.

Elements of Family-Centered Care

FCC is best understood by extracting and explaining the elements or components of this philosophy of care that work together to move an individual or an institution toward providing a family-centered approach (Chart 1–3). Each of these eight elements serves to reinforce, facilitate, and complement the implementation of the others. In pediatric healthcare, the elements of FCC recognize each family's uniqueness, acknowledge the influence of the family as a constant in the child's life, and emphasize the importance of providing services that demonstrate the value of collaboration among the healthcare provider, the child, and the family. FCC is based on the premise that a positive adjustment to a child's level of health and well-being requires the involvement of the whole family (Lewandowski & Tesler, 2003; Shelton & Stepanek, 1995).

Despite the ongoing validation of the importance of FCC, actualizing FCC practices remains problematic.

CHART 1-3 KEY ELEMENTS OF FAMILY-CENTERED CARE

The Family at the Center

Incorporating into policy and practice the recognition that the *family is the constant* in a child's life, whereas the service systems and support personnel within those systems fluctuate.

Family–Professional Collaboration

Facilitating *family–professional collaboration* at all levels of hospital, home, and community care—care of an individual child; program development, implementation, evaluation, and evolution; and policy formation.

Family–Professional Communication

Exchanging complete and unbiased information between families and professionals in a supportive manner at all times.

Cultural Diversity of Families

Incorporating into policy and practice the recognition and *honoring of cultural diversity*, strengths, and individuality within and across all families, including ethnic, racial, spiritual, social, economic, educational, and geographic diversity.

Coping Differences and Support

Recognizing and respecting *different methods of coping* and implementing comprehensive policies and programs that provide *developmental, educational, emotional, environmental, and financial supports* to meet the diverse needs of families.

Family-Centered Peer Support

Encouraging and facilitating *family-to-family support* and networking.

Specialized Service and Support Systems

Ensuring that *hospital, home, and community services and support systems* for children needing special health and developmental care and their families are *flexible, accessible, and comprehensive* in responding to diverse family-identified needs.

Holistic Perspective of Family-Centered Care

Appreciating families as families and children as children, recognizing that they possess a wide range of strengths, concerns, emotions, and aspirations beyond their need for specialized health and developmental services and support.

From Maternal and Child Health Bureau <http://mchb.hrsa.gov> and Institute for Family-Centered Care <http://www.familycenteredcare.org/> Used with permission.

Technology, economic trends toward downsizing services and staffing, and the presence of a more culturally diverse population of patients are challenges to implementing FCC. Nurses struggle to find the time and energy to reach beyond the procedural boundaries of

their work to meet family needs. Barriers have been created by complex organizational structures and policies that can separate the child from the family. In addition, Newton (2000) identified family role stress, negotiation failures, and power struggles as issues that affect the collaborative relationship between the family and the health-care providers, and often impede FCC.

A growing body of research has further noted the lack of congruence between family needs as perceived by the patient and the family, and the same needs as perceived by members of the healthcare team (Agency for Healthcare Research and Quality, 2005). Violence in the healthcare setting has produced additional challenges to providing FCC. Concerns regarding infant or child security have tightened visitor policies and have forced hospitals to place more monitors on the children's activities and whereabouts in the hospital. A family-centered approach usually supports liberal visitation of family members for both young and old, yet it is recognized that the increased number of visitors can lead to increased confusion and security risks within a clinical facility. In addition, there is a concern that increased infection rates and spread of contagious diseases accompanies liberal visitation policies. Certainly, these concerns are valid. They can be addressed by security and infection control screening measures that are aimed at safeguarding the child while still supporting FCC.

Family-Centered Care Interventions and Strategies

FCC is a philosophy of care that must be translated into action. The relevance to the child and the family goes unnoticed unless active measures are taken to ensure that family-centered practices are integrated into every aspect of the healthcare arena. Nursing diagnoses can be formulated from the family assessment to articulate the problems identified for a family encountering a situational or developmental crisis (Nursing Plan of Care 1–1). The interdisciplinary team can use these diagnoses to guide interventions to promote family integrity in the presence of developmental and situational issues faced by the family and its members. From legislation supporting family-centered practices to an interdisciplinary team focused upon the needs of the entire family, the elements of FCC care can be operationalized via a variety of unique strategies (Nursing Interventions 1–1). These family-centered strategies need to continue to be described in the healthcare literature, noting exactly which strategies have been truly effective in meeting family needs (Lewandowski and Tesler, 2003). In the same manner, nurses need to continue to *assess* family needs, *document* how FCC has been implemented, *define* factors that facilitate or hinder FCC, and *record* the cost-effectiveness of FCC.

FCC interventions recognize the importance of families in facilitating the growth of their children, especially children with special healthcare needs. The needs and resources of each family member and the degree to which the family wants to become involved differ with each family. Yet, the goals remain the same: to optimize the family's ability to interact, intervene, and nurture the

NURSING PLAN OF CARE 1–1: THE FAMILY ENCOUNTERING SITUATIONAL OR DEVELOPMENTAL CRISES

Nursing Diagnosis: Readiness for enhanced family coping related to situational or developmental crisis.

Interventions/Rationale

- Assess family member's perception of the crisis/ current event, including precipitants of the crisis, past and present coping skills and their effectiveness, strengths and abilities of family members to meet demands of the crisis, potential sources of additional stress and available support systems.

Provides baseline information about individual family member's understanding of the current situation.

Assists in determining whether all members have a realistic and shared perception of the events and intervening variables. Provides an opportunity for expression of thoughts and feelings. Family members may be unaware of differences in individual perspectives about the current crisis.

- Assist in identification of new coping skills, personal/family strengths and abilities, and support systems that will assist the family to resume a state of functioning comparable with or better than that experienced during the pre-crisis state.

During the crisis state, past methods of coping may not be satisfactory to meet the current situation. Recommendations for new coping and problem-solving strategies can provide renewed hope and encouragement to family members.

- Facilitate family discussion as members evaluate roles, sources of family conflict, family strengths, and other related family issues.

Uses therapeutic relationships established between the nurse and the family to share feelings in a non-threatening manner. Determines areas of dissatisfaction and/or conflict, and whether family members want to resolve these issues and move to more productive ways of interacting with one another.

- Assist family to develop a chosen course of action, including formulating a time frame for implementation and criteria to determine whether plan has been effective.

Helps family members establish new goals that are different from their current manner of functioning, and are directed toward a more competent way of handling current stressors.

Expected Outcomes

- Family members share a realistic perception of the event, and can discuss the impact of the current crisis on themselves and the family as a unit.
- Family members develop adaptive responses by changing responsibilities to meet the demands of the situation by using strengths of family members to enhance coping and by selecting new strategies to manage stress caused by the current situation.

- Family members identify support systems to assist them and participate in mobilizing those systems.
- Family members identify potential sources of additional stress and make efforts to reduce or eliminate additional stressors.

Nursing Diagnosis: Readiness for enhanced parenting related to developmental and situational challenges of child rearing (e.g., child's illness, adolescent/parent conflicts).

Interventions/Rationale

- Assess parent's knowledge and understanding of the physical, psychological, social, and spiritual needs of their child.

Identifies if parents have a realistic understanding of developmentally appropriate norms for child and the unique attributes of their child that impact their child's behavior.

- Teach normal physiologic, emotional, and behavioral characteristics of children.

Assist parents to better understand and promote the physical, psychological, social, and spiritual growth and development of their child.

- Allow parents to express their feelings about their diminished capacity to perform usual parenting roles and to use parenting skills to meet demands of the current crisis situation.

Facilitates expression of parental feelings. Helps parents to identify frustrations and specifically identify areas of concerns in their interactions with their children and with other persons sharing parenting responsibilities for the child.

- Assist parents to identify strategies to enhance parenting (e.g., ways to communicate more effectively with the child, discipline techniques, and techniques to manage parent-child conflict). Refer parents to a support group or parenting classes, as appropriate.

Provides concrete strategies to improve parent-child communication, manage the child's behavior, and use conflict for enhancing mutual understanding. Provides an opportunity for parents to learn new parenting skills in a nonthreatening environment with parents facing similar issues.

Expected Outcomes

- Parents express knowledge of their child's developmental needs and are able to meet the developmental needs of their children.
- The child meets developmental milestones appropriate for his or her age.
- Parents convey love and warmth and acceptance to their child.

- Parents express confidence in their ability to meet the infant's or child's needs.
- Parents recognize when assistance is needed and seek help from others to manage the infant, child or adolescent.

Nursing Diagnosis: Readiness for enhanced spiritual well-being related to managing current stress and improving family/individual coping.

Interventions/Rationale

- Assess family members' feelings about usual and current religious and spiritual beliefs (see Table 8–3 in Chapter 8 for an assessment tool).

Provides baseline data to evaluate spiritual well-being.

- Assist family members to identify barriers and attitudes that hinder growth and self-discovery. Assist family members to identify factors that may enhance growth and self-discovery.

Exploring both growth barriers and facilitators identifies beliefs and practices that can be used to cope with current stressors. Open discussion with family members encourages self-revelation that may enhance understanding of spiritual stagnation or distress.

- Encourage participation in activities that enhance spiritual connection with a greater power (e.g., prayer, attending worship services, listening to spiritual music, reading the Bible or Koran, reading spiritual articles or books, listening to

inspirational speakers on tape, radio, or television).

Religious practices provide many individuals a connection with a greater power. Sharing these experiences with other family members may strengthen the family unit and relationships with one another.

- Teach methods of guided imagery, relaxation, meditation, and use of silence.

These activities can assist individuals to call upon their inner strength to focus on finding comfort, strength, and hope in their life.

- Refer family for pastoral care, to a spiritual caregiver, support group, mutual self-help group, or other spiritually based program, as appropriate.

Provides additional sources of spiritual guidance and support for the family members. Enhances personal understanding of spiritual issues through contact with mentors/leaders who have strong spiritual/religious values, knowledge, and practices.

Expected Outcomes

- Family members identify areas of spiritual ambivalence and conflict resulting from current situation.
- Family members seek appropriate support persons to assist in overcoming spiritual distress.
- Family members use strategies to ease spiritual discomfort and facilitate growth in their capacity to connect harmoniously with their inner strength and with a greater power.

child during times of both physical and psychological stress. Through interdisciplinary interventions that provide education and knowledge to the family, parents and others can be empowered to make informed decisions about their child's care (Lewandowski & Tesler, 2003; Shields and Tanner, 2004).

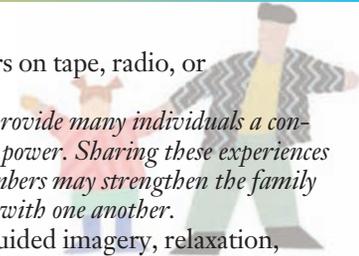

Implementation of FCC interventions and ongoing ways to support FCC have been consistently documented over time to elicit positive feelings from healthcare staff, and reports of increased parent and child satisfaction (Johnson, Jeppson, & Redburn, 1992; LeGrow & Rossen, 2005; Lewandowski & Tesler, 2003; Neal et al., 2007; Shields & Tanner, 2004). Family anxiety is often reduced as the family's understanding of and involvement in the child's healthcare activities are promoted through these interventions.

The Medical Home

The focus on FCC has led to a national imperative to ensure that people of all ages have a place they identify as their "medical home." A **medical home** is more than a building, house, or hospital, or a specific healthcare team the person sees on a regular basis. The concept of a medical home is also an approach to providing healthcare

services in a high-quality and cost-effective manner (Sobel & Healy, 2001). The American Academy of Pediatrics (AAP) first defined this concept in 1992, and later refined the interpretation of the concept and the operational definition (American Academy of Pediatrics, 2002). According to the AAP, the term *medical home* represents a concept in which healthcare to children is accessible, continuous, comprehensive, family centered, coordinated, compassionate, and culturally effective (American Academy of Pediatrics, 1997, 2007). Well-trained physicians and healthcare professionals who focus on providing primary care and managing all aspects of the child's health needs deliver such care. The concept encourages a partnership between the physician (healthcare team) and the child and his or her family that promotes mutual trust and respect. See [thePoint](#) for Supplemental Information for more information regarding the desirable characteristics of the medical home. Through identification of a medical home for every child, it is expected that healthcare costs can be reduced and be more effective as the family interacts with a care provider well acquainted with the unique characteristics and needs of the child.

As part of the medical home concept, care is family centered and can be provided in various locations such as the physician's office, hospital outpatient clinics, and

NURSING INTERVENTIONS 1–1

Strategies to Enhance Family-Centered Care

- Change visiting policies to promote the presence of the family at the bedside.
- Establish family support groups, placing invitations to attend meetings on each child's bed.
- Develop activities or programs to support the family as they make the transition from one unit to another (e.g., from the pediatric intensive care unit to the pediatric floor).
- Be sure there are an adequate number of sleeping cots for parents.
- Establish a sibling hospital visiting policy.
- Encourage family visiting in the postanesthesia room.
- Use parent questionnaires to better understand family needs.
- Involve parents in playroom activities.
- Develop mechanisms to support regular contact between the child and out-of-town parents.
- Establish a parent committee or family advisory council to advise the hospital on issues of importance.
- Create a parent information board containing community resources and information pamphlets.
- Create a parent information and orientation program to familiarize parents with the hospital.
- Provide a brief parent welcome and orientation program.
- Incorporate the family in interdisciplinary conferences regarding the child's care.
- Use preoperative videos and tours to ease the child's and family's fear about the pre- and postoperative processes.
- Establish programs to support the infant or child's transition to home after a lengthy hospitalization.
- Encourage parents to chart the child's progress.
- Contract with parents to provide care for periods of time during the day.
- Provide the family with a copy of the child's care path.
- Coordinate and record all of the child's daily activities on a large calendar that is visible to everyone.
- Provide a parking discount for parents.
- Establish volunteer child care services for siblings while parents visit the sick child.
- Call parents with reports of the child's progress or send notes from the child for those hospitalized for a long period of time.
- Recognize and integrate ethnic, racial, and cultural activities as appropriate into the clinical setting (e.g., foods, play items, pictures on the wall).
- Aim for diversity in healthcare staff.
- Encourage families to bring in culturally significant items such as foods, and healing and religious symbols.
- Encourage all family members to participate in home care activities.
- In the acute care setting, provide support services such as laundry and kitchen facilities to families experiencing long hospitalizations.
- Provide activities such as picnics, movies, and special events for children and their families to interact with other families who have children with the same chronic or acute condition.

school-based clinics (Clinical Judgment 1–1). The key component in any venue is that care is provided and coordinated by a designated physician who has established a health partnership with the family (American Academy of Pediatrics, 2002, 2007).

FAMILY THEORIES

This section presents an overview of some of the theoretical approaches that have contributed the most to nursing practice and our understanding of how families cope with the challenges and stressors of everyday life. These theoretical approaches include family systems, developmental, family stress and coping, structural–functional, and interactional theories. Two graphic models are also presented that have emerged from these theories. Healthcare professionals can use these models to assess family needs and dynamics, and from these assessments can develop a plan

of care to support family needs. (See [thePoint](#) for Supplemental Information for various family assessment tools.)

Family Systems Approach

Viewing the family as a system is a modification of general systems theory as described by von Bertalanffy in 1968. A system is defined as a goal-directed unit made up of interdependent, interacting parts that endure over a period of time (Friedman, Bowden, & Jones, 2003). There are both open and closed systems. An open system is one that receives input from the surrounding environment. That is, the system shares information, materials, and energy with its environment. The functional goal of the system is to ensure survival, continuity, and growth of its components (Friedman et al., 2003). The open system depends on the interactions with the surrounding environment to achieve growth and change. In contrast, the

CLINICAL JUDGMENT 1–1

Promoting an Interdisciplinary Approach to Family-Centered Care

Matthew is a nurse working on a pediatric unit in a community medical center. During the past several months he has become concerned regarding the readmission rates of several school-aged children with asthma. In particular, he believes that management of the children's asthma in the home and school has not been effective. In addition, he has noted that the children are missing many days of school because of the frequency of the readmissions and the extended length of their stay in the hospital. The physicians who manage these children are members of a private practice group who take turns monitoring the children's progress when they are hospitalized. Parents have verbalized that when their child is hospitalized they do not understand the plan of care and feel the care is fragmented.

Questions

1. In this situation, what are some of the problems you can identify?
2. Who are the members constituting the interdisciplinary team caring for the children with asthma?
3. What barriers exist in regard to providing an interdisciplinary family-centered approach to the care of these children?
4. What interventions could Matthew initiate to improve patient care and enhance communication among the members of the interdisciplinary team?
5. How could Matthew determine whether any of these interventions were successful in improving the care provided to this group of children?

Answers

1. High readmission rate of children with asthma, potential ineffective home and/or school management of these children, difficulties in communication and coordination of care among members of the interdisciplinary team, parent frustration regarding healthcare services, and lack of parental involvement in approach to care
2. The members of the physician group, including nurses at the physicians' office; the care providers at the medical center, including nurses and the respiratory therapist; the child and the child's family; the child's teacher; and the school nurse
3. Lack of coordination and communication among team members, variety of sites in which healthcare is provided to the child, and no identified mechanisms to reduce the number of readmissions
4. Plan a meeting with representatives from the family, nursing unit, physician group, and school to discuss and analyze the problems; devise a communication mechanism that assists all members of the team in understanding the needs and plan of care for each child; provide education to school personnel regarding the management of children with asthma; and provide information to families on expected educational outcomes for children with asthma
5. Parents verbalize improved satisfaction with healthcare services, readmission rate decreases because of more preventive actions instituted by school personnel and parents, and children attend more days of school

closed system does not receive input from the environment. Using a closed system, the units depend wholly on the relationships within the system itself for sustenance, growth, and change. Therefore, the capacity for growth and change over time is limited.

In this context, the family is viewed as a complex open system consisting of two or more persons tied together by mutual interactions, goals, and needs. Each member of the family influences and is influenced by every other family member, as well as by the environments with which the family members come into contact. The interrelationships within the family system are so intricately tied together that change by any one person invariably results in changes in all family members. For instance, a woman who loses her job will have reverberations on other family members as the family deals with issues such as loss of income, stress associated with the job loss, and a separation from daily social contacts.

As a unit, the family has boundaries that separate it from other systems. These boundaries act to filter or translate information that comes in to and flows out of the system. Boundaries consist of the rules, sanctions, communication patterns, attitudes, and values that bind family members together and guide their beliefs and practices. The family unit belongs to the many other systems that impinge on its boundaries. It also determines its own degree of interaction with other systems. As an open system, the family is capable of being influenced by and having an impact on the systems adjoining the boundaries. These adjoining systems include other families, the child's school system, the parent's work system, and the community in which the family lives. The interchange with other systems may include sharing of information, physical contact, shared responsibility, mutual goals, shared territory, and common language. For the family to exist as a system among other systems, a certain

amount of exchange must take place. However, among families there are varied degrees of openness, depending on the specific reaction of the family to change from the outside. The family with a high degree of openness provides for change. Change is welcomed, and is considered normal and desirable. Furthermore, communication and rules within the family are related, and individual self-worth is of primary importance. A family that has little exchange with the environment is one that resists change. A closed-unit family depends on edict and law and order, and operates through force, both physical and psychological. Self-worth is secondary to power and performance.

The family is a homeostatic system. This implies that, as the family is undergoing a process of continual growth and change, the unit strives to maintain a sense of balance or equilibrium. Parson and Bales (1955) referred to this as the “steady state” of an “ongoing system.” The family reacts to change in its steady state by attempts to reestablish equilibrium. Adaptation within the family refers to the ability of its members to modify their behavior toward each other and the outer world as the situation demands. As mentioned in the previous example, any disruption in the function of one family member results in a compensatory change in the functions of all other family members. Therefore, to restore equilibrium, all members of the system must be involved in the adaptation process.

Family systems theory is consistent with many nursing theories and conceptual models that incorporate concepts from von Bertalanffy’s systems approach. Examples include theories developed by Martha Rogers, Dorothy Orem, Myra Levine, and Sister Callista Roy. Family systems theory allows the nurse to examine both external and internal factors that may influence family adaptation to health crises. Family systems theory helps us to understand why an issue that arises with one family member (mother loses job) can affect all other family members (tension between spouses, loss of family income to make house payment or pay college tuition). When a child has a health-related problem, the nurse needs to consider how this one issue reverberates and affects other family members.

Olson Circumplex Model

One of the most widely used models to describe the family that uses a systems framework is the Olson Circumplex Model. The circumplex model builds on family developmental theory and systems theory to hypothesize that families change as they deal with normal transitions in the family life cycle (Olson, 1988). These changes can and should be beneficial to the maintenance and improvement of the family system as the family transforms in composition, role structure, and role functioning. According to this model, the goal of the family system is to accommodate developmental and situational change and stress, while at the same time preserving its integrity and organizational cohesion. A variety of family coping strategies are used to help the family accommodate and adapt successfully to internal and external stressors. It is believed that the effects of these coping activities can be measured in terms of the family’s level of cohesion, flexibility, and communication. **Family cohesion** addresses the degree

of emotional bonding that family members have toward one another. **Family flexibility** is the amount of change in the family’s leadership, role relationships, and relationship rules. **Family communication** is a facilitating dimension; it helps families make changes in the cohesion and flexibility dimensions (Olson, 1993, 1994). It is hypothesized that the central or balanced levels of these two concepts make for optimal family functioning. The extremes of cohesion (disengaged or enmeshed) and the extremes of flexibility (chaotic or rigid) are generally viewed as problematic to families (Olson, 1988). The family that is evaluated as “too” close and the family that is “too” rigid in its expectations of family members are examples of environments that are considered harmful because they do not allow and encourage individual growth within the family unit. It has been hypothesized that families with balanced levels of flexibility and cohesion have more positive communication skills than extreme families. In addition, positive family communication enables balanced families to change their levels of flexibility and cohesion more easily than families on the extremes. Thus, positive communication skills enhance family adaptation to situational and developmental stressors (Galvin & Brommel, 1986; Olson, 1988).

Levels of family functioning change over time and as the family passes through different developmental stages. It is hypothesized that families with the balanced levels of flexibility and cohesion generally function more adequately across the family life cycle than families with extreme levels (Olson, 1988). Being balanced signifies that the family system can operate at the extremes for short periods of time, and when appropriate, because of situational and developmental stressors. In these families, extremes are tolerated and even expected; yet, the balanced family does not operate continually in that fashion. On the other hand, extreme family types tend to function only at the extremes and strongly discourage any deviation from this pattern of functioning by individual members (Olson, 1988, 1993).

During healthcare crises, the balanced family is more likely to adapt and change to meet the needs of the situation. The crisis may draw family members closer to one another; yet, as the event passes, family members are able to regain their independence and use their experiences to help them grow as individuals.

Developmental Approach

The developmental framework focuses on examining the longitudinal career of the family—that is, how the family develops and changes over time. The developmental approach may also be called the **family life cycle** or the **family career**. The central theme of the developmental approach is that the family is a unit that changes over time as a result of the physical and psychosocial transitions of both adult and child members. Nurses need to be aware of these expected, normative changes and be able to provide families with anticipatory guidance as they transition through developmental changes within their family system.

Family Life Cycle

QUESTION: Would you expect the positions, roles, and norms of the Tran family to be the same as in your family?

Duvall (1962) was among the first to divide the family life cycle into eight stages with developmental tasks at each stage. These stages were based on the criteria of (1) major change in family size, (2) the developmental stage of the oldest child, and (3) the work status of the primary wage earner. These stages are

1. Couple without children
2. Oldest child less than 30 months old
3. Oldest child from 2½ to 6 years old
4. Oldest child from 6 to 13 years old
5. Oldest child from 13 to 20 years old
6. When the first child leaves until the last child is gone
7. Empty nest to retirement
8. Retirement to death of one or both spouses

Carter and McGoldrick (1988) conceptualized the family life cycle in a six-phase framework:

1. Leaving home: single young adults
2. The joining of families through marriage: the new couple
3. Families with young children
4. Families with adolescents
5. Launching children and moving on
6. Families in later life

Several other authors have delineated stages of the family life cycle, primarily adding stages to Duvall's model to account for the childless couple and to add more detailed transitions in the elderly couple. (See [thePoint](#) Supplemental Information for various theorists' views of the developmental stages of the family.)

Each developmental stage is separated from the next by the amount of **family transition** that is required by a particular life event. For example, moving from a family unit of two adults to the addition of a newborn child signifies tremendous changes in family roles, family finances, and family allocation of time in specific home activities. Thus, the family without children is acknowledged to be at a different developmental stage than the family that is expecting the arrival of its first child. These family transitions are considered “normal,” and they have implications for individual members who must critically assess their own well-being and alter their role functions and expectations to meet the changing developmental tasks of the family over the life course. Just as the child, adolescent, and adult need to accomplish individual developmental tasks or milestones, the family must also move through predictable transitions for optimal family growth and development. Milestones of individual development, such as starting school, reaching adolescence, marriage, the birth of a new baby, and retirement, often serve as the normal transitions that affect the entire family. Unexpected events or paranormative transitions are

events that do not occur in every family, such as illness, disability, miscarriage, change in socioeconomic status, or divorce, and can result in crises within the family. These events or transitions can change the developmental course for all family members, altering the natural movement of the family

The developmental theories are based on the assumption that the family is a semiclosed social system made up of interacting personalities (Hill, 1971). Using principles from systems theory, it can be said that the interrelationships within this system are so intricately tied together that change in any one part invariably results in change in the entire system (Friedman et al., 2003). In the family, each member has specific positions, roles, and normative expectations to fulfill at various points along the family life cycle. **Position** refers to the location of the family member in the family structure, such as husband–father or wife–mother. **Role** is defined as a “set of behaviors of an occupant of a particular social position” (Friedman et al., 2003, p. 322). Examples include the roles of breadwinner, disciplinarian, and student. **Norms** are the role behavioral expectations commonly shared by family members, such as it is expected that all family members will share in chores around the home. According to developmental theory, it is assumed that family members change their positions, roles, and norms at various stages in the family cycle to accommodate the addition and emancipation of children and to maintain family stability.

WORLDVIEW: It should be noted that family positions, roles, and norms often vary greatly from family to family and from culture to culture. Although it is not possible to identify the numerous variations of these concepts within all families, social scientists have observed dominant family configurations and family activities that are identified as normative for certain populations.

Within the developmental approach, the family is not homeostatic and cannot simply exist to maintain an equilibrium. Rather, the family is an interactive system that should demonstrate fluidity and adaptability as members grow, mature, and leave the household. It is expected that the bonds of cohesion and unity will change within the family system, depending on the developmental stage of the family and the individual needs of its members. At different stages in the family life cycle, patterns of togetherness and independence emerge and exist in direct relationship to the psychosocial crises and the developmental goals of family members (Olson, 1988). With the changes in family configuration and organization there are family life events, or transitions, that may be marked by feelings of tension, anxiety, uncertainty, and loss. Stages in the family life cycle are therefore viewed as critical periods of role change in which members are called to adjust, reorganize, consolidate, and adapt to meet the changing needs of maturing individuals in the family unit. The ability of the family to adapt, reorganize, and move to the next stage requires changes in boundaries and roles within the family. The family's ability to move through the crisis facilitates its development. If the crisis is not handled adequately, old tensions or new conflicts arise.

Family therapy is often necessary when families are overwhelmed or caught in a particular stage. Therapy is then directed toward moving the family into the next developmental stage. Nurses can use developmental theory to determine the types of stressors a family may be facing at each developmental stage. For instance, anticipatory guidance can be given to the family with children who are entering their teenage years regarding changing family rules as the adolescent seeks more independence.

Family developmental theory has addressed the family from a traditional, two-parent view of family life. Its use can be limited, given the diversity of family forms found in today's society. It does not take into consideration couples who choose not to marry or couples who choose not to have children, because this theory uses children as markers for movement from one stage to the next. Some theorists have developed variations of the traditional family developmental stages for the divorced or remarried family in an attempt to depict the additional stages through which these families are required to move (presented later in this chapter). Other theorists have embraced the concept of critical role transitions to explain differences in the sequencing of stages and a family's approach to a new stage. Other approaches developed to better explain the changing dynamics of the family unit include the family life spiral and the changing life cycle.

ANSWER: The Tran family positions, roles, and norms may be similar in some areas and yet different in others. For example, Tung, the father, is the primary breadwinner. Loan, the mother, is the caregiver of the house. The children are expected to achieve high grades in school. In addition, like most adolescents, Ashley is attempting to exert her independence, which in turn causes some conflict with her parents.

Family Life Spiral

The family life spiral is a developmental model devised by Combrinck-Graham (1990) that incorporates overlapping developmental tasks of each generation in the family (Fig. 1–1). For example, Erikson's (1963) stage of "generativity" of the adult leads to childbearing and raising children. The midlife crisis of the adult usually occurs at the period in which the family unit is also dealing with the turmoil of adolescence and the retirement of the grandparents. How a person works through individual developmental tasks has a profound effect on the others who are also trying to move into the next stage of their development. Combrinck-Graham (1990) conceptualized that the family oscillates from periods of closeness, or a **centripetal family atmosphere**, to periods of differentiation, or a **centrifugal family atmosphere**. The child requires constant care and nurturing, whereas the adolescent is moving toward independence. Centripetal forces lead to marriage, sexual intimacy, and childbearing. Centrifugal forces lead to adolescence, retirement, and preparation for death. The family moves between these two forces throughout the family life spiral. The nurse can use this model to identify the life stages of the family members and the impact they have on the family. For instance, the couple caring for a teenager with cystic fibrosis may also be caring for elderly parents, while also trying to manage successful and busy careers.

Changing Life Cycle

Rankin (1989) developed a framework that describes the tasks and transitions commonly seen in the family as it develops over time. (See [thePoint](#) Supplemental Information for additional descriptions of the developmental tasks and their characteristics.)

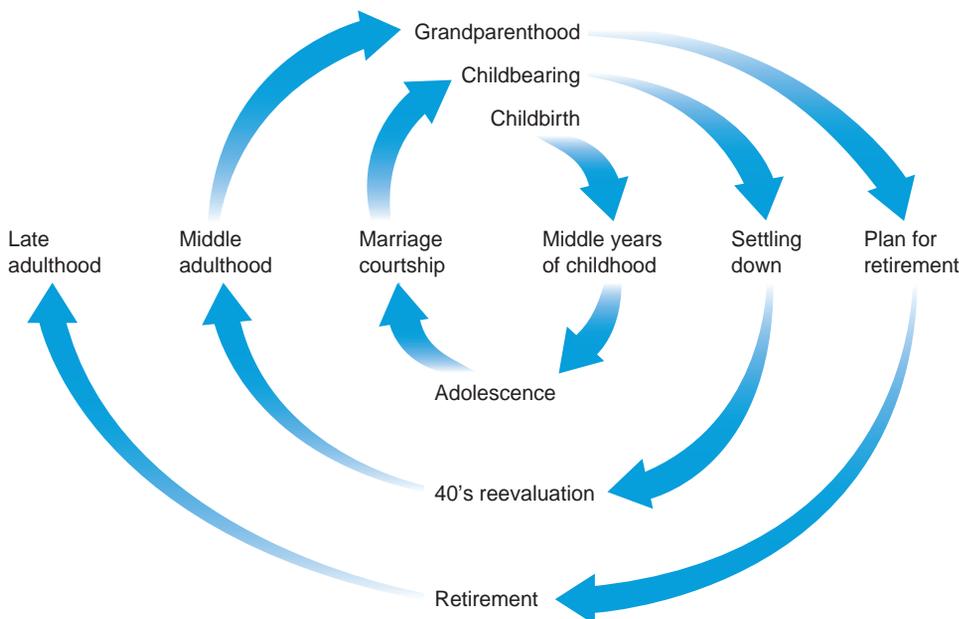

FIGURE 1–1. The family life spiral shows the overlapping developmental tasks of family members from different generations. Redrawn from Combrinck-Graham, L. (1985). A developmental model for family systems. *Family Process*, 24(2), 139-150. Reprinted with permission.

Emerging Family

The *emerging family* is one that is concerned with the tasks of becoming a family unit. According to the traditional life cycle, this is the stage of beginning families and childbearing families. In this framework, changing emerging families include opposite- or same-sex partners living together with a nonformalized bond. Common, expected transitions encountered by these families include changes in personal relationships, changes in family relationships, and changes in role status. The new couple must establish new roles in their relationship with each other and in their relationship with their families of origin. They must also decide whether to move into a parental role. The transition to parenthood is often challenging for the traditional family as well as the non-traditional family. Decisions need to be made to define the role each parent will play in the development of the child.

Solidifying Family

The *solidifying family* is the family with the primary tasks of stabilizing the bond between the parents and socializing the children. This stage is consistent with the traditional life cycle with preschool, school-aged, and adolescent children. Common transitions that occur in these families require increasingly flexible boundaries to account for the developing independence of children and adolescents.

Reconstituting Family

The *reconstituting family* is one that occurs because of changes in the relationship of its members, such as divorce, death, or separation. The members need to adapt to the loss of the previous family form and adapt to a new type of family, whether it be a single-parent family or a new step-parent family.

Contracting Family

The *contracting family* is one that is involved in the launching and release of children to environments separate from the family. Common transitions encountered in this family type are the changes in the relationships between the children and the new roles that come with these relationships if children are a part of the family. Adaptation to the loss of an adult partner through divorce or death and the changes that come with retirement, such as decreased income and increased leisure time, are also common transitions.

Family Stress and Coping Frameworks

Family stress and coping theories evaluate the impact of acute, unanticipated, and severe external events on the family system. In addition, these theories are used to describe the effects of chronic, persistent stressors that may bring long-term hardships to the family. The family experiences normative and non-normative challenges that may undermine family functioning. The challenge for the

healthcare team is to help family members optimize their resources and coping behaviors for managing the multiple stressors that can affect family life. The child's family may be a source of stress; but, more important, the family should be a resource or refuge that protects the child from the negative effects that are associated with stress (Patterson, 2002). Stress and coping theories can be used to better understand the alterations in family dynamics during times of stress. Crisis theory, the ABCX model, and the Family Adjustment and Adaptation Response (FAAR) model, described in the following sections, are examples of models that can be applied to families facing illness, loss, and grief. A criticism of the stress and coping models has been their inability to explain children's stress coping processes. The models are typically based on using adult-level cognitive and emotional processes to deal with stressful situations. There exists a definitive need for the development or modification of a stress coping theory specific for children.

caREminder

Children's stressors are not the same as adult stressors. Many of the stressors affecting children are related to situations with parents, teachers, and other family members that are outside the child's control. The stressors children deal with may not be amenable to change by the children themselves; adult assistance is often necessary.

Crisis Theory

A **crisis** is defined as a disruption of psychological homeostasis that occurs when a person faces an obstacle to important life goals that is, for a time, insurmountable through the utilization of customary methods of problem solving. A period of disorganization ensues, and a period of upset, during which many different abortive attempts at solution are made.

A crisis is generally self-limiting, lasting 4 to 6 weeks. During that time, the individual or family experiences four developmental phases (Lewis & Roberts, 2001). First, there is an increase in tension as the stimulus (crisis event) continues and more discomfort is felt. This is followed by unsuccessful attempts to cope with the situation, leading to more feelings of discomfort and a state of disequilibrium (second stage). The increase in tension causes the individual or family to move into the third stage, during which internal and external resources (balancing factors) are mobilized and emergency problem-solving methods are tried. During the fourth stage, the problem continues and cannot be solved or avoided, and stress and tension increase, which leads to major disorganization. Or, during the fourth stage, the problem is solved and equilibrium is restored to the family. Certain balancing factors influence the return to equilibrium at any time during the various stages of the crisis. These balancing factors include having a realistic perception of the event, adequate situational support, and adequate coping mechanisms.

Crisis intervention therapy occurs when nurses use measures to enhance these balancing factors and to assist

families to return to a state of equilibrium. Crisis intervention is intended to assist the individual or family to resolve the immediate crisis and to restore equilibrium to at least the precrisis level. Crisis intervention is not an appropriate intervention method to use with a family that has a history of dysfunction and problems related to coping with stressors. These families need to be referred to more intense, long-term therapy and counseling provided by an advanced practice nurse or specialist in counseling or psychiatry.

When using crisis intervention, the nurse should view the family as previously healthy and able to cope with day-to-day stressors. At the point of crisis, the overwhelming nature of the situation may temporarily paralyze the family. If interventions are not used, damage to family functioning could be permanent. The time frame for nursing intervention is limited, because of the self-limiting period of the crisis event. For instance, in the case of a child who is hospitalized after a motor vehicle accident, the nursing assessment would focus on the event that precipitated the crisis and on the problems that

have arisen as a result of the crisis. The accident may have been caused by a lack of parental supervision. Now that the child is hospitalized, the parents may be at the bedside all the time, leaving other children at home unattended. A teaching program may be needed to review and institute child safety issues with the family. The nurse must act in an assertive manner with the family, assuming the role of teacher, consultant, change agent, or counselor, as needed.

Crisis intervention is a helpful short-term approach that works nicely within the context of the brief encounters the nurse may have with the child and his or her family. Using this approach, however, the nurse may fail to recognize more serious, longstanding problems in the family. Optimizing communication among the family's healthcare providers, whether they be in the clinic, the school, or the acute care setting, can assist in providing an accurate assessment of the family, members' coping abilities, and the eventual resolution of the crisis (Clinical Judgment 1–2).

CLINICAL JUDGMENT 1–2

A Family in Crisis

Becky is a 16-year-old girl who attends public school. She is brought to the nurse's office by her friend Anna. Becky looks pale and sullen, and has an unkempt appearance. Although the nurse has not seen Becky recently, she is shocked by her appearance and affect. Becky has always been particular about her appearance and has done well in her classes. A quick review of her student file reveals that she is now getting Ds in four of six classes. Anna tells the nurse that Becky is having family problems. After some discussion with Becky, the nurse learns that Becky is 3 months pregnant. Becky is afraid to tell her parents and her brothers. Her parents are separated right now, and Becky thinks they have enough problems of their own. She states that she does not love the baby's father and she thinks she is too young to be a mother.

Questions

1. To assist Becky to work through this crisis, what further data should the nurse collect?
2. What developmental characteristics of adolescents may have contributed to this current situation?
3. What roles has Becky had in her family? If she were to keep the child, how would those roles change?
4. What three interventions could the nurse use at this time with Becky?
5. Becky and the nurse agree to meet again the following week. How can the nurse determine whether Becky and her family are working through this crisis?

Answers

1. Determine whether Becky has a clear understanding of what has occurred and whether she knows the full range of choices available to her at this time. Determine the level of support Becky may have from friends, family, and the baby's father. Determine how Becky and her family have coped with problems in the past.
2. Egocentrism; focus on body image; lack of cognitive maturity; belief that, although she was engaged in sexual activities, *she* would never get pregnant
3. Becky has had the roles of student, sibling, and daughter. If she keeps the child, she will take on the roles of mother and provider. Becky's family will also have additional roles, such as grandparents and providers.
4. Encourage Becky to speak with her family, offer to meet with Becky and her family, put Becky into contact with a support group that deals with teenage pregnancy, refer Becky to a physician if she has not already seen one, provide Becky with information about her choices, give Becky information about nutrition and personal care
5. Becky's affect and appearance are improved, Becky says that she has spoken with her parents, Becky arranges for her parents to meet with the nurse, Becky articulates what her choices are in this situation regarding the baby

ABCX and Double ABCX Models

Hill (1949) was the first to conceptualize a model that describes the processes a family undergoes when a stressor event occurs. The ABCX model describes the precrisis variables that account for family differences in adaptation to a crisis (Mederer & Hill, 1983, p. 45): A (the stressor event) interacting with B (the family’s crisis-meeting resources) interacting with C (the definition the family makes of the event) produces X (the crisis). McCubbin & Patterson (1983) expanded this model and added four factors that are believed to influence the family’s adaptation over time. Their double ABCX model includes postcrisis behaviors as well and explains how a family adapts to crises over time (Fig. 1–2).

The double ABCX model can be useful for healthcare professionals in their attempts to better understand families who are responding to a medical crisis among the family members. On the basis of the model, several actions can be used by the healthcare team to assist the family in achieving a high degree of adaptation to the current crisis (see Nursing Plan of Care 1–1).

The model has some weaknesses and may not be the ideal theory to apply to every family. Specifically, the double ABCX model has been criticized for its presentation of a crisis as an event-specific stressor, with commentators recognizing that most stressors in family life are not related to a single event. However, the nature of healthcare issues is such that one can often mark a crisis situation as the period during which a trauma or critical diagnosis involving a family member was made.

The A Factor

During the precrisis time period in the double ABCX model, the stressor (or A factor) is a life event or transition that affects the family unit that produces, or has the potential to produce, change in the family social system (McCubbin & Patterson, 1983). Family values, boundaries, goals, roles, and interaction patterns are but a few areas of the family life that may change.

The B Factor

The B factor includes the family’s resources for meeting the demands of the crisis. Families that are adaptable and capable of making modifications in their actions are able to resist the crisis. Four types of resources used by families are family members’ personal resources, the family’s internal resources, social support, and coping (Mederer & Hill, 1983).

The C Factor

The C factor refers to how the family defines the stressor and its hardships. This is the subjective meaning that family members place on how they feel they are affected by the stressor. Family values, cultural influences, and previous experiences in dealing with change all affect the definition of the current event.

The X Factor

The A, B, and C factors interact to produce the X factor, or crisis event. This event is a family stress or stressor characterized by the inability of the family to restore stability.

During the postcrisis period, ongoing variables may affect adaptation to stress. These variables include

- Additional life stressors and strains that affect family adaptation
- The critical resources the family uses over time
- The changing definitions the family associates with the stress events
- The coping strategies the family may use
- The eventual outcomes of the family (McCubbin & Patterson, 1983)

The aA Factor

Recognizing that families seldom deal with one stressor at a time, during the postcrisis period the aA factor refers to the pileup of stressors. This pileup can occur particularly

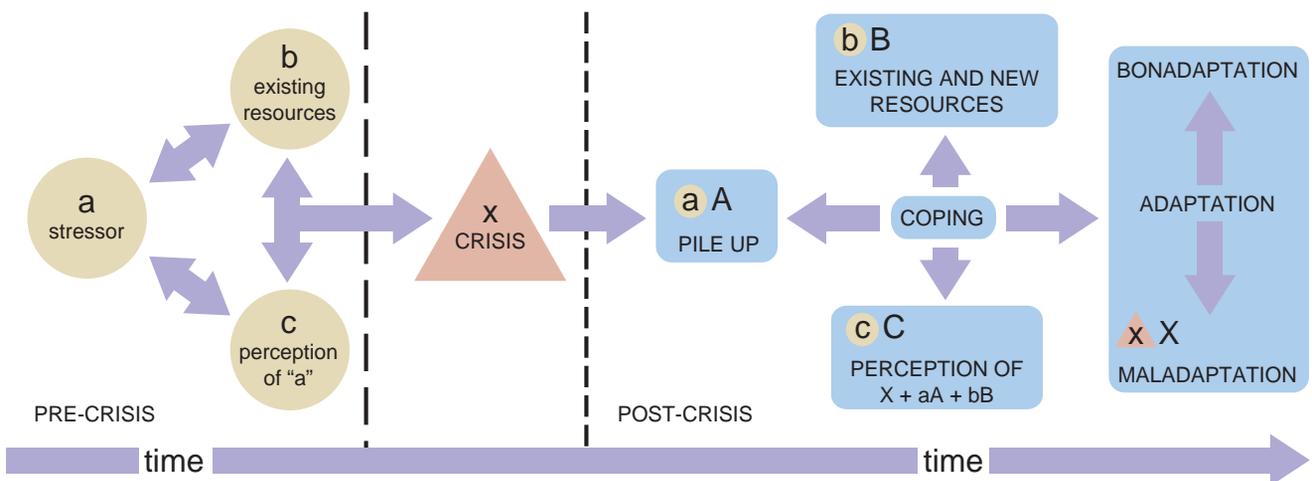

FIGURE 1–2. The double ABCX model shows how stressors can affect the family over time. Redrawn from McCubbin, H., & Patterson, J. (1983). Family stress process: The double ABCX model of adjustment and adaptation. Redrawn from McCubbin, H., & Patterson, J. [1983]. The family stress process: The double ABCX model of adjustment and adaptation. In H. McCubbin, M. Sussman, & J. Patterson [Eds.], *Social stress and the family*. New York: Haworth Press. Reprinted with permission.

in the aftermath of a major change in the family, such as a death or divorce. Additional stressors may emerge from individual family members, the family system, or the community in which the family and its members are a part.

The bB and cC Factors

In response to the crisis, the family calls on existing resources and expanded family resources to meet the demands and needs of the crisis; this is the bB factor. The cC factor is the meaning that family members give to the total crisis situation, and is influenced by the family's belief about what caused the original crisis, the presence of additional stressors, and the old and new resources the family is using to cope with the current situation. Families that are able to redefine the crisis situation as a "challenge" or an "opportunity for growth" are those that are more likely to adapt.

In the model, *coping* is a bridging concept wherein resources, perception, and behavioral responses interact as families try to adapt and achieve a balance within the family system. During the coping process, the family may focus energy on one or more of the following areas:

- Eliminating or avoiding stressors and strains
- Managing hardships associated with the situation
- Maintaining the integrity and morale of the family system
- Acquiring new resources
- Implementing structural changes within the family to accommodate new demands (McCubbin & Patterson, 1983)

The xX Factor

The xX factor reflects the interplay between all previous factors. The goal is to reduce or to eliminate disruptions within the family system and to restore a sense of homeostasis. This does not mean that the family returns to its precrisis state of existence; rather, through the crisis process, the family makes changes in roles, relationships, and responsibilities that are reflected in this "new" family system. Failure to resolve the crisis or to allow the crisis to facilitate change and growth in the family system results in maladaptation.

FAAR Model

QUESTION: How would you categorize the demands on the Tran family related to Ashley's socializing and schoolwork?

The FAAR model is a framework that allows nurses to assess a family's level of stress on the basis of demands the members face and their capabilities for meeting those demands. Using this model, family adaptation to stress (crises) depends on maintaining a balance between demands and capabilities. **Demands** are the sources of stress and can cause tension for an individual or family unit. Demands can emerge from individual members, the

family unit as a whole, or the community. The three major types of demands are *stressors*, *strains*, and *hassles*. *Stressors* are either normative events (e.g., getting married) or non-normative events (e.g., a tornado) that happen at a discrete time and produce or call for a change in individual or family functioning. The death of a family member, an acute illness, parents divorcing, and the birth of a child are examples of stressors that may affect the family. *Strains* are ongoing tensions resulting from prior stressors or from enacting life's roles. The parent who feels overloaded in caring for a new baby, who is unable to pay bills after a marital separation, and who is unable to care for an elderly parent are examples of strains on the family. Daily *hassles* are the minor upsets that can throw off one's schedule and sense of well-being. For instance, losing your car keys, getting a call that your child is ill at school, and running out of diapers are hassles that add to the stress factor in a family (Patterson, 1988, 1995, 2002).

Families never deal with a single demand at one time. Often, the healthcare professional intervenes solely on the basis of the major stressor affecting the family (an acute illness), when in fact the strains and hassles a family is coping with may be more difficult to manage than the stressor alone.

The mediators of stress are called **capabilities**. The FAAR model emphasizes two types of capabilities: *resources* and *coping behaviors*. The family attempts to balance functioning by using both types of capabilities to meet demands (stressors, strains, and hassles). Resources are both tangible (e.g., money, healthcare services, extended family assistance) and intangible (e.g., self-esteem, family flexibility, and safe neighborhoods). Resources for the family may come from the individual, the family unit, or the community.

Coping is what families do to manage stress and restore family balance (Patterson, 1995, 2002). Families that rely on diverse coping strategies are more successful at achieving a balance in family functioning. Coping behaviors are learned. Children need to be taught how to manage demands and experiment with new behaviors to cope with the variety of demands that affect their development. Pediatric nurses can provide families strategies for children to adapt to multiple demands, and to assist children in determining priorities or ways to eliminate some demands. Nursing personnel should be aware of the multitude of stresses faced by children in today's society, including family issues, age-related fears, and school and extracurricular demands. Many of these issues are discussed in Chapters 4 through 7.

The FAAR model also illustrates that the meaning the family attributes to the situation is a critical factor in achieving a balance in family functioning. The family's shared meanings include members' perceptions about a *specific stressful event*, their *identity as a family*, and their *view of the world* or worldview (Patterson, 1995, 2002).

The outcome of the family's effort to achieve balanced functioning is called either family adjustment or family adaptation. **Family adjustment** is associated with achieving stability in relation to relatively minor demands (e.g., child breaks out with chickenpox). **Family adaptation** is required when more intense or complex demands are

made on the family (e.g., newborn child is diagnosed with cerebral palsy). A crisis or state of disequilibrium occurs when family members cannot adjust by using their repertoire of capabilities in relation to the demands they are facing. Family adaptation occurs when, in the presence of a crisis, the family restores homeostasis by acquiring new resources and coping behaviors, reduces the demands it faces, and/or changes the meanings and perceptions associated with the situation (Patterson, 1995, 2002).

Nurses can promote family adjustment and adaptation by focusing on family strengths and teaching family members about their own capabilities. The interdisciplinary team can use the FAAR model to understand the family's complex issues and intervene in ways that encourage family members to discover the best solutions to meet their needs and the circumstances of the situation.

ANSWER: Ashley's socializing and her schoolwork—demands on the family that are a source of stress—would most likely be categorized as strains. These strains are the result of ongoing tensions resulting from prior stressors, such as not achieving her parents' expectations for her schoolwork or from enacting life's roles, such as when an adolescent attempts to establish her independence.

Structural–Functional Approach

The structural–functional approach focuses on the relationships between family members and how well the family performs its functions. **Structure** refers to how the family is organized, the manner in which members and their roles are arranged, and how members relate to each other. The structure of the family includes the form it may take, such as a single-parent family, step-family, or nuclear family. In addition, the manner in which members relate to one another can be examined in reference to such areas as their communication patterns, the family power structure, and the family roles. The family structure serves to facilitate the achievement of family functions.

Function refers to the outcomes or consequences of the family structure—that is, the goals of the family that are important to its members and to society. In other words, what the family does, or the reason for its existence, is said to be its function. There are five family functions said to be most germane to assessing the family (Friedman et al., 2003): affective function, reproductive function, economic function, healthcare function, and socialization and social placement function (Chart 1–4).

The structural–functional model has been criticized for its static view of the family and its focus on individual members. The importance of family growth and changes over time are not emphasized as they are in the developmental and systems theories. The structural–functional model is effective for nurses who are assessing families confronted by a critical event. The model allows nurses to evaluate the impact of an event (e.g., a critical illness) on the family structure. When a change in the family structure alters the family's ability to function, it

CHART 1–4 FUNCTIONS OF THE FAMILY

Affective function: provides for the emotional support of its members through love, encouragement, intimacy, and acceptance. Children from families who rate high on measures of affective support have higher self-esteem, are better able to cope with stress, and have fewer behavior problems.

Reproductive function: provides for the continuation of society as well as the family

Economic function: requires the parents or adult family members to provide the economic resources to meet the needs of the family financially. Poverty and having insufficient resources are the best predictors of poor health outcomes for children.

Healthcare function: requires parent or adult family members to provide food, clothing, and shelter, and adequate healthcare for all family members

Socialization and social placement function: is met when adult members take the responsibility of raising their children to be functional members of society. This occurs through effective parenting, education, and instillation of the family's culture, values, and religion. Parental involvement in the child's school and education has been associated both with better academic performance and improved social maturity.

is appropriate for the healthcare team to intervene. Interventions include reinforcing, modifying, or changing the family's structure to help it meet the demands of the new situation. Nurses should respect and encourage adaptive coping mechanisms, and counsel family members as needed to help them gain additional coping skills. Families should be encouraged to use their existing supports to meet their needs, modifying the family structure and redistributing responsibilities as necessary to account for the impact of the crisis on individual members.

Interactional Approach

The focus of the interactional approach is on the way in which family members relate to one another. Viewing the family as a set of interacting personalities, this approach highlights internal family dynamics. The processes that are evaluated in the family include role-playing, communication patterns, decision making, coping patterns, and socialization processes (Friedman et al., 2003). The framework makes no attempt to view the family in relation to its interactions with external social environments; rather, the focus of this approach is solely on analysis of the internal dynamics of the family.

In the interactional approach, a **symbol** is defined as a stimulus that has a learned meaning and value for an individual. For instance, silence may be a interactional symbol. In some families, silence from a parent may indicate

to all family members that this individual is thoughtfully considering his or her course of action, and chooses to be silent until he or she has formulated a plan of action. In another family, silence by a parent may indicate anger and hostility—the proverbial “silent treatment.” Silence, as the interactional symbol, is thus understood and interpreted differently between these two families. People learn about symbols through their interactions with other people and, during this process, come to have shared meanings and values regarding these symbols. How family members respond to a situation is determined by the value and meaning each family member and the family as a whole have assigned to aspects (or symbols) of the event.

The interactional approach can be useful to the nurse who wishes to focus attention on how the family functions as its members interact between and among themselves. As the family is affected by a crisis, this model is helpful in identifying and isolating potential or real sources of difficulty among family members as they cope with a new situation. Family members may encounter problems because they do not share the values and meanings of symbols surrounding a particular event. Therefore, members can feel alienated, misunderstood, and in conflict with others who do not understand their feelings and actions.

The interactional approach can be limiting because it does not take into context the interactions between the family and external social systems. Using this model, the family is considered to be a self-contained unit; interactions with other social organizations or individuals outside the family are not analyzed in terms of their impact on family interactions.

FAMILY STRUCTURE

QUESTION: What type of family structure does the Tran family currently demonstrate? Is this structure different from the structure they had when they first came to the United States?

The type of family structure the nurse caring for children may encounter in practice has never been more diverse. The type of family to which a child belongs is less important than the relationships developed or the level of cohesion within that family. Regardless of the family structure, children need to feel that their family is an acceptable family form to feel secure and to feel free of prejudicial thinking from others.

The traditional nuclear family—two parents, two or more children, with one parent who stays at home with the children—is a family structure that no longer reflects the diversity and complexity of our contemporary lifestyles. The *postmodern family*, or what Elkind (1996) terms the **permeable family** (dual-earner families, adoptive families, single-parent families, blended families, and the like), is more fluid, flexible, and vulnerable to pressures from outside the family. Several trends in society

have significantly altered the composition of the traditional family home, including

- Increase in divorce
- Increase in number of mothers employed outside the home
- Lower birth rate coupled with higher life expectancy
- Number of adults choosing to remain single and never marry or to remain unmarried after divorce or the death of a spouse
- Number of adults delaying marriage and childbearing until later years
- Gay and lesbian couples entering into long-term partnerships or marriages
- Use of technology-driven methods to conceive (e.g., in vitro fertilization, insemination)

The number of alternative family forms has increased. Nonrelatives raising children and relatives raising children are among the fastest growing family compositions. Single-parent families and stepfamilies are also two of the fastest growing family compositions. The numbers of relatives (not parents) raising children increased from 142,100 in 1990 to 221,200 in 2003; the numbers of nonrelatives raising children increased from 34,600 in 1990 to 79,300 in 2003; and the numbers of single parents raising children younger than 18 years increased 9% from 1994 to 2006 to an estimated 12.9 million one-parent families (U.S. Census Bureau, 2004c; U.S. Census Bureau News, 2007). In addition, in 2003, 37.8% of female and 26.5% of male same-sex unmarried partner households had children younger than age 18 living with them (U.S. Census Bureau, 2003a).

Nuclear Family

The **nuclear family**, once considered the traditional family in many industrial societies, consists of a married couple and their immediate biologic children. In the United States, married-couple households with biologic children decreased from 40% of all households in 1970 to 23% in 2003 (U.S. Census Bureau, 2004a). Asian families have the greatest percentage of married-couple households (83.1%), followed by non-Hispanic white families (76.8%), Hispanic families (64.6%), and African American families (34.8%) (U.S. Census Bureau, 2004a).

The nuclear family faces many challenges. At one time the extended family (see discussion later in this section) was more the traditional norm. This structure allowed a greater distribution of responsibilities among family members. These responsibilities included working to obtain finances to manage family needs, child rearing, and maintaining the home and family daily needs. The trend toward more nuclear family constellations placed these responsibilities solely on two adults. Stressful economic circumstances, juggling multiple jobs, the strains of parenting, and the need to maintain a cohesive partnership all place tremendous stress on the nuclear family. Although the financial standard of living may be higher in a nuclear family than in other family structures, stress levels are often high when extended family members are

not available to assist in providing economic support and child care support.

To balance the needs of the family with the internal and external stressors affecting family life, several strategies are being used to “extend” the nuclear family. Many families hire individuals to clean their home and maintain the yard. Couples may live in close proximity to their parents, with parents providing child care or baby-sitting services. Many parents are making more concerted efforts to share parenting responsibilities, rather than rely primarily upon the mother to serve as the child care provider, transporter, and disciplinarian. Although it has been debated that there is little federal support for the nuclear family, activists are working toward tax laws and access to services that will support the nuclear family rather than be an additional source of stress.

ANSWER: Currently, the Tran family structure is that of a traditional nuclear family—that is, two parents and two or more children, with one parent at home with the children.

Dual-Career Family

A variation of the traditional nuclear family is the **dual-career family**, also known as the *dual-earner family*. In this type of family, both parents have decided to work either for economic reasons or for personal satisfaction. This type of family is becoming more prevalent, with two thirds of all nuclear families having both parents working outside the home (White & Nielsen, 2001). When circumstances arise, one parent may choose to stay at home to care for the children while the other parent is employed. Dual-career families are faced with challenges as they struggle to maintain the family. Parents in these families must perform at least four jobs: two market jobs for pay and two unpaid jobs in the family. The unpaid job is considered “family work” and includes household chores and child care tasks performed by the family to function effectively (Fig. 1–3). Although family work was the once considered a woman’s responsibility, dual-career families have been forced to redefine and renegotiate roles and tasks within the family to be functional. With both parents working, child care and the completion of household chores have become important issues for the family.

The dual-career family must often find affordable child care services to take care of their children’s needs when the parents are not available. Some dual-career families deal with this situation by arranging alternating work schedules. That is, while one parent works during the day, the other is at home. In the evening, the “day worker” parent returns home to watch the children while the other parent goes to work. Although this situation eliminates the high cost of child care and maximizes parental contact with the children, it can place stress on the parent relationship, because spousal contact is sacrificed.

During the past several years, little attention has been given to the nuclear family or dual-career family and the

FIGURE 1–3. In dual-career families, both parents work and share family care duties.

struggle that these families face in trying to maintain and promote the nuclear family. As more and more legislation and other support systems have arisen to support the nontraditional family, nuclear families may feel as though they are struggling against governmental, economic, and societal reform to maintain the strength of this type of family system. More research is needed to evaluate challenges to families that choose to maintain the nuclear family structure.

Extended Family

Another more traditional family unit is the extended family. The **extended family** consists of several generations of the family, including the immediate nuclear family, grandparents, and other relatives such as aunts, uncles, and cousins. Although every nuclear family is part of an extended family unit, few nuclear families elect to live and share resources with members of their extended family. In the past, the rural and agrarian focus of society promoted and often required multigenerational families to cohabitate and share their resources. It was not uncommon for adult children, their spouses, and their children to live with their older parents. The family as a whole engaged in one common occupation, such as farming. Thus, family members of all age ranges lived and worked together, benefiting from the sharing of resources and responsibilities.

As society changed to a more mobile, industrialized focus, so, too, has the extended family separated and restructured into smaller family units. In some communities and cultural groups, cohabitation of extended family members continues to be highly valued. However, in many cases, the nuclear family forms its own household

FIGURE 1–4. Grandparents may assume care of grandchildren, to offer additional support to families.

and members seek a living pursuing their own unique areas of interest, separate from extended family members. Many nuclear families continue to rely on members of their extended families as business partners, child care providers, and caregivers of the elderly (Fig. 1–4). In addition, extended family members enjoy socializing together and sharing special family events. In times of stress and crisis, extended family members are likely to offer many resources to support the family, even when long distances may separate the households.

ANSWER: When the Trans first arrived in the United States, they lived with Loan’s parents and her sister. This is considered an extended family structure.

Single-Parent Family

During the past three decades, one of the most dramatic changes in family configurations has been the shift toward more single-parent families or attenuated families. Currently, the number of single-mother families in the United States exceeds 10 million. This is increased from 3 million in 1970. The number of single-father families has grown from less than half a million to 2 million (U.S. Census Bureau, 2004a). Single parenting occurs when one parent manages the affairs of a family without a partner.

Often, this type of family is formed when the nuclear family unit dissolves through divorce, separation, abandonment, or death of a spouse. A shift from two-parent to one-parent families has also been noted as a result of several demographic trends, including increased proportion of births to unmarried women who conceive either by natural or medically supported methods (in vitro fertilization), delay of marriage increasing the likelihood of a nonmarital birth, single persons agreeing to raise another family member’s child, and lessening of legal restraints on adoption by single parents (U.S. Census Bureau, 2004b).

The single-parent family is likely to encounter several challenges because of economic, social, and personal

restraints. Economically, single-parent families often have to adjust to a lower level of income. Of the 12 million one-parent family groups recorded in the 2003 census, for example, the 10 million maintained by women were more likely than the 2 million maintained by men to have incomes below the poverty level (32% compared with 16% [U.S. Census Bureau, 2004a]). Divorced single mothers typically have financial and social advantages over never-married single mothers because, as a population, they are typically older, have more education, have higher incomes, and may have an economic source from their ex-spouse to aide in child-rearing expenses (U.S. Census Bureau, 2004b).

Sources of social support for the single-parent family may also be lacking. The single parent may find it difficult to maintain social relationships as a result of time and economic restraints. Balancing the family, the job, and the details of everyday life leaves little time for the single parent to focus on people and events outside the home. In addition, in cases of divorce, separation, or spousal death, the family’s network of social support may erode as previous friends distance themselves from the restructured family. The event that caused the family to restructure into a single-parent household may also lead to the family seeking a new home, a new community, and a new school for the children. Although the single parent may feel a sense of independence and renewal in making these changes, the child may be overwhelmed by a sense of loss and instability.

The personal or emotional challenges of a single-parent household affect both child and parent. For instance, in the case of divorce or parental separation, a major shift in family dynamics may occur as the family becomes oriented to a single parent serving as the sole (or primary) authority and provider. If the single parent brings a new partner into the home, other relational adjustments must be made. Children from single-mother households are at increased risk for difficulties, including social impairment, psychiatric problems, and low math scores in school. Single-mother families also have higher rates of family dysfunction, maternal depression, and lower social support (Lipman, Boyle, Dooley, & Offord, 2002).

Single parents are called on to provide most of the emotional support and sustenance for their children. There may be few volunteers to give the parent a break from the stream of decisions or to serve as the disciplinarian, chauffeur, or cook. The single parent may have to overcome feelings of inadequacy, guilt, anxiety, grief, or loneliness that accompany any major life event, loss, or transition. In some cases, the single-parent family must accomplish most of the same developmental tasks as two-parent families but without all the resources. For some single parents, extended family members provide an essential support structure to assist in child care, transportation for weekly activities, and ongoing emotional support.

To serve the single-parent family better, specific family concerns can be addressed by demonstrating a sense of empathy, giving credence to the family’s problems, and providing specific strategies for intervening therapeutically when necessary (Nursing Interventions 1–2).

NURSING INTERVENTIONS 1–2

Concerns and Interventions for the Single-Parent Family

Concern	Nursing Interventions
Parent feels helpless and overwhelmed	Encourage parent to <ul style="list-style-type: none"> • Work through their own emotions • Practice good health habits • Keep in touch with family members and friends • Socialize with other adults
The single parent feels uncertain regarding parenting and child management practices	Provide parent with information regarding normal growth and development, and predictable effects of divorce or death on children
Child exhibits behavioral problems	<ul style="list-style-type: none"> • Teach parent to provide consistent discipline • Encourage parent to allow children to express their concerns regarding the change in the family
Child takes on a parent helper role	Determine whether the child is still able to have his/her needs met
Child becomes the parent's companion and confidante	Encourage the parent to seek other sources of emotional support
Issues related to the absent parent	Openly discuss issues regarding the absent parent with all family members
Introduction of a new adult into the household	Assist the parent to prepare the child ahead of time for the entry of a new family member Discourage the parent from casually and frequently having partners of the opposite sex stay the night or move in Assist family members to define clearly the roles and responsibilities the new adult will have in the household and in regard to child rearing
Making ends meet	Encourage the parent to record income and expenses, and keep a budget Encourage the parent to plan shopping trips, using lists to avoid purchasing nonessential items
Managing home responsibilities	Encourage the parent to teach the children to do many tasks on their own Assist family members to list and divide housework with an assignment for each family member

Binuclear Family

Ahrons and Rodgers (1987) coined the term **binuclear family** to refer to the familial structure of joint custody families. Coparenting, or the binuclear family, occurs when the child is a member of two families, after remarriage of one or both parents. The responsibility of raising and parenting the child is still considered a joint venture between the two families. Joint physical custody gives both parents legal rights and responsibilities while granting the children equal time with both parents. On the other hand, although joint legal custody can also give both parents legal rights and responsibilities for the child, the child may live predominantly with one parent, usually the mother. Because the child can benefit from frequent contact with both parents, the judicial courts recognize joint physical custody arrangements as a good answer to custody disputes (Table 1–2).

Research has shown that a father's continued involvement with his children is associated with a positive outcome for the children (Friedman et al., 2003; Harper & McLanahan, 2004). Research also indicates that marital conflict is a more important predictor of child adjustment than the divorce itself or the parental conflict that may exist after the divorce. In other words, children in homes in which there is parental conflict are more likely to have conduct disorders, antisocial behavior, depression, difficulty with peers, and academic problems. Children of divorced families have been shown to experience more adjustment and academic problems than children in never-divorced families. However, if parental conflict is ongoing in the home, this, too, can negatively affect the child's adjustment (Kelly, 2000). Children in joint custody relationships have been shown to have fewer adjustment problems than those where only one parent has legal custody of the child (Kelly, 2000).

TABLE 1 – 2

Joint Custody: Pros and Cons

Pros	Cons
<ul style="list-style-type: none"> • Maintains parent–child relationships • Increases the likelihood child support will be paid • Gives parents a sense of involvement with children; maintains active participation in the parental role • Allows continued involvement of extended family members such as grandparents, aunts, and uncles • Decreases the load of the single parent, resulting in higher quality parenting 	<ul style="list-style-type: none"> • Expects parents who cannot agree during the marriage to make joint decisions after the divorce • Has physical impact on the child, who must move from one parent’s house to the other parent’s house on a daily or weekly basis • May require parents to reside within the same community • Children may be involved in lengthy judicial processes to acquire joint custody

Blended Family

With the growing rate of divorce and remarriage, more and more children are either part of or know someone who is in a stepfamily. A remarried family consists of a husband and wife maintaining a household, with or without children in the home, and one or both of the spouses have

previously been in a marital relationship. The **blended family** or stepfamily is a remarried family with a child younger than 18 years of age who is the biologic child of one of the parents and was born before the remarriage.

In 2001, of the 51.1 million children who lived with two parents, 5.4 million children lived with one biologic parent and either a step-parent or adoptive parent. This

TABLE 1 – 3

Developmental Issues in Remarried Families

Prerequisite Attitude	Developmental Issues
<p>Step: Entering the new relationship</p> <ul style="list-style-type: none"> • Recovery from loss of first marriage (adequate “emotional divorce”) 	<ul style="list-style-type: none"> • Recommitment to marriage and to forming a family with readiness to deal with the complexity and ambiguity
<p>Step: Conceptualizing and planning a new marriage and family</p> <ul style="list-style-type: none"> • Accepting one’s own fears and those of new spouse and children about remarriage and forming a stepfamily • Accepting need for time and patience for adjustment to complexity and ambiguity of multiple new roles • Boundaries: space, time, membership, and authority • Affective issues: guilt, loyalty conflicts, desire for mutuality, unresolvable past hurts 	<ul style="list-style-type: none"> • Work on openness in the new relationships to avoid pseudomutuality • Plan for maintenance of cooperative coparental relationships with ex-spouses • Plan to help children deal with fears, loyalty conflicts, and membership in two systems • Realignment of relationships with extended family to include new spouse and children • Plan maintenance of connections for children with extended family of ex-spouse(s)
<p>Step: Remarriage and reconstitution of family</p> <ul style="list-style-type: none"> • Final resolution of attachment to previous spouse and ideal of “intact” family • Acceptance of a different model of family with permeable boundaries 	<ul style="list-style-type: none"> • Restructuring family boundaries to allow for inclusion of new spouse–step-parent • Realignment of relationships throughout subsystems to permit interweaving of several systems • Making room for relationships of all children with biologic (noncustodial) parents, and other extended family • Sharing memories and histories to enhance stepfamily integration

From: McGoldrick, M., & Carter, E. (1982). The family cycle. In F. Walsh (ed.). *Normal family processes* (p. 192). New York: Guilford Press. Reprinted with permission.

is statistically unchanged from 5.2 million in 1996 and up from 4.5 million in 1991 (U.S. Census Bureau, 2005a).

Many adults who divorce will eventually enter into another marital relationship. In 2001, of the men age 25 and older who had ever divorced, 42% were currently divorced and 55% were married. A slightly higher percentage of women than men 25 years and older who had ever divorced were currently divorced (47%), whereas a lower percentage were currently married (44%) (U.S. Census Bureau, 2005b).

The transitions that accompany remarriage and the formation of the stepfamily present a variety of stressors for the parents and children involved. Even in the most adaptive of families, several developmental issues must be addressed and resolved if the stepfamily is to create its own new identity (Table 1–3). The time it takes to create a new sense of family varies for each family system and is almost always longer than the adults expect. For toddlers and preschoolers, this process takes at least 18 to 24 months; with older children, it may take as long as 5 to 7 years (Engel & Visser, 2005).

The concerns of the children and adults involved may emerge in several different ways (Developmental Considerations 1–1). In addition to the stress of a new marital relationship, the step-parent often experiences difficulties with parenting of stepchildren, adjusting to the children's personalities and habits, and gaining acceptance (Engel & Visser, 2005). Other stresses experienced by step-parents include relationships with former spouses, adjustment to the new roles of step-parents, and unrealistic expectations in the transition to the new role. This transition is also stressful for the children. Children often react to remarriage by experiencing feelings of anger, anxiety, and depression. Children may also respond to a blended family with a deeper sense of happiness and security. If the previous home environment was affected by a high level of marital discord, changing to a more harmonious family environment may assist in reducing stress for the child. In addition, the blended home may create a more secure financial environment for the child (Dunn, 2002).

Gay or Lesbian Family

The gay or lesbian family is another nontraditional family that is becoming more prevalent (see Nursing Interventions 1–3). The gay or lesbian family can include committed relationships with same-sex partners, single lesbian or gay adults rearing a child, and extended families involving several close homosexual and/or heterosexual friends. Many gay and lesbian couples choose to formalize their relationship with some type of ceremony and/or legal commitment. Legal sanction of same-sex marriages varies by state and country.

Increasing numbers of gay men and lesbians are choosing to become parents. Because of the careful planning involved in conception, the gay or lesbian couple usually has a strong commitment to parenting. Gay men and lesbians can become parents in a variety of ways. Lesbians can decide to have children through insemination from a known or unknown donor, heterosexual intercourse,

adoption, foster parenting, and coparenting. Gay men can become parents through the use of a surrogate mother or through adoption and/or foster parenting. Because some gay men and lesbians have had children in a previous heterosexual relationship, new homosexual relationships may result in blended or reconstituted families.

Contrary to common misconceptions, children of gay and lesbian parents do not differ from children of heterosexual parents in terms of psychological health and social relationships. Children raised by gay men and lesbians are no more likely to be gay or straight than those raised in heterosexual families (Patterson, 1992). Studies have shown that children raised in two-parent homes, regardless of gender, are better adjusted than children raised in single-parent homes (Gold, Perrin, Futterman, & Friedman, 1994). A common concern is that children of gay and lesbian families will experience the same prejudice that their parents have had to endure. Although prejudice may still occur, studies have found that children of lesbians and gay men are more aware of the diversity in our society and are better prepared to handle the ignorance and bias of homophobia.

Communal Family

A **communal family** can be defined as any group of adults (with or without children) most of whom are unrelated by blood or marriage, who live together primarily for the sake of some ideological goal for which a collective household is deemed essential (Aidala & Zablocki, 1991). Communal living came of age during the late 1960s, with many individuals joining during times of major social and cultural disjuncture. People join communes to be surrounded by individuals who share common beliefs and practices; in many cases, these are religious beliefs. Principles that guide communal living include collective ownership, the absence of private property accumulation by individual members, and the collective responsibility for all material, cultural, educational, and health needs of the family.

Some communal communities have been described as cults that adhere to a set of beliefs or standards that are viewed as deviant by the general society. A charismatic individual is often the source of governance for these communes. Interactions between commune members and outsiders are often discouraged. Thus, healthcare practices may be neglected or overlooked, because commune members rely on internal resources to deal with illness and health promotion issues.

A polygamous family, also referred to as a *plural family*, is a form of the communal family. The polygamous family consists of one wife with multiple husbands and children or one husband with multiple wives and children. The latter configuration is predominant. In the United States, polygamy is uncommon. However, polygamy continues to be a common practice in many areas in the world. In 1852, the Mormon religion officially adopted polygamy as a church doctrine and practiced it until the 1890s, when the U.S. Congress enacted legislation to control polygamy. Since 1904, the Mormon church has officially adopted a policy to excommunicate any member

DEVELOPMENTAL CONSIDERATIONS 1–1

Child's Response to Divorce and Stepfamily

	Responses	Healthcare Interventions
Early childhood	<ul style="list-style-type: none"> • Clinging to parents • Regressive behaviors such as thumb sucking and bed-wetting • Belief that their angry thoughts or behaviors led to family disruption (magical thinking) • Belief that they can magically reunite the family 	<ul style="list-style-type: none"> • Reassure children that they are not responsible for the dissolution of their parents' marriage. • Include children in family discussions using simple terms. • Praise children for age-appropriate behaviors. • Read age-appropriate books to children about stepfamily situations.
Middle childhood	<ul style="list-style-type: none"> • Anger about their powerlessness to stop dissolution of the family • Imagining that they caused the marital breakup • Wishing their parents were together, and fantasizing that if they are "good," "bad," or "sick" the parents will come together to help • Acting out anger and guilt by having tantrums, fighting with siblings or classmates, developing psychosomatic symptoms, becoming accident prone, failing in schoolwork, or trying to break up the new marriage • Acting "angelic" and, in doing so, hiding their true feelings 	<ul style="list-style-type: none"> • Accept the children's feelings. • Do not force the children to understand the perspective of adults. • Reassure the children they are not responsible for the dissolution of their parents' marriage. Encourage the children to communicate with parents and step-parents. • Help the children put feelings into words rather than negative behaviors.
Adolescence	<ul style="list-style-type: none"> • Sexual tensions, such as trying to deal with their own identity and sexuality in the presence of step-siblings or a step-parent of the opposite sex • Loss of status of being "in charge" as they make way for the new head of the household • Acting out in a negative way toward the step-parent as a result of divided loyalties • Angered by step-parent who does not view them as mature • Reluctance to become part of the stepfamily because of the developmental drive for independence and autonomy 	<ul style="list-style-type: none"> • Have the family adopt a dress code and make appropriate bedroom arrangements. • Allow adolescents to maintain their independence and integrate at their own pace. • Encourage step-parents to make clear to the adolescent that they are not a replacement for a deceased or absent parent. • Emphasize that the adolescent must act in a respectful, if not warm, manner toward the step-parent. • Encourage the adolescent to communicate with parents and step-parents.
Parents	<ul style="list-style-type: none"> • Conflict with new spouse with regard to loyalty to their own children, which predates loyalty to their new spouse • Inability to form solid bond with new spouse because to do so would seem like a betrayal to their relationship with their children • New spouse may feel like an outsider in an established household 	<ul style="list-style-type: none"> • Listen to the parents' concerns. • Provide anticipatory guidance and direct parents to sources of information that provide realistic information about stepfamily life. • Reassure parents that a strong relationship with one another is not a betrayal of their biologic children. • Encourage the biologic parent to require respect from his/her children toward the new

Responses	Healthcare Interventions
<ul style="list-style-type: none"> • Sense of failure and resentment when feelings of love do not happen immediately • Conflict regarding dissimilar parenting styles 	<p>partner as these new relationships develop between the children.</p> <ul style="list-style-type: none"> • Encourage the biologic parent to maintain or become the enforcer of rules for his/her children while the step-parent supports the biologic parent in the discipline process. • Encourage the formation of the “parenting coalition” for raising the children. This means that all parents and step-parents cooperate in the parenting experience. • Encourage the new spouse to accept that he/she does not have to try to be an “instant parent.” • Recommend that the parents take a parenting course together. • Direct parents to support groups.

either practicing or openly advocating the practice of polygamy. Despite these rulings, many people continue to practice polygamy today.

FAMILY FUNCTIONS

The basic unit in our society is the family. Friedman et al. (2003, p. 4) stated that “the purpose of the family is mediation. The family has to mediate the needs and demands

of the family member with those of society.” The family, then, is a medium for the transmission of societal values. From a developmental viewpoint, the primary function of the family is to support the development of its members by meeting basic needs such as food and shelter, carrying out developmental tasks for individual growth and family growth through the life cycle, and adapting to hazardous events such as illness and death. From a systems point of view, the main function of family members is to support one another. Another viewpoint is that the family has two

NURSING INTERVENTIONS 1–3

Working With Gay and Lesbian Families

Examine your own attitudes and beliefs toward homosexuality and gay and lesbian parenting. Become better informed about the research and misconceptions regarding gay parenting.

Be supportive of the diversity of family forms in today’s society.

Ask questions such as: Who do you include in your family? Who helps raise your child(ren)?

Convey acceptance through the use of gender-neutral terms such as parent or family member when gathering a family history.

Use terms such as family member or significant other rather than husband or wife.

Do not assume all parents are heterosexual. Do not assume that an absent parent is of a different gender.

Ask questions such as: Who else is in your household? Who else is taking care of your child? Do you have a significant other?

Use books, pamphlets, magazines, and posters in the healthcare setting that show a diversity of family structures.

Acknowledge parents who are a couple, jointly parenting, and treat them as such. However, inquire about legal arrangements regarding medical consent.

Ask parents about whether they would like information about their family structure shared with other healthcare providers so that they do not have to reexplain their family arrangements continually.

Provide anticipatory guidance to the parents regarding developmentally appropriate discussions with their child about his or her origin, concepts of a variety of loving relationships, sexuality, sexual behavior, and dealing with harassment and stigmatization.

Become an advocate for change in social policy and attitudes. Homophobia can lead to decreased self-esteem in children of these functional, caring families.

primary functions: to provide material support and supervision (e.g., food, clothing, shelter, safety, healthcare) and to provide affective and cognitive support, socialization, and education. From a structural–functional perspective, the family has affective, reproductive, economic, healthcare, and socialization functions (see Chart 1–4).

These functions not only meet the needs of the family, but also, in doing so, meet the needs of the individual and the society. At times, the family may have difficulty performing some of these functions. For example, providing financially for the family is difficult when a primary wage earner is laid off from work. He or she might also have lost the family medical insurance, making it difficult to provide for adequate healthcare. When these challenges occur, it is important for the nurse to help the family identify additional resources to meet their functional needs.

Family Roles

Family roles and family functions are closely related. Roles are the set of behaviors of an occupant of a particular social position. The family determines the role each family member should play to carry out the functions of the family. Roles within the family can be formal or informal. Formal roles are those that must be fulfilled for the family to function smoothly. Parents take on many roles, such as providing the financial resources necessary for family needs (breadwinner), taking care of the home (homemaker), and raising the children. Similarly, children’s roles might include taking care of siblings (babysitter), playing with siblings (playmate), and participating in school (student).

When family members are unable to fulfill their formal roles, other family members and friends need to take on these roles to keep the family functioning. This can lead to role overload for the family members and the friends stepping in. For example, when parents divorce, the single parent must take on all the roles previously shared with the second parent. In addition, the older child might have to add the responsibility of taking care of siblings while the single parent is working to fulfill the family’s financial needs. In some cases, families choose to pay others to complete jobs that may have been a part of their responsibility in the home (e.g., housekeeper, daycare provider, gardener). Pediatric nurses need to assess the roles each family member plays to ensure that role overload does not occur and that the functions of the family are fulfilled. Referral to social work and community resources may provide the family with access to support for services such as transportation, child care, family counseling, and financial assistance.

Compared with formal roles, informal roles in the family are less explicit. Informal roles are the roles family members play to meet the emotional needs of the family and to help maintain the family’s equilibrium. These roles change with the circumstances encountered by the family. Some informal roles include serving as the mediator between family members, providing comic relief, and helping family members compromise on an issue (Fig. 1–5).

FIGURE 1–5. Siblings can play important roles in the family.

Identification of the family’s informal roles can assist the pediatric nurse in assessing the coping mechanisms of the family. For instance it is easy to assume that the family “jester” is unconcerned about a particular family issue, when in reality his or her light-hearted approach may mask emotional pain and serve as a method to help ease family tension during conflict.

The Healthy Family

QUESTION: What areas would you need to assess to determine whether Tung and Loan Tran are a healthy couple?

What makes a family a healthy family? What strengths, coping skills, or other characteristics are found in families that are able to adapt and reorganize when faced with the normal transitions and the unexpected transitions that accompany the family life cycle?

Many researchers believe that a healthy family starts with the quality of the couple’s relationship. Beavers (1985) identified the attributes of a healthy couple through research on couples that have been successful in maintaining satisfying relationships for many years. He asserted that the beliefs and attitudes that are associated with a healthy couple include the following:

- *A modest overt power difference.* Healthy couples are relatively similar in power levels. Roles of the healthy couple are complementary.
- *The capacity for clear boundaries.* Healthy couples have the ability to tell the difference between one person’s feelings and wishes, and those of another.
- *The ability to operate mainly in the present.* Healthy couples focus on the present. They look at the past as a guide rather than as a directive.
- *A respect for individual choice and autonomy.* Healthy couples encourage expression of personal perceptions and wishes.

- *Skills in negotiating.* Healthy couples have the ability to negotiate solutions that meet the needs of both people.
- *The ability to share positive feelings.* Healthy couples enjoy what they do and express their enjoyment. They find their relationship to be fun, effective, and optimistic.

In the healthy family, honest differences can become opportunities to develop new understandings, rather than sources of struggles and fights. The healthy family believes that family members are not adversaries; they are friends and partners. This allows people to err or disagree without the threat of isolation. Healthy families believe that human encounters can usually be rewarding. Trust and cooperation with one another are key components of family interactions. The healthy family is optimistic and hopeful even when human situations are bad. There is meaning to the human enterprise. These families share a belief that there is purpose outside the realm of the family. The healthy family participates in and contributes to the community around them.

Olson (1993) has stated that healthy families are able to balance their level of togetherness versus separateness. Members are able to experience independence from the family while remaining connected to the family unit. The physical and emotional boundaries of the family allow for sharing of family space and a value for time spent together. At the same time, private space is respected. Members are encouraged to participate in friendships outside the family and to share those friendships with the family.

WORLDVIEW: In some ethnic groups (e.g., Hispanic, Southeast Asian) or religious groups (e.g., Amish, Mormon), it may be expected that family members have a higher level of togetherness, and independence and separateness is discouraged. This should not be considered dysfunctional if all family members wish the family to be this way. Cultural beliefs are a central part of the family's character and must be considered when evaluating family dynamics.

Olson (1993) further asserted that the healthy family has positive communication skills that help the family to balance their levels of flexibility and cohesion in the presence of situational stress or developmental change. Rules exist to guide expectations of family members, yet these rules can be changed when necessary to adapt to family stressors.

Healthy families are characterized by parents who have the knowledge, ability, and resources to adjust their child-rearing strategies and goals in view of the unique characteristics of the child, their own strengths and weaknesses as parents, and the social and familial context in which interactions take place. Parenting goals are clear and support the well-being and survival of the children. It has been noted that family rituals, characterized by routines and celebrations, are an integral part of a stable family. Routines are an important aspect of family life to consider when families encounter illness and hospitalizations that may disrupt the family's patterns.

caREminder

Although a child may be ill or hospitalized for a lengthy period, encourage families to maintain and incorporate as many of their family rituals as possible into the new care routines they establish during this period.

It is important for the nurse to recognize the characteristics of both healthy and dysfunctional families, and to institute a plan of care that is based on the unique characteristics of each family. Crises related to changes in the health status of a family member will affect families in different ways. The healthy family is more likely to be adaptive to change, although still in need of resources (family, financial, social) to strengthen them as they adjust to situational and developmental stressors. Other families may need more support from the healthcare system in the form of counseling, and financial and community referrals to establish a functional level of coping.

ANSWER: To determine whether the Trans are a healthy couple, you need to assess the level of power of the couple and their roles, their capacity for establishing clear boundaries, their ability to focus on the present, the degree of respect they hold for individual choice and autonomy, their negotiating skills, and their ability to share positive feelings.

SPECIAL FAMILY ISSUES

The preceding discussion provided an overview of typical family structures and roles. Within these family structures, other issues may arise that may alter family dynamics. A blended family may choose to adopt a child, a divorce may lead to custody of the children by the grandparents, incarceration of a single parent may necessitate placing the children in foster care. The following section discusses selected family issues and their impact on the family system.

Adoption

Adoption is a means to provide some children with security and to meet their developmental needs by legally transferring ongoing parental responsibilities from their birth parents (or the state, if the child has no relations) to their adoptive parents. Through the adoption process, a new family system is created. Emotional, social, and physical ties may, however, continue to bind the child to his or her biologic family. For example, even if adoption takes place during infancy and the birth parents choose to sever contact with the child, the child may wish to reopen relationships with the birth parents as he or she matures. The ties to the family of origin may never be severed completely.

Adults choose to become adoptive parents for many reasons. Traditional adoptive parents are couples that are

unable to conceive their own biologic children but still wish to raise a child. Preferential adoption occurs when couples decide to add children to their family for a variety of religious, moral, or personal reasons independent of fertility. Declining social and legal barriers to single-parent adoption, and gay and lesbian partner adoptions have also led to an increase in the number of unmarried women and men choosing adoption as a way to start their family.

In 2000 and 2001, about 127,000 children were adopted annually in the United States (U.S. Department of Health and Human Services, 2004). There has been a decline in the number of infants available for adoption, as a result of contraception, declining pregnancy rates, abortion, and more single women (including teenagers) keeping and raising their children (Adoption Statistics, 2005). There has been an increase in the number of children with special needs available for adoption; as a result of parental abuse (including prenatal substance abuse), neglect, and abandonment; or as a result of parental death. Special needs children also include certain minorities, children older than 6 years, children with chronic illnesses or psychological problems, and children who must be adopted with a sibling. The adoption is at a higher risk for discontinuation when special needs children are involved. If the child is older, has been moved to several different homes, or there is a child of the same age already in the home, difficulties with regard to family adjustment are likely to occur. Special needs children place more physical and emotional challenges on the family. Therefore, families considering adopting a special needs child must spend time critically evaluating their resources and ability to meet the challenges of these special children. Many families assess that they have both financial and personal resources to support the child with special needs, and actively pursue adoption of children who can benefit from their loving home environment.

An increasing number of families are selecting to adopt children from foreign countries. The U.S. Department of State figures for international adoptions were 22,728 for 2005, which has increased from 7,093 in 1990. In 2005 there were 7,906 children adopted from mainland China and 4,639 adopted from Russia, comprising 55% of total international adoptions (U.S. Department of State, 2005). Children adopted from overseas often come from high-risk backgrounds and locations where they have lived under conditions unlike those found in the United States. Recognizing the special needs of the child who is adopted internationally, healthcare providers should assist prospective parents in preparing for the challenges associated with integrating that child into the family (Chart 1–5).

The transition to parenthood for the adoptive parent(s) does not come without its share of challenges. For instance, the unanticipated crisis of infertility places the couple and the individuals at risk for psychological problems. Infertile couples often describe feelings of guilt, unworthiness, decreased self-esteem, depression, decreased marital sexual relations, and marital discord (Ceballo, Lansford, Abbey, & Stewart, 2004). Successful transition to adoptive parenthood requires the couple

CHART 1–5 ISSUES RELATED TO INTERNATIONAL ADOPTIONS

Issues

- Child comes from high-risk background where poverty is common and there is limited access to prenatal care.
- Child lived in an institution (baby home, hospital, or orphanage) prior to adoption.
- Child had a lack of nutritional food, shelter, clothing, and healthcare.
- Child presents with behavioral abnormalities, attachment difficulties, conduct disorder, or either extremely aggressive or extremely passive behaviors.
- Child presents with developmental delays.
- Child is easily overwhelmed by new environment.
- Child lacked a consistent caregiver.
- Child experiences difficulty forming attachments.

Strategies to Support the Child and His or Her Adoptive Family

- Preadoptive consultations with an international adoption specialist can help ascertain whether the referred child is one the family feels adequate to parent
- Complete physical, developmental, and emotional evaluation to determine areas of concern
- Screening the child for infectious diseases acquired in the country of origin (e.g., tuberculosis, hepatitis B, HIV, hepatitis C, syphilis, and gastrointestinal pathogens) and specific diseases not previously screened (e.g., phenylketonuria and sickle-cell anemia). Previous screenings should not be considered reliable.
- Review of immunization records. If documentation is lacking, the child should be considered unimmunized and receive the full series of immunizations.
- Completing developmental testing to compare chronological age-appropriate norms with the child's abilities
- Seeking comprehensive healthcare support for behavioral issues that arise
- Adjust parenting expectations to the child's developmental, rather than chronological, age
- Providing remedial activities specific to the delay
- Expecting that some delays may not be reversible and may indicate a lifelong physical or cognitive impairment
- Minimizing contact with friends and family until the child has an increased level of comfort with the parents
- Minimizing sensory overload and providing opportunities to master gradually new sights, sounds, smells, and textures
- Spending time with the child, teaching them how to play
- Ensuring parents serve as a consistent and reliable source of giving and receiving of affection
- Providing opportunities for the child to develop a balance between a sense of independence and reliance

to mourn and resolve issues related to their infertility. Single people who adopt may feel they must constantly justify to others why they chose adoption and why they

feel secure in the knowledge that they can provide a supportive environment for raising a child.

Although the adoption process can be quite long, the suddenness of learning that a child is available for adoption may not allow the parent-to-be much time to prepare emotionally or physically for the actual presence of the wished-for child. After the adoption, parents may have idealized expectations about the child's behavior that are not realized, such as the child being smarter or more compliant than he or she actually behaves. If information about the birth parents was unclear and contact with the birth parents is not possible (*closed adoption*), adoptive parents may worry about genetic and hereditary traits that may emerge in the child. In an *open adoption*, birth parents and adoptive parents maintain a degree of ongoing communication. The adoptive parents may initially perceive the openness as a threat to their skills and confidence in establishing a new family structure.

Throughout the life cycle, the adoptive family faces normal transitions associated with child rearing as well as unique transitions related to the adoptive situation. LePere (1987) found the most critical points in the adoptive family life cycle to be

- The application process
- The waiting period after being accepted as adoptive parents
- The time of receiving physical custody of the child
- The waiting period after receiving the child and legalization of the adoption
- Finalization of the adoption by a formal decree of the courts
- School entrance by the adopted child
- Realization by the adopted child of the loss he or she has experienced related to adoption
- The adopted adolescent seeking information about his or her biologic family
- Beginning of a family by the adopted child

A particular challenge to the adoptive parents is how the child, and how outsiders, may react to the adoption. The “adoptee’s” understanding of the adoption changes as the child develops (Developmental Considerations 1–2). As they mature, children should be given every opportunity to learn more about their biologic parents if this is their desire. Children who avoid talking about or thinking about adoptive issues are at risk for emotional problems and identity confusion (Borchers, 2003). Parents are encouraged to answer questions honestly, and to consider the child’s age and level of comprehension when answering questions. As children grow, it is natural for them to want to hear their adoption story and to learn more about their birth parents. The adoption story should be explained at the child’s developmental level and should include the following elements:

- The adoptive parents’ motivation for adoption
- Acknowledgment of the important role of the birth parents in the creation of the child
- The information that the child was conceived, grew inside the birth mother, and was born just like all children

- A suggestion that the decision of the birth parents to place the child for adoption was in no way the fault of the child
- Acknowledgment that there are happy and sad feelings associated with adoption
- A statement of the adoptive parents’ love for the child

The specifics of each adoption story will vary according to the circumstances. Often, there is limited information available about one or both birth parents. Even so, children should be encouraged to think positively about their birth parents and the circumstances surrounding their adoption.

People outside the immediate family may express curiosity about the adoption simply because the child looks different from the adoptive parents. In answering these queries, it is important to respect the child’s right to privacy regarding the details of the adoption and the birth parents (Borchers, 2003).

It is important for the nurse to be aware of these potential concerns and to help the family focus on its strengths and resources during the transition period of the adoption process. Parenting classes specifically for adoptive parents can assist the family in adjusting to their new roles. These classes should cover the physical aspects of child care and the emotional aspects of adoption while allowing time for sharing so that adoptive parents can gain support and insights from one another. In addition, after the child has joined the family, a comprehensive medical evaluation should be completed to identify medical needs. This type of evaluation can help identify acute and chronic medical problems, vision and hearing loss, developmental delays, and behavioral and emotional concerns (Borchers, 2003).

Foster Care

Foster care, also known as *home care*, is a child welfare service in which children are placed in homes away from their parents in an effort to ensure their emotional and physical well-being. The foster placement system exists to protect children who are abused, neglected, or abandoned, or whose parents or primary caregivers are unable to fulfill their parenting obligations because of illness, emotional problems, or a host of other reasons. The placement into foster care by parents may have been voluntary. In many cases, children are reunited with their parents when the family has demonstrated that interventions to improve the individual, home, or family problems have been instituted. The child in foster care may be placed with relatives, in **kinship care** (care by family relatives), in nonrelative family foster care, or in residential group care (Scahill, 2000). Foster parents receive training prior to placement of children in the home, with additional training given if the placement will be for special needs children.

Children placed in foster care often enter the new living situation at risk for emotional, developmental, physical, and behavioral problems (Sobel & Healy, 2001). Several factors contribute to the increased number of problems that foster children may experience. The

DEVELOPMENTAL CONSIDERATIONS 1–2

Issues Related to Adoption

Age	Issues	Family Interventions
Infancy	<ul style="list-style-type: none"> • Separation from interim caregivers and introduction of new adult caregivers • Disruption of care routines 	<ul style="list-style-type: none"> • If possible, the adoptive family should take a paternal leave from work to become acquainted with the child. • Provide as much consistency as possible regarding who will be caring for the child (including daycare providers and baby-sitters). • Follow infants' previous caregiving routines as much as possible, introducing changes as tolerated by the child. • Allow the infant to keep treasured security objects such as a blanket or stuffed animal.
Early childhood	<ul style="list-style-type: none"> • “Where did I come from?” • Generally accepting of being adopted • Want reassurance that they are loved • Introduction into a new home 	<ul style="list-style-type: none"> • Tell the child he or she is adopted. • Use books to discuss adoption. • Use the family photo album to depict the child's story of adoption. • Answer questions about the child's birth parents honestly, yet in very simple, positive terms. • Establish behavioral expectations for the child and family routines as soon as possible to help the child define his or her new boundaries.
Middle childhood	<ul style="list-style-type: none"> • “Why was I adopted when most people are not?” • Worried that their value as a person is less because they are adopted • Aware that they have lost someone who played an extremely important role in their life • Imagine birth parents as rich, famous, and more attractive than adoptive parents • Adoptive parents may view child's questions about birth parents as a rejection of them • Concerns about being different from adoptive family 	<ul style="list-style-type: none"> • Review the child's adoption story with him or her. • Assure the child that he or she is a loved and welcome member of the family. • Share letters and pictures of the birth parents with the child, if desired. • Reveal who the birth parents are, if desired. • The healthcare provider can reassure parents that the child's questioning is part of the normal development sequence. • Openly acknowledge any racial difference between the child and the adoptive parents. Assist adopted children to learn more about the country of their birth and their ethnic heritage.
Adolescence	<ul style="list-style-type: none"> • Task of developing an identity and discovering how they are different and how they are connected to “their” family • Concerns about physical appearance, traits, and family illnesses of their birth family • Interest in meeting parents 	<ul style="list-style-type: none"> • Give the child more information about his or her birth parents if it is available. • Provide the child with pictures, and information about traits and family illnesses if possible. • Allow the adolescent to meet his or her birth parents.

Age	Issues	Family Interventions
	<ul style="list-style-type: none"> • May have idealized picture of birth parents 	<ul style="list-style-type: none"> • If the identity of birth parents is unknown, encourage the adolescent to wait until young adulthood to begin a search for his or her parents.

interplay of factors that led the child to foster care placement is a key issue to consider. The child may have come from an abusive home situation or may have been considered to have such severe behavioral problems that the parents felt incapable of caring for the child. A majority of children placed in foster care live with their families in poverty (Sobel & Healy, 2001). Children in court-involved kinship foster care are more than twice as likely as children living with nonkin foster parents to live in families with incomes less than 200% of the federal poverty thresholds (50.2% vs. 23.8%) (Macomber, Geen, & Main, 2003).

Children placed in foster care may have medical problems. Ideally, the child should have a medical exam within 24 to 48 hours of removal from the home. Comprehensive medical, dental, and visual examinations are recommended within 30 days. These examinations should include a mental health evaluation, developmental testing, and an educational assessment (Scahill, 2000). Ongoing monitoring of the child should be conducted every 6 months during the first year of placement, and yearly thereafter.

Alert! Children in foster care have a disproportionately higher incidence of pediatric acute and chronic conditions. Careful evaluation is needed to determine whether the child has been receiving regular and ongoing treatment for these conditions. It is not uncommon for children to arrive in protective care services without their inhalers or medications for such conditions as seizures and attention deficit hyperactivity disorder (ADHD).

The foster child may experience difficulties related to the transitions from one home or placement setting to another. It may not be easy for the child to establish a trusting relationship with foster caregivers. The child must learn to be flexible and to adjust to new standards for discipline and “house rules.” The child may be placed in a new school, where it takes time for teachers to address any special educational needs. Healthcare may be discontinuous, because foster children often have frequent changes in primary care providers. Abuse and neglect can occur in the foster care setting. Each of these conditions is an issue that may negatively affect the foster child’s health and well-being.

Foster care is intended to serve as a therapeutic and healing intervention to assist children and families in crisis. Nurses are in a position to support the positive adaptation of the child and the promotion of the child’s

general health and welfare. Every effort should be made to provide consistent healthcare, or a medical home, to the child to avoid discontinuation of necessary services and exacerbation of chronic problems (see [thePoint](#) for Supplemental Information). The nurse should be attuned to problems voiced by the child or the foster parents with regard to the foster care experience. Appropriate referrals can be made if the foster parents are not equipped to manage serious problems. Physical and behavioral markers of child maltreatment should be assessed, with appropriate interventions to remove the child from the foster care setting if justified. The healthcare professional can serve as an advocate for the child in foster care, assisting in monitoring behavioral problems and general health concerns, and determining the child’s ability to meet developmental norms. In addition, between the ages of 18 and 21 years of age, adolescents “age out” of foster care and are expected to transition to independence. Lack of financial resources, poor access to healthcare, and few stable family connections may place these adolescents at risk for poor physical and mental health, unemployment, potential poverty status, homelessness, and incarceration. It is essential for the healthcare team to identify and assess the needs of these youths and to implement an individualized transition plan, with referrals, to ensure that ongoing physical, emotional, and financial needs are met (Lopez & Allen, 2007).

Multiple Births

Seeing a family with twins, triplets, or even quadruplets can cause a great deal of interest among casual observers. Strangers sometimes stop the family to ask questions about the children’s personalities and the parents’ ability to tell their children apart (Fig. 1–6). Multiple births such as twins, triplets, quadruplets, and quintuplets may be the result of one zygote (identical), several zygotes (fraternal), or a combination thereof (some of the children are identical and some are fraternal). In the United States, approximately 3% of babies in this country are born in sets of two, three, or more (March of Dimes, 2002).

WORLDVIEW: The incidence of dizygotic twins is positively influenced by ethnicity and socioeconomic class. Dizygotic twins are more likely to occur in the African American population and are least likely to occur in the Asian population (Zach & Pramanik, 2005).

All childbearing families experience similar developmental tasks. For instance, the new infant must be

FIGURE 1–6. Identical versus fraternal: characteristics of twins.

Identical Twins	Fraternal Twins
Monozygotic (Mz)	Dizygotic (Dz)
Fertilization of single ovum by single spermatozoa	Fertilization of two separate ova by two separate spermatozoa (possible not from the same sexual partner)
Same implantation site, one placenta, one chorion, two amnions	Separate implantation site, two placentas, two chorions, two amnions (placentas have been known to fuse)
Same gender	Same or different gender
Same genetic blueprint and physical characteristics	Different genetic blueprint and physical characteristics
High similarity in behaviors that are governed by heredity	Lower rate of similarity for behaviors influenced by heredity
30% of twin births	70% of twin births
Tendency not influenced by familial patterns, maternal age, parity, or ethnicity; may be some relation to therapy for infertility	Tendency affected by familial maternal pattern of inheritance, advanced maternal age, increased parity, more frequent in blacks, increased levels of follicle stimulating hormone and leuteinizing hormone, pregnancy within 1 month of stopping oral contraceptive use, use of infertility drugs (clomiphene citrate and Pergonal), and in vitro fertilization

integrated into the family, parents must learn new skills and reallocate tasks, grandparents must adapt to a new role, and parents must nurture and maintain their bonds of intimacy in a new context. For the parents of multiple children, these tasks are often complicated by the necessity of managing more than one child with the same amount of support generally afforded the family with one infant. In addition, multiple births are frequently preterm. Almost 60% of twins, more than 90% of triplets, and virtually all quadruplets and higher multiples are born preterm (March of Dimes, 2002). These preterm infants may require lengthy hospitalizations and medical treatment. They are also at high risk for long-term complications related to their prematurity, such as mental retardation, vision and hearing loss, and cerebral palsy. Siblings in multiple births are likely to be discharged from the hospital at different times, requiring

parents to manage the care of a newborn at home and to monitor and support the activities of the remaining hospitalized children.

The family of multiples can expect to undergo many lifestyle changes and have many concerns related to the care of their children (Developmental Considerations 1–3). The mother of multiples is generally homebound after the birth for a longer period of time than a mother who delivered one child. Living space, including size of the car, bedroom, and play areas, and storage places for child supplies and equipment are often found to be inadequate. The physical and emotional energy to support the marital relationship and the relationship with older siblings can also be tested.

Equally challenging for the parents of multiples is the task of developing an attachment to and relationship with each child as a unique personality. To promote individuation,

DEVELOPMENTAL CONSIDERATIONS 1–3

Concerns of Parents with Multiples

Infancy

- Efficient organization of household responsibilities
- Time management skills
- Obtaining, maintaining, and storing a stock of baby equipment and supplies (cribs, high chairs, diapers, wipes, formula, baby food)
- Ability to breast-feed or bottle feed babies simultaneously
- Developing same feeding and sleep schedule for all infants
- Ability to respond to babies as separate individuals

Early childhood

- Delays of verbal and motor skills
- Providing adult stimulation
- Providing activities separate from other siblings
- Providing discipline and praise on a consistent and fair manner based on each child's behavior
- Comparing one child with another in terms of behavior
- Higher incidence of delayed toilet training

Middle childhood and adolescence

- Entry into school and separation into different classrooms
- Individualizing educational process to meet each child's learning needs
- Discouraging excessive comparisons by teachers and peers
- Promoting independent goals, activities, and peer relationships

Ongoing

- Stress management
- Financial concerns
- Neglecting sibling needs
- Parental self-care needs and personal time
- Parental relations
- Frequent transmission of childhood illnesses among siblings
- Treatment of complications resulting from preterm birth

parents are encouraged to select different-sounding names for the children and to use individual names when referring to them. The children should not be dressed alike all the time and, as they grow, should be encouraged to select clothes that reflect their personalities. Parents are encouraged to spend quality time with each child separately. Praise and discipline should be merited individually. Siblings should be encouraged to develop their own toy

preferences, friendships, special activities, and hobbies. Others who come into contact with the children should be encouraged to treat them as individuals, and expect them to think and behave differently. Several organizations, newsletters, and computer resources are available to connect these special families with others facing the same circumstances (see [thePoint](#) for Organizations).

Divorce

Most children do not want their parents to get a divorce. Nevertheless, many marriages end in divorce and most of those marriages involve children. In 2003, more than 10% of men and 13% of women older than 15 years of age were either divorced or separated (U.S. Census Bureau, 2004a). This is an increase from 3.5% of males and 5.7% of females in the same age population in 1970. The steady increase in the divorce rate has affected parents of all age groups, particularly young adults. Many families involved in a divorce have children in the infant, toddler, and preschool age groups. By 2010, it is expected that more than half of school-aged children will have spent a substantial part of their youth living in a single-parent family or a stepfamily (Sammons & Lewis, 2001). Because the incidence of divorce is higher in second marriages, children who have coped with one divorce are at risk for experiencing the crisis of divorce a second time. An increasing number of divorced parents are selecting to cohabitate with someone, forming unmarried partner households. In the 2000 census, of the 105.5 million households surveyed, 5.5 million households were occupied by unmarried partners (U.S. Census Bureau, 2003b).

The frequency with which divorce occurs has forced family theorists to reevaluate the application of the family life cycle model. Carter and McGoldrick (1988) developed an alternative description of the family life cycle for the family affected by divorce (Table 1-4). They described four phases of the divorce stage and two phases of the postdivorce stage. As described in Developmental Considerations 1-4, there are certain prerequisite attitudes that assist family members in making the transition through each phase and in working through certain developmental issues. The impact of divorce affects families differently, depending on the stage of the family life cycle at the time of the divorce. For instance, if divorce occurs after the children have reached adulthood and left the home, fewer issues regarding custodial arrangements and the economic consequences of the divorce for the children need to be discussed.

The impact of divorce also affects children differently depending on their developmental age, gender, and the degree of conflict between the parents (Developmental Considerations 1-4). It has been found that most children experience a period of emotional distress after the divorce. Many children receive deficient clear communication about parental separation and thus feel confused and hurt by the changes in their family (Dunn et al., 2001). Studies have indicated that children from divorced families experience a higher degree of emotional distress, inability to commit to relationships, and greater acting out behaviors and academic failure during adolescence.

DEVELOPMENTAL CONSIDERATIONS 1–4

Impact of Divorce on the Child

Erikson's Developmental State	Family Reactions and Nursing Interventions	
Trust versus mistrust in infants younger than 1 year	<ul style="list-style-type: none"> • Little impact unless infant's basic needs are not being met 	<ul style="list-style-type: none"> • Encourage consistency in caregiving: feeding, bathing, comforting. • Encourage frequent contact of absent parent to establish bonding. • Educate parents on regression as a normal response to stress in this age group.
Autonomy versus shame and doubt in children 1 to 3 years	<ul style="list-style-type: none"> • Self-blame for the divorce • Regressive behaviors • Sleep disturbances • Anger 	<ul style="list-style-type: none"> • Have parents confer and agree how to handle disciplinary issues. • Encourage consistency and stability in the new family form. • Encourage new schedule or routine for daily activities and visitation.
Initiative versus guilt in children 3 to 6 years	<ul style="list-style-type: none"> • Self-blame for the divorce • Aggressive fantasies • Regressive behavior • Sleep disturbances • Tantrums • Bowel and bladder difficulties • Clinging • Fears of abandonment 	<ul style="list-style-type: none"> • Develop consistent patterns of joining and separating from the child. • Continue contact with noncustodial parent. • If contact with noncustodial parent is unavailable, encourage contact with grandparent or other relative. • Encourage consistent disciplinary actions.
Industry versus inferiority in children 6 to 12 years	<ul style="list-style-type: none"> • Responsibility for divorce • Fantasies about parental reconciliation • Sadness • Fearfulness • Loyalty conflicts • Declining school performance • Depression • Anger toward one or both parents 	<ul style="list-style-type: none"> • Provide regular opportunities for children to talk about their feelings. • Avoid blaming and speaking in a derogatory manner about either parent (children will want to choose sides). • Support children's continuing relationship with both parents. • Offer reassurance.
Identity versus role confusion in children 12 to 18 years	<ul style="list-style-type: none"> • Engagement in self-destructive behavior: substance abuse, truancy, sexual promiscuity, eating disorders, suicide • Declining school performance • Feeling of responsibility for taking care of and nurturing their parents • Depression • Anger • Sleeper effects (seems to have no impact on the child until later events bring out true feelings), especially in females • Worries about own future • Questioning of ability to maintain relationships • Vulnerability regarding gender identity as a result of the absence of the same-sex parent 	<ul style="list-style-type: none"> • Empathize with children's feelings. • Avoid seeking companionship from adolescents. • Provide opportunities for open discussion. • Offer appropriate support, including other family members, friends, church groups, and peer support groups. • Encourage involvement in classes that teach alternative ways to handle disagreements and to manage anger. • Encourage noncustodial parent to engage in activities with adolescents (e.g., "boys' time together"). • If noncustodial parent is not available, seek out another same-sex family member or adult friend to spend time with the adolescent.

TABLE 1 – 4

The Family Life Cycle When Divorce Occurs

Stage	Emotional Process of Transition	Developmental Issues
Divorce		
Deciding to divorce	<ul style="list-style-type: none"> • Accepting inability to resolve marital tensions sufficiently to continue relationship 	<ul style="list-style-type: none"> • Accepting one's own part in the failure of the marriage
Planning the breakup of the system	<ul style="list-style-type: none"> • Supporting viable arrangements for all parts of the system 	<ul style="list-style-type: none"> • Working cooperatively on problems of custody, visitation, and finances • Dealing with extended family about the divorce
Separation	<ul style="list-style-type: none"> • Being willing to sustain a cooperative coparental relationship and joint financial support of children • Working on resolution of attachment to spouse 	<ul style="list-style-type: none"> • Mourning loss of nuclear family • Restructuring marital and parent–child relationships and finances; adapting to living apart • Realigning relationships with extended family; staying connected with spouse's extended family
Divorce	<ul style="list-style-type: none"> • Continuing to work on emotional divorce: overcoming hurt, anger, guilt, and so forth 	<ul style="list-style-type: none"> • Retrieving hopes, dreams, and expectations from the marriage
Postdivorce		
Single-parent (custodial household or primary residence)	<ul style="list-style-type: none"> • Being willing to maintain financial responsibilities, continue parental contact with ex-spouse, and support contact of children with ex-spouse and his or her family 	<ul style="list-style-type: none"> • Making flexible visitation arrangements with ex-spouse and his or her family • Rebuilding own financial resources • Rebuilding own social network
Single-parent (noncustodial)	<ul style="list-style-type: none"> • Being willing to maintain parental contact with ex-spouse and support custodial parent's relationship with children 	<ul style="list-style-type: none"> • Finding ways to continue effective parenting relationship with children • Maintaining financial responsibilities to ex-spouse and children • Rebuilding own social network

From: McGoldrick, M., & Carter, E. (1982). The family cycle. In F. Walsh (ed.). *Normal family processes* (p. 192). New York: Guilford Press. Reprinted with permission.

Parenting practices during the postdivorce period may be affected by a disproportionate increase in the number of stressors and strains related to residential relocation, economic hardship, changes in employment, and changes in school for the children (Sammons & Lewis, 2001; Strohschein, 2007). Nursing interventions with families who are experiencing a divorce are aimed at helping the family move through each phase of the divorced family's life cycle, helping parents build on the preexisting strengths and support systems, and finding ways to minimize the impact of the divorce on the children as much as possible.

Nurses in schools, clinics, and hospital settings frequently come in to contact with children who are struggling with the emotional fallout of their parents' divorce. Withdrawal, depression, somatic complaints, poor academic achievement, and destructive behaviors are but a few of the responses the nurse may encounter in working with children of divorce. The healthcare team can serve as an advocate for the child, rallying support systems in

the school, the community, and the child's home to provide mechanisms for the child to adjust to the changes in his or her world. Community Care 1–1 highlights common difficulties that can be anticipated in divorce situations with suggestions for ways to support the child and the family when these scenarios occur.

Grandparent Families

The number of grandparents raising grandchildren is increasing. It is estimated that there are nearly 2.4 million American households in which children younger than 18 years live with their grandparents or other relative (U.S. Census Bureau, Facts for Features, 2006). This is an increase from 1.4 million in 1990. In approximately one third of these homes, neither parent is present to share some of the child-rearing responsibilities (U.S. Census Bureau, 1999). Although grandparent-maintained families can be found in all cultural groups regardless of

COMMUNITY CARE 1–1

Challenging Situations for the Divorced Family

Children’s Adjustment to the Divorce Does Not Meet Parents’ Expectations

Child’s Response

- As the child gets older, divorce issues that were previously “resolved” seem to reappear and become problematic again for the child.

Anticipatory Guidance

- Assist parents to understand the lengthy process of grief and adjustment within the context of the child’s developmental age.
- Revisit issues about the divorce as the child transitions to a new developmental stage.
- Allow the child to talk with healthcare providers about his or her feelings.

Child Is Displeased With the Visiting Schedule

Child’s Response

- Child starts refusing to go to parent’s house.
- Child verbalizes anger about the schedule.

Anticipatory Guidance

- Encourage the child to participate in visiting schedule negotiations.
- Revisit the negotiations on a regular basis to allow for changes in the child’s schedule based on school and extracurricular activities.

Phone Calls to the Absent Parent Are Viewed as Disruptive and Disturbing

Child’s Response

- Child becomes visibly emotionally distressed during calls.

Anticipatory Guidance

- Set up a mutually agreeable schedule for when and how the child can contact the absent parent.
- Avoid emotionally charged times for calls like bedtime or dinnertime.

Transitions and Handoffs Are Traumatic

Child’s Response

- Child acts out and becomes very tearful, angry, or depressed.

Anticipatory Guidance

- Minimize the number of weekly transitions from one household to another.
- Return the child to some neutral place after an overnight or weekend stay (e.g., school or daycare center).
- Allow the children to contact the parent they are not with during a time period agreeable to both parents.

Divorce Contract Binds Children, Setting Limits on Their Time, Flexibility, and Personal Freedoms as They Move Between Two Households

Child’s Response

- Child feels angry and hostile about divorce agreements.
- Child feels powerless to modify or influence the divorce agreement that affects his or her daily life.

Anticipatory Guidance

- Give the child a shortened version of agreement to read and review.
- Ask for the child’s input on negotiations of time when possible.

Parents’ Argue About Money and Expenditures in the Presence of Children

Child’s Response

- Child feels pressure to minimize parent expenses.
- Child feels unwanted because they know they “cost too much.”

Anticipatory Guidance

- Encourage parents to hold such discussions away from children.
- Encourage parents to have a mediator discuss with them issues regarding child expenses.

Parents Are Dating and Having Sexual Relationships With Other Partners.

Child's Response

- Children are unsettled by demonstrations of affection and physical contact between their parent and another adult.
- Children may mimic parental behaviors in inappropriate ways.

Anticipatory Guidance

- Parents should attempt to confine their social and sexual explorations to the nights and weekends when their children are away.

Child Refuses to Spend Time With One Parent

Child's Response

- This may be an attempt to get the rebuffed parent to come back home or pay more support, or may be an attempt by older children to display more independence.
- Child may be avoiding some activity or circumstance at the other house.

Anticipatory Guidance

- Encourage the child to discuss what is going on at the other home and why contact is being avoided.
- Analyze the visiting schedule with the child and determine whether there is conflict with the child's other activities.
- Determine whether a parent is giving out a message that visiting the other parent is not important to them.

Children Have Increased Household Responsibilities

Child's Response

- Child may feel overburdened.
- Child may volunteer to do more, yet this creates a situation of overdependence on the child.

Anticipatory Guidance

- Child should not become the disciplinarian of other children in the household.

socioeconomic level, children raised by their grandparents are more likely to be African American, children of immigrant parents or foreign-born themselves, younger than age 6, and living in southern states (U.S. Census Bureau, 1999). Grandparents living with grandchildren in grandparent-maintained households are more likely to be in the labor force and are most likely to have incomes below the poverty level (U.S. Census Bureau, 2003c). Of the grandparents who were responsible for their own grandchildren younger than 18 years, 35.8% were on Supplemental Security Income (SSI), cash public assistance income, or food stamps; 58.9% were in the labor force; and 19.5% lived in poverty (U.S. Census Bureau, 2005c).

Grandparents become the caregivers of their offspring's children for a variety of reasons. The primary reason has been associated with the negative consequences of parental drug or alcohol abuse and, more recently, with the increased numbers of unmarried teenage mothers and fathers (Paskiewicz, 2004). These consequences include poverty, homelessness, exposures to HIV and AIDS, and child abuse and neglect. Other reasons grandparents may become caregivers include death, mental illness, or incarceration of one or both parents. Under any of these conditions, the grandparents may become caregivers through informal arrangements made among family members or through formal arrangements made by the child welfare system (e.g., kinship care). When legal or physical custody of the child is removed from the birth parents, many grandparents accept responsibility for their

grandchildren rather than allow the children to be placed in a nonrelative foster care home.

Healthcare professionals need to be aware of the impact this new family constellation has on the child, the grandparents, and other affected family members. For the younger grandparent, caring for grandchildren may come as an addition to their current parenting role. They may still have young children of their own residing in their household. The addition of more children may lead to financial, emotional, and marital stress. Aunts and uncles (who are still children themselves) may resent the intrusion of the new family members.

Grandparents who are older usually do not expect to take on a parenting role again. At this point in their lives, they may have been looking forward to their retirement years, when they would be freed from the responsibilities of child rearing. Although they may be financially secure and in good physical condition, raising grandchildren leads to increased physical, emotional, and economic vulnerability of the grandparents (Leder, Grinstead, & Torres, 2007). Decreasing energy levels, higher incidence of illness, and the many symptoms of aging are all factors that compete against the growing needs of active young children and rebellious teenagers. In addition, many children placed with grandparents have physical as well as emotional problems as a result of the parent's problems that have led to this alternative caregiving situation. Extra medical and financial resources may be needed to support these children. Both the physical health and the financial health of the retired grandparent

can be quickly depleted by the constant demands of a medically fragile child.

Raising grandchildren leads to major changes in at least three relationships the grandparent has formed. First, the grandparents may no longer be like their peers. The grandparent may experience feelings of social isolation from friends whose interests and activities are no longer the same. These friends may be traveling or volunteering their time to a service organization, whereas the “new parent” grandparent must worry about getting children off to school and to other social events.

The grandparents’ role is also changed with respect to the relationship they have with the child’s parents. Feelings of anger and resentment may exist as they are forced to take on the responsibilities of parenting. In addition, it may be difficult for the grandparents to witness the deterioration of their own child, who is addicted to drugs, for example, and thus is unable even to care adequately for him- or herself. For some of these grandparents, caring for their grandchildren may relieve some personal stress because they now know the children are in a safe and secure environment in their home.

Last, the grandparents’ relationship with the grandchild is altered by their new role as parents. Typically, grandparents can be permissive and generous with their grandchildren. However, in the parenting role, the grandparent now becomes the disciplinarian, and the birth parent (who may come by for occasional visits) may become the more fun-loving adult figure.

Along with the strains, there can also be many rewarding aspects of caregiving for both the grandparents and their grandchildren. Much joy and love can be shared in these new relationships. For some grandparents, it is an opportunity to enjoy parenting the second time around with more confidence and self-assurance. For the grandchildren, being raised in a safe and secure environment is an immeasurable benefit of this new family constellation.

Nurses can serve as a resource to grandparent caregivers to connect them with information and services that can assist them in their parenting responsibilities (Nursing Interventions 1–4). Access to support groups and individual or family counseling has been found to be beneficial in helping grandparents deal with the stressors they may experience. In 1993, the American Association of Retired Persons (AARP) established the Grandparent Information Center to provide information and resources for grandparents who are raising their grandchildren. The names and addresses of this and other resources for grandparents can be found on [thePoint](#) for Organizations.

Teenage Parent Families

Marital rates among adolescent parents are relatively low. In 2003, the overwhelming majority of teenage births were to unmarried young women (97.1% for teens younger than age 15 and 81.3% for 15- to 19-year-olds), compared with slightly more than one half of births to women ages 20 to 24 (53.2%), one quarter of births to women ages 25 to 29 (26.4%), and approximately 15% of births to women in their 30s (Child Trends Data Bank, 2005).

NURSING INTERVENTIONS 1–4

Ways to Support Grandparents as Caregivers

- Provide grandparents with information about their state’s policies on financial assistance available to kinship caregivers.
- Direct caregivers to apply for Aid to Families of Dependent Children benefits if eligible.
- Ensure that grandparents have the same visiting and rooming-in privileges granted to parents in inpatient healthcare settings.
- Provide parenting classes for updating child care skills.
- Provide education of the special needs of their grandchild who may be medically fragile or who had prenatal exposure to drugs.
- Encourage grandparents not to neglect their own healthcare needs.
- Provide transitional care through the use of home nursing visits for newborns or the child with special needs who is discharged to the grandparents’ home.
- Refer grandparents to support groups and individual or family counseling when needed.
- Refer grandparents to legal aid agencies or law firms that can assist them in working their way through the complexities of the child welfare system.

To work effectively with adolescent mothers and their children, pediatric nurses need to be aware of the strengths and weaknesses of these families. Teen mothers experience difficulties that include low job status and educational achievement, increased likelihood of living in poverty, less partner involvement, and more time depending on welfare, all of which lead to higher stress and depression. The children of teenage parents are at risk because of such factors as poor prenatal care, nonstimulating environments, lack of preventive healthcare, poor nutrition, possible low social support, and inadequate supervision (March of Dimes, 2004).

Despite these difficulties, adolescent parents can become independent, successful, productive members of society. Their strengths often include physical health as well as energy to care for an active child, optimism and idealism to look toward the future, strong support groups made up of peers and extended family, and the developmental readiness for change and advancement. Although teenage parents tend to be more impatient with their children and have low levels of verbal interaction, they typically demonstrate considerable warmth and love toward their children. Nurses need to build on the strengths of these adolescents to increase their chances for success while assisting them in overcoming some of the difficulties associated with being a teenage mother. In

terms of health outcomes, children of adolescent parents are at high risk for delays in cognitive development, poor academic achievement, and behavioral problems (March of Dimes, 2004). Support from their families, peers, and healthcare professionals can help these adolescent families achieve success.

When most teens are struggling to gain independence from their families of origin, the teenage mother is often forced to rely on her family even more for social and economic support. Many of these mothers choose to stay at home to finish high school. If this is the case, communication between the grandparents (especially the grandmother) and the teenage mother regarding the parenting responsibilities for the new infant is essential. Grandparents need to provide support for the adolescent without taking over the teenager's parenting role. If the grandparents become the primary care providers for the new infant, the adolescent may fail to develop her own parenting skills. Consistent parenting and discipline practices are important in fostering the development of the young child. Toddlerhood can be a challenging time for both the mother and the toddler. Most adolescent parents have high developmental expectations of their toddler. Expectations that are too high, especially with regard to obedience, can lead to the mother's frustration and may put the toddler at high risk for abuse. This has profound implications for pediatric nurses. Providing education to adolescent mothers on the normal occurrence of developmental milestones as well as appropriate disciplinary techniques is an essential task for the nurse (Fig. 1-7).

Homeless Families

A homeless person has been defined as an individual who lacks a fixed, regular, and adequate nighttime residence,

or a person who resides in a shelter, welfare hotel, transitional program, or place not ordinarily used as regular sleeping accommodations (e.g., cars, abandoned buildings) (Institute for the Study of Homelessness and Poverty, 2004). According to one study, approximately 3 million people (1.3 million of them children) are likely to experience homelessness in a given year (National Law Center on Homelessness and Poverty, 2008). Families with children are the fastest growing homeless population. Homeless families that have both a mother and a father usually find themselves homeless because of job loss, insufficient income, or eviction. However, the majority of homeless families are headed by a single female parent. Among homeless women, 60% have children younger than age 18, but only 65% of them live with at least one of these children. Among homeless men, 41% have children younger than age 18, but only 7% of these fathers live with at least one of their own children (U.S. Department of Housing and Urban Development, 1999). The single mother usually has limited education and inadequate economic and social supports. Many of these women become homeless in attempt to escape a physically abusive relationship with a male. Other women have found themselves in a homeless situation as a result of a family crisis such as parental physical abuse, drug abuse, mental illness, or violence leading to the loss of life of one's partner. The lack of social and emotional support available to these women has been found to increase their likelihood of becoming homeless (Clinical Judgment 1-3). The number of homeless adolescents is also on the increase. The homeless youth population (younger than 18 years) is estimated to be between 1 and 1.5 million young people each year. Unaccompanied youth account for 5% of the urban homeless population, which is a marked increase from 3% in 1998 (National Coalition for the Homeless, 2008), with a growing

FIGURE 1-7. Adolescent parents face many challenges as they balance child-rearing activities with their own personal and social needs.

CLINICAL JUDGMENT 1–3

The Homeless Family With a Hospitalized Child

Cassie is a 12-month-old white female. She was admitted to the hospital after being seen by a nurse practitioner at a nursing center on the grounds of a homeless shelter. The nurse practitioner had seen the patient on two prior occasions one month apart. Cassie has lost weight during the past 2 months despite the education on nutrition and feeding that was provided to the family. After the initial evaluation, Cassie was diagnosed with nonorganic failure to thrive.

Questions

1. What information and observations should be included in the nutritional assessment of the child?
2. Optimally, what members of the healthcare team should participate in the interdisciplinary care of the child with nonorganic failure to thrive?
3. What are the essential components of the discharge plan for Cassie and her family?
4. When a meal tray is brought for Cassie, you note that she gets very little of the food. Instead, the mother tells you Cassie would not eat so she finished eating her meal. What interventions should you take with Cassie and her mother?
5. What criteria should be met by Cassie and her family prior to discharge?

Answers

1. Growth parameters: length, weight, head circumference, child's general appearance, feeding schedule, description of daily nutritional intake, interactions between child and parent during feeding, availability of food and/or competition for limited food among family members, current community services the family is using to access food (e.g., Special Supplemental Food Program for Women, Infants and Children [WIC], food stamps); interaction; the feeding relationship
2. Physician: conduct a medical evaluation
Nurse: assess child–parent interactions during feeding times, and coordinate care of interdisciplinary team and discharge planning
Dietitian: assess nutritional intake and develop a meal plan to include required nutritional intake
Occupational therapist: conduct a developmental assessment including oral–motor feeding skills
Social worker/psychologist: assess the family resources and support systems, assist with obtaining necessary resources
3. Develop a feeding strategy with family input and concerns. Contact services that will enable the family to meet the nutritional, emotional, and developmental needs of Cassie. These services may include WIC, food stamps, a local food bank, long-term housing assistance, a parenting program with a nutritional component, possibly supervision by a representative from the Department of Children Services/Child Protective Services.
4. Remain present when Cassie is fed. Determine whether Cassie is truly not eating and assess the need to change the type of food offered to her. Review with the mother the importance of Cassie obtaining nutritious food. Discuss with the social worker the possibility of obtaining free meal trays for the parents while Cassie is hospitalized.
5. Cassie has demonstrated a weight gain and interest in eating. The family demonstrates understanding of the feeding plan and strategies to enhance their daughter's nutritional intake. Services that will enable the family to have access to food and shelter have been arranged.

number of adolescents running away from home or being thrown out of their home as a result of conflict with their parents about substance use, violent behavior, and actions related to their choice of sexual orientation and sexual behavior (Rew, Whittaker, Taylor-Seehafer, & Smith, 2005).

Homelessness has an impact on the health and welfare of children and their families. The pediatric nurse and school nurse need to be aware of the special health needs of children in homeless families. Children younger than 5 years make up 42% of the homeless children in the United States (National Law Center on Homelessness and Poverty, 2008). Infants in homeless families are at higher risk for low birth weight and prenatal drug exposure, whereas

older children are at higher risk for malnutrition and physical delay leading to developmental and behavioral problems such as aggression, dependency, sleep disorders, and speech difficulties. Many of these children receive inadequate or delayed healthcare, including immunizations and well-child or ill-child services. In addition, children of homeless families live in environments such as crowded shelters, where they are exposed to other children and adults with contagious diseases. School-aged children have been noted to show more psychiatric symptoms such as depression, suicidal tendencies, anxiety, and poor school performance. School-aged children also have been noted to have a fear of being stigmatized as poor and

living in a shelter (Minick & Carmon, 2001). These findings demonstrate the need for programs to meet the physical, medical, developmental, emotional, and educational needs of these at-risk families to prevent negative outcomes for child development and socialization.

Pediatric nurses in multiple settings such as schools, communities, and clinics should be able to identify the children and families at risk, and begin to act as an advocate for the family. School nurses can act as catalysts in the school system to influence negative attitudes about homelessness and to eliminate the stigma associated with being a homeless child or “shelter kid.” The nurse should be aware of community resources available for the family, such as public health and education programs, mental health services, free clinics, and shelters (Minick & Carmon, 2001) Chapter 2 provides a thorough description of many programs that can benefit the homeless family. In addition, the nurse should be aware of the perceived barriers to obtaining well-child care for these families. These barriers include unfamiliarity with healthcare providers, waiting for appointments and waiting during appointments, and the cost of transportation and/or parking. The nurse can collaborate with members of the healthcare team to ensure that families understand the medical benefits available to them and the steps they must take to access these services. Educational materials and scheduled meetings at homeless care centers to discuss healthcare issues can be provided as a means to provide knowledge of the healthcare system to homeless families.

CULTURAL AND RELIGIOUS INFLUENCES ON THE FAMILY

The cultural composition of North America is changing, with an increase in the number and diversity of minority groups. According to U.S. Census population estimates for 2004, there were 293,655,404 persons in the United States, 67% of whom were white (not Hispanic or Latino), 12.8% were black, 4.2% were Asian, 13.9% were Hispanic or Latino only, 0.96% were Alaskan Indian or Native American, and 0.17% were Native Hawaiian or Pacific Islander (U.S. Census Bureau, 2004b). To adapt to this diversity, healthcare professionals need to adopt a transcultural and pluralistic perspective to work with families with diverse ethnic, religious, and cultural beliefs.

Cultural and Religious Concepts

QUESTION: What examples do you see in the case study that suggest that the Tran family has become acculturated?

Leininger (1991, p. 47) defined **culture** as “learned, shared, and transmitted values, beliefs, norms and life ways of a particular group that guide their thinking, decisions and actions in patterned ways.” Cultural groups can

be distinguished by such characteristics as mode of dress, food preferences, values, politics, language, and health-care practices. **Ethnicity** refers to a common social and cultural heritage of a group that is passed on from one generation to the next. A shared ethnicity is thought to create a sense of identity for a group (Giger & Davidhizar, 2008). **Race** refers to the biophysiologic characteristics of a population group that make it different from others. Not every person in the population group has all the characteristics, but in general the population group as a whole can be distinguished by these characteristics. **Biculturalism** occurs when a person crosses two cultures, lifestyles, and sets of beliefs. For instance, this might occur when an African American child is adopted by a white North American couple or when an Asian woman marries a Hispanic man. During childhood, the cultural values and beliefs of the couple are transmitted to the child, and as the child matures, the parents encourage the child to learn more about and relate to the cultural beliefs of the family of origin. The adolescent grows to understand that she or he is a product of the unique blend of two cultures. **Acculturation** is the process in which a cultural group adapts to or learns how to take on the behaviors of another cultural group. Complete acculturation usually never occurs and is not even necessarily desirable. **Multiculturalism** is the concept that, although cultural differences exist, there are also many similarities and areas of common ground between cultural groups that have immigrated to the United States.

In addition to the cultural similarities and variances among families, it is important to consider the spiritual or religious factors that motivate individual and family beliefs and actions. Spiritual and religious beliefs can directly or indirectly influence the health of children and families. **Religion** can be defined as an organized system of commonly held beliefs, rituals, and observances in the worship of God or gods. **Spirituality** is often defined as the basic quality in all humans that involves a belief in something greater than the self and a faith that positively affirms life. Spirituality most often refers to personal beliefs, transcendent experiences, and principles (Dell’Orfano, 2002; McEvoy, 2003). In essence, one can be spiritual without belonging to an organized religion.

ANSWER: Some examples of acculturation by the Tran family include the father learning to speak English, Ashley’s desire not to be called by her Vietnamese name outside the home, and Ashley’s association with her friends, most of whom are not Vietnamese. Ashley’s dress and use of makeup also may reflect her adoption of her social group’s culture.

Culturally Sensitive Healthcare

It is important for healthcare professionals to be aware of their own cultural beliefs that affect the healthcare they provide to others. The AAP (American Academy of Pediatrics, 2004, p. 1677) defines culturally effective healthcare as “the delivery of care within the context of appropriate

physician knowledge, understanding and appreciation of all cultural distinctions leading to optimal health outcomes.” Professionals should become knowledgeable about the cultural groups represented in their client populations. To provide culturally competent care, it is important to have an understanding of, and respect for, the beliefs and priorities of the families they are serving. Cultural competence begins by developing a knowledge base about other cultures and by developing strategies to communicate and intervene in ways that support the cultural beliefs and values of others. In some instances, individuals may restrict their view of other groups and be unable to accept the beliefs and behaviors of other cultural groups, or they may be unaware of the different cultural beliefs guiding a family’s health decisions (Wolf & Calmes, 2004). Thus, miscommunication and cultural conflict may occur. Stereotyped assumptions about a child or parent based on their physical traits may not fully indicate the different racial and ethnic backgrounds of family members. Optimal support of families can be given by recognizing, accepting, and supporting families of all types (Ahmann, 2005) (Tradition or Science 1–1).

Health Beliefs and Practices of Culturally Diverse Families

When examining the health and illness beliefs and practices of a different cultural group, it is important to remember that this information is general and not universal (Spector, 2004). It cannot be applied to every individual in that cultural group. The traditional belief systems of a group are adapted and modified through

interactions with other cultures and through the socialization that has taken place within the context of the family (acculturation). Differences within a race, culture, or ethnic group are related to variables such as the social context of the family, the economic class, kinship ties, and geographic location of the family. The goal of the nurse is to acknowledge cultural differences while underscoring similarities and belonging. A knowledge of traditional beliefs provides a *framework* for the healthcare professional to begin to assess and intervene in a manner that is safe and effective. As the nurse collects data about the specific cultural and religious practices of a child and his or her family, care can be further modified to ensure optimum outcomes. The U.S. Census Bureau uses incidence, prevalence, and mortality rates of common illnesses to calculate and report racial and ethnic disparities. Although this practice is helpful to identify those at risk for certain health conditions, caution also needs to be taken because healthcare providers that rely too heavily on the “conventional wisdom” of “race-equals-risk” diagnosis may blind themselves to alternative explanations for the health problems of the individual (Tashior, 2005). Discussions of cultural beliefs regarding grief and loss are presented in Chapter 13, and details regarding response to pain are presented in Chapter 10.

Alert! A cultural or spiritual practice may have the potential of interfering with the welfare and safety of a child. For instance, a child who is not fed animal products may be at risk for nutritional deficiencies such as vitamin B₁₂, calcium, iron, vitamin D, and zinc. Cultural and spiritual practices should be assessed carefully and sensitively to ensure the child’s physical and developmental needs are not being inadvertently compromised.

TRADITION OR SCIENCE 1–1

Do racial and ethnic disparities still exist in regard to treatment of illness in children within various healthcare settings?

EVIDENCE-BASED PRACTICE

Mounting evidence indicates that a person’s race can significantly influence the treatment he or she receives (Tashior, 2005, p. 209). A 2003 report published by the National Academy of Science searched published studies for the preceding 10 years to identify documented racial and ethnic differences in healthcare. Some notable discrepancies in pediatric care include less access to kidney transplants for African American patients compared with whites, fewer psychotropic medications provided to African American youths compared with white youths, fewer prescriptions provided to African American and Hispanic children, an increase in charges for diagnostic testing, an increase in length of stay for non-English-speaking families, and parental reports of worse care provided to African American, Native American, and non-English-speaking Hispanic and Asian parents (Smedley, Stith, & Nelson, 2003; Tashior, 2005).

Cultural and Spiritual Assessment

Health and illness are perceived differently from culture to culture, and these perceptions affect the way a person responds to the healthcare environment and treatment modalities. Obtaining a person’s view of health and illness is an integral component of the health assessment process (see Table 8–2 in Chapter 8). Understanding cultural perspectives can help the nurse anticipate and be aware of why families make certain health decisions. Knowledge of a cultural group’s characteristics serves as an indicator of the family’s background, but it is the nurse’s responsibility to clarify the characteristics that the family or individuals have chosen to identify and integrate into their lifestyle. The nurse should have some generalizations about the specific culture to which the family belongs and, by assessing and communicating with the family, the nurse should be able to clarify what does and does not apply to the family. This interaction enables the nurse to learn about the family’s values, beliefs, and attitudes toward health that influence behavior (Wolf & Calmes, 2004). A continual assessment of the family’s perceptions of healthcare should be incorporated into ongoing discussions with the family. These data can provide useful information that can help the nurse to

modify the plan of care and to illuminate areas of patient teaching.

Just as it is important for the nurse not to make care decisions based solely on a family's ethnic heritage, it is equally important for the nurse not to make assumptions on the basis of the family's religious affiliation. Individuals and families may have a certain religious affiliation without adhering to all of the religion's beliefs and practices. Nurses tend to ignore the spiritual needs of the child and family because they feel they do not know enough about the particular religion to be of any assistance. The nurse should assess the role of religion and spirituality in the family and understand the influence of religion/spirituality as a potential coping mechanism for the family (Kloosterhouse & Ames, 2002) (see Table 1–5). The role of the nurse is to show the family and the child a willingness to listen and care for them spiritually, and to intervene in a manner that supports the family's spiritual needs. When nurses do not know the practices of a particular religion, every attempt should be made to discuss with the family their spiritual needs and to develop a plan of care that meets those needs. Studies indicate that nurses are actively involved in providing spiritual support in the form of activities such as prayer, home visitation with prayer, providing privacy and a safe place for family members to express their beliefs, and providing words of healing and encouragement (Van Dover & Bacon, 2001).

WORLDVIEW: Rhee (2005) examined race-/ethnic-specific prevalence for 10 symptoms in American youth. White youths reported the highest frequency of headaches, musculoskeletal pain, and dizziness. Black youths more commonly reported feeling hot, having chest pain, having cold sweats, and having urinary symptoms. Musculoskeletal pain was more likely in families with higher income, and chest pain, cold sweat, feeling hot, and urinary symptoms were reported by those with lower family incomes. Clearly, each racial/ethnic group of adolescents had its own particular tendency to certain physical symptoms. This information can be used to help guide symptom assessment and early diagnosis of physical problems when adolescents are evaluated by nurses in school or outpatient clinical settings.

Healthcare Implications

QUESTION: When caring for George Tran in the emergency department, what would you do to ensure the delivery of culturally competent care?

Cultural and religious beliefs and practices of the family can be expected to affect the management of the ill child. The nurse needs to determine whether these practices and beliefs are beneficial for the child. When possible, these beliefs need to be incorporated into the nursing care plan. When these beliefs and practices are detrimental to the health and welfare of the child, compromises need to be made to respect the family's beliefs and still maintain the health of the child. When a compromise is not possible, a legal intervention may be necessary to

ensure that care is provided that is in the best interest of the child's health.

WORLDVIEW: When working with families, the nurse needs to encourage the use of benign or neutral folk practices while discouraging practices or remedies that have a detrimental effect on the child. It is important to share with the family the ill effects some healing practices can have on the child.

Some religious institutions offer rituals or beliefs that might help an individual prevent illness, or offer support should an illness occur. Many religions offer direction on social, moral, and dietary requirements to prevent illness. For example, the Mormon religion, as part of its belief system, discourages smoking, excessive alcohol use, and illicit drug use. Many people believe that illness is a punishment for breaking a religious code (Spector, 2004). Many religious institutions have rituals related to having and raising children. Childbearing is an example of an event that is affected by many religious and cultural beliefs and practices. Orthodox Jewish women feel that producing children fulfills the measure of their creation and shows obedience to the ancient rabbinical law to multiply and replenish the earth. Male circumcision is another practice with which religious rituals are associated. The ritual of circumcision is practiced on the eighth day of life by a trained *mohel*, by the child's father, or by a pediatrician. These are just a few examples of child-rearing practices that are influenced by religious beliefs that should be considered and incorporated into FCC practices.

Beliefs about health and illness can often affect a family's ability to comply with western medicine and nursing care. In the healthcare setting, providers can promote culturally competent care through interventions that bridge or link the healthcare system with the child and family who are responding from a different cultural context. The nurse must use knowledge of traditional cultural and religious practices as a framework in which to assess the patient and build a plan of care. The healthcare plan that has the most success is the one that demonstrates an appreciation for the cultural variations and similarities of each family.

ANSWER: When caring for George, you need to realize that, as the oldest son, he is the one eventually to inherit the family's worth. When communicating with him, be aware that he may wish to avoid any confrontations with healthcare professionals and might answer questions with information he thinks you want to hear. In addition, he may avoid eye contact (eye contact is considered rude in his culture). Also, do not use your hand or finger when motioning to him, because this is considered an insult, and do not touch his head. The head is considered sacred in his culture, because it is where one's consciousness lies. Moreover, support any wishes that the family may have related to the use of a shaman or healer for possible remedies and spiritual healing ceremonies.

2

Advocating for Children and Families

Case History

Lindsay Jenkins is a 10¹/₂-year-old girl with type 1 diabetes mellitus. She is the only child of Jean and Tom Jenkins. Next year she will attend middle school. She has been wearing an insulin pump for the past 6 months and the regulation of her diabetes is going well. Lindsay must check her blood sugar regularly to calculate the amount of insulin the pump will deliver. She does not use separate lancets; the lancet is contained within a case and withdraws after use. In her elementary school, Lindsay is allowed to test her blood sugar in the classroom and, if she needs a snack, she is allowed to eat in the classroom as well. Her parents' concerns and questions are that in middle school, where she will move from classroom to classroom, will Lindsay be allowed to have a snack if she needs to and will she be allowed check her blood sugar in a classroom?

There are several laws to protect children with diabetes and other chronic conditions, yet there remain great variations in practice. The right to manage medical chronic conditions at school is based on Section 504 of the Rehabilitation Act of 1973, the Americans with Disabilities Act, and the Individuals with Disability Education Act (IDEA). Under these laws, diabetes is considered a disability, and schools that receive federal funding are not to discriminate against a child who has diabetes, or any chronic condition. They can, however, refuse to grant a request for accommodations that are not thoroughly documented and they can refuse to allow blood glucose testing in the classroom. States vary in their regulations of who can administer glucagons during an episode of severe hypoglycemia. A few states have additional legislation to protect children with disabilities; many school districts, however, have their own individual interpretation of the

federal laws. Some schools have not allowed children to have a snack in the classroom and many have not allowed the child to test their blood sugar. Some school regulations require a student to leave class, go to the school nurse's office, wait for the school nurse, and test in the office with the nurse present.

Lindsay is a conscientious student and is anxious enough about the changes and demands of middle school without having to leave a classroom during instructional time. Lindsay has also experienced very low blood sugars right after exertion in her physical education classes. Going to the nurse's office and waiting to see the nurse to test her blood sugar would place Lindsay at risk for a hypoglycemic seizure. Lindsay's parents are meeting with the school administrator to discuss blood sugar testing in the classroom, to make sure Lindsay's 504 Plan is on file, and to determine whether she should also have any updates made to her individual education program (IEP) plan. Lindsay's endocrinologist has a pediatric nurse practitioner (PNP) who works closely with the families. The PNP is a member of the National Association of Pediatric Nurse Practitioners (NAPNAP) who has been working with the state professional nursing organization to monitor the bills coming through the state legislature. Recently, a neighboring state debated legislature that would prevent classroom blood sugar testing.

Tom and Jean are supporters of the American Diabetes Association, which is a nonprofit organization that provides research, information, and advocacy. They are also members of Children with Diabetes, which lobbies on behalf of families of children with diabetes.

As you read this chapter, consider the Jenkins family and determine whether the following objectives are applicable to them.

CHAPTER OBJECTIVES

1. Review various factors and issues in the sociopolitical and medical arenas that affect the care of children and their families.
2. Describe selected strategies that nurses, parents, and the community can use to promote health maintenance in children.
3. Describe ethical principles that may affect the care of children and their families in either standard clinical or research settings.
4. Review and contrast the legal rights of children, emancipated minors, and parents.
5. List safety and documentation strategies unique to caring for children who are involved in research studies.
6. Identify public, private programs and community sources of public healthcare and support for children and their families.
7. State the educational programs available to support children with special healthcare and learning needs.

See [thePoint](#) for a list of Key Terms.

The challenges in providing care to children are many as we allocate scarce human, financial, and social resources to meet the health needs of children and their families. Despite numerous social, medical, and legal achievements made to secure the health and welfare of the young, the health status of children around the world remains in jeopardy. This chapter covers some of the challenges to children's health and strategies for enhancing future care through advocacy activities, attention to ethical concerns, legislation, and healthcare research.

MAJOR THREATS TO CHILDREN'S HEALTH

QUESTION: Is Lindsay's experience with diabetes applicable to many other children? Is it a condition influenced by poverty and education?

The state of children's health in the United States is evaluated by specific determinants and measures of health status and use of healthcare services. Determinants of health generally include such factors as age, poverty, race and ethnicity, health insurance coverage, health behaviors, and risk factors. Measures of health status for children include, but are not limited to, prevalence of asthmatic episodes, chronic health conditions, and causes of mortality. The health of individuals living in North America continues to improve overall, with substantial advances in research, healthcare, public health programs, and health education. However, much room for improvement remains.

Many childhood infectious diseases, such as mumps and measles, have all but disappeared in North America because of the emphasis placed on immunization against

certain preventable diseases. However, the prevalence of chronic diseases is increasing. The incidence of overweight and obesity in young children and teens is increasing rapidly. The *Youth Risk Behavior Surveillance—United States, 2003* data reported that, nationwide, 15.7% of students were at risk for overweight (Centers for Disease Control, 2005). The number of overweight children coupled with the decline in physical activity in Americans of all ages is extremely worrisome from a public health perspective, because overweight and obesity are known risk factors for many chronic diseases and disabilities such as cardiovascular disease, diabetes type 2, and hypertension.

Poverty continues to be a risk factor for parents' rating their children as either in fair or poor health. In 2003, more than 60% of black and Hispanic children younger than 18 years were poor or nearly poor. Non-Hispanic black children between the ages of 3 and 10 years experienced higher asthma attack prevalence rates than did non-Hispanic white or Hispanic children in this same age category (National Center for Health Statistics, 2005). Likewise, racial and ethnic factors are associated with substantial disparities in infant mortality rates.

Some positive changes in health outcomes have been noted. The birthrate for teen mothers (ages 15–19 years) has seen a significant downward trend—down 36% since its peak in 1990. The teenage abortion rate has dropped 50% from its peak in 1988 (Guttmacher Institute, 2006).

Health behaviors and risk factors play an important role in health outcomes. Nursing Interventions 2–1 lists selected risk behaviors that affect children's health, and ways in which the nurse can intervene to minimize these risks. In addition, measures of morbidity and mortality are additional gauges of the status of children's health. Mortality trends that are of great concern in pediatrics are infant mortality and unintentional injury rates (Fig. 2–1). For example, infant mortality has increased as a result of the numbers of infants born weighing less than 750 g. Unintentional injury rates have been decreasing; however, drowning and motor vehicle occupant injury remain among the highest causes of unintentional injuries. National data also continue to reflect substantial disparities in mortality rates among racial and ethnic groups.

Healthcare coverage is also an important risk factor. The most current statistics indicate that about 8.3 million children in the United States, or about 11.3%, lack insurance coverage. Hispanic children (2.9 million) and African American children (1.6 million) are among the highest groups of children to be uninsured. Uninsured children are nearly 10 times as likely as insured children to lack a usual source of healthcare. More than 7 in 10 uninsured children are eligible for Medicaid or other state insurance programs (Robert Wood Johnson Foundation, 2005).

ANSWER: New cases of type 1 diabetes are diagnosed in approximately 19.0 per 100,000 youth younger than age 20 each year. Non-Hispanic white youth have the highest incidence rate of all ethnic groups (National Diabetes Information Clearinghouse, 2007). Poverty and education have no influence on the likelihood of a child being diagnosed with this type of diabetes. However, these factors

NURSING INTERVENTIONS 2–1

Risk Behaviors in Children

Selected Risk Behaviors ^a	Examples of Nursing Interventions and Advocacy Activities
<ul style="list-style-type: none"> • Cigarette smoking • Smoking during pregnancy • Use of seat belt: “rarely” or “never use” • Rode with driver who had been drinking alcohol • Physical inactivity • Obesity • Use of illicit drugs • Episodic heavy drinking • Carried a gun 1 day or more during the past 30 days • Injured in a physical fight during the past 12 months • Feelings of sadness or hopelessness during past 12 months almost every day for 2 weeks or more 	<ul style="list-style-type: none"> • Educate parents to start discussion of issues before those behaviors become a risk. • Encourage parents to discuss family values. • Nurses can advocate for school policies and legislation to promote health behaviors (e.g., requiring recess time, nutritional lunches at school). • Establish support groups for students needing additional support managing their stress. • Provide school programs that advocate abstaining from alcohol use and substance use. • Establish no-tolerance policies for bullying within schools and other youth-oriented venues.

^aBased on 2003 statistics as reported by the National Center for Health Statistics. (2005). *Health, United States, 2005 with chartbook on trends in the health of Americans*. may affect ongoing management of the child’s condition if the family lacks an understanding of effective management or lacks the funds and access to a medical home to ensure ongoing care for the child’s chronic condition.

CHILD HEALTH INITIATIVES AND MAJOR CHILD ADVOCACY GROUPS

Data about the status of children’s health provide ample evidence that the status of children’s health issues must continue to be a focus of public concern. Pediatric nurses need to be familiar with three key health initiatives that serve as standards to judge whether outcomes demonstrate if goals for improving child health have been achieved (see [thePoint](#) for Evidence-Based Practice Guidelines).

Healthy People 2010: National Health Promotion and Disease Prevention Objectives for the Year 2010 is a key national initiative that has identified areas that need improvement and provides benchmarks to indicate success. Areas identified include immunization rates; injury and violence prevention; maternal, infant, and child care; and physical activity and fitness. Clinical preventive services needed from birth through adolescence also have been identified in the AAP’s *Bright Futures in Practice* publications, which are part of the AAP *Healthy Steps Initiative* (Hagan, Shaw, & Duncan, 2007). The American Medical Association (AMA) developed its *Guidelines for Adolescent Preventive Services* (American Medical Association, Department of

Adolescent Health, 1992), which include standards for best care practices in adolescent healthcare.

Several key national child advocacy groups also serve as watchdogs for promoting child health. These groups include the National Association of Children’s Hospitals and Related Institutions, the Children’s Defense Fund, The World Health Organization’s and the United Nations Children’s Funds, and the Annie E. Casey Foundation (Kids Count Data Book). For more information and websites for these and other advocacy groups see Organizations on [thePoint](#).

Three national pediatric nursing organizations serve the professional needs of nurses working with children and their families: the National Association of School Nurses (NASN), the Society of Pediatric Nurses (SPN), and the National Association of Pediatric Nurse Practitioners (NAPNAP) (see [thePoint](#) for Organizations). These professional nursing organizations have advocacy groups within their membership that support local and national efforts on behalf of children. The NASN promotes programs to improve the health and education success of children. The SPN has several position statements regarding advocacy issues such as promoting literacy, preventing violence against children and pediatric injury prevention. The Keep Your Child/Yourself Safe and Sound (KySS) program and the Healthy Eating and Activity Together (HEAT) initiatives are examples of nationally based work undertaken by NAPNAP. These two initiatives focus on nurses’ role in the prevention and early identification of psychosocial morbidities and obesity issues.

ADVOCATES FOR CHILDREN'S HEALTHCARE ISSUES

An **advocate** acts to safeguard and to advance the interests of other persons—in this case, the child and family—as a means to help meet their healthcare needs. Advocacy can take a number of forms, from calling an agency on behalf of a child to writing letters to legislators to improve their understanding of an issue, to working to change agency policy to better meet the needs of the families it serves. If parents need assistance beyond what the nurse can offer, they can be referred to local protection and advocacy agencies.

A variety of strategies exist to improve child health, from seeking additional funding for key programs so they can serve more children, to creating healthier and more supportive communities, to directing families to services and

teaching, and supporting them as they advocate for themselves and their children. The potential roles for nurses are limitless. In caring for children and families, look for any opportunity to improve health for all children.

Nurses' Role

QUESTION: How does the PNP who works with the pediatric endocrinologist serve as an advocate for the Jenkins family?

Nurses serve in myriad ways to improve child health and to serve as an advocate for children and their families. Effectively teaching children about resources, self-care, and

FIGURE 2–2. Family members must be provided the information they need to promote optimum health and to prevent illness.

other health promotion activities is a key role for nurses (Fig. 2–2). Because the intended audience may be children or adults, those with low literacy skills, or those who speak a language other than English, teaching strategies must effectively meet the needs of many types of learners.

An important role for nurses in relation to public health programs and third-party payers is that of child advocate. Not all service systems are child friendly, easy to access, or understandable to those outside the program. Eligibility criteria can be confusing, the application process complicated, or the services offered inadequate.

Another key role for nurses is that of care coordinator or case manager. In this capacity, the nurse attempts to improve access to needed care and reduces gaps or duplication in services by developing and implementing an appropriate plan of care. During the care coordination process, nurses assist and collaborate with the child and family to determine their strengths and needs. They then jointly establish goals and develop a plan of care. The plan explicitly states who will do what and when, specifying the person who will assume accountability for each action item. The child and family are periodically reevaluated to determine the appropriateness of the plan and the need for any revision. The case is closed when the child has been transferred to another agency or is no longer in need of services. Case closure is a key element of care coordination, not merely the end. Children and families should be told how and under what circumstances they may reenter the service system. If they are no longer receiving services because they are ineligible, nurses should make every effort to refer them to a program that may be able to serve them.

In addition to working directly with children, nurses may work toward improving child health by developing programs or policies needed to better meet the needs of children and families. Community Care 2–1 summarizes the many interventions the nurse can use to support community health needs. Opportunities to work in the community are available through public health agencies, hospitals, and community-based programs.

Because delivering community-based services often involves more than one agency, the nurse must be especially sensitive to issues of confidentiality. In particular, nurses need to be aware of the effect of the Health Insurance Portability and Accountability Act of 1996 (HIPAA), which required states to reform their health insurance markets to ensure that individuals with preexisting conditions could not be excluded from health insurance plans (Anderson, Rice, & Kominski, 2001). In addition, regulations were put in place to protect patients' privacy in healthcare settings, including hospitals, doctors' offices, and clinics. This regulatory atmosphere complicates nursing practice, because nurses are often called upon to share information as part of their work on behalf of children and their families. Agencies and facilities serving children and families have their own HIPAA guidelines with which the nurse needs to become familiar.

ANSWER: Assisting the family with the forms and paperwork required by the school helps to create a situation in which Lindsay's blood sugar is well managed during school hours. This assistance is a type of advocacy and it has a great impact on Lindsay's current and long-term health. Another example of advocacy is being a member of NAPNAP.

Parents' Role

QUESTION: How are Lindsay's parents acting as an advocate for their daughter?

The family is the basic system in which health behavior and care are organized, secured, and performed. In most families, the parents or guardians, as advocates for their child, provide health promotion and health prevention

COMMUNITY CARE 2-1

Community Healthcare Services for Children and Their Families

Location	Services Provided by the Nurse or Advanced Practice Nurse
Schools	
Healthcare provider's office	Preventive care
School-based clinics	Primary care
	Coordination of services (case management)
	Participation in Individual Education Programs (or IEPs)
	Child and family advocacy
	Child and family teaching
	Consultation to teachers and administrators
	Program development
Homes	
Home healthcare	Direct patient care
Hospice	Assessments of the home environment
Public health	Care planning
	Coordination of services (case management)
	Child and family teaching
	Consultation with other health professionals
	Program development
Community-Based Facilities	
Skilled nursing facilities	Direct patient care
Community nursing centers	Environmental assessments
Extended care facilities	Care planning
Shelters	Coordination of services (case management)
Daycare and respite facilities	Child and family teaching
Community clinics	Consultation with other health professionals
	Program development
Specialty Camps	
Cancer	Preventive care
Cystic fibrosis	Primary care
Asthma	Direct patient care
	Child and family teaching
	Consultation with camp staff
	Program development
	Environmental assessment
	First aid and injury education
	Outdoor safety education

care, as well as primary management of care when the child is sick. Parents and guardians have the prime responsibility for initiating and coordinating services rendered by health professionals. Because parents have primary responsibility for meeting the health needs of their children, strategies to improve child health must be family centered and appropriately adapted to meet the cultural, language, and learning needs of families. Health practices and the use of healthcare services vary tremendously from family to family. Assess for the diversity in healthcare practices and incorporate these family differences into the collaborative plan of care with the family. Encourage parents to take responsibility for learning about resources for their

family members, and follow up when referrals have been offered to them. Likewise, encourage parents to ask questions and challenge information that appears to be incorrect or otherwise limits access to needed services. Nurses can be very helpful in teaching parents to advocate for themselves and their children effectively.

ANSWER: Lindsay's parents are being effective advocates for their daughter by meeting the administrators of the new school prior to school starting and by documenting their daughter's needs. They have also joined two organizations that advocate for children with diabetes.

Community's Role

QUESTION: How have some states been an advocate for children?

Communities can help improve the health of children and families by ensuring that resources are available, appropriate, and accessible. For families of children with special healthcare needs, communities should also ensure access to community activities and resources, and should nurture children's participation in them.

To ensure the most comprehensive array of resources for their members, communities should undertake periodic needs assessments to identify service demands that are not being met. Nurses are well positioned to take part in these needs assessments, because they are often involved in multiple facets of community life and are in contact with diverse members of the community in schools, public health clinics, private offices, hospitals, home health agencies, and other local programs, where they become aware of unmet needs.

After a needs assessment is completed, and strengths and deficiencies are identified, communities can develop multiagency collaboratives to meet the needs of community members. Nurses can be involved in this effort to ensure easy entry to needed care and seamless transitions from one program to another; they may also identify gaps and duplications in services. Nurses may participate in community planning meetings to develop strategies for providing services. Participation may also involve seeking funding for proposals by writing grants or making presentations to community groups.

Communities should offer support to children and their families through tangible services such as self-help groups, counseling, food banks, and homeless shelters. Communities should also develop strategies to enhance access to services that already exist. Strategies may involve such ideas as providing free or low-cost local transportation, providing low-cost child care, or collocating services to make one or more programs available at the same site. Improving access may also involve working with individual programs to increase "family friendliness" with extended hours, bilingual or bicultural workers, printed materials in easy-to-read formats, and a clear and simplified application process.

Within the community, employers can also use strategies to improve the health of their employees' children and the community in which they are located. To ease the burden on families to provide healthcare, employers can provide health insurance, family leave to care for ill family members, and other flexible benefit arrangements to meet individual families' needs. In addition, employers can establish information and referral services for their employees and the community at large to encourage effective use of existing services.

ANSWER: A few states have enacted legislation beyond the federal laws to protect children with disabilities.

ETHICAL ISSUES IN THE CARE OF CHILDREN

Nurses are frequently called upon to advocate for children about ethical issues related to the care of children. Nurses may find themselves in situations that require ethical decision making related to concerns of informed consent, parental permission, and child assent, as well as the challenging treatment issues encountered in the care of critically, chronically, or terminally ill children.

Ethical decision making should not be a unilateral process pursued solely by one healthcare professional. The values of the patient and family must be ascertained and considered, and nursing input is important and often sought. Every institution has an **Institutional Ethics Committee (or IEC)**, which is required by the Joint Commission. The IEC should always be consulted in difficult or unusual cases when conflict and lack of agreement exists between parents and physicians or among the professional staff regarding the course of action that is in the best interest of the child. The purpose of having an IEC is to educate healthcare professionals, patients, and families about ethical issues, and to provide individual case consultation and recommendations based on an ethical analysis of the relevant facts and feelings of all parties. The IEC's deliberation may shed new light on the situation, help with conflict resolution, and enhance communication between healthcare providers and parents; it may also provide needed guidance about whether to continue life sustaining medical treatment (LSMT) or to transition from a "cure" to a "care" treatment focus.

Decision Making and Informed Consent

Informed consent is a legal condition whereby a person is said to have given consent based upon an appreciation and understanding of the facts and implications of an action. Adults have the right to self-determination for medical care after consultation with a physician or other healthcare provider, and their voluntary and informed decisions generally focus on personal preferences and values. Until children reach the age of majority or are *legally emancipated* (see this "Rights of Emancipated Minors" later in this chapter), they lack the legal empowerment and often the decisional capacity (the ability to reason, deliberate, and analyze the elements in decision making) to make medical decisions on their own. The age at which a child or adolescent can legally exercise voluntary and informed consent for treatment without parental permission varies from state to state and also depends upon the medical condition. For example, treatment for sexually transmitted infections, family planning, and drug or alcohol abuse may not require parental consent, depending upon state statutes.

The principles of informed consent for research participation are discussed in detail in the research section of this chapter. The key ethical issues related to informed consent for treatment have similarities to those required for research participation: consent must be voluntary and based upon shared information about the risks and benefits

FIGURE 2–3. Obtaining informed consent from a child’s responsible parent is essential before any procedure. A signed form, however, does not mean that full disclosure has occurred.

of the treatment. Furthermore, the parent must understand the information and be cognitively and mentally competent to make the decision (Fig. 2–3).

Nurses are in a position to alert physicians or others if they determine that the parent or child does not comprehend or lacks the decision-making capacity to give voluntary informed consent or **assent** (i.e., agreement to participate in a procedure or in research). A situation could also arise in which the nurse believes the physician has unduly coerced parents in their treatment decision. Such intentional or unintentional action violates ethical principles of conduct, and the nurse is obliged to intervene and disclose any concerns to the healthcare administration or IEC. Other ethical problems can arise when dissension occurs between parents or when the wishes of parents conflict with those of an older child or teen. Respect for a child’s developing capacity for autonomy and self-determination requires that the child’s wishes be considered and that the child agree with the decision being made.

After the parents and the child have been informed of the treatment options, after all healthcare options are considered, and after the wishes of the parents and child are known, the underlying ethical principle that must guide the overall decision-making process is to determine what is in the best interest of the child. Parents do not have the sole right to decide whether their decision is not in the child’s best interest, and the child does not have the sole right to dissent if the intervention is deemed essential to his or her welfare. For older children to give their assent, they need help to understand their condition and what they can expect as the outcome of treatment. In addition, the child must be cognitively able to comprehend this information, not feel pressured into a decision, and must willingly agree to the proposed intervention. For example, if a 16-year-old girl tells the nurse that she does not want to undergo the final stage of plastic surgery to repair a cleft lip deformity, and her parents have signed the consent, the nurse would participate as an advocate

for the child, voicing the child’s desire to not have the surgery.

Sanctity and Quality of Life

Life is sacred and, thus, healthcare professionals must always act in a manner that respects the **sanctity of life**. Likewise, their actions must focus on doing what is in the child’s best interest to achieve an acceptable **quality of life**. These two concepts are closely linked and provide the foundations for much of the decision making in challenging ethical situations. The healthcare provider is obligated to focus on these two basic principles. LSMTs are interventions, such as organ transplantation, ventilator therapy, dialysis, and use of vasoactive medications, that prolong life or alter substantially the expected progression toward death. They can also include other less dramatic interventions, such as use of antibiotics, chemotherapy, or artificially provided nutrition and hydration.

For children with life-threatening or terminal conditions, medical treatment should only be used if the benefits outweigh the burden on the child undergoing such therapies. This is often an emotionally challenging time, when the focus of care of the critically ill child or the child with a terminal illness changes from “cure” to “care.” However, this change in no way implies that the child’s life is less sacred. It just signals a change of emphasis to palliative care, in which pain and other symptom control is paramount (see Chapters 10 and 13). Indeed, this change, from “cure” to “quality care,” with symptom management as the primary focus of the treatment plan, only reinforces the focus on life with dignity rather than technologically sustained life. The distinction between certain LSMTs and palliative care measures can be difficult to make, and at times LSMTs and palliative care measures are integrated as part of the “care” treatment plan.

Perhaps the most emotionally charged decisions that must be made and carried out are those that deal with withholding and withdrawing life-sustaining treatments. Most ethicists believe there is no moral distinction between withholding or withdrawing interventions that are not medically indicated. However, because of the uncertainty inherent in children's responses to treatments, most professionals working in pediatrics believe it is preferable to withdraw treatment if the patient does not respond rather than not treat or fail to provide an intervention and, thus, never know whether this individual child might have responded positively. However, withdrawing treatment, even if the child does not respond, is often an emotionally wrenching experience for parents. Withdrawing or withholding artificial hydration and nutrition is one of the most difficult decisions to be made in pediatrics. However, a decision to withhold or withdraw LSMT does not imply that the primary intent is to hasten the child's death. Likewise, the use of adequate sedation and analgesia to relieve rapidly progressive symptoms of pain and dyspnea is not assisted suicide or a choice to end life, but is rather a commitment to relieve symptoms that detract from the child's quality of life.

Sanctity of life is also an important factor in treating newborns with disabilities and with special healthcare needs. Federal regulations specifically prohibit withholding medically beneficial treatment from newborns with disabilities, except under specified conditions: permanent unconsciousness, "futile" treatment, and "virtually futile" interventions that are excessively burdensome for the infant. In a similar vein, ethical issues of fetal well-being and treatments arise with debate about the appropriate balance between maternal and fetal interests. For instance, when a pregnant woman refuses needed medical or surgical intervention that will affect the health of her fetus, or her behavior negatively affects the well-being of her fetus, warning flags are raised. The key ethical questions to be considered regarding interventions are whether the intervention has proven benefits; the harm to the fetus is certain, substantial, and irrevocable; and the risk to the mother is negligible. Such situations may require consultation with the IEC. Issues related to problematic behaviors generally revolve around use of illicit drugs and alcohol, and their harmful effect on the fetus. These cases are very difficult to resolve successfully, whether the course of action is inside or outside the legal system.

Do Not Resuscitate or Do Not Attempt Resuscitation Orders

A decision not to attempt cardiopulmonary resuscitation (do not resuscitate or DNR) is one aspect of limiting LSMT. Review hospital, healthcare agency, or school policies on pediatric DNRs to determine the conditions and protocol that must be followed before a DNR order can be initiated, and to find out how often it must be reviewed and renewed. The presence of a DNR order does not mean that other interventions are to be withdrawn or withheld. Basic care such as suctioning, oxygen administration, and medication administration must

continue unless ordered otherwise. A DNR order should be discussed in a quiet setting that respects the parents' need for privacy and in a way that allows the parents the opportunity to ask questions. Seeking permission for a DNR order is an undeniable signal to the parent that the healthcare team believes further lifesaving measures are not in the best interests of the child. For parents to agree to such an order often requires time for quiet thought to reflect on the decision to forgo any further painful or invasive treatments for their child. Some parents may acquiesce right away, others may take hours or days to agree, and some may never give permission, despite knowing the futility of further treatment. The nurse's role is to remain empathetic and to acknowledge the parents' feelings. The wishes of parents of a child with a life-threatening or terminal condition who have agreed to a DNR should be respected in both hospital and out-of-hospital settings, such as the child's school (see Chapter 13).

Genetic and Technological Advances, Innovative Therapy, and Other Practices

QUESTION: Many individuals hope that the cure for diabetes may be found through stem cell research. Does this present an ethical concern?

Routine screenings and genetic testing are examples of genetic and technologic advances that present ethical concerns for the pediatric population. Screening is the search for asymptomatic illness and can be done for the purpose of diagnosis, treatment, counseling, or research. Routine fetal monitoring is an example of screening for the purpose of intervention if fetal problems are identified. Likewise, genetic testing can be done to diagnose inherited conditions or to screen prospective parents to determine whether they are carriers. The exponential growth in genetic knowledge has benefited many individuals while at the same time producing challenges. Newborn blood screening panels present an opportunity for early identification and treatment of conditions known to benefit from treatment. However, genetic screening for other conditions poses ethical questions about costs, benefits, and risks. The sensitivity, specificity, and predictive value of a screening program are important considerations. For example, knowledge of a late-onset disorder may have limited benefit, could increase emotional stress, and may potentially result in denial of insurance coverage, because it is a pre-existing condition.

Ethical issues have arisen when determining whether certain screening should be voluntary ("opt in"), routine with the ability to "opt out" or refuse, or mandatory. Nurses often educate parents about screening tests and explain why these tests are in the best interests of their children. Nurses may also find themselves in situations in which parents need their help and understanding when struggling to decide when, and sometimes whether, to tell a child that he or she may have a late-onset genetic disease or be a carrier of a medical condition.

Innovative therapy is not considered to be research; however, by its very nature it can present ethical concerns. Such therapy is defined as new and unproved interventions that are performed with no intent to gather new information, as would be done during a research investigation. Innovations in healthcare practices include a wide range of new diagnostic or therapeutic methods that are aimed at improving health outcomes beyond those of existing methods, but that have not yet been fully assessed for safety and/or efficacy. Innovative therapies vary widely from minor variations of existing methods, or extensions of existing methods, to new indications, to completely novel technologies (National Health and Medical Research Council, 1999). Unlike research studies, innovative interventions lack specific designs and strict sampling and procedural protocols, and therefore are not subject to research regulations. However, because less oversight is required, the potential to cause harm is greater, and some believe that clinicians are morally obliged to submit their innovative therapies for formal or peer review.

The use of “off-label” medications in pediatrics is also a practice that has generated much ethical debate. Because children are not participants in the research trials for most marketed medications, many drugs currently are not labeled for use in children. This means that no pediatric-specific dosing, administration, or adverse effect information is available on the label packaging, or in any product information available from the manufacturer.

Alert! Nurses administering off-label medications to children must be alert for potential adverse reactions.

An ill child could possibly benefit from off-label use of a medication, however, and many consider it inappropriate to deny the child an opportunity to receive the drug if it might prove therapeutic when medications approved for pediatric use have proved ineffective. Off-label use of medications thus is a common practice. The Food and Drug Administration (FDA) Modernization Act of 1997 has called for increased pediatric drug research and labeling; subsequently, pediatric-specific dosing information is increasingly available on commonly used medications in the pediatric population.

ANSWER: The use of stem cells to cure disease is controversial. The application of stem-cell research to children to cure diabetes would open the door for many discussions and many concerns, including research studies and innovative practice.

LEGAL ISSUES IN THE CARE OF CHILDREN

The health and welfare of children are highly influenced by the legal rights of children and their parents. Nurses must be aware of these legal issues, and must follow legislative guidelines and statutes in the implementation and delivery of child healthcare programs.

Rights of Children

QUESTION: Which laws protect Lindsay’s rights while she is attending public school?

In this century, it is recognized that children have rights, and these rights should be maintained and valued in all societies around the world. It is expected that the family will be the primary resource for ensuring that these rights are met. The reality of this goal may not exist in all countries; therefore, agencies such as the United Nations and the World Health Organization actively engage in operations to protect children and to ensure their rights. Chart 2–1 presents the rights of children as identified in a hallmark

CHART 2–1 THE RIGHTS AND NEEDS OF CHILDREN

Rights	The right to . . .
Social	Life and optimal survival and development; best possible health and access to healthcare, education, play, family life that is in the best interests of the child; social inclusion of the special needs child to the fullest extent possible
Economic	An adequate standard of living for proper development; protection from economic exploitation
Cultural	Respect for language, culture, religion; abolishment of traditional practices that negatively interfere with children’s health
Protective	Promotion of the child’s best interests; protection from sexual exploitation, violence, child abuse and neglect, armed conflict, harmful drugs; not to be separated from the parents unless it is in the child’s best interests
Civil and political	Be heard and taken seriously; privacy; freedom from violence, torture, or cruel and inhuman treatment; nondiscrimination
Physical needs	Shelter, healthcare, water, food, adequate clothing, sanitation, protection from environmental pollutants

Based on American Academy of Pediatrics (AAP). (2006). *AAP’s Highlights of the UN Convention On the Rights of the Child: Module 2 A Course for Health Professionals. Children’s Rights and Child Health*, pp. 2–9. Retrieved May 22, 2006, from <http://www.aap.org/commpeds/resources/ChildrensRightsCurriculumModule2final.doc>.

CHART 2-2 SAMPLE CHARTER OF CHILDREN'S RIGHTS

Charter of Children's Rights

As a child who is seeking or receiving healthcare in this healthcare facility, I have the right to

- Receive the best possible care and treatment
- Be involved in decisions related to me, based on my developmental capabilities
- Be listened to respectfully and have my thoughts, views, and feelings taken seriously
- Be given information in a way that I will understand my treatment
- Ask for advice and be treated in an emotionally supportive manner
- Not be touched unless I have been asked for my permission
- Be treated in a respectful manner
- Expect confidentiality in my healthcare and respect for my privacy
- Receive equal treatment and care that has no bearing on my gender, religion, race, ethnicity, abilities or disability, or parents' level of income
- Be nurtured and protected in promoting my health and well-being
- Be protected from all forms of violence and abuse

document created by the United Nations. These rights form the core beliefs and values that are inherent to ensure a bright future for all children.

The rights of children related to healthcare that are inherent in the delivery of optimal nursing caring to children can also be articulated (see Chart 2-2). Children have the right to be free from abuse and exploitation. It is also the right of the child that, within the context of the family, the child should receive food, shelter, protection, and healthcare management.

Federal laws about education and school health services also protect children and youth with disabilities. These laws are discussed in detail later in this chapter. Two important federal mandates address rights of the individual: the Family Educational Rights and Privacy Act (FERPA) and the Health Insurance Portability and Accountability Act (HIPAA). FERPA allows parents the right to access their child's education records and prohibits the release of student-specific information, such as student health records, to others. HIPAA addresses confidentiality of health records and information.

Nurses must be advocates, championing the rights of children in all aspects of a child's life. The nurse must be the voice for those who cannot speak for themselves and must be strong for those who cannot yet defend themselves. The invisibility of children in arenas of power and politics, and the traditions and attitudes that are not child friendly must not be tolerated. In fact, one of the most serious ethical problems facing this nation's healthcare system is inequality of access to care and the lack of basic healthcare coverage that many children still experience.

ANSWER: The right to manage medical chronic conditions at school is based on Section 504 of the Rehabilitation Act of 1973, the Americans with Disabilities Act, and the IDEA.

Rights of Emancipated Minors

Emancipation is the process by which an individual becomes liberated from the authority and control of another person. In pediatric care, this term refers to the emancipation of a child from the authority and control of parents or other guardians. The emancipation process for a child who is a *minor* (younger than 18 years, the age of majority) is governed by individual state laws. Most states have a specific code that lists both the specific situations and the legal proceedings necessary to secure a declaration of emancipation. Conditions that state law may require before approving a declaration of emancipation may include that the minor be at least 14 years of age, willingly lives separate and apart from parents or guardians with their consent or acquiescence, demonstrates an ability to manage financial affairs, and has a source of income other than criminal activity. A valid marriage or service in the armed forces usually qualifies as acceptable conditions for a declaration of emancipation. If all conditions for emancipation as stated in state code are satisfied, the minor then obtains full rights as an adult. When a court proceeding is needed because of a special condition or circumstances not identified in state code, the decision to grant emancipation generally takes into account both the maturity of the minor and his or her need to secure adult status. A minor who is recognized as emancipated by state-mandated criteria can consent to medical, dental, or psychiatric care without parental knowledge, consent, or liability.

Rights of Parents

The rights of parents or guardians in decision making are based on acting in the best interest of the child in matters of life issues and health, and on the emerging independence of that child as he or she grows and develops. Thus, an older child's or adolescent's need for autonomy and developing capacity for self-determination are factors that must be considered, along with the rights of parents to make decisions for their child or to impose a certain lifestyle. In addition to legal obligations as the child's guardian until the age of majority or legal emancipation, parental roles and authority have additional dimensions determined by social, cultural, and religious views. Parents' rights relevant to child health issues include the right to give consent (or permission) to treatment; to provide direction and guidance to their child; to be assured of the privacy and confidentiality of health information; and to raise their child according to their own religion, culture, and philosophic convictions. As healthcare providers, nurses must respect these parental rights unless such rights are legally terminated or evidence exists of a need to seek immediate legal suspension of parental rights.

Parents are granted wide discretion in determining how their child is to be raised. However, sometimes parents do not make decisions that are in the best interest of their child, deliberately injure their child, or act in ways that put the child in harm's way. All states have laws that define child maltreatment—physical, sexual, or emotional abuse, or neglect. Healthcare providers are responsible for reporting suspected child maltreatment even in those circumstances when parents assert that they were acting in the best interests of their child.

If parents of a child are married to each other or have jointly adopted a child, they both have parental responsibility for the health, education, and welfare of the child, and the right to make medical and educational decisions. In the case of parents who have never married, the mother has parental responsibility for the child. Unmarried fathers can get legal responsibility for their children in a number of legally sanctioned ways. Nurses are often involved in caring for children whose parents or grandparents are entwined in custody issues. Various types of custody arrangements exist, such as legal custody and decision-making authority, physical custody, sole custody and decision-making authority, and joint custody and decision-making authority. Promptly and clearly identifying legal rights regarding visitation and ability to make medical decisions is important to avoid turmoil in care and unnecessary emotional trauma for the hospitalized child.

Guardians are adults who are legally responsible for protecting the well-being and interests of their ward, who is usually a minor. In most cases, parents are “guardians” for their child. The guardian is charged with the legal responsibility for the care and management of the child and for the minor child's estate. *Legal guardians*, on the other hand, may be appointed by the courts or designated in legal documents by the parents upon their death. Legal guardians are under the supervision of the court and are required to appear in court to give periodic updates about the child and the status of the child's estate. A *guardian ad litem* is a unique type of guardian in a relationship that has been created by a court order only for the duration of a legal action. Courts appoint these special representatives for infants, minors, and mentally incompetent persons, all of whom generally need help protecting their rights in court. Court-appointed guardians are most often assigned in divorce cases, child neglect and abuse cases, paternity suits, contested inheritances, and so forth, and are usually attorneys.

The protection of legal rights comes under the auspices of the courts. The right to health and education is generally viewed as entitlements for children. However, how this entitlement to health and education is defined and implemented is open to debate. Parents are responsible for ensuring that their child is able to grow and develop in as healthy and productive a manner as possible. Only when parental choices put a child at substantial risk for harm does the moral focus turn to what is best for the child, rather than the parental right to choose a particular course of action for their child. In such cases, a court order may be necessary for medical and surgical treatments. For example, the parents of a preterm infant who needs a blood transfusion may refuse because of religious

convictions (e.g., Jehovah's Witnesses), or parents may refuse chemotherapy for a child newly diagnosed with leukemia because they do not believe in pharmacologic intervention (e.g., Christian Scientists).

RESEARCH ISSUES IN THE CARE OF CHILDREN

The focus of research is to generate new knowledge. Because research is not part of standard healthcare, and participation is voluntary, certain safeguards must be in place in healthcare settings for the protection of human research subjects. Ensuring safety is particularly pertinent for children (who are considered vulnerable subjects) and their families. The potential for physical or nonphysical injury is an inherent risk for any research participant, only much more so for children. Physical injury can be related to the use of investigational devices, experimental procedures, or medications. Nonphysical injury can take many forms, such as loss of confidentiality, psychological distress, emotional vulnerability, or social embarrassment.

Nurses caring for children and their families must know the rules, regulations, and guidelines that define research risk. Any research project conducted or supported by federal agencies must comply with Title 45, Code of Federal Regulations Part 46, Protection of Human Subjects, known as *the Common Rule* (U.S. Department of Health and Human Services, 2005). The Common Rule specifies that federally funded research projects must be carefully reviewed by an **institutional review board (IRB)** to ensure the safety and welfare of individuals participating in U.S. Department of Health and Human Services-sponsored research. In a healthcare facility, the IRB is a committee of healthcare providers, scientists, and community members that ensures that all research projects are conducted ethically. The IRB is charged with evaluating the scientific merit of the study, determining and weighing the risks and benefits of participation, and protecting subjects' rights. The U.S. Department of Health and Human Services Office for Human Research Protections (OHRP) has guidelines titled *Special Protection for Children as Research Participants* (U.S. Department of Health and Human Services, Office for Human Research Protections, 2006). The OHRP is a particularly useful source of information for nurses working with children (see [thePoint](#) for Organizations).

Ethical Conduct of Research

Several principles govern the ethical conduct of research. These include respect for persons, beneficence, justice, maintaining confidentiality, and securing informed consent.

Respect for Persons

Respect for persons requires that the subject is able to volunteer independently and autonomously to participate in a study. Because infants and children do not have this

ability, parents must consent on behalf of their children. In addition, cognitively intact children older than the age of 7 years should always be asked to give their assent. If the child **dissents** (i.e., does not agree to be a research subject), his or her wishes must be respected. Factors inherent in respect for persons are the way children and parents are contacted and recruited for participation, and the issues surrounding the consent process.

Beneficence

Beneficence implies doing “good” and avoiding harm. Thus, it requires weighing the benefits and risks associated with participation in a study. Some research studies have no direct benefit to the subject but will benefit society, whereas others result in advantageous or positive outcomes for subjects. Typically, minimal risk is considered to be the probability or likelihood of harm or discomfort (physical or nonphysical) no greater than what occurs during ordinary daily life or during routine physical or psychological examinations or tests (Thomas, 2005). Research involving children can be categorized into four risk categories: minimal risk (also called *nontherapeutic research*), greater than minimal risk but likely to confer direct benefit, greater than minimal risk with no direct benefit; and any other type of research study not falling into the previous three categories. Research on children involving any risk that exceeds minimal risk expectations must be heavily scrutinized. Other review processes are conducted (in addition to securing parental permission, child assent, or both) when a research study is judged to represent more than a minor increase over minimal risk but offers hope that knowledge gained from the study will improve the health and welfare of children (Kim, 2004). In such circumstances, if the study is federally funded, the researcher must apply to the Department of Health and Human Services for special permission.

Justice

Justice focuses on the distribution of burden and benefits among the population of interest. Who is to assume the burdens and risks of participation, and who benefits from the knowledge gained? Pediatric subjects must be selected fairly and without exploiting a group that will not benefit from the study’s outcomes. For example, infants in an underdeveloped country cannot be selected by a pharmaceutical company for use in testing high-risk vaccines or medications.

The use of incentives as recruitment tools for children, parents, or both to participate in research is also an important ethical issue. Pediatric subjects should not be offered incentives that are clearly not equivalent to the care or services provided to nonparticipants. The types of incentives offered by the investigator to parents and children can influence their decision about whether to participate. Incentives can range from intangible rewards, such as altruistic feelings of helping society, to reimbursement for “services” such as time and effort, to financial reimbursement for expenses. Using incentives to motivate or encourage subjects to join a study is not inherently unethical. However, when children and families are

financially or emotionally vulnerable, recruitment incentives can place them at greater than usual risk if they believe the goods or services offered through participation in the research study are things they need (Rice & Broome, 2004). Examples of vulnerability include a family living in poverty that will receive significant payment for “services” if the child enters a drug study, and offering gift certificates for large amounts of money or expensive computer equipment to disadvantaged children. Therefore, incentives such as financial reimbursement for expenses or wage payment for time, effort, or burden must be scrutinized carefully for their ethical implications. The duration of the study, its burden on participants, out-of-pocket expenses for transportation, and institutional rules are some of the aspects considered when determining the type and amount of incentives.

caREminder

The overriding principle that should guide the use of incentives is that neither parents nor the child should profit financially from enrolling in a research study.

Confidentiality

When conducting research, it must be asked to what extent will confidential information about subjects and research data be protected to safeguard the subject’s identity? Parents and children must be fully informed regarding what will be done to protect their identities and to avoid sensitive issues such as embarrassment, stigmatization, or prejudicial treatment. A discussion of confidentiality is typically part of the informed consent process and often outlines certain security strategies that the investigator will use, such as using subject code numbers or separating identifying data from research data. Exceptions to confidentiality must be identified in advance of a parent’s or child’s agreement to become a research subject (e.g., when mandated reportable conditions, such as child maltreatment or sexually transmitted diseases, are uncovered during the research study).

Informed Consent

Informed consent is a central concept in ensuring patient safety and maintaining ethical practices during the research process. Numerous elements must be addressed as part of the informed consent process. Chart 2–3 lists critical information that must be addressed as part of informed consent. Much of this information appears on the consent form and serves as legal documentation that the parent and child were appropriately informed. In most circumstances, the consent form must be signed, and a copy must be given to the parent or child.

Be aware of factors that may place undue pressure on parents or children in their decision to participate in research. Examples that bear special attention include situations in which the individual providing care is one who recruits and acquires consent from the subject and those in which financial inducements may be considered excessive

CHART 2-3 INFORMED CONSENT: CRITICAL INFORMATION NEEDED TO PROTECT INFANTS AND CHILDREN AS RESEARCH SUBJECTS

Basic Issues

The Parent, Child, or Both Should Know

- That what they are agreeing to participate in is research and not part of standard care
- Why the study is needed
- Who the investigator is and how to contact him or her
- What the time commitment will be
- If there are any costs that will be incurred by them to participate
- If applicable, how a study intervention differs from routine care
- Whether they will have access to study findings
- That they can ask questions about the research at any time before, during, or after the research process
- Whether they will receive compensation and, if so, what will it be
- Who to contact in the agency if they have questions or concerns about human subject research participation

Issues Related to Beneficence

The Parent, Child, or Both Should Know

- Risks—physical and/or nonphysical—that are associated with participation in the research and actions that can be taken to reduce risks
- Potential adverse effects and what will be done (e.g., treatment, who will cover costs) if they occur
- Expected benefits—direct and indirect—associated with participation

Issues Related to Confidentiality

The Parent, Child, or Both Should Be

- Fully informed regarding the extent of confidentiality
- Made aware of strategies used to safeguard their identities
- Told who has access to their names, identifying information, or data
- Told of any circumstances that would necessitate revealing their identities or study information to others (e.g., mandatory reporting)

Refusal Rights

The Parent, Child, or Both Should Be

- Told they can refuse to participate and that such refusal will not alter their standard care
- Aware that they can withdraw from the study at any time without prejudice
- Aware that they can refuse to answer any question

This listing is not meant to be all inclusive. Other items may need to be noted in an informed consent, depending on the type of research study.

in light of the family's circumstances. Families may also think (albeit incorrectly) that participation in the research will improve the care their child receives. Similarly, parents of terminally or critically ill children may agree to have their child participate in experimental research interventions out of feelings of distress or despair when all other conventional treatment options have failed. Such situations require special attention by healthcare professionals. One safeguard that may be required is to require a waiting period (even as brief as 24 hours) before a final decision to participate can be made, rather than allow parents to make quick decisions based solely on feelings of despair.

Nurses can take on a variety of key leadership roles in research, including principal investigator and data collector. However, all nurses are responsible for protecting human rights and monitoring safety when their patients are involved in research studies or clinical research trials. This responsibility starts from the time patients are recruited into a study and sign the appropriate permission forms, and lasts until the termination of the investigation. Because children are considered vulnerable subjects, the pediatric nurse needs to monitor vigilantly for any deviations in protocol, to document and report possible adverse events, and to report any other safety concerns to the appropriate groups, including the healthcare agency's IRB. If deemed necessary, a nurse can also report concerns to the OHRP, U.S. Department of Health and Human Services. Such reports are confidential, and the nurse is covered by whistle-blower protection (Thomas, 2005).

HEALTHCARE DELIVERY RESOURCES FOR CHILDREN AND THEIR FAMILIES

Nurses, as members of the interdisciplinary healthcare team, have a long history of working with communities to obtain and use public health resources for children and their families. This section describes the public and private programs that provide financial aid, health services, and educational resources for children in the United States.

Public Programs for Community Care Services

Many publicly funded health programs serve children and families (see [thePoint](#) for Organizations). Some programs serve selected clients, such as those who meet certain income or diagnostic eligibility criteria; others are available to all who apply (Clinical Judgment 2-1).

Programs and agencies that serve children and families, including those with special needs, are constantly in flux. Legislation changes the eligibility, services, and funding for these programs, often from year to year. The programs described in this chapter are, for the most part, susceptible to legislative change and may look different in the future. To be effective in planning, providing, and directing care for children and families, nurses must be

CLINICAL JUDGMENT 2–1

The Child With Multiple Special Needs

Mrs. Thompson has recently moved to the area and is beginning prenatal care in a family practice clinic for low-income families. With her for today's visit is her 2-year-old daughter who is not yet walking, appears small for her age, and has visible dental caries. At the end of Mrs. Thompson's prenatal visit, you ask to speak with her regarding her daughter.

Questions

1. What information do you want to elicit from Mrs. Thompson about her daughter?
2. When Mrs. Thompson answers your questions, which information may be particularly relevant?
3. What are the current possible problems for this child?
4. What interventions or referrals are appropriate for the child and family?
5. What factors would indicate that this child is receiving appropriate services to meet her needs?

Answers

1. What are Mrs. Thompson's perceptions about her daughter? Does she have any concerns about her health or development? Does she have a regular healthcare provider for her child? Has she received services from any agency or program in the past? What is her daughter's general health and developmental history?
2. A history of health problems or developmental delays, her mother's affirmation or denial that potential health or developmental problems exist, her history of past service use
3. Dental caries, possible developmental delay, possible poor nutritional status, possible lack of appropriate immunizations and other preventive healthcare
4. Depending on need and current service use, referrals to a pediatric primary healthcare provider, the local early intervention program, WIC, a pediatric dentist, and the local social services agency to apply for food stamps, Medicaid, and Temporary Assistance for Needy Families (TANF), as needed. If special needs are identified, additional referrals may be necessary.
5. The child has an ongoing source of preventive and primary healthcare; she is enrolled in an early intervention program for assessment, monitoring, and intervention as needed; she receives WIC food coupons to meet her nutritional needs; she receives regular dental care, her mother has received information about preventing dental caries, and the child has had a health supervision visit and is current on her immunizations. She and her family are receiving TANF, Medicaid, and food stamps if determined to be eligible. Additionally, her mother receives WIC coupons as well to promote good nutrition during pregnancy.

aware of these changes and their effects. Self-education can be achieved in a number of ways, including membership in professional organizations; attendance at conferences; regular review of newsletters, journals, and newspapers; participation in advisory boards; and contact with legislators.

When working within a particular community, establish relationships with professionals from other agencies who may also serve the same clients. The school nurse, for instance, develops relationships with professionals from the local health department clinics, the office of Women, Infants, and Children (WIC), the Head Start program, regional centers, and others to understand the programs fully and to facilitate access to services. In this way, the school nurse serves children more effectively through enhanced collaboration and coordination.

Obtain in-depth information about commonly used programs and services. If you routinely refer families to the WIC program, for instance, these children will be better served if you have a working knowledge of services provided, eligibility requirements, application procedures, waiting periods, any costs involved, and the

address and telephone number of the local office. Simply giving a family an agency name and telephone number is not enough to promote access to services. Public agencies often welcome healthcare visitors from other programs and the community, thereby providing firsthand knowledge about services. Through appropriate referrals to community health programs, you can help ensure the health of the child as well as the entire family (Tip 2–1).

Nurses are integral to the success of community healthcare programs. Many nurses perform outreach services to identify eligible families and encourage participation. Nurses may also serve as program administrators, overseeing operations, ensuring the quality of care offered by various providers, and training providers and their staff in program specifics. Some nurses serve children directly by providing primary care as nurse practitioners or work in supportive and facilitative roles by providing immunizations, teaching patients and families, and coordinating services through case management. Through their numerous contacts with families, nurses are in a position to work toward increasing the number of children receiving these valuable services.

TIP 2 –1 A Teaching Intervention Plan for the Family Accessing Needed Services

Nursing Diagnosis and Family Outcomes

Readiness for enhanced family coping: potential for growth related to self-actualization of needs

Outcomes:

Family will successfully receive services to meet child and family needs.

Family members will verbalize feelings of personal growth.

Guidance for Families

- Assist the family in identifying strengths and needs.
- Identify resources in the community that may be available to meet child and family needs. If none appear to be available, call closely related programs and agencies to ask for referrals or information about needed services.
- Contact prospective agencies to determine services available, eligibility criteria, application procedures (including what the family should bring to apply), location, transportation routes, and any other information specific to the program.
- Present the information to the family. Identify benefits to be gained as a result of program participation.
- Ask the family to help identify impediments to follow-up or use of services so that these obstacles can be minimized whenever possible (e.g., “Is there anything you can think of that will keep you from applying for WIC services?”).
- Some agencies and programs allow person-to-person referrals. If this is the case, and families request or require this kind of assistance, seek parents’ consent and then contact a key individual at the referral agency.
- Advise families to maintain a file of all correspondence, appointment notices, and so on, and to request the name of the individual whenever contact with the agency is made.

Medicaid

Medicaid is a form of health insurance for low-income and disabled individuals. Established in 1965 as Title XIX of the Social Security Act, Medicaid is a federal **entitlement program** (i.e., an open-ended program that serves all eligible individuals entitled to the service, with no budgetary cap). It is financed by federal and state funds, and is administered by the states. The federal government pays from 50% to 80% of each state’s medical assistance payments. Medicaid is not a direct provider of service; rather, it provides compensation for healthcare services. Federal guidelines define the scope of basic services, the extent of coverage, and certain administrative requirements. The states administer the program and determine income eligibility criteria, specific services to be covered, and payment levels and methods. States may offer optional services beyond those required by federal statute.

Of particular relevance to community-based nurses is the ability to use Medicaid as a source of payment for home or extended care or school-based health services. Because long-term hospitalization can negatively affect a child’s growth and development, and the entire family’s well-being, the option of home care for a seriously ill or disabled child is very important. Through home- and community-based waivers, authorized under the Omnibus Reconciliation Act of 1981 (OBRA 81) and the Tax Equity and Fiscal Responsibility Act of 1982 (TEFRA), state governments can coordinate medical and support services to children living at home, thus avoiding costly institutional

care. Eligibility criteria for these programs are broader than Medicaid standards. Thus, more children and families may be served. In addition, individual states may offer expanded medical services and respite care.

Chart 2–4 describes individuals eligible for Medicaid. Because Medicaid is a state-based program, families must be residents of the state in which they apply for services.

WORLDVIEW: To be eligible to receive Medicaid, an individual must be a citizen or lawfully admitted to the United States. Income-eligible children can qualify if they were born in this country, even if their parents are not citizens or reside in this country without appropriate legal documentation. There are provisions for undocumented children to receive Medicaid for medical emergencies, and prenatal care and delivery.

Families may apply for Medicaid at their local welfare offices or at “out-stationed” sites in federally qualified health centers and disproportionate-share hospitals (i.e., hospitals that receive extra federal funding to care for large numbers of clients receiving Medicaid). Some states allow a mail-in application for specific Medicaid subpopulations such as pregnant women and children. Waits in welfare offices can be long, and the application process itself can be difficult. These facts may discourage some families from seeking much-needed assistance. In addition, fear of being reported to immigration authorities, or

CHART 2-4 INDIVIDUALS ELIGIBLE FOR MEDICAID

Recipients of TANF

All pregnant women, infants, and children younger than 6 years of age with family income up to 133% of the federal poverty level, whose resources do not exceed state-set limits

All children born after September 30, 1993, with family incomes up to 100% of the federal poverty level

All infants born to Medicaid-enrolled women, for up to 1 year (no separate application required)

Supplemental Security Income (SSI) recipients

Some “medically indigent” families in which the members’ income falls below a certain level

Certain additional low-income pregnant women and children as determined by individual states

Children in federally assisted foster care and adoption placements

the stigma associated with the receipt of welfare, may discourage families as well (Stuber and Kronebusch, 2004).

The current trend in Medicaid is to encourage recipients to enroll in managed care programs to help contain program costs. In a managed care system, a defined package of services is offered for a preset monthly fee (a premium) paid by Medicaid. The Balanced Budget Act of 1997 altered the structure of the Medicaid program considerably, expanding states’ discretion in administering the program and allowing states to require that most Medicaid beneficiaries enroll in managed care programs, most often health maintenance organizations (HMOs).

Each Medicaid recipient enrolled in a managed care program chooses a primary care provider, who coordinates and oversees the delivery of healthcare services to that client. This approach should result in increased access to preventive and primary care, and decreased fragmentation of care, especially for low-income individuals who previously had poor access to providers. It is also expected to decrease the use of inappropriate sources of healthcare, such as emergency departments used for primary care. However, because the managed care plan receives one preset monthly amount to provide all care, the provider may be reluctant to make referrals to expensive specialists or to use high-cost diagnostic tests. The health plan or provider group also may impose financial disincentives to refer.

Although Medicaid provides tremendous benefits to eligible recipients, it has several shortcomings. Because of eligibility requirements, the program serves only a portion of those who need it, and eligible individuals whose income increases only modestly may see their benefits cut. These potential cuts are a particular problem for children with special healthcare needs, for whom ongoing care is vital. Additionally, the near poor or working poor who are uninsured may not qualify, but still have no healthcare insurance. Some providers are unwilling to accept Medicaid

because of low reimbursement rates, especially in certain areas—a circumstance that may result in lack of care and inappropriate use of emergency departments. Dentists and mental health providers have particularly low participation rates in serving children eligible for Medicaid services (Kaiser Commission on Medicaid Facts, 2005).

Early and Periodic Screening, Diagnostic and Treatment Program

A very important component of Medicaid for children is the Early and Periodic Screening, Diagnostic and Treatment (EPSDT) program. This separately mandated program serves Medicaid-eligible individuals younger than age 21. As with the basic Medicaid program, providers are reimbursed for services; the EPSDT program is not a direct-service program.

The EPSDT program was enacted through a 1967 amendment to the Social Security Act as a mandatory service under Medicaid. It was established as a federally financed, state-administered program with the goal of ensuring that children enrolled in Medicaid receive a basic set of comprehensive services to promote health and to identify and treat health problems at early stages.

The mission of the EPSDT program is to prevent unnecessary childhood illness, disability, and death by offering prevention services, and to identify problems before they become serious. Under the EPSDT program, children receive a variety of comprehensive health services as described in Chart 2-5. States must help children receive these services by informing eligible families about the program, helping families make appointments, arranging transportation, providing services in a timely

CHART 2-5 EPSDT REQUIRED SERVICES

Comprehensive health and developmental history (including physical and mental health and nutritional status)

Comprehensive unclothed physical examination with appropriate follow-up care

Vision and hearing service with appropriate follow-up care

Immunizations

Appropriate laboratory tests including blood lead level and radiographic services

Comprehensive preventive, restorative, and emergency dental care

Health education

Anticipatory guidance

Any medically necessary treatment for identified conditions

Pregnancy care including pregnancy testing; medical care, nutritional assessments, psychosocial assessments; counseling on hazards of tobacco, drug, and alcohol use; vitamins; childbirth education and parent training; and family planning services

fashion, and ensuring an adequate supply of providers. EPSDT services may be provided by physicians, nurse practitioners, and physician assistants in clinics, schools, hospitals, health departments, and Head Start programs.

caREminder

Adolescents, too often overlooked, are eligible to receive EPSDT benefits and should be encouraged to do so. Developmentally appropriate examinations and anticipatory guidance to prevent sexually transmitted diseases, pregnancy, and drug and alcohol use are components of the program. The examinations may be used as camp or sports physicals to allow teenagers the opportunity to participate in these activities.

State Children's Health Insurance Program

The Balanced Budget Act of 1997 authorized the State Children's Health Insurance Program (S-CHIP), as Title XXI of the Social Security Act. The purpose of this program is to expand health insurance to children whose families make too much money to qualify for Medicaid, but who cannot afford to purchase health insurance. As a result of the legislation, states had three options: to expand their Medicaid eligibility to include children of families with higher incomes, to establish a separate health insurance program for higher income families, or to use a combination of these two approaches to achieve the goal of insuring more children. Like Medicaid, S-CHIP is a state-federal partnership in which the federal government contributes a percentage of the funding, and each state provides the balance. It is designed to cover children who have family incomes of less than 200% of the federal poverty level, although individual states may expand beyond this target and may include parents as well.

Service delivery varies from state to state, but many states use a managed care model for the S-CHIP program to provide cost-effective and comprehensive services. The benefit package is often less comprehensive than that of Medicaid, but includes health, dental, and vision coverage, and must be equal to the federal employees' health insurance plan, the state employees' health insurance plan, or that of the largest commercial HMO in a state. States may require that families pay a part of the cost through modest premiums or copayments. Copayments for preventive services are not permitted, nor can Native American/Alaskan native children who are members of a recognized tribe be charged any copayments.

Nurses can help to reduce the number of uninsured children by being aware of the various public insurance programs and the services they provide, knowing how to refer families to programs, and assisting them in applying. Activities such as follow-up phone calls and educational programs may help to increase awareness and to improve enrollment in public insurance programs. Many of the nation's uninsured children are eligible for a publicly funded program; however, their parents may be unaware of the program or do not think they would qualify. Promoting and ensuring the health of children through adequate insurance is the responsibility of all nurses.

caREminder

Because each state varies in how it provides S-CHIP coverage and how it determines who is eligible for the program, nurses need to become familiar with the S-CHIP program in the state in which they work to provide families with accurate information.

To determine the federal poverty level for any given year, consult the Department of Health and Human Services website's Poverty Guidelines (see [thePoint](#) for Organizations). These figures are updated annually, and the website includes instructions for using the guidelines. Because programs calculate financial eligibility in different ways, counting certain income and disregarding other income, it is always best to refer a child and family to a program that might be helpful to them, and allow program administrators to determine eligibility.

Special Supplemental Food Program for Women, Infants and Children

WIC provides nutritious food, health education, and links to healthcare resources to pregnant and lactating women, infants younger than 1 year of age, and children up to age 5 years who are at risk for nutritional problems. Since its inception in 1974, the WIC program has expanded to serve more families and provide other activities such as outreach. The program is funded by the Food and Nutrition Service of the U.S. Department of Agriculture and is administered through grants to states, and then to local health and human services organizations. Some states offer additional financial support to the program. Eligibility for the program is based on financial need and a demonstrated risk for the development or presence of a nutrition-related health problem, such as iron deficiency anemia. The program is not an entitlement—that is, it is not required to serve everyone who is eligible—and it operates within a fixed budget determined each year by Congress. As a result, not all eligible families can be served. Pregnant and lactating women, and infants up to age 1 receive priority, followed by children up to age 5. Almost all pregnant women with a family income at or below 185% of the federal poverty level qualify for WIC.

WIC provides coupons that families use to purchase specific foods meant to provide certain key nutrients, such as protein; iron; calcium; and vitamins A, C, and D. Typically, such foods include infant formula, cheese, eggs, iron-fortified baby and regular cereals, fruit juice, beans, and peanut butter. The coupons can be used at most grocery stores, although some agencies distribute food directly (Fig. 2-4).

caREminder

Some mothers may feel self-conscious using coupons, feeling that others view them in a negative light. Frequent reminders and support by the nurse about the importance of good nutrition during pregnancy and infancy may help mothers refocus on the importance and necessity of this program.

FIGURE 2-4. WIC provides coupons so eligible recipients can purchase healthy food items for their families.

WIC includes an educational component. Each family meets with a nutritionist to assess and discuss specific needs. In addition, classes are held periodically on nutrition-related topics and such topics as breast-feeding, car seat use, and immunizations. WIC staff members recognize that breast milk is the preferred form of infant nutrition and, therefore, promote breast-feeding through educational programs, one-on-one and group support, and breast pump loaner programs.

WIC provides important links to healthcare providers, social services, and other public programs (such as Medicaid) to ensure that all children receive appropriate care. Some WIC offices are freestanding. Many are located in health department clinics so that families can access many services in one location. The program also includes outreach and, in certain areas, transportation to WIC offices.

Supplemental Security Income for the Aged, Blind, and Disabled

SSI is a program that provides monthly payments to income-eligible individuals who are older than age 65, blind, or disabled. Payments vary based on income, living arrangements, and other factors. The money can be used as income or to purchase services not otherwise available, including caregiving assistance. For parents of a disabled child, the money also can pay for incidental expenses related to healthcare, such as parking or child care, or can help compensate for the loss of income resulting from the need to care for the child.

The program was enacted as part of the Social Security Amendments of 1972. The federal government provides matching funds to the states, which determine income eligibility guidelines and payment levels. In most states, families receiving SSI also receive Medicaid and may receive food stamps, although in other states the food stamp allotment is included in the monthly SSI payment.

A child who is a citizen or a lawful permanent resident of the United States is eligible for SSI benefits, even if the parents are neither. The child also must meet certain income eligibility criteria based on the family's income

and resources. Finally, the child must be medically eligible.

Children may be determined to be disabled because of physical, mental, or developmental disorders. An appeals process exists for children found to be ineligible for SSI benefits. Parents may initiate this process if they feel a determination has been made erroneously. If they file an appeal, the child may be required to see a medical provider with whom the family is unfamiliar, chosen by the Social Security Administration (SSA) to offer an additional opinion about the child's eligibility. This examination is provided at no cost to the family.

Nurses play an important role in ensuring that all potentially eligible children are referred to the SSI program. Because supportive documentation is needed to establish eligibility, nurses may help families gather and submit appropriate records, and may provide support and assistance during the appeals process. Because the SSI program is an important link to Medicaid in most states, establishing eligibility for SSI can be very important in ensuring access to healthcare.

caREminder

Instruct families to save all correspondence from the SSA as well as copies of any documentation sent to the agency, in case additional or duplicate information is needed.

Maternal and Child Health Services Block Grant

The Maternal and Child Health Services Block Grant (Title V of the Social Security Act), originally enacted in 1935, provides federal funds to the states for preventive, primary, and specialty care for pregnant women, mothers, infants, children, and adolescents. In this federal-state partnership, the states contribute a minimum of \$3 for each \$4 of federal money received.

The states must use the block grant funds to develop a maternal and child health (MCH) system that ensures comprehensive, coordinated services to improve the health of all mothers and children. They must direct these services to low-income families and those with poor access to services. Chart 2-6 defines states' goals for the MCH block grant funds. They may carry out this mandate by providing services directly or by promoting access to services through program development, coordination, or oversight. Individual states may establish their own priorities and use the money to provide MCH services within the state according to local, regional, and statewide needs.

At the state level, MCH services are managed through the state health agency. Services are usually delivered by local health departments. Private physicians, hospital-based clinics, community health centers, and school-based clinics may also be involved in MCH service delivery through grants, contracts, or reimbursement to independent community agencies and providers. The organizational structure, staff responsibilities, and specific programs and services vary from state to state. To avoid duplication and to ensure effectiveness, states must coordinate and integrate services with other programs,

CHART 2-6 STATES' GOALS FOR THE USE OF MATERNAL CHILD HEALTH BLOCK GRANT FUNDS

To provide and ensure access to quality MCH services for mothers and children (especially those with low income or limited availability to services).

To reduce the incidences of infant mortality, preventable disease, and handicapping conditions in children; to reduce the need for inpatient and long-term care; to increase the number of children appropriately immunized; to increase the number of low-income children receiving health assessments and follow-up diagnostic and treatment services; to provide prenatal, delivery, and postpartum care to at-risk women; and to promote the health of children by providing preventive and primary care to low-income children.

To provide rehabilitation services for blind and disabled individuals younger than age 16 years receiving benefits under Title XVI (Supplemental Security Income [SSI]) when those services are not provided by Medicaid.

To provide and promote family-centered, community-based care (including care coordination services) to children with special healthcare needs and their families, and to facilitate the development of community-based systems of services for such children and their families.

including health (such as the EPSDT program), social services, child nutrition (such as WIC), and education at the state and local levels.

Currently, Title V includes three components: the MCH program, the Children with Special Health Care Needs (CSHCN) program (formerly the Crippled Children Services program), and two discretionary grant programs—Special Projects of Regional and National Significance (SPRANS) and Community Integrated Service Systems (CISS). SPRANS projects include grants for MCH research and training, genetic disease services, hemophilia services, and other projects to improve MCH. SPRANS programs provide grants, through a competitive process, to health departments, universities, and other community agencies for research, training, genetic disease education, testing, counseling, referral and follow-up, regionalized hemophilia care, and innovative demonstration projects. CISS grants support home visiting programs, projects to increase the numbers of obstetricians and pediatricians who serve poor children, integrated MCH delivery systems, pregnancy services, and services for children with special healthcare needs.

People are often confused about Title V and Medicaid. Title V provides money to states, which determine how it will be used to improve the health of *all* women and children, especially those at high risk or living in poverty. It requires the states to develop systems that ensure access to high-quality care. Unlike Medicaid, Title V is not an entitlement program; rather, it provides a set level of

funding to each state as determined by Congress. Medicaid is a form of health insurance for low-income, disabled, and elderly persons that focuses on primary acute and long-term care and only *reimburses* for services. Title V programs, in contrast, may provide services directly (for instance, in a community prenatal clinic) or may be used to plan for a comprehensive service system in a community. In fact, a family may visit a prenatal clinic established with Title V funds, but may pay for the clinic's services with Medicaid.

Nurses play various important roles in MCH programs. For instance, in a maternity care program that uses Title V funds, nurses may serve as nurse midwives or nurse practitioners delivering primary care (Fig. 2-5). They may also be involved in delivering clinic, patient education, case management, or care coordination services. Within a CSHCN program, nurses may be responsible for a range of services, from case finding to determining family eligibility, developing plans of care, making referrals, coordinating services, and providing patient care. In a number of states, the director of the CSHCN program is a nurse.

Temporary Assistance for Needy Families

TANF is an assistance program developed in 1997 as a successor to the Aid to Families with Dependent Children (AFDC) program to provide cash assistance to indigent American families with dependent children. The program aims to provide assistance to needy families so that the children can be cared for in their own homes or in the homes of relatives. The program has commonly been known in the past as “welfare.” In the current TANF program, there is a maximum of 60 months of benefits within one's lifetime and there is a component that requires recipients to attempt to find employment. Failure to participate in work requirements can result in a reduction or termination of benefits to the family. Unmarried minor parents have to live with a responsible adult or guardian. Paternity of children must be established to receive benefits.

FIGURE 2-5. Using Title V funds, nurse practitioners can provide child healthcare to eligible families.

Community and Migrant Health Centers

Authorized by Title II of the Public Health Service Act, Community and Migrant Health Centers (C/MHCs) are federally funded, comprehensive primary care clinics, usually located in medically underserved areas. The program was established in 1965 and is administered by the Bureau of Primary Care, U.S. Public Health Service. C/MHCs provide basic preventive and primary care; ancillary services such as laboratory tests, radiographs, and pharmacy; and related services such as health education, transportation, translation, and referrals of families to other programs such as WIC and Medicaid. Each facility is governed by a board, most members of which are users of the clinic services. A major component of these clinics is MCH services, which are designed to decrease infant mortality rates and to improve the health of mothers and children, especially those from low-income families. Nurses function in a variety of roles in these clinics. They may provide direct services such as primary care, core public health functions, traditional clinic support, patient and family teaching, and case management, and they may be involved in clinic administration. Nurse midwives and nurse practitioners play a substantial role in delivering primary care, improving access, and helping to control costs. Because a center may offer a wide range of services, from prenatal to pediatric to adult care, the nurse can draw on expertise from a variety of areas. Also, because the center may provide preventive and primary care to all members of a particular family, the nurse may get to know the entire family and be able to affect the family's overall health and well-being positively.

To refer children and coordinate care properly, nurses who work outside C/MHCs should know the system, the location of local clinics, the services they offer, and procedures for accessing services.

Americans With Disabilities Act

The Americans With Disabilities Act of 1990 consists of civil rights laws that prohibit discrimination based on disability. The Act defines disability as a physical or mental impairment that substantially limits a major life activity. The determination of whether any particular condition is considered a disability is made on a case-by-case basis. Certain specific conditions are excluded as disabilities, such as current substance abuse and transsexuality. These laws affect the care of children and adolescents in several ways. For instance, the law requires that no individual may be discriminated against on the basis of disability with regard to the full and equal enjoyment of public goods, services, facilities, or accommodations. Children and others with disabilities must have access to buildings with stairs and be able to ride on amusement park rides similar to nondisabled children. In addition the law helps adolescents seeking employment, because it ensures that people with disabilities are not discriminated against as they apply for jobs and receive the benefits and privileges of employment. The law also states public transportation systems, such as public transit buses, must be accessible to individuals with disabilities. Nurses can work with

families to ensure the rights of their children under this law are being maintained, especially in the child's school and other places where the child participates in extracurricular activities.

Education Programs for Children with Special Healthcare Needs

Many nurses play a critical role in providing health services in schools and early intervention programs for children with special healthcare needs and their families. Nurses who do not work in these areas must understand the types of services offered and know which children may be eligible to receive them to be able to refer families and coordinate services. This section describes the key education and early intervention legislation focusing on children with special needs. It also discusses how the nurse may assist in providing services. Chapter 13 supplies additional information about the ways these programs can support the needs of chronically ill children.

QUESTION: In which of the following programs is Lindsay eligible and participating?

The Education for All Handicapped Children Act

Public Law 94-142, the Education for All Handicapped Children Act, was enacted in 1975 and became effective in 1977. This law represented an educational bill of rights for handicapped children. It required free, appropriate, and individualized education in the least-restrictive environment for individuals 6 to 21 years of age, and mandated procedural protections to ensure that these requirements were met. In 1986, the Education for All Handicapped Act, Amendment of 1986 (PL 99-457) was passed. This act mandated early intervention services for 3- to 5-year-olds (previously an optional service to be provided at states' discretion) through comprehensive, coordinated, and interdisciplinary statewide programs. In addition, it required each state to develop a plan to serve children from birth through 2 years who are at risk for developmental disabilities. The law provided financial assistance to states to develop and implement the plan, to facilitate coordination of payments for early intervention services, and to provide for quality services. Agencies under this federal mandate included those dealing with education, health, human services, developmental disabilities, mental health, public welfare, children, and youth through an interagency coordinating council. Table 2-1 describes which children must be served, professionals who may be involved, and which services may be provided.

The law also requires that care be provided in a family-centered manner, with active participation of family members in developing the plan, choosing providers, and designating a service coordinator (see Chapter 1 for a discussion of family-centered care). It requires the development of an Individualized Family Service Plan (IFSP) for each child served. This is an interdisciplinary plan

TABLE 2-1

Education of the Handicapped Act (Public Law 99-457^a) and the Individuals with Disabilities Education Act (Public Law 102-119^b)

Who Will Be Served	Who May Provide Services	Services That May Be Provided
Child with a delay in physical, cognitive, language and speech, psychosocial, and/or self-help skills	Nurses	Assessments
Child with a known physical or mental condition resulting in developmental delay (e.g., Down syndrome)	Physicians	Speech therapy
Child at risk for developmental delay (this may be a biological or environmental risk such as perinatal maternal substance abuse)	Special educators	Physical therapy
	Speech–language professionals (pathologists and audiologists)	Occupational therapy
	Occupational and physical therapists	Infant stimulation
	Psychologists	Counseling
	Social workers	Home visits
	Nutritionists	Case management
		Psychological services

		Special education
		Family training

^a1986.
^b1993.

developed to determine the specific health outcomes sought for a child, and the services and support that will be provided to the child and the family to help the child meet these outcomes. Specific components of an IFSP plan are described in Chart 2-7.

Nurses help identify appropriate infants, toddlers, and families, and assist them in accessing needed early-intervention services through appropriate referrals, education about potential services, and follow-up. Children who are prospects for early intervention may be identified in neonatal or pediatric intensive care units, general pediatric units or newborn nurseries, outpatient clinics, physicians' offices, or anywhere else the nurse has contact with children and families. During the course of a truly

family-centered approach to delivering care, the nurse may even identify siblings of children already in the program or children of adult patients who may benefit from early intervention services.

Within the early intervention service system, nurses play a variety of important roles while working in schools, agencies for children with special healthcare needs, regional centers for the developmentally disabled, home health agencies, private case management companies, or outpatient clinics. Nurses may be involved in interdisciplinary assessments, serve as case managers, provide education and support to families as they work their way through the system, or provide direct service as defined in the IFSP.

CHART 2-7 COMPONENTS OF THE INDIVIDUALIZED FAMILY SERVICE PLAN (IFSP)

- Statement of family's concerns about their child *at this time*.
- Assessment of family strength and needs
- Present level of development (physical, cognitive, communicative, socio-emotional, and adaptive)
- Major outcomes for the child and family
- Specific services needed to meet needs, including frequency, intensity, and method of delivery
- Dates for initiating and completing the services
- Any modifications of outcomes or services needed
- Identification of a case manager
- Transition plan (to other services providers)

The Individuals with Disabilities Education Improvement Act

IDEA is the primary federal program that authorizes state and local aid for special education and related services for children with disabilities. The legislation was reauthorized in 2004 and is now called the Individuals with Disabilities Education Improvement Act (IDEIA). This law changed the name of special needs students from "handicapped children" to "children with disabilities." This law also established the right of adolescent students to receive further education or employment as early as age 16. The law also required special education to begin as early as 3 years old. Under IDEIA, educational services are to be offered to students with disabilities from the time they are toddlers until the time they received a stable job (Slavin, 2006).

Another component of the law requires an IEP for all children receiving services. The term *IEP* refers to the educational program to be provided for the child with a disability and the written documentation that describes this

educational program, which has been mutually decided by the school, parents, and child (when appropriate). The IEP plan must be child centered and must address the long-term developmental needs of the child. The law outlines many procedural requirements for determining eligibility and maintaining ongoing assessments of children and their educational outcomes. Individual states have guidelines indicating time frames within which the steps of the IEP must take place. In addition, an appeals process exists to allow parents an avenue for resolving conflicts with school or other professionals about the plan. Typically, the family approaches the school principal or the district's special education unit to request changes to the IEP or to request an appeal. All requests should be in writing, and the parents should keep a copy their reference.

caREminder

Parents must be notified of IEP meetings. They may bring additional support persons of their choosing, such as child advocates, lawyers, psychologists, friends, and relatives. Parents must sign a form indicating they have been informed about the IEP. They do not have to agree with the plan details and they may request or appeal for changes.

Encourage parents to be actively involved in the IEP process, which includes assessments, plan development, referrals, and periodic reevaluation (see TIP 30–1). Nurses may be involved in the IEP process in a variety of ways. They may inform team members about the child's healthcare needs, help interpret complicated medical reports, be involved in making referrals or recommendations, and may also provide support to families through appropriate advocacy (Fig. 2–6). Although these tasks are most likely carried

out by the school nurse, they may also be performed by a child's home healthcare, hospital, or clinic-based nurse, or one involved in providing transition for the child from another program, because parents are allowed to invite additional professionals to the IEP meetings.

Section 504 of the Rehabilitation Act

Another avenue exists to obtain assistance in school settings for children with special healthcare needs. Section 504 of the Rehabilitation Act of 1973 assures students with disabilities the right to a free public education with other students without disabilities as appropriate and to the maximum extent possible. Students with chronic medical conditions who are in a regular education program can receive reasonable accommodations to assist them with their special healthcare needs while attending school. For example, students with type 1 diabetes are entitled to reasonable accommodations to test their blood glucose levels and to inject insulin. Parents, teachers, physicians, or school nurses can request a 504 Plan for students with disabilities that restrict one or more major life activities, such as caring for one's self, performing manual tasks, walking, seeing, hearing, speaking, breathing, working, and learning. The school must then meet with the parents to discuss the situation and to determine what must be done to integrate the child's health needs into the educational program (see TIP 30–1).

ANSWER: Lindsay has a 504 Plan with her school and an IEP plan. The 504 Plan entitles her to manage her diabetes at school. The IEP plan is related to educational challenges of a child with a chronic condition.

FIGURE 2–6. The nurse plays an active role in initiating and implementing IEPs in the school.

Head Start

Another program that serves preschoolers, including those with special healthcare needs, is the Head Start program. Head Start, begun in 1965 by the U.S. Office of Economic Opportunity, is funded by the federal Department of Health and Human Services, Administration on Children, Youth and Families. It is a child development program aimed at preparing low-income preschoolers for school entry by including child development, school readiness, health, nutrition services, and linkages to other social services in its program focus. Early Head Start is a program similar to Head Start that targets low-income pregnant women and children, birth to 3 years of age, and their parents. Early Head Start programs are not as well funded as Head Start, nor are they as widely available.

Substantial health, educational, and social benefits have been noted among children who have participated in the program (Silverstein et al., 2003). The program is locally administered by community-based, nonprofit organizations, Native American tribes, and school systems (Administration on Children and Families, 2006).

The Head Start program has four major components: health (including medical, dental, mental health, and nutrition services), education, parent involvement, and social services. The health component includes examinations; immunizations; health education for children, families, and staff; and meals and snacks that meet at least one third of the daily nutritional needs of the children. In addition, referrals to healthcare providers are made. Health services and health education are often provided by an onsite nurse. Each child participating in Head Start is required to have a physical examination, which is oftentimes performed by a nurse practitioner.

The education component is designed to meet a preschooler's individual learning needs, such as an introduction to the concepts of numbers and letters. Additionally, it meets the ethnic and cultural needs of the communities it serves by, for instance, providing bilingual teachers. Parents are encouraged to be actively involved in the program by helping in the classroom, serving on advisory committees, and attending parent education programs. The social services component offers families referrals to other programs and resources.

Head Start is required to provide services to children with special healthcare needs. Ten percent of its enrollment must be available to these children. Head Start programs may coordinate services with other programs, such as the developmental disabilities, early intervention, and mental health systems, or public school special education to meet the special needs of individual students.

Nurses are often involved in Head Start programs by serving on advisory boards and by providing direct services to children. In addition, nurses may serve as consultants, providing health education programs to staff, children, and parents, or may be involved in assisting program staff to develop strategies to address prevalent health problems, such as childhood obesity or asthma.

No Child Left Behind Act

The No Child Left Behind (NCLB) Act is legislation designed to ensure that every child in America receives a proper education. Congress passed the NCLB Act in January 2002, which aims to increase the performance of primary and secondary schools in the United States by holding states, school districts, schools, and educators more accountable for the success of each student. NCLB requires states to have annual standardized tests given to at least 95% of all students. The tests are designed to assess the adequate yearly progress of students in reading and math. These standardized tests must be given to students once a year in grades 3 through 8 and once in grades 10 through 12. NCLB requires annual reports to be sent to parents that include graduation rates, teacher information, and test assessments broken down by subgroups. NCLB has negative sanctions for schools that fail to meet adequate yearly progress standards. After 2 years, a failing school must provide paid busing and school choice to students; after 5 years of failing, a school will be taken over and managed completely by state authorities. This act promotes an increased emphasis on reading, especially for young children. NCLB also provides more flexibility to parents in choosing which school their children will attend (Essex, 2006). Even though this act was not specifically aimed at students with special education needs, the concept of "leaving no one behind" means that students with disabilities are able to benefit greatly from the measures in this legislation (Zipkin, 2007).

Private Programs for Community Care Services

QUESTION: Which private program do you think provides a summer camp for children with diabetes?

A wide range of community-based services, from preventive, primary, and specialty care, to respite and long-term care, are available to children and families. Children may receive health and related services in schools, clinics, daycare programs, camps, homeless shelters, and other locations in which nurses are often key to service delivery.

Nurses who provide care to children and families must be knowledgeable about the community resources available to them, for several reasons. First, a working knowledge of these programs lets the nurse make appropriate referrals for services to meet specific needs. Second, by knowing how to access the programs and by knowing the services that are offered, the nurse can educate families to apply for appropriate services efficiently and effectively. Applying for public services can be a difficult task, because not all service systems are child friendly. If families know which services are available, what to expect, and what paperwork to bring to appointments, they may be more likely to access and use these services. Third, by being aware of the individual programs and the service

systems available, the nurse can help coordinate resources and provide referrals in a way that avoids gaps, duplication, and confusion. Fourth, by knowing about these programs, the nurse can help redirect the family if family members receive inaccurate or confusing information, or cannot access services for other reasons. Finally, by understanding the service systems and their strengths and limitations, the nurse can advocate with policy makers to improve and ensure adequate funding for care.

In addition to publicly funded programs, a number of charitable and nonprofit organizations exist to serve children with special needs and their families. Groups such as the Muscular Dystrophy Association, the American Cancer Society, Easter Seals, and others may provide direct assistance to families in the form of transportation, equipment, or special camps for children. They may also aid families by providing educational materials geared toward children and adults. Often, services are offered for free or at a minimal cost. Many of these organizations also provide written resource materials or courses and conferences for professionals, and fund research activities (see [thePoint](#) for Organizations).

The Web has given professionals and families alike the opportunity to search for additional resources to help them care for their children who are developing typically, as well as those with special healthcare needs. Although not all families have access to the Internet in their homes, public and school libraries and family resource centers (FRCs) have computers available for public use, and often have paid or volunteer staff available to assist families in seeking information. When referring families to the Internet for information, warn them that some information may not be appropriate to their particular child or situation, and that consultation with their healthcare provider can help clarify the quality and appropriateness of the information they find.

A resource often not known to nurses but of tremendous benefit to families is the FRC. FRCs are located in communities within schools, hospitals, public health departments, clinics, and other public agencies. They provide information and support to families of children with special needs, and help to educate families about their child's condition and the system of care. They are often staffed by parent volunteers or parent professionals. In addition to providing information, they can often link families with other families for parent-to-parent support. Family Voices is a grassroots advocacy organization for families and providers of children with special healthcare needs (see [thePoint](#) for Organizations). With chapters in each state, they are often able to assist families in locating resources, including their local FRC.

Nurses should identify resources within children's communities and become familiar with the eligibility requirements and services offered. In addition, nurses can support the work of these groups by sitting on advisory committees, volunteering within organizations, or supporting fundraising efforts.

ANSWER: Each summer Lindsay attends a camp sponsored by the American Diabetes Association. In Chapter 12, Chronic Conditions as a Challenge to Health Maintenance, you can see the affect summer camp has on Lindsay and her family.

Principles and Physiologic Basis of Growth and Development

Case History

Joellen Rollins, who is in the last trimester of her third pregnancy, and her husband, Chris, are the parents of two children: Selena, a 5-year-old girl who will be entering kindergarten in the fall, and 2¹/₂-year-old James. Selena was born at 39 weeks' gestation via vaginal birth and experienced no problems. James was born vaginally at 32 weeks' gestation as a result of the abrupt onset of preterm labor that could not be halted. James weighed 3 lb, 5 oz at birth and was 18 in long. He spent a short time in the neonatal intensive care unit for evaluation. During his stay there, he developed some respiratory distress requiring the use of oxygen therapy. Since that time, he has not experienced any further significant respiratory problems other than two upper respiratory infections.

James is an extremely curious and active child. He is constantly "getting into things." He seems to shift his attention quickly from one thing to another and gets sidetracked easily. During the past few weeks, he has started toilet

training, which has been somewhat problematic. He

has had beginning success with bowel training but has had little success with bladder control.

"He's always on the go, and never wants to stop what he's doing," says his mother. Moreover, when his parents ask him to do something, such as use the potty or put his toys away, he responds with a definitive "No!" Running and playing outside are his favorite things to do. His parents do report that he is a bit clumsy sometimes. There have been several instances when he has fallen, but James only experienced some bruising, cuts, and scrapes. "It's a miracle he hasn't broken anything," remarks his father.

During the past couple of months, James has started throwing temper tantrums. During some of these tantrums, James holds his breath until he collapses, at which time he begins to breathe spontaneously. Joellen and Chris have tried various methods to get James to stop his tantrums, but they have been unsuccessful.

CHAPTER OBJECTIVES

1. Explain 10 principles fundamental to understanding the growth and development processes of children.
2. Examine the biologic and environmental factors that can influence the growth and developmental processes in children.
3. Describe the development of the body systems in children from birth through adolescence.
4. Articulate selected theories that describe the psychosocial, cognitive, interpersonal, sexual, and moral development of children from birth through adolescence.
5. Choose strategies the nurse can use to institute the process of developmental surveillance.

See [thePoint](#) for a list of Key Terms.

Human growth and development is sustained by the process of change. Changes in the physical body occur as tissues form, structures enlarge, and organs and muscles achieve their full degree of strength and function. Developmental changes occur in the individual as cognitive, language, and social skills are achieved. Developmental theories help to explain the multitude of factors that shape our personalities and the processes that affect our growth.

PRINCIPLES OF GROWTH AND DEVELOPMENT

QUESTION: What would you expect about James' growth considering he was a preterm newborn?

The study of human growth and development provides explanations of the similarities and differences among us that blend to create our individual physical and social self. To understand the basic principles of growth and development, it is important to understand how these and related terms are defined.

Growth refers to changes in size and function of the whole body or any part of the body. These are quantitative changes that can be measured by assessing changes in weight, length, height, and functional output. **Development** refers to the qualitative changes that are seen as an individual acquires new skills. Language and thought processes, the capacity to develop social relationships, and the emergence of a unique personality are all products of human development. Developmental assessment tools, cognitive abilities tests, and psychological assessments can measure changes over time in these areas. **Maturation** refers to those aspects of development that are genetically influenced. For instance, toilet training, riding a bike, and reading are skills that cannot be achieved until maturation of neurologic and muscular functions has taken place. Interaction with the environment has little influence on maturational changes.

The individuality of a child's growth and development is highly influenced by factors such as heredity, the envi-

ronment, nutrition, sensory stimulation, and affection. Growth is systematic and occurs in a sequential pattern. Although each person emerges at birth as a unique individual, basic patterns and trends are predictable in the growth and development of all humans, in all societies. Because of the regularity of the growth processes, stages of growth and development can be differentiated. This text differentiates the stages as infancy (newborn through 11 months), early childhood (1–4 years), middle childhood (5–10 years), and adolescence (11–21 years) as identified in *Bright Futures, Guidelines for Health Supervision of Infants, Children, and Adolescents* (Hagan, Shaw, & Duncan, 2008). Within these stages, particular growth events and maturational processes are expected to occur, and differentiation and integration of growth tasks evolve. For instance, the child learning to extend his or her arm aimlessly eventually learns to grasp an object purposefully, bring that object to the mouth, transfer the object to another hand, and throw the object when requested.

Although growth is a systematic process, body systems vary in their rates of development. For example, the cardiovascular and respiratory systems, although not fully mature at birth, must carry out functions essential for the viability of life outside the womb. In addition, these systems are necessary for the progressive maturation of other organs to complete their development. The lymphatic and genital systems are examples of two systems with rates and patterns of growth that occur over an extended period of time and influence the body at a later point in life.

When evaluating a child's growth, it is important to assess the child's patterns of growth over several months or years, rather than base an entire assessment on a single evaluation of the child at a particular time. The terms *normal* or *average* have been used to describe the predictable patterns of growth and development that have been studied and are known to occur within a certain time frame. From this normal or average pattern, each child can be viewed as a *variation of the theme* (Fig. 3–1).

caREminder

Although two children are raised in the same family, and may even be identical twins, the interactions and experiences each child encounters will be different. Therefore, two children can be expected to respond differently based on their past experiences, stage of development, current disposition, and genetic potential.

That is, given certain expected growth or developmental norms, each child as an individual may grow and mature faster or slower, while still demonstrating adherence to a consistent and predictable pattern of growth and development. For example, one child might be at the 90th percentile of height for his age, while another is at the 25th percentile for the same age. One child may learn to read sooner than another child. Each individual's growth and development trajectory, however, is influenced by environmental factors such as nutrition and sensory stimulation. If these environmental factors are either strongly negatively or positively affecting the child,

FIGURE 3–1. Although these children are all in fifth grade, developmental differences are significant with respect to their height, shape, and body proportions.

growth and development patterns may be altered. For instance, the child who is acutely malnourished will demonstrate delays in both physical growth and psychosocial development. However, early identification and intervention can prevent potentially irreversible outcomes. Often, with intervention, children can undergo a **catch-up period**, during which growth and development occurs, bringing the child back to his or her own trajectory (Tradition or Science 3–1).

The child's development of skills and functions proceeds from the simple to the complex and from the general to the specific. A young child, for example, does not progress straight from learning to talk to learning to

write. Instead, several other developmental achievements must take place, each building on the previous accomplishment, to achieve a more specific and higher level skill. Development progresses in a head-to-toe, or **cephalocaudal**, fashion and in a **proximodistal**, or midline to the periphery, progression (Fig. 3–2). For example, the infant who learns to lift his or her head and then sit, crawl, walk, and run is developing in a cephalocaudal manner.

TRADITION OR SCIENCE 3–1

Is there a critical window for catch-up growth of small-for-gestational-age (SGA) term infants?

EVIDENCE-BASED PRACTICE

Most authors suggest that the period for achieving catch-up growth in SGA term infants is the first 6 months of life for weight and the first 9 months of life for length. This is the period when breast or formula milk intake would be a predominant part of the infant's diet. Fewtrell et al. (2001) found that when SGA infants were fed nutrient-enriched formula during this critical growth period, they sustained greater gains in body length and head circumference up to 18 months of age compared with infants who received standard formula. These findings are consistent in that the critical period for affecting the growth trajectory in SGA infants includes the early postnatal period, and that nutritional interventions can influence the growth trajectory and sustain the gains in growth beyond the period of intervention.

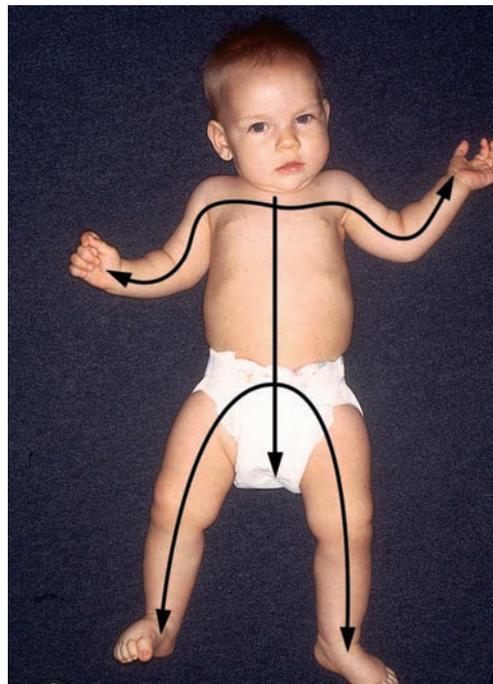

FIGURE 3–2. The child's pattern of growth is in a head-to-toe direction, or **cephalocaudal**, and in an inward-to-outward pattern called **proximodistal**.

The child who demonstrates random total body movements and then develops the use of a specific limb and then the use of individual fingers to grasp a small object is developing in a proximodistal progression. Knowledge of progressive traits helps the nurse to predict the sequential patterns of development. With this knowledge, the nurse can provide anticipatory guidance to parents to enhance the child's achievement of developmental skills.

As the child grows and matures, some **critical periods** are known to exist. These time periods refer to points in which the individual is highly sensitive or ready for certain actions. During a critical period, the child is vulnerable to positive and negative stimuli that can enhance or defer the achievement of a skill or function. For instance, infants who are born deaf vocalize as all infants do during the first year of life. However, by 1 year of age, the child who is deaf will likely cease these vocalizations and will not progress to other audible verbalizations without active intervention by the caregivers. Research regarding critical periods continues to accumulate, providing valuable information regarding times to ensure that opportunities are given for children to acquire specific skills and knowledge.

All humans have an inherent desire to learn and grow. Abraham Maslow called this *self-actualization*, and Carl Rogers called it *directional growth*. Children are constantly exploring their environment and testing parameters to seek new information and to acquire new skills. Factors such as illness, sensory deprivation, and physical and mental abuse can negatively affect the child's ability to focus on these inherent desires and to demonstrate progressive developmental achievements. Development is a lifelong process. As the child moves through adolescence toward adulthood, changes will continue to occur in the psychosocial, cognitive, physical, and emotional domains of the individual.

ANSWER: All newborns, regardless of their gestational age at birth, experience growth and development in a cephalocaudal fashion and proximodistal progression. Each newborn is individual in his or her growth, with some growing and maturing faster or slower than others. However, all newborns demonstrate adherence to a consistent and predictable pattern of growth and development. James' preterm status and exposure to environmental factors such as increased nutritional needs and possible sensory overload and deprivation from his stay in the neonatal intensive care unit may have affected his growth and development, necessitating a catch-up period to help bring him back to his trajectory.

FACTORS INFLUENCING DEVELOPMENT

The research contributions of psychologists and others interested in human development have made it increasingly evident that no single factor can explain the intricacies of growth and change from infancy to old age. Rather, there are multiple biologic and environmental factors, and these are so interrelated that it is often difficult to relate an individual's behavior or growth pattern to any specific ori-

gin. *Biologic factors* are those agents that affect patterns of development by primarily influencing the basic building blocks of the human organism—genes, chromosomes, cell division, and human reproduction. Physical traits are determined through genetic factors. However, emotional and behavioral patterns might also be influenced by genetic and hereditary factors; for instance, attention-deficit hyperactivity disorder (ADHD) is strongly linked to genetic (biologic) factors. *Environmental factors* are the psychological, social, and ecologic influences that affect the child's development. Factors such as parenting practices, interactions with peers, and frequent hospitalizations are examples of the psychological and social factors that influence individual development. Exposure to hazardous agents and nutritional intake are examples of ecologic factors that affect development. For example, a child's access to adequate calcium intake and the amount of fluoride in local drinking water can have an impact on the development of strong bones and teeth. Ongoing research aims to analyze the ways in which nature (represented by genetics and heredity) combines with nurture (represented by a person's environment) to produce a given outcome. Nurses play an important role in educating families about the biologic and environmental factors that will influence their child's development, emphasizing both the harmful and beneficial outcomes that may occur when nature and nurture interplay.

Biologic Factors

From the moment of conception, the role of genetics and heredity has a tremendous influence on the biologic growth and development of the fetus. These influences continue throughout childhood as the individual matures physically, interpersonally, and socially. Other biologic influences on development are the child's sex/gender and race/ethnicity.

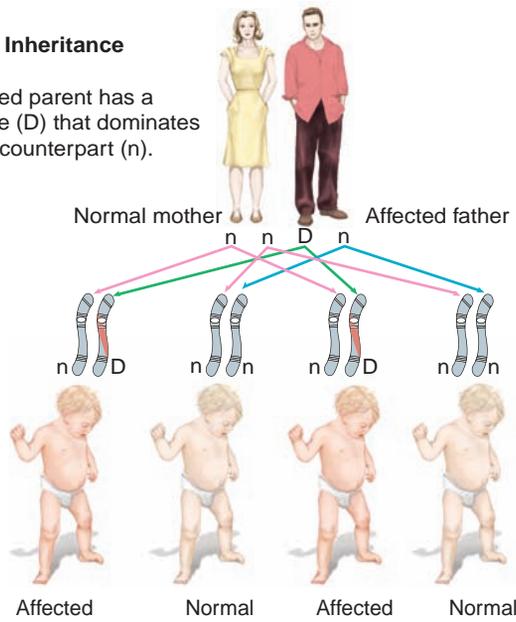

Genetics and Heredity

Genetics examines the physical and chemical properties of the molecules that govern the structure and function of every cell in the body. These molecules, or genes, influence who the child is and who he or she will become. The child's genes and chromosomes carry specialized codes that have instructions to determine the child's sex, eye color, height, predisposition for certain illnesses, and even the triggers that make all the metabolic pathways work correctly. In addition, scientists are investigating the role of genetics on the presence of certain behavioral traits, such as homosexuality, depression, addictive behaviors, and violent behaviors (Burt, 2005; Fox et al., 2005; Middeldorp et al., 2006; Saudino, 2005).

Heredity is the process by which living things transmit genetic codes that specify certain patterns of growth and organization to their offspring. The primary patterns of inheritance are dominant inheritance, recessive inheritance, and X-linked inheritance (Fig. 3–3 and Table 14–1). These patterns of inheritance influence the transmission of traits such as eye and hair color, and the appearance of genetic defects. Several conditions in

Dominant Inheritance

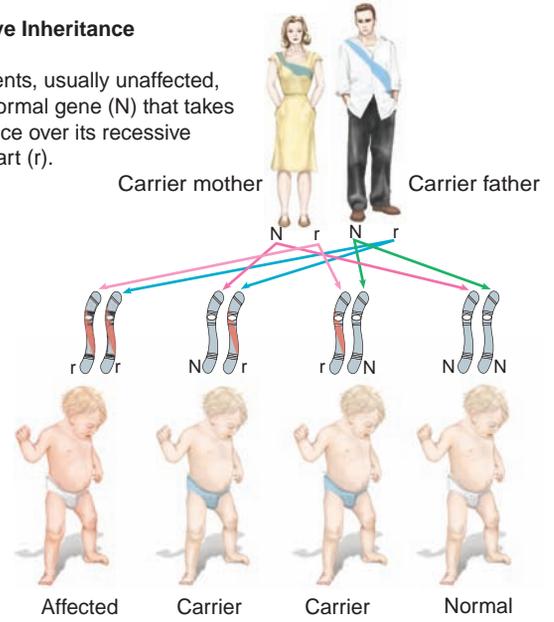

One affected parent has a single gene (D) that dominates its normal counterpart (n).

A. Each child has a 50% chance of inheriting either the D or the n from the affected parent.

Recessive Inheritance

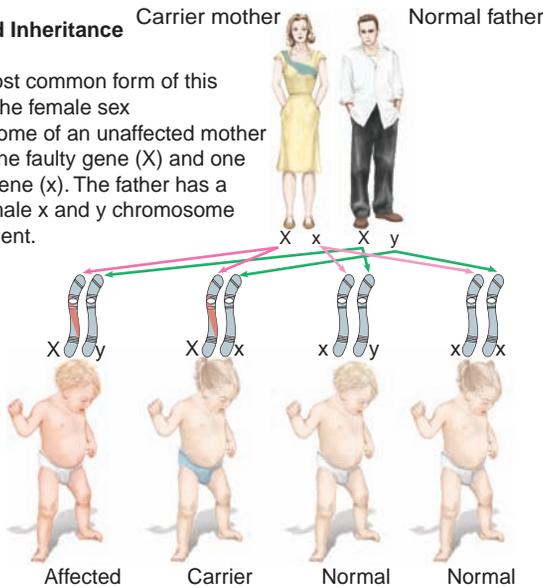

Both parents, usually unaffected, carry a normal gene (N) that takes precedence over its recessive counterpart (r).

B. Each child has a 25% chance of inheriting two r genes, which may cause a serious birth defect; a 25% chance of inheriting two Ns, and thus being unaffected; and a 50% chance of being a carrier, like both parents.

X-Linked Inheritance

In the most common form of this pattern, the female sex chromosome of an unaffected mother carries one faulty gene (X) and one normal gene (x). The father has a normal male x and y chromosome complement.

C. Each male child has a 50% chance of inheriting the faulty X and the disorder, and 50% chance of inheriting the normal x and y. Each female child has a 50% chance of inheriting the faulty X, and thus to be a carrier like the mother, and a 50% chance of *not* inheriting the faulty X.

FIGURE 3-3. Patterns of inheritance. A. Dominant inheritance. B. Recessive inheritance. C. Xlinked inheritance.

children can be attributed to genetic abnormalities. Table 14-2 presents selected genetic aberrations, their clinical features, and healthcare interventions.

Through the use of genetic screening techniques such as amniocentesis, chorionic villus sampling, and genetic counseling, many chromosomal aberrations and other disorders can be detected before conception or in the developing fetus (see Chapter 14 for further discussion of

these diagnostic tests). Through genetic testing, the analysis of human DNA, RNA, chromosomes, proteins, and certain metabolites are examined to detect inheritable disease-related genotypes, mutations, phenotypes, or karyotypes. As discussed in Chapter 2, genomic-based research includes investigation to analyze how behavior and environment affect susceptibility to certain disorders; how specific molecular changes influence disease

susceptibility; and how social, ethical, and cultural factors influence genomic health (Conley & Tinkle, 2007).

Genetic testing is done for both clinical diagnostic purposes and for predictive purposes. When a child appears with certain physical characteristics or symptomology that may be indicative of a clinical condition, genetic testing may be used as a diagnostic tool. For instance, the parents of a child born with a meconium ileus may be asked to consent to genotyping to determine whether the meconium ileus is related to the presence of cystic fibrosis. **Predictive genetic testing**, however, is considered more controversial by healthcare providers. Predictive testing may be completed on children who are considered pre-symptomatic for a specific disease (i.e., if the child has this particular genotype, he or she will likely develop the disease) or predispositional for a specific disease (i.e., if the child has a particular genotype, he or she is at increased risk for developing a particular condition, but not all will). Predictive genetic testing can be completed to determine whether a child is at presymptomatic risk for Duchenne muscular dystrophy or Huntington's disease, for example. Predictive testing can also be used to determine whether a child is at a predispositional risk for the development of type 1 diabetes in childhood or breast cancer as an adult (Tradition or Science 3–2) (see [thePoint](#) for Evidenced-Based Practice Guidelines to locate the essential nursing competencies for genetics and genomics).

Gender

During the early stages of conception, the child's gender is determined when the sex chromosomes of the parents are joined. There are two X chromosomes in females, and one X and one Y chromosome in males. The child's gender affects myriad physical, personal, and social factors related to the child's growth and development. Internal and external sex-specific biologic differences are present at birth and continue to be demonstrated throughout the course of the person's life. The most obvious biologic difference is the presence of either male or female genitalia. Other physical traits influenced by gender include hair distribution, height, and body physique. Overall health and longevity are also influenced by gender. Some diseases are noted to be more prevalent in one gender than another. For example, scoliosis is more prevalent in females, and hemophilia, muscular dystrophy, and colorblindness are more common in males. Females, in general, have a longer life span than males. In addition, premature female infants have a higher survival rate than do premature male infants.

Gender identification is the process by which children learn and acquire the attitudes and behaviors that are attributed to feminine and masculine roles in their culture. This process continues throughout the course of the child's development. Gender identification is considered to be influenced by both biologic (gender determined at conception) and environmental factors. Gender-based interactions with family members and peers, activities, personal-social attributes, and societal values interplay to influence the way in which children perceive themselves as gender typed.

TRADITION OR SCIENCE 3–2

Should predictive genetic testing be completed on an asymptomatic child for whom there is no medical treatment during childhood that can change the course of the disease? And should results of genetic testing be shared with the child?

MORE INQUIRY NEEDED

Rapid advances in clinical genetics have given rise to a variety of ethical concerns for clinicians and the families they serve. The research evidence remains inconclusive regarding the potential harms and benefits of both testing and disclosure, with little focus on the impact on children. Benefits of predictive testing can include the relief from uncertainty, knowing current or potential offspring's risk for the specific disease, relief from self-monitoring if the results are negative, and a greater ability to plan for the future (Lerman et al., 2002; Williams et al., 1999). Hamilton, Bowers, and Williams (2005) report that positive disease findings do not necessarily then equate to open disclosure to all family members. Rather, they found that adults tested for Huntington's disease or hereditary breast and ovarian cancer chose to disclose their findings to family members selectively, and the timing of disclosure was influenced by the disease and the person's perceived need to prepare. Disclosure of test results appeared to be a complex process of selecting which family members to include in the telling, the content of the information shared, and the style used to share the information. More research is indicated to determine both the harm and benefit of predictive testing, specifically on children, and the process of disclosing this information to family members, particularly children who are extremely vulnerable to the negative consequences this information may have on their lives.

Race and Ethnicity

The child's race and ethnicity influence patterns of growth and development in both obvious and subtle ways. **Race** refers to the biophysiological characteristics of a population group that make it different from others. Race has a genetic/hereditary influence on development. Easily visible are the influences of race on physical attributes such as skin color, hair color, body size, and physique. It is known that the incidence of specific malformations varies among population groups (Chart 3–1). In addition, certain physical variations and minor abnormalities may be considered normal findings among children of the same race. For instance, epicanthal folds, which are the vertical folds of skin that partially or completely cover the inner canthi of the eye and may indicate Down syndrome; glycogen storage disease, or renal agenesis, is normally seen in Asian children and in some non-Asian children. Similarly, lordosis, or an excessive backward concavity of the spine, is commonly seen as a normal finding in African American females. A careful review of family history can assist in determining whether specific clinical features should be further evaluated using genetic testing and other diagnostic

CHART 3-1 COMMON MALFORMATIONS AND DISEASES FOUND IN CHILDREN OF DIFFERENT POPULATION GROUPS

Disease	Population Group
Cystic fibrosis	Northwestern European
Phenylketonuria	Northwestern European
Sickle cell anemia	African and Mediterranean
Tay-Sachs disease	Ashkenazic Jewish
Gaucher's disease	Ashkenazic Jewish
Clubfoot	Polynesians
Cleft lip and palate	Chinese
Neural tube defects	Whites
Postaxial polydactyly	African
Ellis-van Creveld syndrome	Amish Mennonites
Thalassemia	Quebec, northern New Brunswick regions
Umbilical hernias	African
Adrenogenital syndrome	Eskimo
Glucose-6-phosphate dehydrogenase (G-6-PD) deficiency	African and Chinese

tests to determine the presence of an actual clinical condition. Likewise, carrier testing can be offered to couples who are planning pregnancy to determine whether their racial characteristics will enhance the risk of having a child affected by a specific genetic disease.

A child's **ethnicity** refers to the common social and cultural values, mores, and traditions that are passed on from one generation to the next and that create a sense of identity among members of the ethnic group. Ethnicity infers an environmental influence on growth and development of the child. Ethnicity may influence personal mannerisms, social interactions, responses to pain, and the development of one's self-concept. Race and ethnicity are another example of two closely intertwined variables that emphasize how both nature and nurture influence the way in which children grow and develop.

Environmental Factors

Throughout the child's life span, several environmental factors can impede or enhance physical, behavioral, and emotional growth (Table 3-1). Childhood illnesses, trauma, and nutritional deprivation are examples of factors that many affect the child's long-term health status.

Physically healthy children who have limited early social, educational, and environmental experiences are also "at risk" for developmental delays. Children who experience

the negative environmental influences of parental deprivation, abusive family relationships, or limited social contacts with other children their age will have difficulty achieving developmental norms unless early intervention is provided to alter the child's developmental trajectory. Other vulnerable children include teenage mothers, children who live in poverty, and children who are hospitalized frequently.

Health Status Influences on Growth and Development

As the child grows, good nutritional practices and health surveillance activities can promote optimum development. On the other hand, environmental factors such as physical trauma, ongoing exposures to chemicals, communicable diseases, and the outcomes of natural disasters are all factors that can dramatically change the growth and developmental patterns of a previously healthy child. Trauma and illness can impair physical growth and can cause the child to regress developmentally. These regressive actions and behaviors might be permanent if critical functions of the body have been affected. For example, a child who was involved in a motor vehicle accident might only be able to walk with an assistive device.

caREminder

Although some children may be developmentally disadvantaged because of alterations caused by a genetic condition or illness acquired later in life, opportunities to maximize the child's potential can come through the psychosocial, familial, and community assets that enhance development. These include positive relations developed within the family system, exposure to a wide variety of learning opportunities, and a community that supports the child and the family socially and politically.

Exposure to Teratogens

A number of drugs, chemicals, and maternal illnesses have been linked to birth defects in children. Agents that can disrupt fetal growth and produce birth defects are called **teratogens**. The effects of prenatal exposure to teratogens depend on the characteristics of the chemical agent, maternal and fetal physiology, placental factors, and the time during fetal development in which the exposure took place. Figure 3-4 presents a schematic illustration of critical periods in prenatal development during which the fetus is highly sensitive to teratogens. It is well known that by the fifth week of embryonic development, virtually all chemical agents and drugs will cross the placenta. Many of these agents will have no harmful effects on the growing fetus. Others, such as alcohol, thalidomide, heroin, antidepressants, and cocaine, are known to have direct and predictable negative effects on fetal development. At the same time, it is not always easy to predict why some teratogenic agents may affect one fetus more severely than another. For instance, a pregnant woman who carefully watches her diet and exercises regularly, yet continues to consume alcohol during her pregnancy may, or may not, deliver a healthy child. Intervening variables such as the mother's

general health, nutritional status, exercise habits, anxiety level, and the lack of prenatal care are factors that may compound the effects of teratogens on the developing fetus. Research regarding the correlations between teratogens and other intervening variables is continuing in an effort to determine both the short- and long-term effects of these elements on the growing fetus.

Table 3-1 presents examples of the teratogens associated with alterations in growth and development. Although many of these agents can cause visible physical deformities in a child, a number of the agents also cause damage to a

child's neurologic function or lead to a premature delivery. The long-term sequelae for children exposed to teratogens in utero and for very-low-birth-weight survivors is a topic of considerable investigation at this time. For example, it has been noted that cocaine-exposed infants are at risk for adverse birth outcomes such as prematurity and retarded intrauterine growth. In addition, health problems beyond the newborn period that have been noted include small stature, hypertonia, poor motor performance, and depressed interactive abilities (Bada et al., 2002; Lester et al., 2002; Singer et al., 2004). Children with a low birth

weight are more susceptible to illness and developmental delay during the early months of life. During the middle childhood years, these children tend to score lower on achievement tests than children who had normal birth weights and may encounter more school difficulties (Breslau, Paneth, & Lucia, 2004; Dezoete, MacArthur, & Tuck, 2003; Kilbride, Thorstad, & Daily, 2004; McGrath & Sullivan, 2002; Saigal et al., 2003).

All healthcare providers share in the responsibilities of preventing prenatal substance exposure, screening for mothers and children at risk, and providing for the needs of the child experiencing physical or developmental challenges resulting from in utero exposures. Families at high risk for teratogenic exposures include young parents, those with low incomes, mobile families, immigrant families, and those with known alcohol or substance abuse.

WORLDVIEW: Low-income women are at a disproportionate risk for teratogenic exposures and their detrimental effects. Sociocultural factors that contribute to this risk include poorly regulated work environments, a higher probability of proximity to hazardous waste, a higher prevalence of nutritional deficiencies, adherence to culturally based practices that have been associated with toxic exposures (e.g., use of pottery for cooking), and drinking water from spent chemical tanks and from local wells.

Many families are unaware of the risk factors associated with intake of certain medications, fluids, and dietary substances that contain agents that are harmful to the fetus and growing child. Elements in the environment such as toxic wastes, secondhand smoke, and radiation also pose a threat to development (see Table 3–1). Exposures to chemical, biologic, and physical hazards in the air, water, soil, and food present ongoing risks to children’s health. Children can be exposed to these hazards at home, at school, and in the community throughout critical stages of their development. Nurses can play an instrumental role in providing guidance to the family related to environmental health hazards that can affect children. Nurses should also integrate assessment of living conditions, including sources of drinking water, dietary practices, and environmental hazards, in routine perinatal and well-child healthcare visits.

Nutritional Deficiencies

QUESTION: How might James’ preterm status at birth have affected his nutritional status?

Maintaining appropriate nutrition from conception throughout the life span can positively affect an individual’s health and quality of life. Nutrition is needed to provide the body with energy to perform several vital functions. Energy is needed for basal metabolism, which keeps the body functioning and maintains body heat. The type of nutrition ingested requires certain amounts of energy to convert the food substances into energy that the body can use for basal metabolism. Nutrition is needed to replenish the body with energy lost from excreta, from normal processes of growth and development, and from

activity requirements. Nutrition is also needed by the body systems when they are threatened or weakened by disease to maintain function and to support the healing process. It is important to note that nutritional requirements change as the body grows and develops. Chapters 4 through 7 discuss the nutritional requirements of children at various stages of development.

Poor nutrition (eating too much or too few nutrients) accounts for several health and developmental problems seen in children throughout the world. Hunger and malnutrition exists even in developed countries such as the United States and Canada. Malnutrition can be caused by several factors and is known to have adverse and, sometimes, irreversible outcomes on the growing child (Chart 3–2). Pregnant women who are malnourished are at a high risk for miscarriages, stillbirths, and premature delivery. If the newborn is carried to term, he or she may be poorly nourished and SGA. It has been demonstrated that iron deficiency in utero or during the first 2 years of life can cause permanent damage to brain cell function and diminished cognitive functioning as demonstrated by lowered scores on developmental, learning, and school achievement tests (Akman et al., 2004; Halterman et al., 2001).

Marasmus is a condition that affects infants who are severely malnourished. A child with marasmus looks emaciated, and has a weakened heart and low resistance to infection. Body weight may decrease to less than 80% of the child’s normal weight for their length. The child may appear fretful, irritable, and voraciously hungry. *Kwashiorkor* is a condition found in children who receive diets low in protein after weaning. These children appear listless, apathetic, and inactive. As a result of their protein deficiency, their legs and abdomen appear edematous. These children are also very susceptible to illness.

In the growing child, inadequate nutrition has been associated with lowered intelligence, poor mental health,

CHART 3–2 FACTORS THAT MAY CAUSE MALNUTRITION

- Lack of adequate food intake to provide the protein and caloric needs of the body
- Social and cultural differences in food habits
- Widespread ease and availability of highly processed and often nutritionally inadequate foods
- Lack of adequate nutrition education in schools and in the home
- Complacency regarding food habits
- Overeating of foods that do not meet the needs of the body
- The presence of disease or illness that interferes with the ingestion, digestion, and absorption of food and/or that causes higher nutritional needs
- Failure to adjust nutritional intake based on changing levels of activity and rest, and on periods of higher metabolic demands (e.g., puberty)

increased susceptibility to childhood illnesses, stunted physical growth, and alterations in emotional development (Alaimo, Olson, & Frongillo, 2001; Bryan et al., 2004; Hughes & Bryan, 2003). For many children, poor nutrition may be one of several variables affecting the child's overall well-being. Poor housing, poor sanitation, little or no medical care, poor child care practices, and limited educational opportunities for the child can all interact to affect the child's growth and development. Malnutrition, however, is more common in children who are experiencing other aspects of poverty. Thus, it becomes difficult to isolate the singular effects of poor nutrition on the child's growth and development when so many other intervening factors exist.

The early introduction of solids in infancy can cause malnutrition. Studies have shown that infants who are consistently given solid foods during the first 3 to 4 months of life have poor nutrition from excessive caloric intake (Baker, Michaelsen, Rasmussen, & Sørensen, 2004; Ong et al., 2006; Stettler, Zemel, Kumanyika, & Stallings, 2002). Early introduction of solids interferes with formula feeding and with breast-feeding, may trigger allergies, increases the chance of the infant choking, and can lead to overfeeding. Malnutrition can also be seen in the child who comes to school each day without having had breakfast. This child may have difficulty concentrating and being attentive in school.

In the older child, malnutrition is observed in teenagers who exist on “fast food” or “junk food” diets. Teens who are left to prepare their own meals may not consistently make nutritious selections. In addition, adolescents coping with anorexia and bulimia are at a very high risk for nutritional deficits, which affect growth and development (see Chapter 29 for a discussion of these two disorders). Hair loss, amenorrhea (cessation of the menstrual cycle), sleep disturbances, bradycardia, cold intolerance, dry skin, and constipation are just a few of the physiologic manifestations of anorexia and bulimia. Preoccupation with food, an obsession with food rituals, and altered family and interpersonal relationships are some of the behavioral manifestations of these illnesses.

ANSWER: James, like other preterm newborns, was probably nutritionally at risk because the nutritional stores established during the last trimester were not achieved. Thus, preterm newborns need optimal nutrition to provide energy that is no longer being provided by the mother. Additionally, immaturity of his digestive system and sucking and swallowing reflexes would most likely interfere with his ability to ingest adequate nutrition. Moreover, his energy expenditure increased as a result of his increased respiratory effort secondary to respiratory distress, causing the need for additional calories.

Family Influences on Growth and Development

The family and the community are the environments in which the child will thrive and grow. The relationships and interactions established within these environments serve as patterns or blueprints for the child's developing

social relations and personal life skills. It is within the family that the child learns about gender and social roles, self-acceptance, and self-control, for example. Within the family milieu, the child learns ways of interacting with others to meet his or her personal goals and needs.

Several family variables will influence the development of the child. These include the family structure, family functioning, and family role modeling (discussed in Chapter 1). Family conditions that place the child at risk for school performance problems include divorce, parental unemployment, single-parent households, working mothers, and violence within the home. The influences of relocation, discipline, travel, play, family finances, and loss of a parent or significant other are among the many variables that affect the child as he or she interacts within the family constellation over the course of time.

Genetically, siblings are similar; they share the same parents and the same home environment, yet their experiences in the family can be different enough to create very individual and unique personal qualities. Factors that are attributed to the development of these differences include birth order, the age gap between siblings, gender, family size, illnesses of childhood, temperament, sibling behavior, and parenting behavior. Parenting behaviors and child-rearing practices are important factors in determining how children will develop. The quality of interactions among the child, the parents, and the siblings influences the relationships that the child will have with others outside the home. Some of the differences between siblings can be attributed to the functioning of the emotional unit at the time each child was born. The variables that affect this emotional unit include the anxiety in the family at the time of each child's birth, characteristics of the child that trigger certain processes in the family, the intensity and direction of relationships, and how the parents relate emotionally to their extended family.

Violence within the family may also affect the child's development. *Family violence* is defined as a crime committed against someone by a family member or a relative. Types of violence that can occur in the family include child abuse (emotional or physical), sexual assault, spousal abuse, and elder abuse. Although many cases are detected and reported to the police, it is believed that more than 40% of cases are not reported to police or healthcare officials (Durose et al., 2005).

A child may be either the direct recipient of violence or a witness to family violence. The child affected by violence against himself or herself will suffer from physical and psychological traumas that impair normal growth and development. These issues are discussed in more detail in Chapter 29. For the child who is a witness to violence directed toward other family members, physical injury may not impair the child's growth, but psychological injury can greatly affect the child's development. Children affected by family violence are at risk for low self-esteem, inability to maintain a relationship, inability to engage in healthy sexual relations as an adult, and post-traumatic stress disorder (Higgins & McCabe, 2003; Litrownik et al., 2003; Margolin & Vickerman, 2007; Martin, 2002; McDonald et al., 2007; McFarlane, Groff, O'Brien, & Watson, 2003).

Community Influences on Growth and Development

The community encompasses all the influences provided by interaction with daycare providers, peers, school officials, religious leaders, and social acquaintances. These interactions take place within the context of a social culture that provides boundaries for acceptable and unacceptable patterns of behavior. Role expectations, gender stereotyping, and age-specific norms must be evaluated within the parameters of the community milieu at a given point in time. For instance, encouraging adolescent girls to marry and bear children might be a socially expected developmental task in some communities. However, in the United States, this practice is generally not encouraged, because the adolescent female is not considered to be ready emotionally, physically, or cognitively to accept parenting responsibilities.

Public priorities and the mass media can have profound effects on children. The political and societal issues that have affected child rearing and child healthcare practices are discussed in Chapter 2. These include the funding and provision of mandated health services for children identified as “at risk,” and the legislation that ensures that the rights of all children are protected. Public priorities are often reflected by the mass media, which in turn can influence a child’s perception of socially acceptable behaviors and expectations. The results of research that has examined the effects of viewing violence on television on children’s mental health suggest that there may be a causal relationship between television violence and violence in real life. Researchers have noted both psychological and physiologic changes in children who view violence on television (American Academy of Pediatrics, 2001a). A more thorough discussion of the influences of the media and suggestions regarding how parents and caregivers can monitor and modify these influences are presented in Chapters 4 and 7.

The relationship between the home environment and health also involves housing and neighborhood factors. Poor housing is one of the leading causes of morbidity and mortality among children in the United States (Sandel, Wright, & Lanphear, 2004). In the past, health problems associated with poor housing have included tuberculosis and typhus. Today, conditions such as asthma and lead poisoning, unintentional injuries from home accidents, and neighborhood violence can severely affect the growth and development of children.

DEVELOPMENT OF THE BODY SYSTEMS

As children grow, the most profound changes noted by the casual observer lie in the physical development of the child’s body. External and internal body structures and functions will undergo changes that are influenced by the child’s gender and age, the child’s nutritional status, the presence or absence of disease, and the individual genetic attributes of a particular child.

Development of the Fetus

The origin and development of the organ systems begin during the embryonic and fetal periods. A review of the changes that occur during these periods provides information about the origins of body structures and highlights critical periods of fetal growth when congenital malformations can occur.

Embryonic Period

By the time a pregnant woman has missed her menstrual period, the embryo developing within her has implanted in the uterus, uteroplacental circulation has begun, and a primitive neural tube and blood vessels have been formed. This is the *embryo stage*, extending from implantation until the end of the second month.

During this period, the embryonic disk is composed of three layers that develop into the major organs and tissues. The ectoderm is the rudimentary formation for the nervous system, skin, hair, nails, and sensory organs. The endoderm develops into the mucous membranes of the mouth and anus; bladder and urethra; endocrine glands such as the thyroid, parathyroid, and thymus glands; tonsils; respiratory tract; and lining of the gastrointestinal system. Major components of the musculoskeletal, genitourinary, reproductive, and cardiac systems arise from the mesoderm. Tendons, muscles, cartilage, bones, connective tissue, kidneys, ureters, heart, circulatory system, blood cells, and all reproductive organs are mesodermic.

During the fourth through the eighth weeks, growth of the cranial and caudal ends, and the budding of arms and legs produce a humanlike shape to the mass of embryonic tissue.

Fetal Period

At 9 weeks of gestation, the *fetal period* begins. During the ensuing weeks, growth of the fetus follows certain predictable patterns (see Fig. 3–4). Although cushioned and protected in the mother’s womb, the fetus remains susceptible to the influences of many teratogens that can permanently alter the structure and function of various body systems. Organs that are formed from the same layer of the embryonic disk are often affected by the same teratogen. For instance, the heart and kidneys are both formed from the mesoderm. Therefore, if one of these organs is malformed, an assessment should be completed to evaluate whether the other organ arising from the same layer has also been malformed. Some teratogens are so harmful that the fetus may no longer be viable. Spontaneous abortions that occur during the first trimester may result from these negative outcomes. When a teratogen affects the fetus later during the gestational period, the effects may be noted at birth when the infant presents with physical or functional impairments.

By the 10th week, the face of the fetus is recognizably human. External genitalia are clearly distinguishable by the 12th week. At this time, ultrasound evaluation of the fetus can be used to help reveal the child’s sex to the expectant parents. By the 20th to the 24th week, primitive

alveoli have formed and surfactant production has begun in the lungs. If birth occurs from this point on, viability of the fetus is possible. By the third trimester, structural development is complete, whereas functional development of the systems continues.

Changes in General Body Growth

From the shape of an oval body to the distinctive features of a human fetus, the child in utero grows in weight and length in a progressive and predictable pattern that continues throughout the childhood years. Failure to grow or growth retardation in utero is termed *intrauterine growth retardation*. Depending on the point in pregnancy when intrauterine growth retardation appears, early delivery of the infant by cesarean section may be completed. During the eighth month, subcutaneous fat is deposited. This fat changes the wrinkled appearance of the fetus to that of a soft, cuddly infant. The fat also aids in thermoregulation. By the third trimester, fetal weight will triple and length will double as the body stores of protein, fat, iron, and calcium increase.

Growth During Infancy

The child's body proportions undergo many changes before adult proportions are achieved (Fig. 3–5). The newborn's head is approximately one fourth of his or her total body length, and the legs are about one third of the body length. The newborn appears top heavy, with short lower extremities.

After an initial small loss of weight, most newborns regain their birth weight within 10 days of delivery. Weight gain during early infancy is approximately 20 g ($\frac{2}{3}$ oz) per day. This gain decreases to about 15 g ($\frac{1}{2}$ oz) per day during the middle and latter half of the first year. Infants double their birth weight by 5 months, although some may double their birth weight by 4 months or earlier. Should this occur, evaluation of the child's nutritional status is warranted. Birth weight is usually tripled by the first birthday. The infant's length increases about

50% during the first year. The crown-to-rump length, or sitting height, measures the same as the head circumference. Head circumference is equivalent to chest circumference during infancy. Almost no variation in head circumference parameters has been found as a result of racial, national, or geographic standards. However, head circumference varies significantly in relation to body weight. Median head circumference at 1 year of age is approximately 12 cm ($4\frac{3}{4}$ in) larger than at birth.

Growth of the Young Child

QUESTION: James, at 2 years of age, weighed 34 lb and was 35 inches in height. What would you expect his adult stature to be?

As cephalocaudal and proximodistal growth continues during the childhood years, chest circumference will exceed head circumference, and the length of the trunk and extremities will surpass the measurement of the upper portion of the body. The rate of growth continues to decelerate during the early childhood years and then remains relatively stable throughout middle childhood. During the second year, the average child gains 2.5 kg ($5\frac{1}{2}$ lb), grows in length by 12 cm ($4\frac{3}{4}$ in), and increases head circumference by less than 2.5 cm (1 in). As a general guide, adult stature equals the following:

Boys: $2 \times$ height at age 2 years = adult height
 $5 \times$ weight at age 2 years = adult weight

Girls: $2 \times$ height at $1\frac{1}{2}$ years = adult height
 $5 \times$ weight at $1\frac{1}{2}$ years = adult weight

From ages 3 to 7, the average child gains 2 kg ($4\frac{1}{2}$ lb) in weight and 7 cm ($2\frac{3}{4}$ in) in length per year. During the school years (ages 6–12), the average weight gain is 3 kg ($6\frac{1}{2}$ lb) per year and the average change in stature is an increase of 6 cm ($2\frac{1}{4}$ in) per year. Accelerated growth

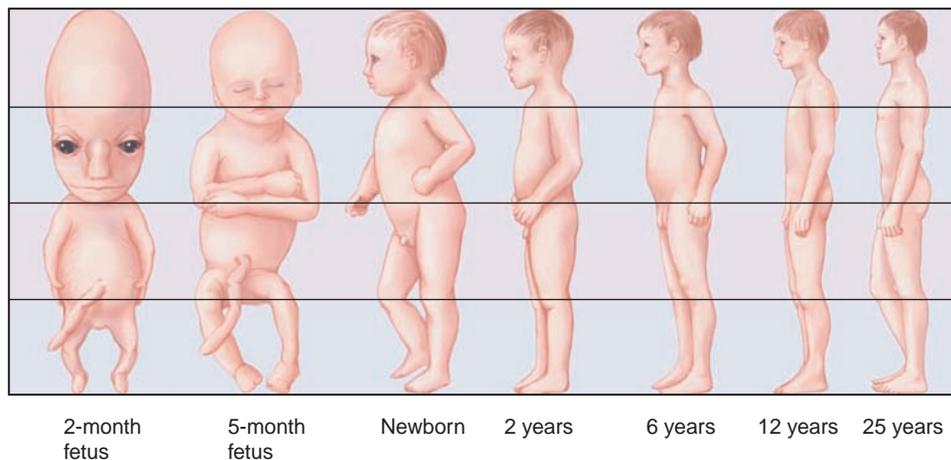

FIGURE 3–5. Changes in body proportion from the second fetal month to adulthood. (Adapted from Robbins, W., Brodey S., Hogan, A., et al. [1928]. *Growth*. New Haven, CT: Yale University Press. Used with permission.)

changes that are characteristic of the pubertal period may occur as early as 10 years of age in girls and around 12 years of age in boys.

ANSWER: Using the formula as a general guide, James' expected adult stature would be

Adult height = 23×7 in = 74 in, or 6 ft 2 in
Adult weight = 5×34 lb = 170 lb

Adolescent Growth

Before puberty, growth in stature predominates in the lower extremities, whereas during puberty, truncal growth predominates. The distal extremities reach adult size before the proximal extremities, thus the common complaint among preadolescents that their feet are too big. In association with the hormonal, physical, and emotional changes that occur during puberty, the adolescent experiences a period of growth acceleration. Age at onset, peak, and termination vary considerably from one person to another. Females tend to experience the growth spurt and other pubertal changes approximately 2 years ahead of males. Therefore, although previous to this period the mean height of girls was less than that of boys, the girls catch up and surpass boys in stature during early adolescence (ages 11–13). Girls achieve mature stature sooner than boys. The male growth spurt, although slower to begin, is of a longer duration. By the completion of the adolescent years, boys will surpass girls in height. During adolescence, boys gain at least 10 cm (4 in) in height and girls about 8 cm (3 in). A small amount of growth in stature may occur after age 18, especially in boys. By the end of adolescence, mature stature is about 3.4 times birth length and mature body weight is about 20 times birth weight unless the individual is obese or underweight.

Growth Measurements

Systematic notation of the changes in the child's body proportions is an important aspect of developmental surveillance. Alterations in length, weight, head circumference, and chest circumference from normative standards could indicate the presence of a clinical condition that requires further intervention by the healthcare team. The most important tools in the evaluation of somatic growth are growth charts constructed by longitudinal, serial measurements of large numbers of children at different ages over a brief period of time. Although physical measurements of a child at a single point in time provide some useful clinical information, serial measurements over months or years provide the most accurate record of the infant's or child's overall general pattern of growth. The physical measurements most often used in assessing children are height and weight, and in infants and young children through age 2, head circumference is used. All these measurements should be made with care and with the use of a consistent technique. Chapter 8 contains a complete description of the methods to obtain weight, height, length, and head circumference measurements.

TABLE 3–2

Causes of Variations in Growth Patterns

Increase or Accelerated	Decrease or Arrest
<i>Weight</i>	
Excessive intake	Nutritional deficits
Pregnancy	Failure to thrive
Use of corticosteroids	Chronic conditions (e.g.,
Clinical conditions (e.g.,	cystic fibrosis, cancer,
acquired hypothyroidism,	celiac disease, congeni-
Cushing's syndrome)	tal heart disease)
Infants of diabetic mothers	Child abuse (neglect)
<i>Height/Length</i>	
Endocrine conditions (e.g.,	Presence of scoliosis
hyperthyroidism, precocious	Endocrine disorder (e.g.,
puberty, pituitary gigantism)	acquired hypothyroid-
Klinefelter syndrome	ism, Cushing's syn-
Chromosomal abnormalities	drome, delayed puberty,
(e.g., XXX syndrome in girls)	Turner's syndrome)
Marfan syndrome	
<i>Head Circumference</i>	
Macrocephaly	Microcephaly
Hydrocephalus	Craniostenosis
Head trauma	

The periodic measurement of physical growth may elicit certain findings that should alert the healthcare provider to the existence of a health problem (Table 3–2). Because of the potential for measurement error, a single significant alteration in height, weight, or head circumference parameters should not cause alarm. The child who shows a significant change in growth parameters should be monitored closely. The need for growth assessments to be evaluated more frequently than the normal schedule for healthy child visits to the care provider may be warranted.

Musculoskeletal Development

QUESTION: James is a very active child. His parents report that he is a bit clumsy at times, which has resulted in some falls. However, he has only experienced some bruising, cuts, and scrapes. How would you explain the reason for why he hasn't broken any bones?

Growth and changes in the musculoskeletal system begin at conception and continue throughout life. Muscular activity is among the primary functions first achieved by the developing fetus. During the fourth to eighth months of gestation, the precursors of skeletal muscle and vertebrae (somites) appear. The back of the forming fetus is bent so the head nearly touches the tail. This tail begins to involute by the eighth week. The presence of arm and

leg buds and rudimentary eyes, ears, and nose can be noted. Ossification begins around the eighth week, and the individual assumes a humanlike appearance. Fingers, toes, elbows, knees, arms, and legs have all developed. Facial features can now be seen. The first muscle contractions occur, soon followed by lateral flexion movements.

By the end of the first trimester, the fetus can move its arms and legs independently of the trunk. By the 17th week, the grasp reflex is present and the fetus can be observed, on ultrasound evaluation, sucking the thumb. By midgestation, the fetus can move its arms and legs just as the newborn can, and, when the mother has periods of rest, is likely to demonstrate a full range of movement inside the womb. This fluttering sensation is called *quickening*. Fetal movements continue in strength and frequency throughout the rest of the pregnancy. By the 29th week, the fetus can kick, suck, and turn, changing positions as needed to find a position of comfort. As the pregnancy nears its completion, these movements can cause discomfort to the mother. During the last 2 months of gestation, further refinement of the musculoskeletal system occurs. Creases in the soles of the feet and an increase in ear cartilage formation occur. The infant born early is missing these features. The neonate at rest will assume the position similar to that maintained in utero. The feet curve inward, the spine is in a rounded position, and the arms remain flexed and close to the body.

The skeleton of the infant and young child is largely made up of preosseous cartilage and physes. The bones are flexible and have a high porosity. The young child's bones can absorb a great deal of energy before breaking and may even bow rather than fracture when a trauma occurs. The young child has an active growth plate at the end of the long bones known as the *physeal* or *epiphyseal plate*. Longitudinal growth and alignment of the long bones takes place at the growth plate through the process of endochondral ossification. During this process, cartilage becomes ossified, turning it into bone. This process continues until skeletal maturity is complete in adolescence. At that time, an increase in androgenic hormones produced during puberty causes the growth plate to gradually stop functioning.

ANSWER: James is a toddler and, as such, his bones are flexible and porous. Bones at this age can sustain a large amount of force or energy before a fracture occurs.

Muscle Tone

The mature newborn most often assumes a flexed position of the extremities. It is believed that this flexion pattern is induced by the position of the infant in utero. In infants who are in breech position, flexor positioning of the lower extremities is often absent. The premature infant also demonstrates less motor tone than the term neonate.

The full-term newborn demonstrates increased resistance against gradual stretching (tonic myotactic reflexes)

in almost all flexor and in many of the extensor muscles. This can be demonstrated by extending the lower arm of the awake neonate. When released, the arm will recoil to its flexed position. Similarly, a newborn in the standing position has a stepping motion as he or she alternately flexes and extends the lower extremities. Some view this as a reflexive mechanism, whereas other researchers assert that this is a precursor to mature function (Kamm, Thelen, & Jensen, 1990). The demonstration of hypotonia (frog legs) or scissoring with spasticity would be indications that abnormalities in the infant's muscle tone are present.

As the child grows and is physically active, muscular strength and agility will increase. Low muscle tone (hypotonia) might be seen in children with hypothyroidism, Down syndrome, or a neurologic problem. During puberty there is an increase in both total body fat and fat-free mass. Muscle tone and muscle mass increase. Strength training (also called *resistance training*) can be implemented to enhance further muscle strength, size, and power. However, gains in these areas are lost after 6 weeks if resistance training is discontinued (American Academy of Pediatrics, 2001b).

Neurologic Maturation

The neurologic and sensory organs are among the first systems to develop. Functioning of these systems is necessary for the functioning and development of other body systems. The brain and spinal cord begin to form during the first month of gestation as a longitudinal neural plate and neural groove that lengthens into a tube with two protrusions at the upper end for the brain. The upper portion will dilate and form the brain, with the remaining portion of the tube forming the spinal cord.

At 8 weeks, the nerves still do not have any anatomic or physiologic connections with either smooth or striated muscle. The embryo is floating freely in the amniotic fluid, with little purposive movement noted. Flexing of the trunk and head extension movements can be elicited in response to tactile stimulation. The hemispheres of the brain become recognizable and cerebellar development is visible.

During the 12th to 14th weeks, the neuromuscular system matures, spreading caudad. By the end of the fourth month, the frontal, temporal, parietal, and occipital lobes may be distinguished. Until about the sixth month of gestation, fetal behavior is largely controlled by spinal mechanisms. As maturation continues, the medulla and lower brain centers participate in the control of specific reflexive movements. The cerebral cortex has no influence on behavior until some time after birth. During the seventh month, there is a period of rapid brain growth. Multiplication and expansion of brain function are at a peak, and the cerebral cortex is undergoing additional refinement.

At birth, brain stem functions and spinal cord reflexes are present. The autonomic nervous system is intact but immature, and the sympathetic nervous system, which innervates the heart, is still incomplete. Functions of the cerebral cortex, such as cognition and fine motor skills, are also incomplete. As a result of this immaturity, the infant

is able to have cardiorespiratory function and to use reflex movements, but is unable to thermoregulate efficiently or to have coordinated gross and fine motor movements.

The infant's brain weighs 25% of its adult mature weight (300–350 g). By age 1 year, brain weight has doubled and is about two thirds that of the adult. Brain growth continues until approximately 6 years of age, when it reaches 90% of the adult weight. The increase in size during the early years is primarily the result of an increase in nerve fibers and the development of nerve tracts. At birth, the infant's cranium is not normally fused, allowing for the skull to compress during the birthing process so the head can pass through the narrow birth canal. The sutures of the newborn's skull are easily palpable, with final closure of the cranium not complete until 16 to 18 months of age. The presence of two fontanels provides a gauge to the processes of cranial fusion. The posterior fontanels will close at 6 to 8 weeks, with the anterior fontanel closing at 16 to 18 months.

Neurologic development continues, with myelination and maturation of the neural system becoming complete around age 2. The development of muscle tone, the extinction of reflexes, and the achievement of gross and fine motor skills reflect the continued maturation of the nervous system.

Children are born with all their neurons formed; however, the connections between these neurons proliferate and branch after birth, reaching a peak count by 3 years of age. Half of these synapses are lost by age 15. This suggests that there are more synapses than are needed for humans to function and that in the brain there is selective “pruning” of unused synapses and strengthening of those that are used to foster environmental adaptation. Thus, a child's early experiences may affect the development of the neural network (Klass, Needlman, and Zuckerman, 2003). The growth of the neuron network permits greater management over large and small muscles that control body movements. Refinement of neural pathways permits the child to have better control and coordination over specific body parts.

Reflexes

Reflexive movements that are characteristic of newborn behavior begin to appear by the end of the first trimester. Among the first of the reflexes to appear is the Babinski toe sign (extension of the large toe, with fanning of the small toes on stimulation of the sole of the foot), with later appearance of the swallowing and sucking reflexes.

Reflexive movements of the newborn are indicative of the motor behavior control exerted by the newborn's spinal cord and medulla. Each reflex requires a specific sensory stimulus to generate the stereotyped motor response. As the child matures, motor control expands to different levels of the nervous system. Therefore, many of the reflexes present at birth will normally disappear around the fourth month of age and cannot be elicited by sensory stimulation. These include Moro's reflex, the rooting reflex, and the palmar grasp reflex. Absence of these reflexes or persistence of these reflexes past the period they would normally disappear may indicate severe problems of the central nervous system.

Gross Motor Development

The acquisition of gross motor skills precedes the development of fine motor skills. Both processes occur in a cephalocaudal fashion, with head control preceding arm and hand control, followed by leg and foot control. All the extremities move randomly at birth without visible coordination occurring for several months. Movements are symmetric with no preference shown before 1 year of age for handedness or hemisphere dominance.

The acquisition of gross motor milestones varies from child to child. Although it can be predicted that particular milestones will be achieved by a certain ages, latitude in the exact month the milestone is attained cannot be predicted. Concerns are raised when a milestone that should have been achieved is obviously not yet attained. Further evaluation of the child for developmental delays may be warranted.

Head Control

The newborn has very little head control, and marked head lag is normal. When the newborn is pulled by the arms into a semi-Fowler position, the head will be hyperextended and will lag behind the alignment of the rest of the body. In the prone position, the infant has the ability to lift the head slightly and move it from side to side. When placed in a sitting position, the infant's head will drop forward onto the chest. Although the infant will attempt to right the head in the correct position, this only serves to make the head flop from one side to another.

At approximately 2 months of age, the infant demonstrates slight head lag and is able to hold the head up reasonably well when held in an upright position. In the prone position, the child can turn the head from side to side and can hold the head erect for 20 to 30 seconds at a 45-degree angle.

Between the third and fourth months, the infant achieves the ability to hold the head at 90 degrees and head lag becomes minimal. By the sixth month, head control is usually well established, as is evidenced by the lack of head lag. When prone, the infant lifts the head and upper abdomen off a surface by bearing weight on the arms. Figures 3–6 and 3–7 illustrate the development of head control during infancy.

Rolling Over

The newborn is not capable of purposefully rolling the body from one side to the other. Between 4 and 5 months of age, the infant learns to roll from front to back, then from back to front between ages 5 and 6 months. After infants can roll 360 degrees, they can then learn to pull to a sitting position and eventually learn to roll from the back to a knee-chest position to a standing position in one fluid movement.

Sitting Up

The development of head control must precede the ability to sit. The newborn infant lacks substantial head control, and the entire back is uniformly rounded;

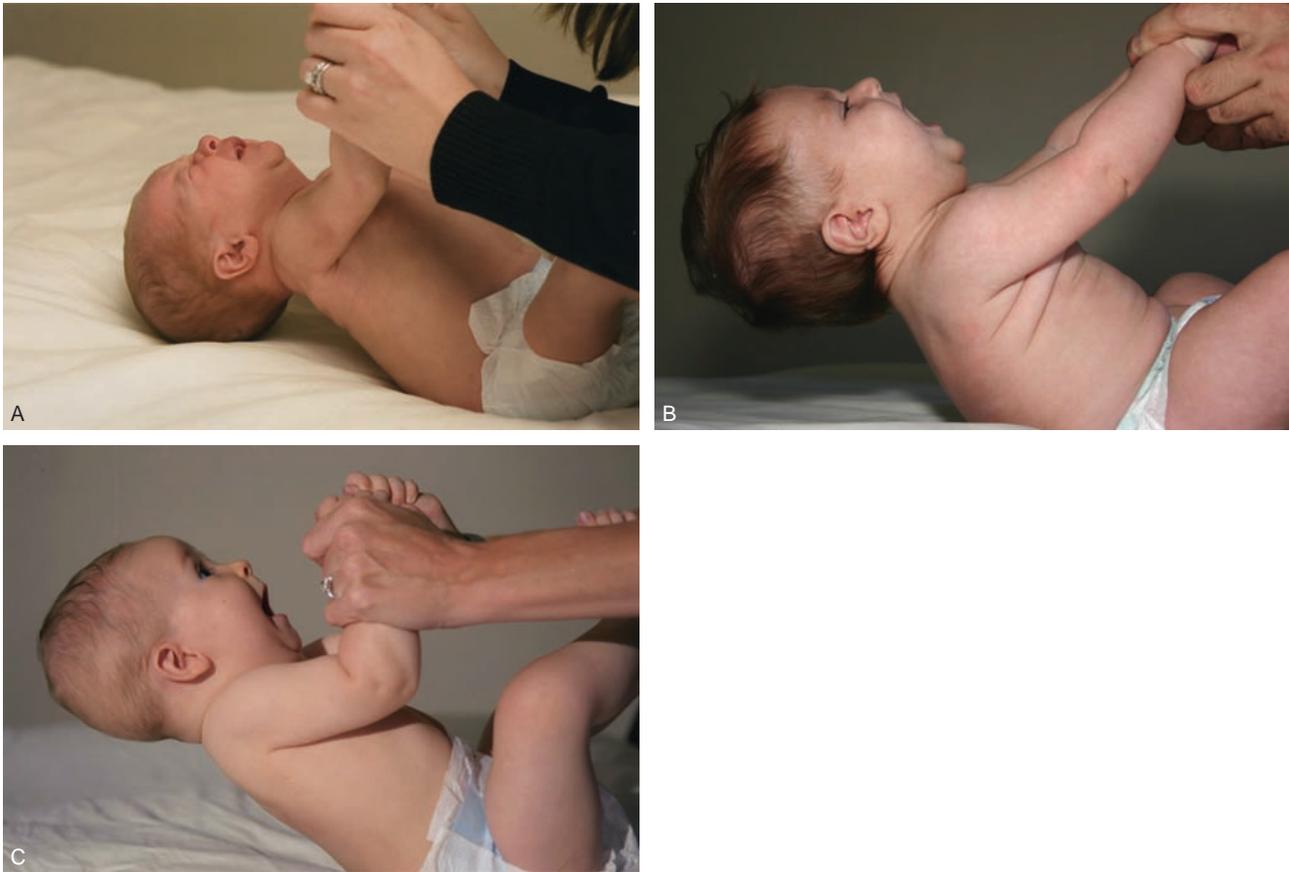

FIGURE 3-6. A. The newborn has marked head lag when pulled from a laying to a sitting position. B. The 2-month-old demonstrates slight head lag. C. By age 6 months, no head lag is present.

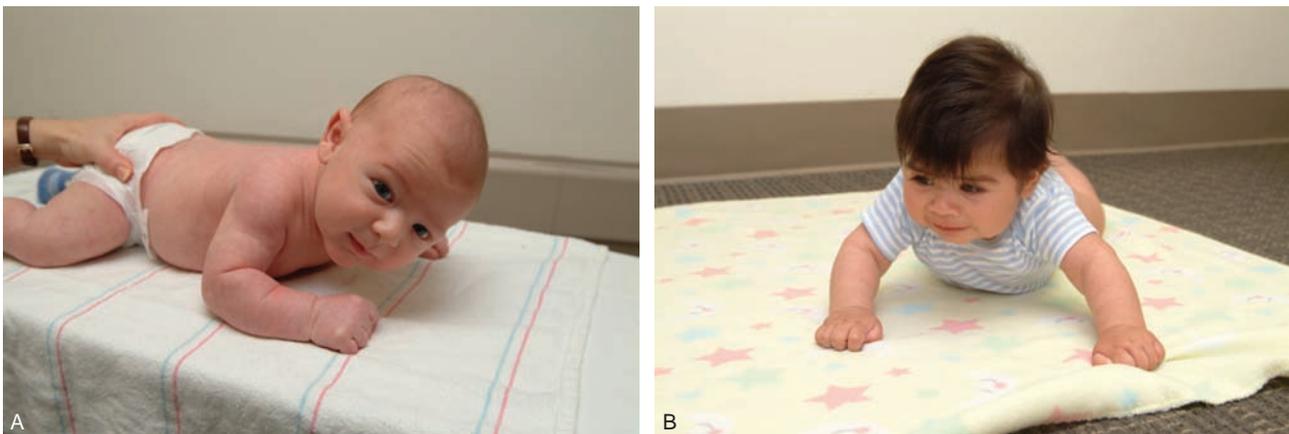

FIGURE 3-7. A. The newborn is barely able to lift his or her head while lying prone. B. By age 6 months, the infant easily lifts the head, chest, and upper abdomen and can bear weight on the hands.

these features prohibit a sitting posture. At 2 months of age, the infant still requires adult assistance to maintain a sitting position (Fig. 3-8A). Therefore, to be upright, the infant must be supported in an angled seat that provides full head, back, and posterior support. Between 5 and 6 months of age, the spinal column has straightened enough and head control is sufficient to

allow the infant to sit in a tripod position. The legs are extended in a wide V-based fashion, and the hands are used to provide support and stability (Fig. 3-8B). By 8 months of age, the infant can sit upright for long periods of time (Fig. 3-8C). The child can also easily change from a laying to a sitting position and vice versa.

FIGURE 3-8. (A) At age 2 months, the infant needs assistance to maintain an upright position. (B) At age 6 months, the infant can sit alone in the tripod position, using the hands for support and stability. (C) By age 8 months, the infant can sit without support and can focus on play activities.

Locomotion

QUESTION: James is 2½ years old. Developmentally, what should James be able to accomplish at this stage related to his gait and ability to get around?

The development of locomotion involves several different but related capabilities. The child must be able to bear weight; use the arms to support, push, and raise the body; and use the legs to propel the body forward in a coordinated fashion. As the child grows, coordination and balance will be refined, permitting the child to learn to run, skip, hop, and jump.

The very young infant is unable and unwilling to bear weight on the legs (Fig. 3-9A). Around 6 months of age, the infant can bear weight fairly well when pulled to a standing position (Fig. 3-9B). Although the infant can use the arms to lift the upper chest off a flat surface, no attempt is yet made to use the arms to pull or push the body. Some infants may begin crawling as early as 7 months; other children may not initiate these movements for a few more months. Crawling involves moving the body forward using the arms and legs while keeping the belly on the floor. This pattern of movement progresses to creeping when the child is able to raise the belly off the floor and support his or her body weight with the

hands and knees. The child can usually maneuver from the sitting position to the creeping position easily (Fig. 3-9C). At 9 months, the child may also be able to pull into a standing position by holding on to something. The infant may continue to creep and pull to a standing position for quite some time without displaying further interest in walking. Creeping is a very efficient method of locomotion. Even when walking is well established during the second year, it is not uncommon for the child to use the hands and knees to move from one place to the next, especially if the child has been playing on the floor.

After the child is able to pull into a standing position, he or she next learns to stand independently and bend the knees to change from a crouching position to a standing position (Fig. 3-9D). The cautious child is likely to stay close to a support mechanism (such as a piece of furniture) as he or she learns how to maneuver upright. Most likely, the first steps will be taken as the child moves from one piece of furniture to the next or from the support of one parent's arms to those of another (Fig. 3-9E). Some infants may begin walking as early as 10 months of age. Ninety-five percent of children walk independently by 18 months of age (Fig. 3-9F). Within 15 months of the initiation of independent walking, the child's gait will be mature. Until that time, the walk is wide based, marked by frequent stumbling. During the initial stages of learning to walk, the young child maintains the arms

FIGURE 3-9. (continued)

flexed and close to the sides of the body. The line of the body while ambulating has a forward lunge to it. As the child becomes steadier on the feet, a more upright position is assumed and the arms relax and move freely as the child walks (Fig. 3-9G).

By 2 years of age, the pace of the child's gait has steadily improved such that running can be accomplished without stumbling. Most 2-year-olds can kick a ball, climb well, and maneuver up and down stairs one at a time. A 3-year-old may go up and down the stairs using alternating feet, can stand on one foot momentarily, and can ride a tricycle (Fig. 3-9H). Locomotion continues as the 4-year-old learns to hop and walk down the stairs on

alternating feet. The arms, no longer needed to propel the body, can now throw a ball overhead and swing a bat. By 5 years of age, the child may ride a bike (with training wheels) and learn to skip (Fig. 3-9I). The school-aged child can stand on one foot for 10 seconds and will learn to jump rope (Fig. 3-9J).

After the child enters school, many opportunities to learn new locomotion skills are presented through participation in organized games and sports activities (Fig. 3-9K). Refinement of gross motor skills such as balancing, throwing, and complex combined activities (run-turn-jump-throw) continue through adolescence. As the child experiences growth changes during puberty, clumsy

FIGURE 3-9. (continued)

FIGURE 3-9. (A) The newborn is unable to bear weight on the legs. (B) By age 6 months, the infant bears full weight on the legs. (C) At 9 months, the infant is able to maneuver into a position for crawling in which the arms and knees bear weight. By 1 year, the child is able stand independently from a crouched position (D) and cruises along furniture (E). (F) At 13 months, the child walks and toddles quickly. The 4-year-old child must have assistance going up stairs. (G) By 15 months, the child can run with arms extended outward. (H) The child is able to walk stairs independently. (I) The 5-year-old is able to ride a bike. (J) The 10-year-old can easily jump rope. (K) The high school student uses multiple locomotion skills to play basketball.

movements may be noted. The rapidity of physical changes in height, in length of extremities, and in distribution of body weight may affect the adolescent's perception of body image and proportion, requiring some mental adjustments to develop a sense of comfort with his or her changing shape. Summary tables of gross motor accomplishments of children of all ages are presented in Chapters 4 through 7.

ANSWER: By 2 years of age, the child should be well established with walking. His gait should be fairly smooth and the child should be able to run easily without stumbling. James should also be able to kick a ball, climb, and go up and down stairs one foot at a time. As he approaches the age of 3 years, he should begin demonstrating the ability to go up and down stairs while alternating his feet, to stand on one foot for a short time, and even to begin to ride a tricycle.

Fine Motor Development

The newborn has very little control over fine motor movement. Actions made with the hands consist of broad sweeping actions and bringing the hand to the mouth. Objects placed in the newborn's hand will be involuntarily grasped and then dropped without notice

by the infant. During the second month, the child's ability to hold an object improves. During the ensuing months, the ability to reach and grasp progresses from the gross hand control of the palmar grasp to a more refined ability to grasp smaller objects using the thumb and forefinger in a pincer grasp (Fig. 3-10). The pincer grasp begins to emerge around the eighth to ninth month. With mastery of the pincer grasp, the infant can learn to hold a cup with handles, pick up small pieces of food, and crudely hold a spoon. By 1 year of age, use of the pincer grasp is well established, as is the ability to transfer objects from hand to hand and hold multiple objects in a hand.

Refinement of fine motor skills continues throughout childhood (Fig. 3-11). By age 2, many children can hold a crayon and color using a vertical stroking motion. The pages of a book can be turned by the child and a tower of six blocks can be built. During the third year, the child uses fine motor skills to copy a circle and a cross, and to build using very small blocks. The 3-year-old may be able to use scissors, and the ability to color becomes more refined (the child is able to color within certain borders). The 5-year-old is taught to write letters and draws a person with body parts.

During middle childhood, writing skills improve. The child advances to cursive writing. Fine motor coordination is enhanced by such activities as building models, sewing, playing a musical instrument, and painting. Fine

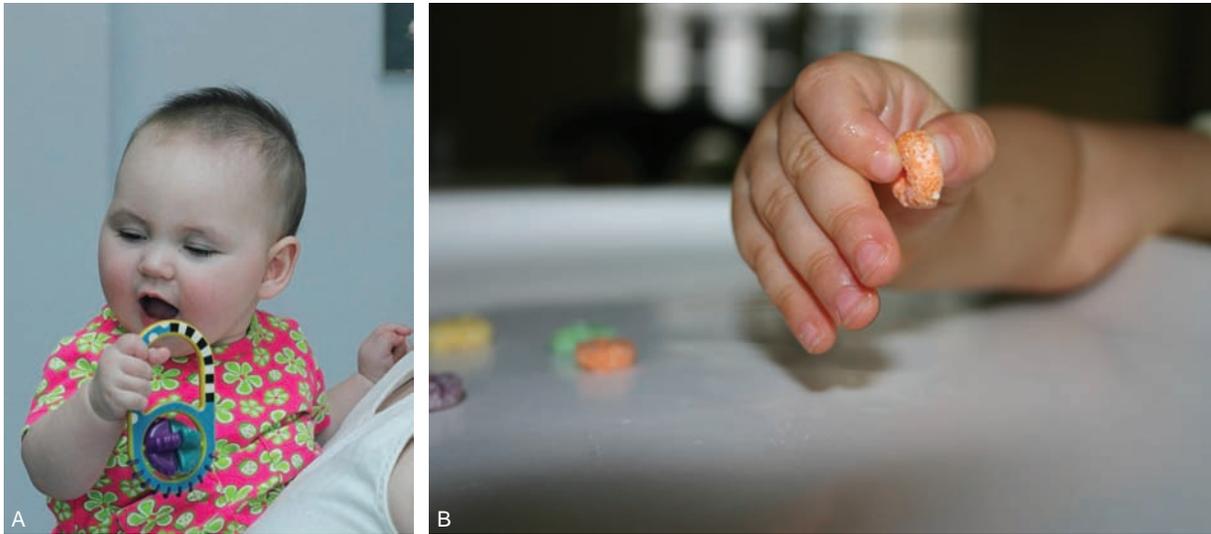

FIGURE 3-10. (A) Palmar grasp. The infant uses the entire hand to grasp an object. (B) Pincer grasp. The toddler uses the thumb and index finger to pick up small objects.

FIGURE 3-11. The child progressively achieves mastery of fine motor skills and cognitive abilities, such as buttoning clothes (A), holding a crayon (B), and using scissors (C).

motor work generally requires focused periods of concentration to complete (Fig. 3-12). Girls demonstrate more interest in these quiet, intense activities than do boys. Middle childhood is an opportune time to introduce typing skills, which can be transferred to activities

on the computer. Both boys and girls are likely to show interest in technology, because these skills are being used more extensively in the classroom (Fig. 3-13). Summary tables of the fine motor accomplishments of children of all ages are presented in Chapters 4 through 7.

FIGURE 3–12. During the school years, the child uses fine motor and cognitive skills to play. The child often becomes engrossed in these quiet, independent activities.

FIGURE 3–13. Use of the computer also involves the integration of fine motor and cognitive skills.

Sensory Organ Development

QUESTION: Approximately how many teeth would you expect James to have at his current age?

Eyes

At the end of the first trimester, the eyes are set far to the side of the head, and the neural connections to the eyes begin to develop. Eyebrows and eyelashes do not form until the sixth month. A thin membrane keeps the eyes fused until the end of the 28th week, when the eyes begin to open and the pupils respond to light.

Visual function at birth is limited, improving rapidly during the next few years as the structure develops (Developmental Considerations 3–1). The blink reflex is present in normal newborns. Tear glands begin to secrete within the first 2 weeks of life, and the infant may experience problems with mucus plugging the tear duct. Transient strabismus is a normal finding during the first few months. By 5 to 6 weeks of age, the infant is able to fixate

on an object and follow a bright light or toy. At 3 to 4 months, the infant is able to reach for objects at varying distances. The ability to fuse two retinal images together in the brain begins to mature at about 9 months of age, but is not fully mature until around age 6. The macula will mature by the end of the first year. Also by the end of the first year, mature adult functioning of eye muscles will be attained. Visual acuity, approximately 20/400 at birth, will not reach 20/20 until the child is about 4 years of age. Full maturation of the visual system and its oculomotor apparatus is almost completed by 5 to 7 years. A discussion of conditions that can alter vision is presented in Chapter 28.

Ears

Ear Formation

Ear formation begins around the fifth week in utero and remains susceptible to teratogenic influences until approximately the 16th week. These teratogens include ototoxic drugs, radiation, and infection. By the end of the first trimester, ear formation is complete and the ears are located in the appropriate position relative to other facial structures. In children younger than 3 years of age, the ear canal is directed upward. In the older child, the ear canal is directed downward and forward. The ears of the term neonate lay flat against the head and are well formed with firm cartilage. The top of the ear is in alignment with the inner and outer canthi of the eyes. Low-set ears may indicate the presence of a chromosomal aberration.

Hearing

The fetus responds to sounds as early as the 26th week of gestation. The newborn is capable of sound discrimination at birth and will fix his or her gaze on the source of the mother's voice, in preference to other human voices, within 12 hours of birth. The neonate responds more readily to high-pitched sound and is startled by loud noises. Mucus in the eustachian tube or vernix caseosa in the external ear canal may limit hearing at birth but resolves quickly.

During the next few months, the infant begins to cease activity when sound is presented at a conversational level. By 5 to 6 months, the infant is able to localize and begins to imitate selected sounds vocalized by an adult. During the 7- to 12-month period, the infant is able to localize to sound presented in any plane and responds to his or her name even when spoken quietly. After the first birthday, the child is able to point to familiar objects or people when asked. By 18 months, the child can hear and follow a simple command without gestures or other visual cues. At this point, children who have difficulty attaining language milestones must be evaluated for hearing loss (see “Language Development” later in this chapter for more information regarding language milestones). Developmental Considerations 3–2 further describes the development of hearing.

Congenital hearing loss is strongly linked to genetic influences. Profound hearing loss is present in 1 of every 1,000 to 2,000 newborn infants (Kochhar, Hildebrand, & Smith, 2007). The cause of congenital deafness can

DEVELOPMENTAL CONSIDERATIONS 3–1

Development of Vision

Birth–2 Weeks

Central acuity is 20/300.
Nystagmus is present.
Alertness is noted to visual stimulus 8 to 12 inches from eyes.
Pupils begin to enlarge.
Tear-glands begin to secrete.

2–4 Weeks

Head and eye follow objects up to 90° arc.
Very little attention is given to stimuli beyond 2 feet.
Blinking is evident at approaching objects.

6–12 Weeks

Alertness is noted to moving objects, although convergence and following are jerky and inexact.
Head and eyes follow object through 180° arc.
Fascination is evident for bright objects.
Tear glands begin to display response to emotion.
Newborn regards own hands.
Visual-motor coordination begins.

16–20 Weeks

Central acuity is 20/200.
Interest is shown in stimuli more than 3 feet away.

20–28 Weeks

Color preference for bright reds and yellows develops.
Ciliary muscle function begins.
Accommodation and convergence reflexes begin.
Hand–eye coordination begins to develop.
True blinking appears.
Ultimate color of the iris can be determined.

36–44 Weeks

Central acuity exceeds 20/100.
Depth perception is developing.

Visual regard for object with movement of the eyes horizontally and vertically to follow the object is present.

1 Year

Pupils have enlarged to midposition and their diameter continues to increase.
Cornea is adult size (12 mm).
Central acuity is 20/50.
Fusion is present, although of poor quality and readily interrupted.
Ability to discriminate geometric forms is present.
Infant stacks blocks and place peg in small round hole.

2 Years

Central acuity ranges 20/30 to 20/40.

3 Years

Central acuity ranges 20/30 to 20/40.
Convergence is smoother.
Amblyopia can occur from disuse.
Attention span is fair.
Fixation on small pictures or toys is approximately 50 seconds.
Afterimages can be described by the child.

4 Years

Acuity is nearly 20/20 to 20/30.
Child is distinguishing letters and shapes.
Lacrimal glands are fully developed.

6 Years

Central acuity is established.
Physiologic hyperopia decreases.
Gross attention span is approximately 20 minutes.
Detailed attention span is approximately 2 minutes.
Color shading can be differentiated.

Data from Johnson, T., Moore, W., & Jeffries, J. (Eds.) (1978). *Children are different*. Columbus, OH: Ross Laboratories.

be genetic or can be acquired from intrauterine conditions such as infections (cytomegalovirus, rubella, syphilis) or anomalies. Hearing loss is greater in premature children who have corresponding postnatal complications (e.g., poor Apgar score, need for mechanical ventilation, hyperbilirubinemia). Permanent partial hearing loss is associated with bacterial meningitis, severe otitis media, certain infectious diseases (mumps, measles, Epstein-Barr

virus), the use of ototoxic drugs, and head trauma. A thorough discussion of hearing disorders in children is provided in Chapter 28.

Nose

The newborn will react to strong odors such as ammonia and fresh onion. Infants are able to detect the smell of

DEVELOPMENTAL CONSIDERATIONS 3–2

Development of Hearing

Age	Expectation
Birth to 3 months	Startles to loud noises Random activity diminishes with sounds
3 to 4 months	Awakens to environmental sounds Turns toward sound of mother’s voice Coos and gurgles in response to speech Quieted by pleasant sounds (voice or music)
5 to 9 months	Mimics sounds Responds differently to angry and pleasant voices Enjoys musical toys Reacts to soft sounds (likes to be whispered to)
12 to 15 months	Responds when name is called Imitates vocal sounds Starts learning words (five to eight)

their mother’s breast milk as early as 6 to 10 days after birth. The ability to smell and differentiate smells continues to improve as the child matures. Discrimination of smell is influenced by the child’s attentiveness to this particular sense. For instance, the child whose temperament style is characterized by a low threshold to stimulus is likely to be highly sensitive to smells in the environment.

The structure of the nose may influence smell only in the sense that a blockage or malformation may impair the ability to smell. The nose of the newborn should be placed midline on the face. A malformed or misshapen nose may occur in the presence of chromosomal problems, choanal atresia, or perforation or deviation of the septum. Infants have a small nasal bridge and are obligate nose breathers until 1 month of age.

Mouth

Oral Cavity

Formation of the palate occurs during the seventh and eighth weeks of gestation, at which time the fetus is sensitive to teratogens that can affect development of the oral cavity. The most common abnormalities seen are cleft lip and cleft palate. Cleft lip is a result of incomplete fusion of embryonic structures surrounding the primitive oral cavity. Cleft palate represents failure of the primary and secondary palatine plates to fuse.

In healthy newborns, the hard and soft palates are intact, the uvula is midline, the tongue moves freely in the

mouth, and lips and lip movement are symmetric. The oral cavity and structures within it continue to grow in proportion to other facial structures as the child matures.

Taste

The sense of taste is immature in newborns, although they can distinguish among sugar, lemon, salt, and quinine. Sensitivity to strong tastes becomes heightened at 2 to 3 months. At this time, the taste buds are maturing and they are more widely distributed on the tongue than are those of older infants. The sense of taste is not fully developed until approximately 2 years of age.

Teeth

Tooth formation begins at approximately the seventh week in utero, with the differentiation of specialized oral epithelial cells. Calcification of teeth begins at 4 months’ gestation and is not completed until young adulthood. Eruption of teeth occurs at about the sixth month of life. Some children may experience the appearance of the first tooth before this time; in others, this does not occur until the latter months of the first year. There are 20 deciduous teeth, with eruption completed by age 2½. The first permanent molar and lower incisor teeth erupt around age 6, and most are present by age 12 (Fig. 3–14).

ANSWER: James, who is 2½ years old, should have a complete set of deciduous teeth (20) at this time.

Tonsils

The tonsils, located in the pharyngeal cavity, are part of the lymphatic system. Tonsillar tissue is usually not evident in the newborn. The tonsils in young children are generally larger than in adults, usually extending beyond the palatine arch until the age of 11 or 12 years.

Organ Development

During the third and fourth weeks of gestation, the main organs begin to form in a cephalocaudal direction. By the eighth week, basic organ development is complete. Although the organs are in place and functioning in a primitive fashion, the organs will not be able to work to sustain life until about the 20th week of fetal development. Further functional development of many organs continues with transition of the fetus to extrauterine life. In addition, other functional and structural changes continue as the child physically grows and matures during the ensuing years.

Skin

The back and the arms of the developing fetus are covered with fine hair called *lanugo*. This hair begins to form at 16 weeks, covers the fetus in utero, and begins to recede around the 36th week. Presence of lanugo will most likely be noted on the infant born prematurely and,

Upper Deciduous

	Erupt (months)	Shed (years)
Central incisors	6 to 8	6 to 7
Lateral incisors	8 to 11	8 to 9
Canine (cuspid)	16 to 20	11 to 12
First molar	10 to 16	10 to 11
Second molar	20 to 30	10 to 12

Lower Deciduous

	Erupt (months)	Shed (years)
Second molar	20 to 30	11 to 13
First molar	10 to 16	10 to 12
Canine	16 to 20	9 to 11
Lateral incisors	7 to 10	7 to 8
Central incisors	5 to 7	5 to 6

Upper Permanent

	Erupt (years)
Central incisors	7 to 8
Lateral incisors	8 to 9
Canine (cuspid)	11 to 12
First premolar	10 to 11
Second premolar	10 to 12
First molar	6 to 7
Second molar	12 to 13
Third molar	17 to 25

Lower Permanent

	Erupt (years)
Third molar	17 to 25
Second molar	12 to 13
First molar	6 to 7
Second premolar	11 to 13
First premolar	10 to 12
Canine	9 to 11
Lateral incisors	7 to 8
Central incisors	6 to 7

Deciduous and Permanent Teeth

to some degree, on the full-term baby. As the infant continues to mature outside the womb, lanugo continues to recede.

Another protective covering that can be found on the developing fetus is the *vernix caseosa*. This cheeselike coating on the skin develops around the 24th week, remaining until the fetus is full term. On delivery, the newborn may have varying amounts of vernix caseosa. The substance can be easily washed off the infant's skin during the first bath.

The newborn's skin is soft and smooth and has a translucent appearance. Superficial vessels are prominent, giving the skin a red color. Sweat and sebaceous glands are present in the newborn but do not become functional until 2 months of age; some do not become functional until the onset of puberty. At this time, considerable development of sweat and sebaceous glands is evident and associated with the development of acne vulgaris and body odor. More information regarding acne and other skin conditions that are common during the childhood years, such as dermatitis, acne, and sunburn, is provided in Chapter 25.

During the first year there is an increase in subcutaneous fat. When the child becomes ambulatory, the proportion of subcutaneous fat begins to diminish. By age 3, most children have a leaner appearance than has been noticed in previous years. During puberty, subcutaneous fat becomes more abundant in certain body areas, especially in females.

The fingernails and toenails began forming at the end of the first trimester. At birth, nailbeds are fully formed on the normal newborn. Infants born prematurely have incomplete formation of their nails.

Cardiovascular System

Formation of the heart begins by the 16th day of gestation. Blood cells join to the yolk sac's wall, and the system of blood vessels and a single heart tube begins to take shape. The heart appears as a bulge on the anterior surface of the developing fetus. By the sixth or seventh week, the septum and then the valves begin to develop. The rhythmic beat of the heart has begun by the eighth week and can be heard with a stethoscope by the 16th week, beating at 120 to 160 beats per minute. Fetal circulation develops slowly, providing blood to the brain, liver, heart, and kidneys. At birth, changes in circulation occur that allow the heart and lungs to work in a coordinated effort to sustain circulation once supported by the placenta (discussed in more detail in Chapter 15).

Thus, at birth, the heart of the normal infant is simply a smaller version of the adult heart with a few minor variations. Cardiac output in the newborn is initially 400 mL/kg/min, dropping to 200 mL/kg/min by adolescence. In the infant, cardiac output is a function of heart rate and not stroke volume. In the young child, the heart rate is usually higher and the stroke volume is lower than in adults.

Therefore, when the body requires higher cardiac output, the young child compensates by a correlated increase in heart rate (i.e., tachycardia). During periods of sleep or persistent vagal stimulation (by suctioning, defecation, or feeding), transient decreased heart rate (i.e., bradycardia) can occur in infants and is generally well tolerated.

The mass of the right ventricle approximates that of the left ventricle in the newborn as a result of the pressure and volume work performed by the right ventricle in utero. During the next several months, the left ventricle increases in mass more rapidly than the right ventricle as it works to pump both systemically. Eventually, the left ventricle is predominant, as seen in the adult heart.

The foramen ovale closes in the normal newborn soon after birth as a result of changes in interatrial pressure. The ductus arteriosus, which generally closes within 18 hours of birth, is not gone anatomically until approximately 2 weeks of age.

During infancy, the heart is placed more horizontally and has a larger diameter in relation to the diameter of the total chest than is apparent in the adult. The apex of the heart is one or two intercostal spaces higher than in the adult. Therefore, the apical pulse, or point of maximum impulse (PMI), is auscultated at the fourth intercostal space in children younger than 7 years of age and in the fifth intercostal space in the child older than 7. The PMI becomes more lateral as the child grows and as heart diameter decreases in relation to chest diameter.

Healthy premature infants are prone to having a high frequency of arrhythmias. This is most likely the result of the immaturity of the autonomic nervous system. Sinus arrhythmias are a normal finding in infants, although they would be considered an abnormal finding in the older child and adolescent. Innocent systolic murmurs are common in infants and young children. Diastolic murmurs at any age are considered pathologic.

The child's heart continues to grow through puberty. Heart growth is closely associated with somatic growth, including increases in body weight, fat-free body mass (FFM), and height during adolescence. FFM is an important determinant of heart size and heart growth for both boys and girls. An increase in the amount of aerobic fitness, presumably attributable to improvements in cardiac function, also affects heart growth in boys (Janz, Dawson, & Mahoney, 2000).

During fetal development, the main site of hematopoiesis is the liver. By birth, hematopoietic activity will primarily occur in the bone marrow. During early childhood years, most of the child's bones contain active hematopoietic activity. As the child matures, this tissue in the long bones is gradually replaced with fat. During periods of extreme hematopoietic stress, the long bones can resume active blood production. During later childhood and into adulthood, the pelvis, sternum, ribs, vertebrae, skull, clavicles, and scapulae are the main production sites for blood.

Respiratory System

The respiratory and digestive systems begin formation at the same time, and form as a single tube. By the fourth

week, separation of the two systems begins and lung buds appear. The lung buds may be seated deep in the abdomen until the diaphragm closes during the seventh week, thus dividing the thoracic cavity from the abdominal cavity. If incomplete closures occur, diaphragmatic hernias with abdominal organ contents extending into the thoracic cavity may be evident at birth. In this case, respiration would be compromised.

Formation of the sinuses begins during the third month of gestation. Until the ages of 2 to 3, the child's sinuses remain very small and poorly developed.

Surfactant is produced by the lungs during the sixth month. This substance is necessary for postnatal lung expansion. Production of surfactant continues through the 28th week, and the alveoli are formed at this time. Viability of the fetus outside the womb is possible after the alveoli are formed and some surfactant is produced. In the womb, the fetus has respiratory movements, although no actual "breathing" is taking place.

At birth, the most dramatic respiratory changes take place when the infant draws his or her first breath. The intake of oxygen pushes amniotic fluid out of the alveoli, allowing for the expansion of the pulmonary bed. Approximately 50 million alveoli are present at birth, and 250 million more are added by 2 years of age, at which time most alveolar formation is complete (de Jong et al., 2003).

The infant and young child's respiratory system is notably different from that of the older child and adult. During the childhood years, changes in the structure and function of the respiratory system occur. The alveoli and airways grow, changing in size and configuration. The child has fewer alveoli than the adult. The collateral pathways of ventilation are not completely developed during infancy; therefore, airway obstruction can have more severe effects in the young child. By later childhood and adolescence, the terminal airways are larger and collateral ventilation is improved. The infant's sternum and ribs are primarily cartilaginous, resulting in a soft chest wall. The ribs are horizontally oriented, and intercostal muscles are poorly developed at this time. This is in contrast to the adult's rib cage, which is more rigid with more vertically angled bones.

The adult uses his or her accessory muscles to aid in the respiratory process. Poor development of these muscles requires the infant and young child to be more dependent on diaphragmatic function to contribute to the movement of the chest wall during respiration.

Infants are obligate nose breathers for approximately 1 month after birth. The cartilage in the infant's larynx is very soft and can be easily compressed if the child's neck is flexed or hyperextended. The narrowest part of the child's airway is the cricoid cartilage, and, as a whole, the larynx is proportionately smaller in diameter and straighter than the larynx in the older child and adult.

Gastrointestinal System

After the digestive system separates from the respiratory system, it begins a period of rapid growth. Because the abdominal cavity is small, from the 6th to the 10th weeks

a part of the abdominal contents will extend into the base of the umbilical cord. As the abdominal cavity grows, the intestines should once again move into the abdomen. This occurs around the 13th week. Failure to do so leads to a variety of disorders, including omphalocele (a condition in which the child is born with the intestines outside the abdominal cavity) and susceptibility to intussusception and bowel obstruction.

During the second month of fetal life, the intestines begin to produce meconium as a result of fetal metabolism. The pancreas develops during the 12th week. The development of the swallowing reflex at 16 weeks allows the fetus to swallow amniotic fluid. If the fetus becomes stressed, hypoxia can cause vagal stimulation, an increase in bowel motility, and a lack of sphincter tone. The meconium may leave the bowel and move into the amniotic fluid, making it likely that the fetus will swallow some of the meconium. This is not a problem until the point of delivery, when the newborn is ready to take his or her first breaths. Further aspiration of the meconium into the newborn's respiratory passages can cause deleterious effects if not noted and treated on delivery of the newborn.

The terminal segment of the anal canal, the anus, arises from a pit invagination of the skin. The anus is supplied by somatic sensory nerves and is sensitive to touch, even at birth. As myelination of the spinal cord becomes complete and the musculature of the anus develops more fully, the child will develop voluntary control over defecation. This generally occurs between 2 and 5 years of age.

At birth, the child's gastrointestinal system remains immature and will not maintain full maturity until approximately 2 years of age. During the first 3 to 4 months of life, the sucking reflex and the extrusion reflex are present. The extrusion reflex protects the infant from ingesting food substances that the gastrointestinal system is too immature to digest. The production of saliva in large enough quantities to begin the process of digestion in the oral cavity does not occur until approximately age 4 months. The infant is prone to frequent spit-ups after feeding as a result of the immature muscle tone of the lower esophageal sphincter. Intestinal peristalsis is faster in young children, with emptying times of 2 1/2 to 3 hours in the newborn, extending to 3 to 6 hours in older infants and children. Faster gastric emptying time affects the ability of the digestive tract to break down and absorb the child's oral intake. For instance, it is not uncommon for the infant to eat corn and then defecate corn that has undergone no physical changes in appearance after having traveled the digestive system. The frequent output of undigested food particles is further influenced by the gastrocolic reflex, which rapidly moves contents toward the colon. The newborn's stomach capacity is 10 to 20 mL, increasing to 100 to 200 mL in a 1-month-old, 360 mL in a 12-month-old, 1,500 mL in an adolescent, and 2,000 to 3,000 mL in an adult.

The infant's stomach is round and lays horizontally until about 2 years of age, when the angle becomes more vertical and upright. The intestines undergo a growth spurt when the child is 1 to 3 years of age and again in the later teen years. The liver is generally palpable 1 to

FIGURE 3–15. The toddler's physique is characterized by a potbellied, bowlegged appearance.

2 cm below the right costal margin during the first year of life. The spleen is normally palpable 1 to 2 cm below the left costal margin during the first few weeks of life. Thereafter, the ability to palpate these organs becomes more difficult as the trunk elongates and the child acquires additional subcutaneous fat.

The diameter of the abdomen is larger than the diameter of the chest in children younger than the age of 4 and often has a "potbellied" appearance in both sitting and standing positions, resulting from poorly developed abdominal musculature (Fig. 3–15). A superficial venous pattern is readily visible on the infant's abdomen, remaining observable until adolescence. The omentum is poorly developed in early childhood, and thus localization of intra-abdominal infection or an inflammatory reaction is less likely to occur than in the older child and adolescent.

Genitourinary System

At 4 weeks of gestation, the kidneys are present in a rudimentary form. Urine forms between the 11th and 12th weeks of development. In utero, the placenta serves as a pseudokidney, regulating fetal fluid and electrolyte balance. The kidneys do not function independently until after birth.

During the first 1 to 2 years of life, the kidneys reach full functional maturity. Until maturity is reached, the infant is more predisposed than older children to dehydration during periods of fluid loss such as those caused by diarrhea, fever, fluid restrictions, and reduced fluid intake. During the early years, renal blood flow is slow, the reabsorption of amino acids is limited, autoregulation is not fully developed, and the ability to concentrate urine is minimal. As the kidneys mature and develop systemically,

there is increased cardiac output and increased plasma proteins, and renal function improves.

The newborn's bladder capacity is approximately 30 mL, increasing to 150 mL at 3 years, 270 mL at 7 years, and up to 600 to 800 mL in the adult. Although the kidneys do not reach maximal size until ages 35 to 40, the kidneys of infants and children have a larger diameter compared with the size of the abdominal cavity present in the adult. The child's kidneys are more vulnerable to trauma because of their size in proportion to the abdomen and because they are less protected by the ribs and have less fat padding.

Genitalia Development and Pubertal Changes

External genitalia are present at 8 weeks, the beginning of the fetal stage. However, the ability to distinguish between male and female genitalia is not possible until further formation takes place. During early embryonic development, male and female genital structures are similar. It is during the third month that primitive urogenital structures enlarge and fuse to form the male's penis and scrotum or shrink and have minimal fusion to form the female's labia and clitoris. These external changes can be detected on ultrasound. The internal sex organs are also developing at this time. The male's testes do not descend into the scrotum until about 36 weeks' gestation. An indirect hernia is produced if the tube that precedes the descent of the testes fails to close.

At birth the external female genitalia have increased pigmentation because of hormonal influences. The clitoris and labia majora are likely to be edematous. Both the edema and increased pigmentation recede within the next month. The scrotum of the full-term male is pink or dark brown, depending on the child's complexion, and rugae are present. Both testes should be descended. Penile erections occur when the penis is stimulated or when the infant is voiding. The foreskin on the penis is not retractable if the child is not circumcised. The foreskin remains adherent until approximately age 3.

Both female and male reproductive organs remain relatively unchanged until early adolescence. The beginning of puberty marks the onset of significant changes in the development of the gonads, reproductive organs, and secondary sex characteristics. The length of time pubertal changes require and the age at which they begin vary from person to person. In general, puberty begins earlier in females (as early as age 10) and is of a shorter duration than what occurs in boys.

Pubertal events are characterized by several other physical changes in addition to those that affect reproductive organs. Skeletal growth and body composition changes occur, increased strength and endurance are attained, and anatomic and biochemical alterations in the central nervous system and the endocrine system are seen. Figures 3–16 and 3–17 summarize the typical progression of female and male development during puberty (also called *Tanner staging*). Early or delayed onset of pubertal signs is a cause for concern because either can indicate endocrine dysfunction and can be a source of personal distress for the child (Clinical Judgment 3–1).

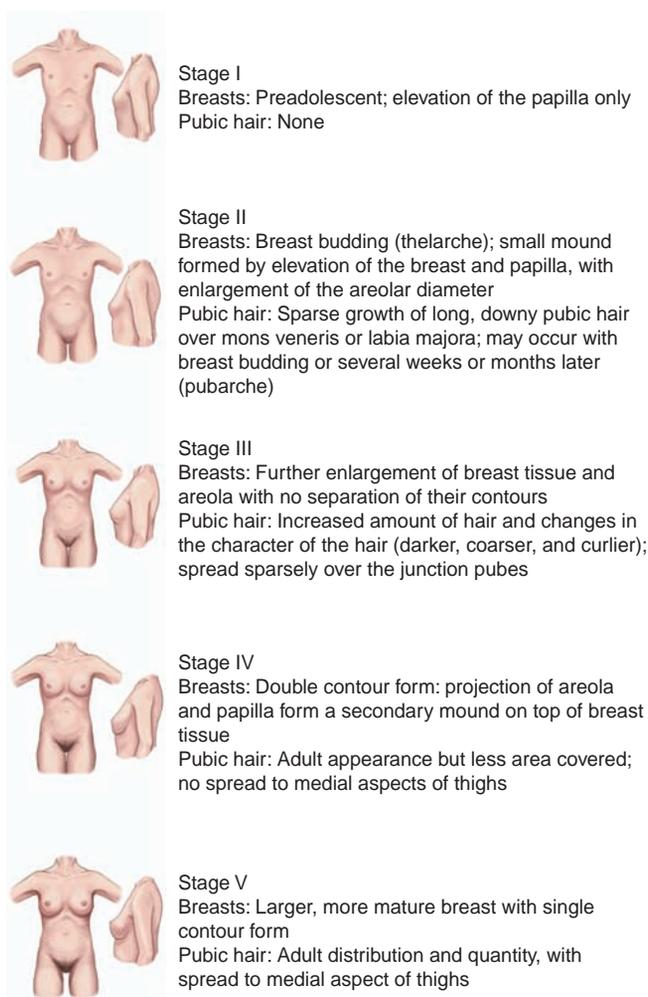

FIGURE 3–16. Tanner staging. Development of secondary sex characteristics in girls.

Endocrine and Metabolic Functions

The thyroid, thymus, and pancreas develop around the 12th week of gestation. Endocrine functions are immature at birth. For example, infants have a high metabolic rate that correlates with higher glucose needs. However, the infant also has low glycogen stores; therefore, the child can become rapidly hypoglycemic during periods of stress. As the youth approaches the adult years, these processes change. Under stress, the adult generally becomes hyperglycemic because epinephrine and glycogen secretion stimulate glycogen breakdown, resulting in an increased blood glucose level.

Stress in the infant also stimulates the secretion of growth hormone, which then increases calcium deposition in the bone, causing hypocalcemia. The infant has immature regulation of growth hormone production. Thus, in cases of severe stress, the infant needs to be monitored for hypocalcemia.

Metabolic functions are established in utero as genetic information is transferred to the developing cells. At birth, metabolic functions should be intact and functioning. Mutational events in utero can lead to the development

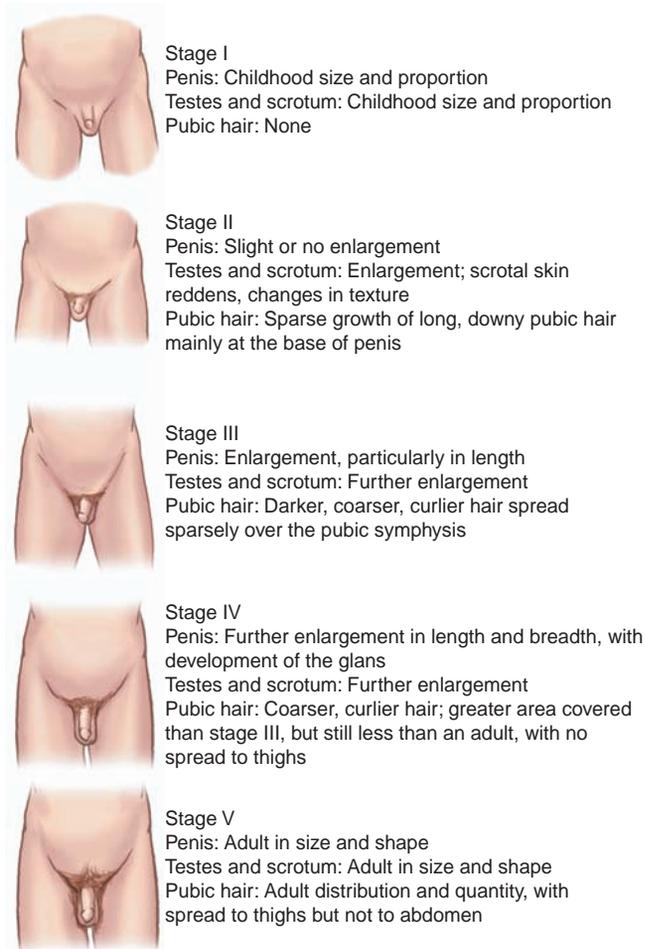

FIGURE 3-17. Tanner staging. Development of secondary sex characteristics in boys.

of biochemical disorders that affect the child's metabolic function. The affected genes result in either a structurally altered enzyme that is not capable of normal catalytic activity or causes an inhibition of enzyme synthesis. In most cases, the neonate appears normal at birth; however, signs and symptoms develop rapidly as the infant's metabolic functions begin to respond to the intake of human milk or formula and the demands of extrauterine life.

Some metabolic alterations do not make themselves known until later childhood. Rarely do problems in metabolic function appear as late as adulthood. The inborn errors of metabolism most commonly seen in the pediatric population are discussed in Chapter 27.

Many endocrine disorders are detected during adolescence because of early pubertal onset or a delay in pubertal onset. In addition, a variety of autoimmune endocrine disorders may appear during normal onset of puberty, including Hashimoto's thyroiditis, Graves' disease, autoimmune hypoparathyroidism, Addison's disease, and type 1 diabetes. With the exception of type 1 diabetes, autoimmune disorders rarely occur before adolescence. Endocrine disorders are discussed in more detail in Chapter 26.

Immune Functions

The lymphoid system performs the same function in children as in adults; however, the maturity of the system varies at different ages. For instance, the fetus passively acquires antibodies from the mother during the sixth month of gestation. Immunoglobulins G, A, and M (IgG, IgA, IgM) are almost completely derived by transfer to the developing fetus from the mother. This allows temporary protection against such diseases as measles, mumps, poliomyelitis, and rubella. At birth, the infant has the immunologic reactivity to respond to a large variety of antigens. At the same time, this exogenous source of immunoglobulins suppresses the infant's own ability to synthesize the immunoglobulins. Therefore, as maternal stores in the infant catabolize, the child experiences a period during which immunoglobulin levels are low because the child's own system is not fully activated to create the antibodies that are needed. This usually occurs around the sixth month. Adult levels of IgM are attained at approximately 1 year of age, with levels of IgG reached at 5 years of age and those of IgA acquired at 10 years of age.

Several other factors make the infant and young child more at risk for infection. The newborn's immune system is not as efficient as that of an adult. Cell-mediated immunity is less well developed than the adult; as a result, recovery from congenital infections may be delayed and the effects of the condition more devastating for the newborn.

Lymph nodes in children have the same distribution patterns as adults. However, the nodes are more predominant in the young child until the time of puberty. The amount of lymphoid tissue is considerable during infancy and continues to increase at a steady rate until after puberty. During early childhood, lymphoid tissue responds to infection by excessive swelling and hyperplasia. These clinical signs may persist long after the primary infection has diminished. The lymph nodes can harbor infection, posing a liability for the child. Swelling of the lymph glands and spleen can lead to other healthcare problems because swollen nodes can block the airway. A swollen and enlarged spleen is more at risk for traumatic injury because the child's abdominal structures have little subcutaneous fat to protect the internal organs from injury.

THEORIES OF DEVELOPMENT

QUESTION: James is developing a personality. At what stage of personality development would James be according to Freud's theory? According to Erikson's theory? What is the major area of focus for the child with each theory? Provide examples about James to illustrate these areas.

The previous section reviewed the physical development of the child. A variety of theories have been developed and tested to explain other aspects of the child's development, including psychosocial, cognitive, behavioral, language, moral, and spiritual.

CLINICAL JUDGMENT 3–1

Assessment of Changes During Puberty

Tom Yee is a nurse and a father of a 12-year-old who plays on a junior high soccer team. Mr. Yee was asked to talk to the team about ways to stay healthy during their adolescent years. After the presentation, Mr. Yee asks if there are any questions. One boy shouts out, “How come my bratty little sister is now taller than I am?” Another boy interjects, “Yeah! My 11-year-old sister is starting to get a big chest too!”

Questions

1. From the comments of the boys, what do you think is at the heart of their concerns?
2. For this preadolescent age group, what are some of the topics Mr. Yee should have covered in his “keeping healthy” presentation?
3. Should Mr. Yee start a discussion about the physical and reproductive changes that occur during puberty at this time?
4. How should Mr. Yee intervene to address the concerns of these boys?
5. What are some of the physical changes Mr. Yee should tell them will occur during puberty?

Answers

1. They see other kids around them going through lots of physical changes and they are concerned if they are abnormal or if they, too, will be growing bigger and taller.
2. Nutrition, sports safety, car safety, the hazards of smoking and substance use
3. Mr. Yee can discuss some of the physical changes that will occur during puberty. However, a detailed discussion of male and female reproduction and changes in the reproductive system would not be appropriate at this time because of the setting (not because of their age). Do plan another session to discuss these other topics.
4. Briefly discuss the physical changes between boys and girls that is occurring in this age group, determine whether there is a need for another presentation that would provide more detailed information about adolescent sexuality, obtain consent from parents to have a second presentation, and ask fathers to attend with their sons.
5. Pubertal changes begin in girls as early as age 10. Boys develop secondary sex characteristics later and may not begin these changes for up to 2 years after girls. This development in boys includes an increase in height. Physique will change with more muscle mass added. Genitalia will enlarge and the shape will change. Hair growth will increase in certain body areas such as under the arms and in the pubic area. The hairline on the forehead may recede a little, the voice will deepen, and acne may begin to appear.

Personality Development

Understanding personality development has been strongly influenced by the *psychoanalytic perspective*, which asserts that children move through a series of stages in which they confront conflicts between biologic drives and social expectations (Berk, 2005). The most widely influential psychoanalytic theorists have been Sigmund Freud and Erik Erikson. Erikson met Freud and studied psychoanalysis under Freud’s daughter Anna. Erikson agreed with the idea that, at certain biologic maturation points, the child was faced with crises or conflicts that needed to be resolved. Unlike Freud, however, Erikson did not believe these conflicts were sexual in their orientation. Rather, he believed that social and cultural factors influenced central issues that are germane to determining behaviors and actions at given time periods in the child’s life. Other theorists such as Jung, Adler, Horney, and Sullivan have contributed to an understanding of personality development (see [thePoint](#) for Supplemental Information: Contributions of Psychosocial Theorists). Their nonstage theories uniformly disagree with Freudian theory regarding the factors that motivate the development of different personality types.

In addition, understanding a child’s personality is also better understood by the practitioner who has knowledge of the various types of temperament inherent in each person. This section reviews the theory of temperament and the influence temperament has on the child’s interactions with others.

Knowledge of the psychoanalytic theories assists nurses to identify needs and concerns of children at specific ages. Understanding theories about temperament helps explain unique differences in children as they deal with day-to-day experiences as well as stressors caused by change. The theories are useful in nursing practice when evaluating a child’s response to hospitalization and the stressors related to the presence of chronic or acute illness.

Freud’s Theory

The work of Sigmund Freud provides the most familiar psychoanalytic theories. Freud believed that humans are driven by a need to resolve certain biologically determined drives that center around sexual urges. Although Freud did not believe that children experienced adult sexual feelings, he did believe that children had certain

TABLE 3–3
Freud's Stages of Psychosexual Development

Psychosexual Stage and Body Area of Focus	Description	Results of Trauma or Fixation
Oral, birth to 1 year (mouth)	Enjoys sucking; chewing; biting on things such as mother's breast, rubber nipple, thumb, blanket, or bottle	Oral fixations such as nail biting, cigarette smoking, gum chewing, excessive eating
Anal, 1 to 3 years (anus)	Libido centered on gaining mastery in using anal muscles; toilet training accomplished at this time	Anal fixations such as parsimony, orderliness, punctiliousness, obstinacy, possessiveness; difficulty controlling anger, aggressive feelings, and impulses
Phallic, 3 to 6 years (genitalia: penis, clitoris, and vagina)	Resolution of the Oedipus and Electra complex; sex roles and moral development take place	Boy will remain overly attached to his mother, fearing father may castrate him; may resent father and authority figures; girl will remain overly attached to father and has "penis envy," wishing to be a man
Latency, 6 to 12 years (sex drives repressed; no area of focus)	Nonsexual urges; children focus on learning to control their impulses and find appropriate outlets for their drives; energies shift to physical and intellectual activities	Prolonged or exaggerated Oedipal or Electra complex
Genital, 12 years to adulthood (genitalia)	Interest in peers as sexual partners; task is to learn mature patterns of heterosexual behavior	Failure to develop mature, acceptable methods of obtaining sexual gratification

sensual and pleasurable urges that they acted on through their behaviors and in their interactions with others. The sexual instinct is called *eros*. The energy created by the sexual instinct is called *libido*. According to Freud's theory, beginning with the newborn, the developing human is focused on a core need to satisfy a sensual drive (Table 3–3).

During each stage of development, a different region of the body becomes the focus of sensual pleasure. The goal of the child is to proceed through each stage without trauma so that he or she will emerge as a "well-adjusted" adult. Freud believed that trauma in any given stage would result in some *fixation* or alteration in psychosexual development. Each stage builds on the next. As the focus of sensual pleasure shifts from one body region to another, the child must be willing to let go of the previous focus and to move on to another stage of development. If conflict has occurred at a certain stage, resolution of that sensual pleasure may not be complete and the child may be reluctant to move on to the next stage. Even if the child does move onward, psychosocial adjustment may be impaired, with fixations becoming apparent as the child continues to mature.

Freud's childhood stages were derived entirely from his experiences with adults. His theory was built on his work with neurotic personalities who sought psychiatric treatment. His theories have been criticized for his views on male supremacy and gender differences. Critics of Freud's work posit that many of the sexual conflicts he believed were developmental are more likely attributable

to the responses of children growing up under the mores and values of late-19th-century European society. Freud's theory also did not take into account any cultural differences among individuals. Although the areas of body focus seem appropriately correlated to the behaviors seen in children of specific age groups (sucking during infancy, gaining bowel control during early childhood), focus on these body parts can also be attributed to the natural acquisition of, and expected changes in, the functional abilities of these body structures. Freud's theories provide insight regarding how parents can manage their child's sexual and aggressive drives as they mature.

ANSWER: Based on Freud's theory, James is in the anal stage, which encompasses the ages of 1 to 3 years. The major focus of this stage is on gaining mastery in using the anal muscles. This is illustrated by attempts at toilet training.

Erikson's Theory

Erikson's theory of personality development is based on the *epigenetic principle*. This principle asserts that personality develops according to predetermined steps that are maturational and set by the growing person's readiness to be a part of a widening social radius. The critical steps are turning points, or moments of decision between progress and regression, integration, and retardation

TABLE 3–4

Erikson's Psychosocial Stages of Development

Stage	Characteristics	Outcomes
Trust versus mistrust, birth to 1 year	Caregiver responds in warm, caring manner to child's needs to create trusting environment. If care is inconsistent and unreliable, mistrust develops.	<i>Positive:</i> hope, tolerates frustration, can delay gratification, sense of trust <i>Negative:</i> suspicion, withdrawal, focus on negative aspect of people's behavior
Autonomy versus shame and doubt, 1 to 3 years	Child practices and attains new physical skills developing autonomy. If not allowed to do things he or she can do, or pushed into doing something when not ready, child may develop sense of shame or doubt.	<i>Positive:</i> will, self-control, positive self-esteem, self-confidence <i>Negative:</i> compulsion, impulsivity
Initiative versus guilt, 3 to 6 years	Initiative is demonstrated when the child is able to formulate a plan of action and carry it out. Believes that desires and actions are basically sound. If the child is punished for expressing his or her desires, then child will develop a sense of guilt.	<i>Positive:</i> purpose, enjoys accomplishments, self-starters <i>Negative:</i> inhibition, afraid to accept new challenges, guilt over one's actions
Industry versus inferiority, 6 to 12 years	Child acquires skills such as reading, writing, and mathematics and social skills. Through acquisition of these skills, he or she develops a sense of industry. If always compared with others, or made to believe he or she is inadequate, child will develop a sense of inferiority.	<i>Positive:</i> competence, enjoys learning about new things, perseverance, takes criticism well <i>Negative:</i> inadequacy, inferiority, gives up easily
Identity versus role confusion, 12 to 19 years	The adolescent investigates and identifies alternatives regarding his or her vocational and personal future. Premature choices, or the inability to make these choices, will lead to role confusion.	<i>Positive:</i> fidelity, confidence in self-identity, optimism, control of one's destiny <i>Negative:</i> diffidence, defiance, socially unacceptable identity, sense of purposelessness
Intimacy versus isolation, 19 to 25 years	Love relationships are developed. Fear of intimate relationships will lead to a sense of isolation.	<i>Positive:</i> love, development of deep interpersonal relationships <i>Negative:</i> exclusivity, avoidance of commitment, avoidance of relationships
Generativity versus stagnation, 25 to 50 years	Parenting, nurturing others, and fulfilling civic responsibilities are the tasks. The adult finds ways to be productive and to be of help to others to grow personally.	<i>Positive:</i> care, concern for future generations of the society, desire to help others <i>Negative:</i> stagnated, rejection of others, self-indulgence, self-absorbed, highly critical of others
Ego integrity versus despair, 50 years and older	Reflection on one's life and one's achievements. A sense of pride or despair is developed regarding the accomplishments in life that have been made or were lost.	<i>Positive:</i> wisdom, self-satisfaction <i>Negative:</i> disdain, disgust, bitterness concerning lost opportunities

(Erikson, 1963). Erikson called his stages or critical points the *Eight Stages of Man* (Table 3–4). Each stage is denoted by an emphasis on two opposing possible outcomes. During each stage, the individual is presented with a crisis. If a particular crisis is handled well, then a positive outcome prevails. If the crisis is not handled well, a negative outcome results. Thus, each stage is characterized and named after the opposing outcomes that emerge as maturation through that age is achieved. The theory

also asserts that each psychosocial strength is related to all others, that each strength is dependent on the proper development in the proper sequence, and that each strength exists in some form before its critical time of emphasis normally arrives. As the child matures, a certain strength becomes more predominant, meets its crisis, and finds its lasting solution during the stage indicated (Erikson, 1963). Each stage lays the foundation for negotiating the challenges of the stages that follow.

Erikson emphasizes that the effects of culture, socialization, and the historic moment will affect identity development. Therefore, his theory cannot be used as a blueprint to describe a single personality type. Children from different cultures develop and achieve the developmental tasks through a variety of socially acceptable mechanisms. For instance, achieving the stage of industry in U.S. society is somewhat dependent on formal school achievements, whereas in other societies, the ability to farm or to catch animals for food is evidence of industry during middle childhood. Erikson's theory has been criticized for being overly broad and general, and for being difficult to evaluate in an experimental setting.

ANSWER: According to Erikson's theory, James is in the stage of autonomy versus shame and doubt. The major focus of this stage is practicing and attaining new skills to develop autonomy. This is illustrated by James' negativism (saying no to everything) and by his temper tantrums. His negativism is a way for him to develop his identity as a separate person. His temper tantrums are a way for him to cope when he becomes overwhelmed with tasks or things that he is unable to complete or a way to make his feelings known.

Temperament

The child's characteristic way of thinking, responding, and behaving is referred to as the child's *temperament*. Temperament is considered to be an intrinsic personality factor—that is, children are born predisposed to respond to their environment in very different ways. Temperament influences the child's characteristic way of behaving and interacting with his or her environment.

Table 3–5 presents 10 temperament categories. Individual temperament characteristics are apparent within the first few months of life and are easily identified by the end of the first year. Three temperamental styles or groups form combinations of the 10 categories of temperament characteristics:

1. The *easy child* is characterized by flexibility, a positive approach to new stimuli, adaptability to change, and predominately has a positive mood.
2. The *difficult child* is characterized by irregularity in biologic functions, negative approach to new stimuli, slow adaptability, and intense mood expressions that are usually negative.
3. The *slow-to-warm-up child* is characterized by a combination of behaviors that are marked by withdrawal tendencies to new situations, slow adaptability, and negative mood expressions of low intensity. Less irregularity is noted in biologic functions. This child is often labeled “shy” (Chess, 1990; Chess and Thomas, 1985).

Temperament is believed to have a major impact on behavior and development. The child's temperament influences the dynamic interactions between the child and other people in his or her environment, particularly parents, other family members, teachers, and peers. To explain the healthy or pathologic interactions between

the child and the environment, a model of “goodness of fit” and “poorness of fit” was developed by Chess and Thomas (1986). Goodness of fit occurs when the environmental expectations and demands of parents and others are consonant, or in harmony, with the child's temperamental characteristics. When goodness of fit is present, healthy functioning and development can occur. Conversely, poorness of fit is characterized by dissonance between environmental demands and the child's capabilities and temperament style. Poorness of fit is likely to lead to the development of behavior problems and poor parent–child interaction patterns. Thus, difficulties can arise when the child's temperament is in conflict with the parent's own behavioral style. For instance, an active child may be quite a challenge for parents who are more low key. A child who has erratic patterns for eating and sleeping may be a behavioral challenge to the grandparents who are very time oriented and orderly in their daily activities (Turecki and Tonner, 2000).

All the temperament styles may enhance positive or negative development and behavior. More important than the child's particular temperament characteristics, however, is the presence of a good fit in the interactions of the child with the environment. Parents often think that their biologic children should be born with many of their own behavioral characteristics and with a similar disposition. Parents may desire to learn about their child's temperamental characteristics so that they can be more accepting of the unique qualities in their child. Understanding temperament is important for parents, in providing guidance toward the proper parenting techniques and how to discipline, and in understanding how it affects the parent's view of the child and themselves as parents. Several intervention programs have been developed to help parents who want to learn to better understand and manage their child's temperament (Gross & Conrad, 1995; McClowry, 2002; Medoff-Cooper, 1995; Melvin, 1995; Wallace, 1995). The first goal of a temperament-based intervention program is to help parents understand the unique characteristics of their child. Standardized temperament questionnaires are usually used to assist in this process. Next, parents are taught how temperament is related to behavior. Last, the parents or caregivers are assisted in developing strategies to manage their child based on the child's temperament. When parents verbalize frustration with their child's behavior, the nurse can offer guidance to families that will foster the child's development and enhance parent–child interactions.

Cognitive–Intellectual Development

The cognitive theories of development explore how an individual comes to think, to perceive, to process, and to understand information about himself or herself and the environment. Some of the approaches evaluate cognition in relation to the child's specific developmental age (Piaget, Elkind), whereas others focus on explaining the processes of cognition that occur regardless of age-specific considerations (information-processing theories).

TABLE 3 – 5

Temperament Categories

Category	Definition	Examples of Characteristic Behaviors
Activity level	Amount of physical energy that drives the child in most situations; includes proportion of active and inactive periods	Low activity, moves at a slower pace; prefers inactive pastimes such as coloring or playing quietly with toys High activity, full of energy; fidgety when asked to sit still; restless on days when has to stay inside; tends to be impulsive (acting before thinking)
Self-control	Ability to delay actions or demands	Is patient if demonstrates good self-control, is impulsive if demonstrates poor self-control
Rhythmicity or regularity	Predictability or unpredictability of the child's biologic patterns such as sleep, hunger, and elimination	Very rhythmic regular sleep patterns; will get tired at almost the same time each day; will have a bowel movement every morning around the same time Arrhythmic irregular sleep patterns; gets tired at different times each day; bowel movements not predictable
Initial response	Typical initial response of the child to a new stimulus such as a new food, toy, person, or situation	Approachable, jumps right in to new situations without hesitation Withdrawn, holds back in a new situation until feels comfortable
Adaptability	Tolerance of change; ease with which gets used to new or changed situations	Very adaptable; tends to be compliant, cooperative, and go with the flow Slowly adapts; tends to be stubborn, strong willed, or headstrong
Sensory threshold	Level of stimulation that evokes a response; how sensitive a child is in each sense (touch, pain, hearing, smell, and vision)	High threshold; does not seem to be sensitive to environmental stimuli that affects the senses (e.g., will be able to wear most any clothes, even those that are tight fitting because of high threshold to touch) Low threshold; highly sensitive to stimuli that affects the senses (e.g., always likes to smell things and may refuse to wear certain clothes because they feel “funny”)
Intensity of reaction	Amount of energy used to express emotions and actions	Low intensity; expresses emotions quietly and in a low-keyed fashion High intensity; tends to be loud and dramatic when expressing emotions
Predominant mood	General quality of mood; amount of pleasant, joyful, and friendly behavior compared with amount of unpleasant and unfriendly behavior	Positive mood; views the world through rose-colored glasses; tends to miss negative and notice positive things Negative mood; tends to miss positive and notice negative things
Distractibility/concentration	Degree to which extraneous environmental stimuli can be distracting and interfere with ongoing behavior	Low distractibility; gets caught up in what he or she is paying attention to and may not notice the things going on in the environment High distractibility; tends to shift attention quickly and often, may get easily sidetracked when trying to complete a task
Attention span and persistence	Length of time an activity is pursued along with the child's capacity to continue the activity despite obstacles	High persistence; tends to stick with difficult tasks and may not give up even when a task is well beyond his or her skill level Low persistence; tends to become frustrated and may quickly ask for help, get angry, or simply give up on a difficult task.

Piaget's Theory

Since the 1930s, Jean Piaget has been a leader in the exploration of cognitive development. He outlined a complex four-stage theory to explain the assimilation and accommodation of information. *Assimilation* refers to the process of taking in information from the environment and incorporating this into one's existing knowledge structure, or *schema*. When this information changes the person's existing schema to include the new information, this process is called *accommodation*. Each stage is characterized by a different way of thinking, or of assimilating and accommodating information. Progress through each stage is gradual and orderly, varying in pace from child to child (Piaget, 1926). Piaget's stages of cognitive development are summarized in Table 3–6. Piaget coined many terms to explain the concepts in his theory. Definitions of these terms are found at [thePoint](#) for Supplemental Information: Piaget's Terminology.

The original work of Piaget has been criticized for its weak scientific approach. Piaget used his own two children as subjects to develop his theory. His experiments were not controlled. He presented the children with a problem and observed how they reasoned and how they tried to solve that problem. Therefore, he may have underestimated the influence of formal learning on the development of cognitive processes. Piaget was able to articulate the sequences of development that lead a child to the point of adult understanding of such concepts as mathematics, time, and space. His theory does point to the importance of active experience in a child's development. Parents are encouraged to seek activities and to provide play experiences for their children that give them the opportunity to solve problems and reason in a logical manner. Piaget's theories are of particular importance to healthcare personnel to better understand how children think about health-related events (Clinical Judgment 3–2). The nurse who is able to articulate the developmental differences in the cognitive abilities of children is better able to implement the nursing process in an age-appropriate, individualized manner.

Elkind's Theory

Piagetian theory has been analyzed and expanded by numerous individuals. Psychologist David Elkind focused some of his work on explaining the nature of egocentrism in children. Egocentrism refers to the lack of differentiation in some area of interaction. At each stage in development, this lack of differentiation takes a unique form and is manifested in unique ways (Elkind, 1967, 1986). Children view reality quite differently at different age levels. Children's view of reality can be distorted to the degree that egocentric thought affects their behavior and actions. During infancy, the child experiences a lack of differentiation between the object and the "experiences of the object" (Elkind, 1967). The young child is unable to differentiate between words and their referents, and to differentiate among self-created play, dream symbols, and reality. As the child matures, middle childhood is characterized by an inability to differentiate between mental

constructs and perceptual givens. Adolescents are able to conceptualize the thoughts of both themselves and others; however, they are unable to differentiate between what others are thinking about and their own mental preoccupation (Elkind, 1967, 1984).

A primary focus of Elkind's work has been on adolescent thinking. Because of the emerging ability to think abstractly, adolescents become preoccupied with ideological issues (social, political, and religious). Concepts like metaphor and simile can be grasped, as well as contradictions in belief systems. On the other hand, the egocentrism of adolescence creates a situation in which the adolescent does not make totally rational choices because he or she is so caught up and consumed by thoughts of self and self-needs.

Elkind described four behaviors that typify adolescent egocentric thought processes. *Pseudostupidity* occurs when the adolescent asks apparently "dumb" questions, indicating difficulty reconciling concrete and formal operations. For instance, a trumpet player who has a band concert that evening may ask the band director if he needs to take his instrument. The *imaginary audience* is characterized by super-self-consciousness. For example, an adolescent may believe that everybody is watching him and evaluating his actions and behaviors. In a sense, he believes he is onstage and everyone is focused on his activity. What he fails to perceive is that all adolescents have the same sense of super-self-consciousness; thus, as individuals, they are all focused on their own actions and what others may think, and they spend little time concerned about the actions of others. *Personal fable* occurs because the adolescent thinks he or she is more special than anyone else and not subject to the natural laws. For example, an adolescent's friend gets pregnant; despite this, the adolescent continues having unprotected sexual relations, believing that she will never get pregnant. Last, the adolescent is characterized by *apparent hypocrisy*. The adolescent expresses an idea and believes that such expression is the same as having worked for and achieved an action. Or, the adolescent will claim a certain ideology and yet take actions that are in direct contrast to his or her stated beliefs. For example, the adolescent will criticize the horrible conditions caused by environmental pollutants and then will drop trash from the window of a car. No correlation is made between expressed ideologies and practical action.

Gardner's Theory

Students of psychology and education have embraced a theory of human intelligence that is broader and more comprehensive in its approach than previously accepted cognitive theories. The study of **multiple intelligences**, developed by Dr. Howard Gardner, addresses the concept that humans possess different talents, or multiple capacities, ranging from musical intelligence to the intelligence involved in understanding one's self (Table 3–7) (Gardner, 1993, 2006).

Gardner's theory specifically challenges the prevalent notion that intelligence is tied to the ability to provide succinct answers in a speedy fashion to problems primarily

TABLE 3 – 6

Piaget's Stages of Cognitive Development

Stage	Characteristics
<i>Sensorimotor Stage, Birth to 2 Years</i>	
Substage 1: use of reflexes, birth to 1 month	Reflex responses to external stimuli Random body movements Genuinely intelligent behavior absent
Substage 2: primary circular reactions, 1 to 4 months	Active effort to reproduce behavior that was first performed by chance Accidentally acquired behavior becomes a new sensorimotor habit
Substage 3: secondary circular reactions, 4 to 8 months	Greater awareness of environment Increased interest in results of actions Understanding causality by recognizing that certain actions have certain results Dim awareness of before and after Achievement of hand–eye coordination Beginning development of object permanence
Substage 4: coordination of secondary circular reactions, 8 to 12 months	Solution of simple problems possible Demonstration of anticipatory behavior More highly developed object permanence
Substage 5: tertiary circular reactions, 12 to 18 months	Rudimentary trial and error activities present Beginning of reasoning Evident object permanence
Substage 6: invention of new meanings through deduction, 18 to 24 months	Well-developed understanding of the nature of objects Understanding of the basic concept of causality Well-developed object permanence View of self as separate from others Ability to use symbols mentally
<i>Preoperational Stage, 2 to 7 Years</i>	
Stage 1: preconceptual stage, 2 to 4 years	Formation of symbolic thought Egocentrism in thoughts, feelings, and experiences Egocentrism in perception of objects and events Display of deferred imitation Understanding of instructions literally
Stage 2: perceptual or intuitive stage, 4 to 7 years	Appearance of prelogical reasoning Judgment of experiences and objects by outside appearances and results Ability to concentrate on only one characteristic of an object at a time (centration) Use of words to express thoughts Demonstration of illogical reasoning (transductive reasoning) Play becomes more socialized
Concrete Operations, 7 to 11 Years	Acquisition of conceptual skills that permit logical manipulation of symbols Thinking is still limited by reliance on what is observed, on tangible concrete events or objects Ability to shift attention from one perceptual attribute to another (decentration) Ability to reverse thinking (reversibility) Acquisition of conservation skills Enjoyment in collecting and classifying objects Ability to appreciate a joke
Formal Operations, 11 Years to Death	Ability to manipulate abstract and unobservable concepts logically Use of scientific approach to solve problems Ability to conceive the distant future concretely and to set realistic long-term goals Ability to solve complex verbal problems

CLINICAL JUDGMENT 3–2

Assessment of Cognitive and Psychosocial Development

Jordan (age 7) and Daniel (age 4) are brothers admitted to the hospital as a result of injuries obtained in a motor vehicle accident. They share a hospital room. They will be discharged later in the day after teaching has been completed regarding care of their wounds. As you enter the room, they are yelling at each other, fighting over which television show to watch. The parents left to eat breakfast. Jordan has a set of small blocks on his bedside table; Daniel has six small race cars on the bed beside him. A unopened model for a plane is located at the end of Daniel's bed.

Questions

1. Based upon your quick assessment of the situation, what will be the focus of your interactions with the boys today?
2. According to their ages, what stages of cognitive and psychosocial development would you place the boys in as a beginning point for your assessment?
3. Do you think the boys are acting in an age-appropriate fashion?
4. After you get the boys to calm down, you tell them that you will be teaching them how to care for their injuries at home. What aspects of this would be appropriate to teach each boy?
5. When the boys are being discharged, how would you determine whether your teaching was effective?

Answers

1. Providing age-appropriate diversionary activities, explaining the rules of conduct while in the hospital, providing discharge teaching regarding wound care

2. Jordan: middle childhood, latency stage (Freud), industry versus inferiority (Erikson), concrete operations (Piaget); Daniel: early childhood, phallic stage (Freud), initiative versus guilt (Erikson), preoperational stage (Piaget)
3. Yes. Sibling fighting would be expected at these ages. The toys they are playing with are appropriate for their age. The airplane model is too advanced for Daniel's level of fine motor skills; however, this is probably why it remains unopened on his bed.
4. Teach the boys separately, because your approach needs to be different with each child. Daniel should be taught first. Terminology needs to be very simple. He can assist in his care by taking off the tape, opening packages, and helping to put the new dressing back on the wound. He can practice these activities on a doll. These activities promote feelings of accomplishment within Daniel's developmental skill level. Jordan can watch Daniel, but should be asked not to intervene. When it is Jordan's turn, Jordan can participate by gathering the necessary equipment, removing the bandage, completing the first cleaning of the wound (parents do the second), and placing a new bandage on his wound. He should also clean up after the task is finished.
5. Jordan is able to tell his parents what they will need to clean his wounds and can demonstrate on a doll how to complete the dressing change. Daniel states he is the helper. His job is to be still and help his parent change his bandage.

involving linguistic and logical skills (Gardner, 1993, 2006). In particular, the theory of multiple intelligences steps beyond the definitions of cognitive development asserted by theorists such as Jean Piaget. Gardner believes that Piaget and others have measured and developed their theories based primarily on a single dimension of cognition: the development of logical-mathematical intelligence. Multiple intelligences theory takes a more pluralistic view, recognizing that there are many different and discrete facets of cognition. Gardner's theory acknowledges that different people have different cognitive strengths and contrasting cognitive styles (Gardner, 1993, 2006). His theory challenges the dependence on the linguistic mode of instruction utilized by most educators and educational systems as the primary and most effective manner in which to help children learn. Gardner believes that all the intelligences are unevenly

distributed, coexist, and can change over time. The responsibility of educators is to capitalize on the student's individual intellectual strengths.

The theory of multiple intelligences stems from the premise that there is a natural developmental trajectory of learning that begins with *raw patterning ability*. The "raw" intelligence is predominant during the first year of life. In subsequent stages, the intelligences are grasped through a *symbol system*. These symbols include learning sentences through stories, learning music through singing and playing songs, and experiencing body-kinesthetic development through dance (Fig. 3–18). Children demonstrate their abilities in the various intelligences through their grasp of the various symbol systems. As development progresses, each intelligence with its accompanying symbol system is represented in a *notational system*. For instance, mathematics, reading, musical notation, and

TABLE 3 – 7

The Eight Intelligences

Intelligence	Application
Linguistic: the gift of language	Poets, authors, writers
Logical–mathematical: problem-solving abilities	Mathematicians, accountants, cashiers, scientists
Spatial: ability to form a mental model of a spatial world and be able to maneuver and operate using that model	Sailors, engineers, surgeons, sculptors, painters
Musical: ability to play an instrument, sing, create music	Musicians, composers
Body–kinesthetic: ability to solve problems or to fashion products using one’s whole body or parts of the body	Dancers, athletes, surgeons, craftspeople
Naturalist: ability to distinguish between different kinds of plants and animals	Zoologists, botanists, microbiologists
Interpersonal: ability to understand other people, what motivates them, how they work, how to cooperate with them	Salespeople, teachers, politicians, clinicians, religious leaders
Intrapersonal: capacity to form an accurate understanding of oneself and be able to use that understanding to operate effectively in life; allows one to understand and work with oneself	Evidence in any life experiences in which it is clear that the person truly understands his or her feelings and emotions and uses this knowledge to understand and guide personal behavior

mapping are second-order notational systems. The marks on the paper come to stand for symbols. In our culture, mastery of these symbols is typically acquired in a formal educational system. During adolescence and adulthood,

FIGURE 3–18. Multiple intelligence theory asserts that a young child’s interest in certain activities and skills should be nurtured, because this may represent a high level of intelligence in that area.

the mastery of an intelligence is expressed through vocational and professional pursuits.

In each of the intelligence domains, it is possible to have *at-promise individuals*. These are people who are highly endowed with the core abilities and skills of that intelligence. For example, Babe Ruth, the famous baseball player, was outstanding in body–kinesthetic intelligence. With each intelligence, the particular developmental trajectory of an individual “at promise” varies. For instance, some young children with mathematical or musical intelligence are able to perform at, or near, adult-level expectations. In contrast, the interpersonal and intrapersonal intelligences appear to develop more gradually, and child prodigies in these areas are rare. In addition, mature performance in one area does not imply mature performance in another area.

Knowledge of these intelligence categories can be used by parents, teachers, and healthcare professionals to provide activities to enhance development of the child’s intelligences. Parents can assist children in their choice of activities and assist adolescents in their choice of careers within the context of their dominant intelligence. Teachers and the educational system can create individual-centered schools where student profiles, goals, and interests are matched to particular curricula and particular styles of teaching and learning.

Behavioral Development

Behaviorism is structured on the interactions that occur between a child and his or her environment, which in turn determines the behavior of the child. Behaviorists believe that the roots of a person’s behavior are tied to his or her experiences. If experience (the environment) is altered, then behavior change follows. This approach has

been very successful in modifying the behaviors of some people in certain circumstances. The two most prevalent behavioral techniques are classical conditioning, developed by Pavlov and Watson, and operant conditioning, developed by Skinner. These behavioral theories have been criticized for their mechanical approach to human interactions. The effects of the consciousness and thought processes on individual action are not well accounted for by these theories. Human behavior is afforded little qualitative difference from the behavior and expected responses in animals. These theories are well tested in the laboratory setting, with an emphasis on the effects of the environment on human behavior. However, translation of these findings to real-life settings, where other mental processes may come into play, demonstrates that classical and operant conditionings can only partially explain a person's behavior.

Classical Conditioning Theories

Classical conditioning was first introduced by Ivan Pavlov and was further explored by John Watson. The approach to learning involves pairing a neutral stimulus with an unconditioned stimulus to elicit an unconditioned response. This process is continued until the neutral stimulus is able to elicit a response without being paired with the original stimulus. The stimulus that elicits the response before conditioning is called the *unconditioned stimulus*. The subsequent response is the *unconditioned response*. The *conditioned stimulus* is a neutral stimulus that, when paired with the unconditioned stimulus, eventually elicits the desired response by itself. The learned response is the *conditioned response*. In a similar circumstance, the individual learns stimulus generalization—that is, to apply the association of a certain behavior with a stimulus to circumstances that feature similar stimuli. The individual eventually learns *discrimination* (the process of differentiating among stimuli) and *extinction* (the weakening and disappearance of a learned response).

Classical conditioning has been thoroughly evaluated in laboratory settings in which the environment and exposure to stimuli can be highly monitored. It is a useful theory in understanding acquired emotional responses in children (e.g., unusual fears about dogs). The theory does not take into account the higher mental capacities of humans to utilize thinking and information-processing abilities to determine response patterns.

Skinner's Theory

QUESTION: Joellen and Chris describe the various methods they have used to control and stop James' temper tantrums. They report using different types of rewards if he does not have a tantrum. They have offered him special snacks, toys, or extra playtime, all without much success. Explain what is happening using Skinner's theory.

Operant conditioning holds that behaviors are repeated or are reduced in frequency based on the environmental

consequences of reinforcement or punishment. B. F. Skinner popularized this concept of *stimulus–response learning*. In operant conditioning, the child's behavior is followed by a negative or positive reinforcer that decreases or increases the likelihood of that behavior being repeated. A *positive reinforcer* is a pleasant stimulus that follows a behavior and that increases the frequency of that behavior. For instance, giving a child a piece of candy each time he sits still during a haircut is a positive reinforcer that rewards the child and encourages him to sit still the next time he has a haircut because the child anticipates receiving more candy. A *negative reinforcer* is activated when an unpleasant stimulus is removed after a behavior has occurred and results in an increase in frequency of that behavior. For instance, a laboratory rat is placed in a box with an electric floor grid that delivers a shock to the rat. Each time the rat presses a lever, there is a cessation in the shocks. Thus, the rat is reinforced to press the lever and remove the unpleasant stimuli. *Punishment* is the process by which an unpleasant stimulus is introduced after a response has been made and the response decreases. The child who receives a spanking for biting a sibling would be expected not to repeat the biting behavior. Skinner and his associates also believed that behavior could be shaped. *Shaping* is the process in which a new behavior is acquired by taking a known behavior and continually reinforcing it to bring it closer and closer to the desired behavior. These principles have been applied successfully as behavior modification techniques to change parenting responses to a child's actions and vice versa.

ANSWER: Joellen's and Chris' actions are acting as positive reinforcers of James' behavior. They are using something pleasant, something that James enjoys, thereby encouraging him to continue the tantrums. James is learning that if he has a tantrum, he will get something good.

Social Learning Theories

The social learning theories explain human behavior based on the processes of imitation, observation learning, and reinforcement. The primary developers of social learning theory are Albert Bandura and Robert Sears. Although the behavioral theories stress the importance of structuring stimuli and reinforcements to create certain behavioral responses, social learning theorists acknowledge that a child does not have to be reinforced or punished to change his or her behavior. Children learn by observing and imitating. They watch and monitor the consequences of the behavior of others. Therefore, others, especially parents, siblings, and peers, serve as models for the child's behavior. Simply observing another person may be sufficient to lead to a learned response. Reinforcement, particularly parental reinforcement, may not be needed to elicit the learned response.

Role models who hold a high status in the child's eyes are seen as especially credible. For example, a child may

watch a cartoon show and see characters interacting and fighting in a certain manner. If he is not familiar with the show, the child will most likely not imitate what he has seen. However, when the child goes to daycare and observes several of the other children pretending to be the same cartoon characters, he will be more inclined to imitate the behaviors of his respected friends. Social learning theories are helpful in explaining the powerful influence that social groups and the media can have on children's behavior. Although parents may choose not to exhibit or to expose their children to certain behaviors in the home, children may be influenced by modeling what is occurring in their play group or by other influential adults, such as grandparents or family friends.

Social learning theories are useful to help understand the presence of certain behaviors in children that may be learned from modeling, such as altruism and aggression. Parents should be encouraged to look at the models in their children's environment and to be aware of the powerful influence others can have on the child's behavior.

Humanistic Theories

The humanistic theories of development are also called the *phenomenologic theories*. These theories emphasize and value the meanings associated with the human experience itself and postulate that what a person perceives the world to be is more important than external reality. From the humanistic viewpoint, all people are seen as basically good, with a desire to become all that they are capable of being. The experiences a person has within the family and the environment either hinder or foster the potential for growth. Humanistic theories are built on the tenet that people cannot love others unless they love themselves. Everyone is unique, and the major focus in psychology should be to emphasize this uniqueness rather than try to fit actions and behaviors into universal laws and behaviors. Thus, a major goal of parenting is to foster an environment in which the individual child feels loved and accepted for what he or she is, even if that differs from parental hopes or expectations. Child rearing should involve few rules, roles, and expectations of what constitutes a "good child." Feelings of guilt and punishment are seen as counterproductive to fostering acceptance and self-actualization. Some of the major theorists who have contributed to the humanistic approach are Abraham Maslow, Carl Rogers, and Albert Ellis (Chart 3–3). Their theories help to explain how people achieve and maintain a healthy personality. The humanistic theorists do not spend a lot of time trying to explain or to understand a person's past experiences as they relate to current behavior. Rather, their emphasis is on the "here and now" and on the belief that all people have the potential to enhance their emotional lives and psychological well-being.

Language Development

Although the word *infant* means "without language," language acquisition is rooted in infancy through the many

CHART 3–3 HUMANISTIC THEORIES

Abraham Maslow

Basic human needs are organized into a hierarchy of relative potency from lower order requirements such as physiologic needs and safety to higher order needs such as love, esteem, and self-actualization.

Carl Rogers

We all shape our own personalities. To change we must acknowledge to ourselves what we are. People should not impose their negative opinions, their directions, and their value systems on others.

Albert Ellis

There are four human life goals: to survive, to be happy, to get along with members of a social group, and to relate intimately with a few select members of this group. People make assumptions about how to meet these goals and evaluate meanings attached to these goals. Belief systems that are based on irrational assumptions and meanings lead to disturbed emotional reactions.

verbal and nonverbal exchanges children have with their caregivers. Language is the symbol system used for the storage and exchange of information, and is a basic tool used for interpersonal relationships. It is also a primary indicator of a child's developmental level. For example, speech acquisition is tied to the achievement of other physiologic and social factors such as neurologic maturation, musculoskeletal development, and the innate desire to communicate with others. The child's ability to read and write are manifestations of language development. The presence of a speech or language disorder can have a profound affect on the child's ability to develop social relations, attain success in school, and feel confident when communicating with others (see Chapter 28 for a complete discussion of communication disorders). Although language development proceeds in certain predictable patterns, some children learn to speak sooner than others their age, whereas some children may acquire language much later. Albert Einstein and Winston Churchill are two famous individuals who are known to have been slow to speak in childhood.

Symbol Systems of Language

Language is conveyed through the use of three different symbol systems. One is *auditory expressive language*, the utterances of sound and eventually words. The earliest forms of auditory expressive language include open vowel sounds such as crying, cooing, and gurgling. By 5 months of age, laughing and the use of monosyllabic utterances, such as "ba" and "ga," appear. Humans also use *auditory receptive language*, which is the ability to listen and comprehend. The auditory receptive language skills of the young child are much more extensive than his or her auditory expressive language system. As early as the 26th

DEVELOPMENTAL CONSIDERATIONS 3–3

Development of Language

Age	Auditory Expressive Language	Auditory Receptive Language	Visual Language
Newborn	Cooing Crying	Responds to vocal stimuli by eye widening or changes in respiratory rate or suck rate	Gives alert visual fixation to caregiver's verbal stimuli Links mother's voice with her face and when crying is comforted by her voice
4–5 months	Laughing Monosyllables (ba, ga) Razzing	Turns head to locate source of a voice or bell	Social smile Visual localization of auditory stimuli (turning to a voice or a bell)
6–8 months	Polysyllabic babbling (lalalala)	Attends selectively to his or her own name when uttered by an adult	Attends to common gesture games like patty-cake and peek-a-boo
9–12 months	Sporadically utters “mama,” “dada”; then learns to spontaneously say “mama” and “dada” and label the correct parent Shakes head “no”	Responds to tones of voice Comprehends the words “no” and “stop” Listens selectively to familiar words	Reciprocates and initiates gesture games Waves bye-bye Expresses desires by pointing to object and making sounds or crying
12 months	Says one or two words other than “mama” or “dada” Begins to acquire one word per week	Responds to one-step commands (give it to me) unaccompanied by a gestural cue Can bring familiar object from another room on request	Uses index finger pointing and single-word naming to signify desired object
18–24 months	Uses 10–20 words	Has receptive vocabulary of more than 100 words	Points to body parts
24 months	Acquires one or more new words per day Has vocabulary of 50 words Begins to produce jargon and two-word phrases (“me down”) Begin to use pronouns Speech is one-half intelligible	Can follow simple novel two-step commands (put your shoes away, then go sit down) Name simple objects on command Has receptive vocabulary of more than 300 words	Points to objects on command
30 months	Beginning of telegraphic speech—three- to five-word sentences containing a recognizable subject and predicate but lacking conjunctions, articles the verb “to be” and other small connecting words (“Me want bear.”)	Points to objects described by use (give me the one we drink with) Follows prepositional commands (put the napkin under the cup)	Uses fingers to count one–two
3 years	Acquires several new words a day Uses three- to four-word sentences Uses regular plurals Uses pronouns (I, me, you) Can count three objects Can tell age, sex, and full name	Has receptive vocabulary of 800 words Knows function of common objects Understands spatial relationships (on, in, under)	Uses fingers to count or show age

Age	Auditory Expressive Language	Auditory Receptive Language	Visual Language
4 years	Speech is three-fourths intelligible Speaks four- to five-word sentences Can tell a story Uses past tense Names one color Can count four objects Speech is completely intelligible	Understands same/different	Begins to make letters and numbers
5–6 years	Normal dysfluency (stuttering) Speaks sentences of more than five words Uses future tense Names four colors Can count 10 or more objects Dysfluencies resolve Uses nouns, plurals, possessives Narrative has cause-and-effect sequence	Recalls part of a story Follows three-part commands Receptive language between 1500 and 2000 words Able to follow three- and four-step commands Understands “where,” “when,” and “why”	Matches identical shapes or figures Discriminates left versus right Copies square, circle, and cross Begins to write words Begins to read
7–9 years	Uses temporal prepositions (before, after) Uses past and future tenses Narrative has proper sequence	Understands passive verb forms (the cat was hit by a car)	No reversals of “b” and “d” persist Sight word vocabulary increases
10–12 years	Changes style of language (formal versus informal) to fit different contexts and different listeners (parents versus peers)	Understands multiple meanings of words Knows meanings of figurative language (simile, metaphor, analogy)	Attempts three-dimensional shapes in artwork Copies complex shapes and figures Begins to understand maps and geography Good sight word vocabulary
13 years	Complex sentence structure Can speak and write about abstract concepts	Understands linguistic explanations of abstract concepts Understands how to “play on words” (Call me a cab. Okay, hi cab)	Understands architectural plans Understands complex spatial relationships Uses and creates maps and schematic drawings

week of gestation, fetuses can respond to sound. Development of auditory expressive and auditory receptive language skills are summarized in Developmental Considerations 3–3. It is important for parents to understand that if they use simple, clear language when speaking to a young child, effective communication can take place, even if the child is not yet speaking.

caREminder

Healthcare providers need to be careful about the topics they discuss in the presence of a young child. The child may comprehend several of the key points of the dialogue, yet may misinterpret their full meaning based on limited cognitive development.

Language is also conveyed *visually*. Gestures and hand signals are used to convey a broad scope of expressive meaning. The American Sign Language system is based on visual language skills. Prelinguistic visual milestones begin with the newborn who attends to language with alert visual fixation. As the child acquires verbal language skills, he or she will be using a broad scope of visual language skills to communicate with others. For instance, the social smile indicates that the child is happy or pleased with the actions of another person. The young child learns to wave bye-bye, blow a kiss, and point to the ground when he or she wants out of a high chair. The child points to objects he or she wants and screams if the parent does not understand this communication. Deaf infants exposed to American Sign Language use their

visual and receptive language skills to acquire language that parallels the stages of oral language development in the hearing child.

Factors That Influence Language Development

Girls are generally more advanced than boys in verbal acquisition. The speech control center of the brain is located in the dominant cerebral hemisphere, which for most individuals is on the left side. During infancy and early childhood, girls demonstrate advanced development of their left cerebral hemisphere, which accelerates verbal fluency. First-born and only children may have more advanced language skills than children who are born later. This is because younger siblings may not receive as much direct verbal input from adults as the first-born child. In addition, the linguistic input from older siblings is not as optimal as that received from an adult in regard to learning correct language rules and structure.

WORLDVIEW: It was once thought that children who were exposed to two languages at the same time had delays in language acquisition and had lower IQs when compared with monolingual children. Current research does not substantiate these myths. Bilingualism does not cause language delays nor does it interfere with cognitive development. Bilingual children who acquired their second language at an early age have demonstrated more flexibility in their use of labels and words. Bilingual children demonstrated higher cognitive capabilities than monolingual children. In addition, bilingual children learn to see the world from two different perspectives and from two different cultures (Fierro-Cobas and Chan, 2001).

A primary influence on impaired auditory expressive language development is the presence of hearing loss (discussed earlier in this chapter). Hearing loss can be congenital or acquired. Mild to moderate transient hearing loss can also be associated with otitis media with effusion.

Alert! Approximately 2.2 million children are diagnosed annually with episodes of otitis media with effusion (Grassia, 2004). The child who experiences an increased incidence of this disorder should be evaluated for hearing loss, and delays in speech development should be monitored carefully as the child's clinical condition improves. If speech development remains delayed or impaired, referral to a speech therapist is warranted.

The presence of a developmental disorder may affect language acquisition. For instance, children who are mentally retarded have language delay in all areas: auditory expressive, auditory receptive, and visual. The child with a developmental language disorder will have variable degrees of expressive and receptive language impairment. Visual language skills are usually normal. Children who are autistic display delayed and deviant language.

Gender Identification and Sexual Development

A child's gender identification and sexual development are influenced by biologic, social, and psychological factors. The biologic factors include the child's chromosomal sex, the external sexual organs, and the internal reproductive structures. Biologic problems can occur in which a child's gender is difficult to determine at birth because of the presence of ambiguous genitalia or chromosomal abnormalities. In these cases, the sexual identification that is assigned and the subsequent style of child rearing may not be consistent with the hormonal and structural factors that were present at birth. Gender identity disorder is a condition in which persons experience persistent discomfort with their assigned gender (gender determined at conception) and feels more comfortable identifying themselves as belonging to another gender.

The social and psychological factors of sexual development interact to create a person's gender identity. Throughout a child's life, interactions with significant adults and peers affect the self-perception, the preferences, and the gender-associated behaviors that are culturally attributed to males or females.

Gender identification and the awareness of one's sexuality begin in early childhood. The foundation for this process has already been laid with the development of trust and consistency of need fulfillment obtained during infancy. As the child's cognitive processes and language skills increase, opportunities arise that reinforce gender identification. The child quickly learns to imitate gender behavior and to pretend to be mommy or daddy. The child learns to name and to draw body parts. Body orifices are explored, and questions about the mother's or father's body may arise. Encourage parents to use correct terminology when referring to body parts and not to overact if the child is seen exploring his or her body parts.

During early childhood, parents may note a definite focus by the child on his or her genitalia and "private" parts. Name-calling using words associated with the genitalia or the elimination processes is common. The child continues to explore the body through masturbation and exploration of other children's genitalia. Parents should be teaching about personal privacy and the social appropriateness of actions. Facts about reproduction should be given.

caREminder

Children at this stage should be taught about who can, and under what conditions someone can, touch their genitalia or "private" parts, and what to do if someone touches them inappropriately.

The middle childhood years mark a change from focusing primarily on the parents for gender identification toward a focus on peers for identity development. Children at this age may engage in kissing, hugging, and other forms of physical contact with members of the

opposite sex. Expressions of sexuality are primarily a response of cognitive and emotional factors, rather than physical desire. The child develops close relationships with boys and girls in his or her age group. Within the context of these relationships, sexual stereotyping and role playing is reinforced. Parents and other significant adults should offer basic information about the changes that occur in the body with adolescence. In addition, discussions regarding reproduction and sexual activity should take place. Both the school-aged child and the adolescent will seek out this information from other “sources” to answer their queries. These other sources may provide inaccurate and misleading information to the young person.

The adolescent experiences tremendous changes in his or her sexual development as he or she deals with the physical maturation of the sexual organs (see the section on genitalia development and pubertal changes earlier in this chapter). Throughout puberty, the adolescent explores the changes in his or her body and the way it functions. Physical sexual desire may emerge, or responses to physical stimuli may be associated more with the need for emotional gratification rather than physical needs (Fig. 3–19). During this period, adults should

encourage the adolescent to express his or her feelings regarding his or her changing body and corresponding emotions. Parents can assist in clarifying values and in making decisions regarding gender-related activities. Information regarding sexually transmitted diseases, contraception, and pregnancy should be readily available for the adolescent. Many healthcare providers are directing their efforts toward encouraging adolescents to delay the start of intercourse. The increasing number of boys and girls having intercourse at earlier ages means that there is likely to be a variety of partners over time with a corresponding increase in the incidence of sexually transmitted diseases and teenage pregnancies.

Moral Development

Moral development is thought to be significantly correlated with intellectual reasoning and age. Psychologists differ in their beliefs regarding how a child’s moral reasoning and subsequent moral behaviors develop.

Theoretical Perspectives of Moral Development

Proponents of Freudian psychology believe that it is the *superego*, the inner conscience of the child, that influences moral behavior. According to this theory, the child seeks to identify and internalize the ideals and values of adults around them, creating an ego ideal. The child’s conscience will cause a sense of guilt when misbehavior occurs. Thus, morality is an outcome of the ego ideal and the conscience acting together to regulate thoughts and actions within the superego.

Giving another view of the process, the behaviorist believes that moral behavior is learned like any other behavior. Sharing, giving, lying, and stealing are actions that are reinforced (positively or negatively) by authority figures and are therefore incorporated into the child’s repertoire of acceptable behaviors. Social learning theorists add that these actions are influenced by watching and imitating others. None of these theories has been widely accepted as a way to explain all the variations found in moral development.

Cognitive developmental theories are used most frequently to explain the processes of moral reasoning—that is, how individuals gain their ideas about right and wrong, and justice and injustice. Piaget outlined two stages of moral development. In the stage of *moral realism*, rules are viewed as sacred, literal, and inflexible. Justice is whatever the law or authority commands. Children in this stage cannot take into account the view of other people and can think of only one thing, or aspect of a thing, at a time. Children will evaluate their own acts based on the consequences and the desire to avoid punishment, not the intent or motivation.

At ages 7 to 8 years, interaction with peers begins to be influenced by a sense of give and take. “Fairness” becomes a prominent issue. The stage called *moral relativism* emerges around age 11 or 12. During this stage, children learn to evaluate the intentions of others before

FIGURE 3–19. During adolescence, emerging sexuality is expressed in the development of intimate relationships.

judging their answers as right or wrong. Thinking is no longer egocentric. Motives and circumstances can be taken into account when making a moral judgment. Rules are more flexible and can be elaborated and applied to several different situations and scenarios.

The sequence of moral development can be more fully understood by evaluating the works of Lawrence Kohlberg and Carol Gilligan.

Kohlberg's Theory

Kohlberg (1981) identified three levels of moral reasoning, with two stages at each level (Table 3–8). Kohlberg's theory has been the most widely tested and successfully applied to many cultures. In this stage theory, sequential development must occur to attain the next higher stage of moral reasoning. Levels of development correlate with the reasoning behind moral decisions, not the decisions

or acts themselves. The higher stages of reasoning place an emphasis on justice, individual rights, and the rights of others.

Gilligan's Theory

Carol Gilligan (1982) has challenged this view, asserting instead that women have a different orientation to moral questions. Gilligan feels that females view moral questions in terms of how the issues affect interpersonal relationships, whereas the male emphasis is on individual rights and self-fulfillment. Gilligan does not believe that Kohlberg's model reflects these gender-based responses to morality. In her view, the differences in moral reasoning can be traced to the differences in child-rearing practices of boys and girls. Boys are more likely to be encouraged to be independent, assertive, and achievement oriented. Duty and fairness are highly emphasized.

TABLE 3–8

Kohlberg's Six Stages of Moral Reasoning

Stage	Moral Outlook	Reasons for Moral Actions
<i>Preconventional Morality</i>		
Stage 1: punishment and obedience orientation, ages 5 to 8	Avoid breaking rules	Avoidance of punishment
Stage 2: instrumental relativist orientation, ages 7 to 10	Right actions satisfy one's own needs and only sometimes the needs of others	Desire to serve one's own interests in a world where everyone has his own interests If you help others, they will owe you something, which is a debt to be collected later
<i>Conventional Morality</i>		
Stage 3: interpersonal concordance of "good boy–nice girl" orientation, ages 10 to 12	Good behavior is that which pleases or helps others and is approved by them	Need to see oneself as a good person Belief in the Golden Rule Desire to maintain rules and follow authority to support stereotypical good behavior Need to gain approval of others
Stage 4: law and order orientation, ages 12 to 25	Orientation toward authority, fixed rules, and the maintenance of the social order	Need to do one's duty and to show respect for authority and the social order
<i>Postconventional Morality</i>		
Stage 5: social contract legalistic orientation, ages 25 to 35 (if reached)	Aware that people hold a variety of values and opinions, although there are also rights and rules that have been constitutionally and democratically agreed on	Obligation to law because of one's social contract with society Good is done because it serves the greatest number of people
Stage 6: universal ethical principle orientation, ages 25 to 35 (if reached)	Self-chosen ethical principles based on abstract principles are the foundation for action; laws or social agreements are considered valid because they are consistent with one's ethical principles	A belief and commitment to the validity of universal moral principles Desire to uphold abstract principles that define right behavior for self Unjust laws may be broken when they conflict with broad moral principles

TABLE 3–9

Gilligan's Stages of Moral Development

Stage	Description
Stage 1: survival orientation	Egocentric perspective describes a great concern for self and a lack of awareness of other's needs. Being moral is surviving by being submissive to authority and the moral sanctions imposed by society.
<i>Transition from selfishness to responsibility</i>	<i>Responsibility for and to others is more important than survival and submission.</i>
Stage 2: conventional care	There is a lack of distinction between what others want and what is right. The right, or moral, action is whatever pleases others best. Being moral involves not hurting others, with no thought of the hurt to self that might be done.
<i>Transition from goodness to truth</i>	<i>Move from not simply hurting others, but also not hurting self through one's moral actions.</i>
Stage 3: integrated care	The needs of self and others becomes integrated. Moral actions take into account equally self-beliefs as well as other's beliefs.

In contrast, girls are more likely to be encouraged to nurture, to take responsibility for others, and to learn to be sensitive and caring. Moral decisions can cause internal conflict between the female's perception of her personal needs and the needs of others. In many cases, a female's decisions are made to maintain or solidify the relationship with others rather than assert her individual rights. Gilligan developed a model of the development of moral reasoning with three levels and two transitional stages to explain how feminine moral development is neither deviant nor arrested, but simply different (Table 3–9).

Spiritual Development: Fowler's Stages of Faith Development

QUESTION: Joellen and Chris have recently developed strong religious ties to a community church, and they ask how they can best foster spiritual development for James. What suggestions would you give based on James' current stage of faith development?

The spiritual dimension of the child encompasses the need to find satisfactory answers to the meaning of life, illness, and death. Although the need to find meaning and purpose for one's life does not generally begin to develop until early adolescence, all children experience a need for love, relatedness, and forgiveness. Throughout the child's life, questions regarding birth, suffering, death, hope, and forgiveness will be introduced and explored within the context of everyday experiences. The child's approach and response to these inquiries will be based on his or her corresponding level of cognitive and moral development.

Little research has been completed regarding spiritual development in children. It is known that faith, or the confidence or trust in a higher power, person, or thing, can be a driving force supporting the child and family through difficult times. Faith is most often associated with religious belief and the attitudes, observances of tenets, and values that are a part of a particular religious group. Fowler (1974) identified stages in the development of faith in children and adults (Table 3–10). Interventions can be provided that help the child meet his or her spiritual needs. These include encouraging children to read stories regarding faith and religious figures, encouraging the use of prayer, and promoting activities with other children that have a religious or spiritual focus (Fig. 3–20). Chapter 13 contains further discussion regarding meeting the spiritual needs of children experiencing grief and loss.

ANSWER: James is in stage 1 of faith development, the intuitive–projective stage. Joellen and Chris would be the primary providers of faith to James. Suggest that they role-model religious gestures and behaviors so that he can learn them. Also encourage them to read faith and religious stories to him, and help him learn prayers (simple ones that he can master, thereby promoting a sense of autonomy as well). Suggest that the parents engage in prayer with James as a role-modeling behavior. In addition, recommend that they participate in religious and faith activities with other families, including James' participation in religious or spiritual activities with other children who are the same age.

DEVELOPMENTAL SURVEILLANCE

Developmental, behavioral, and emotional problems can be difficult to detect in young children. Accurate assess-

TABLE 3 – 10
Stages of Faith Development

Description	Nursing Interventions
<i>Stage 0: Undifferentiated, Infancy</i>	
Feelings of trust, warmth, security, mistrust, and shame are incorporated into the child's conceptual ideas about himself or herself and his or her caregiver. These feelings are the foundation for subsequent faith development.	<ul style="list-style-type: none"> Focus is on supporting caregivers. Reassure parents about the adequacy of their parenting skills. Reassure parents that a child's illness is not a result of supernatural powers punishing them. Provide for trust and security needs of infant in parents' absence.
<i>Stage I: Intuitive–Projective, Early Childhood</i>	
Parents and other significant others provide primary knowledge of faith. Child learns to imitate religious gestures and behaviors. Egocentrism and magical thinking affect perceptions of transcendental beings. Child does not understand differences between natural and supernatural.	<ul style="list-style-type: none"> Minimize magical beliefs that are negative and destructive by focusing on reality. Help child to realize illness is not a result of “being bad.” Promote the continuance of religious rituals during illness and crises.
<i>Stage II: Mythical–Literal, Middle Childhood</i>	
<ul style="list-style-type: none"> Learns to distinguish religious fact from fantasy. Is heavily influenced by attitudes of family and authority figures such as priest, minister, or rabbi. Uses fantasies to explain events or facts that cannot be understood. Begins to learn to differentiate between natural and supernatural. Faith beliefs are concrete and literal. God is perceived as having human qualities and characteristics. Is able to articulate their faith. 	<ul style="list-style-type: none"> Clarify magical and fantastical beliefs through teaching. Explain all events and procedures that are unfamiliar in the healthcare setting. Promote use of prayer and other religious rituals. Allow child to talk about his or her faith.
<i>Stage III: Synthetic–Convention, Early Adolescence</i>	
Begins to reflect and question religious beliefs and practices as exposed to more varied opinions. Relies on authority figures for answers to questions of faith. Begins to perceive God as a spirit and understand spiritual component of others. More clearly understands differences between natural and supernatural.	<ul style="list-style-type: none"> Assure child that illness is not a result of punishment by a supernatural being. Clarify conflicting and confusing information to the child. Encourage visits by respected authority figures. Promote incorporation of religious rituals and articles into hospital environment as desired by the child.
<i>Stage IV: Individuating–Reflexive, Adolescence</i>	
Seeks to come to terms with own beliefs and personalize them. In the process, may reject previous religious training, revert to a previous stage of religious belief and practices, or adopt some other extreme hedonistic attitude. Faith is a blended application of self-expression and beliefs, and practices learned in the past.	<ul style="list-style-type: none"> Provide open and accepting attitude of child's beliefs. Engage in active listening as child “tries out” his or her emerging belief system. Offer support of authority figures, although these may be rejected at this time. Encourage use of religious rituals and articles as the child feels comfortable doing so.

ments of the child's growth and development may be hindered by infrequent access to the child to establish a developmental baseline assessment and to evaluate progress over time. Many problems may present very subtly. Therefore, the uncooperative child may elicit inconclusive or false-positive findings when attempts at direct assessment are being made by the practitioner. In addition, parents may not have accurate knowledge of the

developmental milestones that their child should be achieving at any given point in time.

The astute healthcare practitioner can utilize every contact with the child as an opportunity to apply **developmental surveillance**, the active and intentional evaluation of the child and the family to identify those who may be at risk for developmental variation. Developmental surveillance is a flexible, continuous process in which

FIGURE 3–20. (A) The preschool child might participate in religious rituals without having a full understanding of their meaning. (B) Religious practices and traditions guide adolescents in developing their own concept of spirituality. (Courtesy of Lou Metzger)

both informal and formal assessment techniques are used to evaluate the child’s developmental progress from birth onward. The developmental surveillance process should use parental concerns and informal clinical observation of the child as the basis for early detection of developmental delays. Additionally, nurses providing direct patient care should have a knowledge of the clinical conditions (i.e., low birth weight, birth asphyxia, infection) and the behaviors (i.e., irritability, head positioning, abnormal reflexes) that make the child at risk for the presence of developmental problems (Hertz, 2005). Figure 3–21 depicts the process that should be used to apply developmental surveillance techniques and to determine when to administer formal screening tests. Chapter 8 presents a summary of parental information and healthcare provider observations that can be elicited during contacts with the child and the family as part of the developmental surveillance process.

Developmental Assessment Tools

Valid assessment of children requires a perspective that encompasses quantitative as well as qualitative changes of developmental processes. Use of developmental screening tests has constituted the major approach to identification of children with developmental problems. Accurate screening contributes to parental well-being, helps distribute limited diagnostic services and healthcare dollars in an effective manner, and helps ensure that those children who need intervention are identified as early as possible.

A variety of developmental screening tests are available to assist the healthcare provider assess children suspected of delayed development. Nurses and other healthcare professionals should be aware that a developmental screening test evaluates a child’s development only at the current time, much like a snapshot captures the child’s image at a certain point in time. A common misconception is that a developmental screening test can identify all children who will later be “normal” and all those who will later exhibit delays in development. Attempting to predict later normal development on the basis of the results of a developmental screen is dangerous, because an array of environmental factors may subsequently intervene, influencing a child’s development. Individual variations from developmental norms may be transient and may indicate the need for more comprehensive evaluation. However, if a child exhibits major developmental delays early in life, predicting later developmental problems can be made with a somewhat greater degree of confidence, underscoring the importance of early intervention for children with developmental problems.

Developmental screening should be performed routinely on children to evaluate achievement of developmental milestones. Nursing Interventions 3–1 presents a set of guidelines that should be used during all screening procedures. Well-child healthcare visits are an opportune time to complete the screening. Hospitalized children can be assessed before discharge when they are likely to feel more like participating in the assessment. School and camp nurses may wish to utilize a screening tool if they suspect delays in a child’s development or if a teacher or

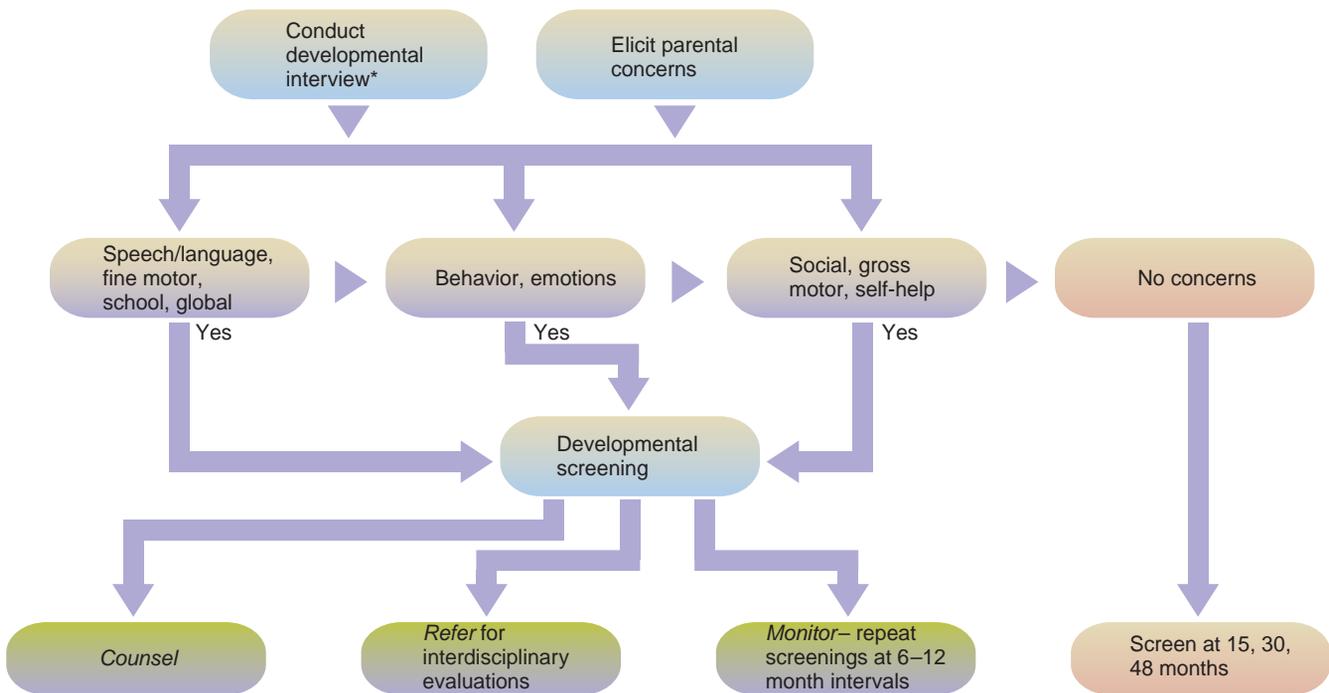

FIGURE 3–21. Developmental surveillance: the decision-making process.

NURSING INTERVENTIONS 3–1

Guidelines for Developmental Screening

- Screening instruments should only be used by those trained to administer the assessment.
- Screening tools should be reliable and valid.
- Developmental screening is best conducted in an environment that is familiar and free from other distractions for the child.
- The results of developmental screening will be more valid if the tasks are familiar and relevant to the child.
- Screening instruments should only be used for a specified purpose.
- Developmental screening should involve input from the child's primary caregiver. Parents, regardless of their education, are able to provide predictive information about their children.
- Screening should be used on a pass/fail basis only with a failed developmental screening leading to further assessment.
- Screening measures must be culturally sensitive. For non-English-speaking parents, use screening kits published in multiple language.
- Developmental screening should take place periodically, and as warranted, based on the parent's concerns.
- Developmental screening is one method to determine the need for more in-depth evaluation of the child.

caregiver shares concerns regarding an aspect of the child's development.

For parents, the data collected during such a screening provide information that can be used to guide activities with the child. If areas exist in which the child falls below age-specific achievements, instructions can be provided to assist the parents to enhance their child's skills in that area. Often, a child may demonstrate a specific delay simply because that task has not been emphasized in the home environment.

WORLDVIEW: Culture may highly influence a child's developmental achievements. For instance, in cultural environments in which fine motor skills are emphasized, delays in the area of gross motor development may be typical for that population. This is attributed to a cultural emphasis on development of fine motor skills in the young child.

When a child has marked developmental problems, a screening tool can be used to gather baseline data and can serve as a measure of future progress. If a developmental delay is assessed, the child should be referred to a specialist for more in-depth assessment and diagnosis. A variety of tools are presented on [thePoint](#) for Diagnostic Tests: Developmental Screening Tools. These tools can be used by the healthcare provider to assess normal achievements or specific tasks for a particular age. The tools are all considered to be valid and reliable, and vary in the amount of training required to administer them.

The Denver II is among one of the most commonly used developmental screening instrument by trained healthcare personnel (see Appendix B). A parent-answered prescreening form is also available called the *Prescreening Development Questionnaire* (PDQ-II). The Denver II provides an overall assessment of development that can be administered in a 15- to 20-minute period by individuals who have received training in the test administration and interpretation processes (Fig. 3–22). The PDQ-II consists of 150 questions from the Denver II. Parents are asked to answer a subset of these questions based on their child's age.

caREminder

If the child is ill, developmental screening may not be an accurate assessment of the child's skills and abilities. The child's weakness, anxiety, and physical restrictions could affect the outcome of the assessment. For instance, if a child has an intravenous line in his or her dominant right hand, then testing of fine motor skills may not accurately reflect the child's dexterity.

Developmental screening tests like the Denver II and the PDQ-II have value as an aid in developmental surveillance, when used in combination with parental concerns, child observations, immunizations, and anticipatory guidance to promote the child's growth and development.

FIGURE 3–22. During developmental screening tests, parents are encouraged to stay near the child and promote a sense of comfort and security. Parents are instructed not to prompt the child or to ask questions during the screening. After the screening procedures, the evaluator will review the results with the parents.

Pediatric nurses are in a prime position to screen for developmental problems. With appropriate training and practice, they can easily and effectively use the Denver II and PDQ-II in their practice.

See [thePoint](#) for a summary of Key Concepts.

Infancy (Newborn–11 Months)

Case History

Lela Diaz is such a different baby than her older brother.

Claudia and Ignacio Diaz have a preschool-aged son, Jose, who as a baby ate like a little barracuda and then slept like a rock. Lela is proving to be much more difficult, even for an experienced mother like Claudia. Claudia breast-fed her son and did not anticipate any difficulties breast-feeding her second child. Lela “did not nurse” well in the hospital, but Claudia was not too concerned. Then Claudia’s breasts became engorged and she does not know what to do. Lela was also confused by the hard “marble statue”-like breasts. Claudia’s hospital discharge instructions included a telephone number to call with any questions. The nurse instructed her to try showering first to see if the warm water sprayed on her breasts would help stimulate a let-down and soften the breasts. This does help, and Lela begins to show more interest in feeding.

When Lela turns 6 months old, Claudia finds a part-time job working the night shift at a nearby hotel. Claudia and Ignacio are pleased that this arrangement will increase their income, but not require them to find day-care. Ignacio is certain that Lela will sleep through the night, because at 6 months, Jose

slept through the night. Claudia will not work two

nights in a row and will nap when the children nap. Claudia is a little worried, however, because Lela is not like her brother. Jose started taking a bottle without a fuss while still breast-feeding when he was just a few months old. If it was food, he wanted it! Lela would rather starve than accept a plastic nipple; she is deeply offended at the very idea. The first night Claudia went to work, Lela kept her father up half the night. She refused a bottle; she refused a cup. Ignacio works long hours with machinery and it is not safe for him to work without sleep. They decide to ask Claudia’s mother, Selma, to come stay with them for a while.

Claudia and Ignacio do not have health insurance. Their children receive their immunizations at a free community clinic. At Lela’s 8-month visit, after clarifying that Lela is taking little supplemental food and is primarily breast-feeding, a hematocrit and hemoglobin count is obtained that shows that Lela is mildly anemic. The nurse at the health department encourages Claudia to give Lela more iron rich-foods and more solid food. Claudia tries to explain that Lela does not like new foods.

CHAPTER OBJECTIVES

1. Describe developmental milestones for neonates and infants and state measures to enhance meeting these milestones.
2. Discuss the needs of the infant related to hygiene, personal care, nutrition, elimination, and safety.
3. Select age-appropriate interventions to promote healthy personal and social development of the infant.
4. Select interventions to promote illness and injury prevention for the infant and the family.

See [thePoint](#) for a list of Key Terms.

A primary goal of the healthcare community is to collaborate with families to promote children's growth, development, adaptation, and functioning. Most parents invest considerable time, personal resources, and finances to meet their children's needs. Many parents seek child-rearing knowledge and assistance from healthcare professionals and others who work with children. Healthcare personnel must serve as an accessible support to parents as they strive to nurture, protect, and socialize their children. The interdisciplinary healthcare team plays a critical role in promoting healthy development. This chapter builds on the information presented in Chapter 3, Principles and Physiologic Basis of Growth and Development, to describe issues related to promoting healthy development of the neonate and infant. Evaluation and treatment of acute disorders commonly seen in the neonatal and infant population are described in Chapters 14 through 31. Chart 4–1 summarizes the location in the text of many of these conditions. In addition, Chapter 14 is devoted to conditions that affect the neonate with altered health status.

DEVELOPMENTAL ASSESSMENT AND SURVEILLANCE

During the first year, parents of a healthy infant are likely to visit their healthcare provider more often than at any other time during the child's life, unless an acute condition arises. These repeated contacts provide the nurse ample opportunity to complete developmental surveillance (see Chapter 3). **Developmental surveillance** encompasses all activities related to detecting developmental problems and promoting healthy development. Hagan, Shaw, and Duncan (2008) use techniques such as directly observing the child, eliciting parental concerns, and completing developmental screening to identify infants who may be at risk for developmental delay. Each encounter with the family is an opportunity to provide guidance and education about the infant's needs. *Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents* (Hagan et al., 2008) provides the most comprehensive set of principals, strategies, and tools that can be used by healthcare providers to guide teaching, health promotion activities, and developmental surveillance. The information provided in Chapters 4 through 7 is consistent with information provided in these comprehensive, national guidelines.

Developmental Considerations 4–1 summarizes the developmental milestones that are accomplished during the infant's first year. This information provides the nurse with direction for specific trigger questions to ask the parents. Simply asking an open-ended question such as "Is your child developing well?" is not effective (Lagerberg, 2005). Most parents would respond positively, even if they lacked the information about what developmental milestones their child should be reaching at any given time. The nurse can also use knowledge of developmental milestones to summarize the developmental achievements that the family should promote and expect to see as the infant matures. Family members are then aware of which developmental milestones the infant should be approaching and can help the infant achieve them.

When a child is hospitalized, continue to provide an environment for the infant that is both developmentally appropriate and family centered. Nursing Interventions Classification (NIC) 4–1 summarizes the nursing activities associated with developmentally appropriate care of the neonate and infant.

Healthcare visits for the infant are scheduled within the first week after birth and at 1, 2, 4, 6, 9, and 12 months of age (Fig. 4–1) (Hagan et al., 2008). A primary focus of illness prevention is to encourage parents to pay attention to the recommended schedule of healthcare visits for their infant and to ensure that these visits are scheduled and attended. Appendix G summarizes the aspects of health supervision that will be covered at each visit. Screening for vision and hearing occurs at each visit. Growth parameter assessment is a key element of each health visit. Developmental Considerations 4–2 provides a more detailed description of the changes in weight, height, and head circumference that should be seen as the infant grows. Chapter 8 also covers the specific immunizations and routine diagnostic tests that are completed throughout the childhood years.

Regular, periodic assessment by the same healthcare provider can help detect developmental problems early. Frequent visits with a primary healthcare provider also help to establish a trusting relationship between the family and the healthcare team. Therefore, when problems do arise, the family is likely to feel more comfortable seeking advice and support from the healthcare team.

HYGIENE AND PERSONAL CARE

Caring for an infant entails bathing and skin care as well as monitoring thumb sucking and pacifier use, sleep habits, and clothing. Becoming a parent does not automatically make an individual competent to perform infant care tasks. The pediatric nurse must have a thorough understanding of infant care needs, and the ability to teach and demonstrate these skills to new parents.

Bathing

The infant does not need daily bathing the first few weeks of life. The diaper area must be kept meticulously clean to

CHART 4-1 QUICK REFERENCE TO CONDITIONS COMMON DURING INFANCY

Condition	Chapter
Anorectal malformations	18: The Child With Altered Gastrointestinal Status
Apnea of infancy	16: The Child With Altered Respiratory Status
Atopic dermatitis (eczema)	25: The Child With Altered Skin Integrity
Biliary atresia	18: The Child With Altered Gastrointestinal Status
Bronchiolitis	16: The Child With Altered Respiratory Status
Cleft lip and cleft palate	16: The Child With Altered Respiratory Status
Colic	18: The Child With Altered Gastrointestinal Status
Common cold (nasopharyngitis)	16: The Child With Altered Respiratory Status
Congenital clubfoot	20: The Child With Altered Musculoskeletal Status
Congenital heart disease	20: The Child With Altered Musculoskeletal Status
Craniosynostosis	21: The Child With Altered Neurologic Status
Croup	16: The Child With Altered Respiratory Status
Dehydration	17: The Child With Altered Fluid and Electrolyte Status
Developmental dysplasia of the hip	20: The Child With Altered Musculoskeletal Status
Diaper dermatitis	25: The Child With Altered Skin Integrity
Diarrhea	18: The Child With Altered Gastrointestinal Status
Epispadias	19: The Child With Altered Genitourinary Status
Esophageal atresia and tracheoesophageal fistula	16: The Child With Altered Respiratory Status
Fetal alcohol syndrome	14: The Neonate With Altered Health Status
Fever	31: Pediatric Emergencies
Gastroesophageal reflux	18: The Child With Altered Gastrointestinal Status
Gastroschisis	18: The Child With Altered Gastrointestinal Status
Hernias	18: The Child With Altered Gastrointestinal Status
Hydrocephalus	21: The Child With Altered Neurologic Status
Hypospadias	19: The Child With Altered Genitourinary Status
Metatarsus adductus	20: The Child With Altered Musculoskeletal Status
Microcephaly	21: The Child With Altered Neurologic Status
Neonatal pain	10: Pain Management
Neonatal skin lesions	25: The Child With Altered Skin Integrity
Obstructive uropathy	19: The Child With Altered Genitourinary Status
Omphalocele	18: The Child With Altered Gastrointestinal Status
Otitis media	28: The Child With Sensory Alterations
Sepsis	14: The Neonate With Altered Health Status
Short bowel syndrome	18: The Child With Altered Gastrointestinal Status
Spina bifida	21: The Child With Altered Neurologic Status
Sudden infant death syndrome	31: Pediatric Emergencies

DEVELOPMENTAL CONSIDERATIONS 4–1

Milestones of the Infant (Newborn–11 Months)

Physical Development*

Newborn

10% loss of birth weight in first 3–4 days of life
73% of body weight is fluid
Head circumference is 70% of adult size
Needs to consume 120 cal/kg of weight per day
Sleeps 20–22 hr/day, with brief waking periods of
2–3 hr
Feeds every 2½–5 hr

2–5 Mo

Posterior fontanel closes
Obligate (preferential) nose breathers until about
5 mo
Begins drooling

5–6 Mo

Doubles birth weight
Teeth may begin to erupt
Moves food to back of mouth and swallows during
spoon feedings
Sleeps through the night for up to 8 hr
Goes 4–5 hr between feedings
Has 2–4 naps/day

7–9 Mo

Begins teething with lower central incisors, followed
by two upper incisors
Mashes food with jaws
Sleeps 14–16 hr/day including naps

10–11 Mo

Sleeps 14–16 hr/day and still naps
Stops drooling
Grows about ½ inch/mo

Sexual

All infants

Oral stage oral gratification and sucking needs
(Freud)

10 Mo

Begins sexual identity

Language

Newborn

Alerting
Social smile

2–3 Mo

Laughs and squeals
Coos
Utters single vowel sounds such as “ah” and “eh”

4 Mo

Utters two-syllable vowel sounds
Includes consonant sounds such as “m” and “b”
Produces belly laughs
Orients to voices of others

5 Mo

Razzing
Intersperses vowel and consonant sounds

6 Mo

Babbles
Uses about 12 speech sounds

7 Mo

Makes “talking sounds” in response to caregiver
while others are talking
Coos and squeals
Vocalizes up to four different syllables

8–10 Mo

Uses “dada” and “mama” in nonspecific way
Responds to own name (receptive language skill
develop first)
Babbles to produce consonant sounds
Vocalizes to toys

9–11 Mo

Imitates speech sounds
Understands name and “no”
Understands “bye” and “pat –a– cake”
Imitates definite speech sounds
Uses jargon
Communicates by pointing to objects and by using
gestures
Responds to simple verbal requests

Vision

Newborn

Fixates on human face and demonstrates preference
Blink reflex present

2 Mo

Follows to midline
Produces rears
Visual acuity is hyperoptic

4 Mo

Follows objects to 180°

5 Mo

Visual acuity 20/200
Recognizes feeding bottle

DEVELOPMENTAL CONSIDERATIONS 4–1

Milestones of the Infant (Newborn–11 Months) (*Continued*)

6 Mo

Inspects hands
Fixates on objects 3 feet away
Strabismus no longer within normal limits
Develops hand–eye coordination

8 Mo

Has permanent eye color
Depth perception developing

10 Mo

Tilts head backward to see up

Hearing

Newborn

Startles to loud noises
Prefers high pitched voices
Quieted by low-pitched noises
Responds to human voice over other noises
Auditory behavior is reflexive; generalized body movement (blinking or crying)
Recognizes certain sounds, ignores others; attends to quiet sounds more than loud ones—these are learned rather than reflexive behaviors
Turns to voice (quiet listening)

5 Mo

Orients to bell (looks to side)
Stops crying in response to music

7 Mo

Orients to bell (looks to side, then up)

10 Mo

Localizes sound from above or below
Orients to bell (turns directly to bell)

Gross Motor

Newborn

Turns head when prone but cannot support head
Adjusts posture when held at shoulder
May squirm to corner or edge of crib when prone
Arm and leg movement are reflexive

6 Wk–2 Mo

Holds head up 45°–90° when prone
May hold head steady when in supported sitting position

3 Mo

Rolls over from back to side
Holds head erect and steady

4 Mo

When supported, sits with rounded back and bended knees
May bear weight on legs when assisted to stand
Head lag disappears when pulled to sitting position

5 Mo

Pulls to sitting position
Rolls from back to stomach
Sits alone momentarily
Shows unilateral reaching

6 Mo

Sits without support
May creep an inch forward or backward
Moves from place to place by rolling
Begins drinking from a cup

7 Mo

Stands while holding on
Early stepping movements
Begins to crawl or hitch
Raises head spontaneously when supine

8 Mo

Pulls to standing position
Raises self to sitting position
Palmar grasp disappears

9 Mo

Walks with help
Crawls, creeps, or hitches when permitted
Sits down
Holds own bottle
Drinks from cup or glass

10 Mo

Continues walking skill development with help
Stands alone
May climb up and down stairs
Sits without support
Recovers balance
Changes from prone to sitting position

11 Mo

May walk alone
 Begins to stoop and recover
 Pushes toys
 “Cruises”

Time Motor**Newborn**

Follows to, and slightly past, midline

2–3 Mo

Keeps hands open predominately
 Reflex grasp replaced by voluntary grasping
 Grasps objects such as rattle in open hand
 May bring hands together at midline

3–4 Mo

Uses ulnar-palmar prehension with a cube
 Reaches for objects
 Hands predominantly open

5 Mo

Attempts to “catch” dangling objects with two hands
 Begins using forefinger and thumb in pincer grasp
 (opposable thumb-prehension)
 Retains two cubes
 Recovers rattle
 Reaches for and grasps objects

6–7 Mo

Can grasp at will
 Holds and manipulates objects
 Scoops pellet
 Transfers from hand to hand
 Demonstrates inferior pincer
 Bangs objects together
 Can release objects

8–9 Mo

Combines spoons or cubes at midline
 Retains two of three cubes offered
 Achieves neat pincer grasp of pellet
 Feeds self finger foods using only one hand
 Releases objects at will
 Rings bell
 Holds bottle and places nipple in mouth
 when wants it

10–11 Mo

Plays “pat-a-cake” (a midline skill)
 Puts several objects in a container
 Holds crayon adaptively
 Bangs two cubes together
 Looks for hidden object
 (object permanency) (Piaget)
 Achieves neat pincer grasp

Play**All infants**

Engages in solitary play
 May be imitative
 Explores and manipulates

5–7 Mo

Resists toy pull
 Picks up tiny objects
 Plays “peek-a-boo”
 Works to get toy that is out of reach

8–9 Mo

Plays “pat-a-cake”
 Recognizes self in mirror

10–11 Mo

Plays ball with examiner
 Achieves object permanence (searches for dropped
 objects)

Cognitive**Newborn****Substage 1 (Piaget)**

Practice of reflexes and reflex-like actions

1–4 Mo**Substage II: Purposeful (Piaget)**

Reproduces of reflex actions

4–8 Mo**Substage III: Objects (Piaget)**

Oriented and imitative actions
 Accidental actions are repeated
 Develops habits
 Responds negatively to removal of a toy

8–11 Mo**Substage IV: (Piaget)**

Coordination, intentional goal direction, and
 achievement
 Experiment with object permanence
 Imitates and models behavior
 No concept of death
 Enjoys “peek-a-boo” game
 Attempts to flee from unpleasant events
 Recognizes anticipatory signs
 Repeats actions that elicit response from others
 Dislikes restrictions
 Shakes head for “no”
 Appears interested in picture book

Social**Newborn**

Regards face and establishes eye contact

(Continued)

DEVELOPMENTAL CONSIDERATIONS 4–1

Milestones of the Infant (Newborn–11 Months) (*Continued*)

1–2 Mo

Smiles responsively
Enjoys cuddling and motion

2–3 Mo

Smiles spontaneously

3–5 Mo

Smiles at mirror image
Shows interest in siblings
Invites social interactions by smiling

6 Mo

Exhibits stranger anxiety
Extends arms to be held

7–9 Mo

Waves hands

10–11 Mo

Demonstrates emotions of fear, anger, affection
Can indicate desires without crying
Offers object to a familiar adult
Talks to mirror

Interpersonal

0–3 Mo

Self-absorbed, egocentric

4–18 Mo

Symbiotic phase—mother seen as an extension of child's body and needs, and vice versa

6–10 Mo

Exhibits stranger anxiety
Waves arms and legs when frustrated

8–24 Mo

Exhibits separation anxiety
Exhibits trust vs. mistrust (Erikson)

Emotional

Newborn–3 Mo

Feeling regulated and interested in the world
Sensitive to parent's joyful interest in him or her

3–7 Mo

Forming attachments
Highly specialized interest in the human world

4–10 Mo

Purposeful communication
Can connect small units of feelings into simple patterns
Purposeful expression of wants and needs
Fluctuates easily between laughing and crying

10–18 Mo

Complex sense of self
Communication is truly interactive, enabling toddler to tune into parent and to appropriately build on parent's response

Moral/Spiritual

All Infants

Moral

Stage I: Preconventional Level (Kohlberg)
May be disciplined by withdrawal of stimuli (e.g., food or toy) and may experience injury related to consequences of actions. However, makes no cognitive connection between these events and does not distinguish right from wrong
No moral concepts or rules exist

Spiritual

Stage 0: Undifferentiated (Fowler)
Not capable of formulating or communicating any conceptual ideas about self or environment
Feelings of trust: sets foundation for subsequent development of faith

avoid diaper rash, but until the cord falls off, the infant should receive sponge baths only. Before starting the bath, collect all the articles needed, including a basin of lukewarm water, two to three towels, a washcloth, mild soap, baby shampoo, lotion (optional), a fresh diaper, and clean clothes.

For the sponge bath, place the infant on a padded flat area near a sink or on a changing table. During the bath, expose only the parts of the body that are being cleansed, to avoid chilling the infant. Begin the bath by cleaning the

eyes from the inner area to the outer area, rinsing the cloth, and proceeding to the rest of the face. Clean the perineal area last. Dry each body part before moving on to wash another part of the body. Wash and dry all body creases carefully, particularly the folds in the neck and perineal area. These areas are particularly prone to rashes, because they are warm and moist. Wash the infant's hair about twice a week with a very mild, tear-free baby shampoo immediately after washing the infant's face and neck.

NIC 4–1 Nursing Intervention Classification: Infant Care

Definition: Provision of developmentally appropriate family-centered care to the child less than 1 year of age

Activities:

- Monitor infant’s height and weight.
- Monitor intake and output, as appropriate.
- Change diapers, as appropriate.
- Feed infant foods that are developmentally appropriate.
- Provide opportunities for nonnutritive sucking, as appropriate.
- Keep side rails of crib up when not caring for infant.
- Monitor safety of infant’s environment.
- Provide developmentally appropriate, safe toys for infant.
- Provide information to parents about child development and child rearing.
- Provide developmentally appropriate activities to stimulate cognitive development.
- Provide stimulation that appeals to all senses.
- Structure play and care around infant’s behavioral style/temperament patterns.
- Talk to infant while giving care.

- Rock infant to promote security or sleep.
- Encourage parents to provide daily care of infant, as appropriate.
- Instruct parents to perform special care for infant, as appropriate.
- Reinforce parent’s skill in performing special care for infant.
- Inform parents about infant’s progress.
- Explain rationale for treatments, procedures, and so on, to parents.
- Restrain infant during procedures.
- Comfort infant after painful procedure.
- Explain to parents that regression is normal during times of stress, such as illness or hospitalization.
- Comfort infant when experiencing separation anxiety.
- Encourage family visitation.
- Maintain infant’s daily routine during hospitalization.
- Provide quiet, uninterrupted environment during nap time and nighttime, as appropriate.

To prevent infection and improper healing, do not submerge the cord area in water until the stump has fallen off, usually in about 7 to 10 days (Tradition or Science 4–1). After the stump has fallen off, tub bathing may begin in a sink or plastic tub. Line the basin with a towel to reduce slipping and to make the surface more comfortable for the infant. Fill the basin with about 2 in of water that is warm, not hot, to the inside of the wrist or elbow (Fig. 4–2). The first few baths should be brief. If

the infant protests too much, sponge baths can be continued for 1 or 2 weeks before trying tub bathing again.

FIGURE 4–1. Routine visits to the healthcare provider ensure the infant is evaluated for achievement of age-appropriate physical and developmental milestones.

DEVELOPMENTAL CONSIDERATIONS 4–2

Normal Expected Increases in Weight, Height, and Head Circumference During Infancy

Weight Gain (Average Weekly Increase)

0–3 months	210 g (8 oz)
3–6 months	140 g (5 oz)
6–12 months	85–105 g (3–4 oz)

Height (Average Monthly Increase)

0–3 months	3.5 cm (1.4 in)
3–6 months	2.0 cm (0.8 in)
6–12 months	1.2–1.5 cm (0.5–0.6 in)

Head Circumference (Average Monthly Increase)

0–3 months	2 cm (0.8 in)
3–6 months (0.4 in)	1 cm (0.4 in)
6–12 months	0.5 cm (0.2 in)

TRADITION OR SCIENCE 4–1

How should parents clean the umbilical cord stump and surrounding area?

MORE INQUIRY NEEDED

Using alcohol to wipe the umbilical cord stump and surrounding area has been the most popular method for cleansing the site until the stump falls off. This method is no longer recommended for pre-term or term infants, because evidence has proved that using alcohol delays stump drying time and increases the opportunity for infection at the site. Shorter cord separation time has been noted when the cord is allowed to dry naturally. Alcohol may also destroy normal flora present around the umbilical cord, thus delaying separation time and increasing the risk of infection. Alcohol use is also more costly than natural drying (Dore et al., 1998; Evens et al., 2004; Medves and O'Brien, 1997; Zupan, Gardner, and Omari, 2004). Mullay et al. (2003) suggest that in developing countries there are significant differences in resource availability, social customs, environmental cleanliness, and bacteriologic profiles that influence the increased number of umbilical cord infections seen in these countries. In developing countries, more research is needed to investigate the role of topical antimicrobials and/or other cord care regimens (e.g., use of alcohol) on infections during the neonatal period.

Parents should use bath time as bonding time by talking, cooing, and singing to their infant. The bath should be unhurried and nonstressful. If the infant is enjoying the experience, extra playtime in the water should be permitted.

When the infant is able to sit upright without much support, a tub ring or tub seat can be used to stabilize the infant as he or she plays in the bath. The older infant is likely to begin moving around quite a bit in the bathtub. The water level should remain low enough so that if the older infant were to lie on his or her abdomen in the tub, his or her face would not easily be immersed in the water. Injuries in the bath resulting from slips and falls are the most common

type of childhood bathtub-related injuries (Spencer, Shields, & Smith, 2005). Such injuries can be prevented by using a slip-resistant bathtub surface in all tubs.

caREminder

Never leave an infant alone or just accompanied by a young child during a bath, whether in a tub of water or on a counter. Instruct parents to prepare for any interruptions by taking the phone off the hook or engaging the answering machine. If the doorbell rings or a sibling screams, the infant should be wrapped up and taken by the parent when responding to a situation.

Skin Care

Infants have relatively fragile and sensitive skin, but do not generally need any lotions or talcum on it. Many parents like to use lotions because it gives them an opportunity to massage their infant, increasing the sense of bonding and togetherness. If lotions or powders are used, they should be hypoallergenic. Lotions should be put on the parent's hands first, to warm the cream before applying it to the infant's skin. Powder should always be placed on the hand first to reduce the amount of powder in the air and to prevent the infant from inhaling it. In general, use of powder is not recommended (or needed) because of the risk that the infant will aspire it during application.

The skin acts as a tough barrier to chemicals and organisms. It is protected by the oily and minimally acidic secretions of the sebaceous glands, called the **acid mantle**, which make the acid level of the skin pH 4.5 to 5. Too much bathing can disrupt the acid mantle. Several normal alterations in the infant's skin, which require no treatment, can be noted during the first few months. Erythema toxicum, a rash of red splotches with yellowish white bumps in their center, commonly appears only during the first few days after birth. Sucking blisters, which look like water blisters and are most commonly found on the hands, wrist, and forearm, are seen on newborns who have sucked a body part in utero. Milia are tiny white or yellow spots on the cheeks, nose, or chin, caused by

FIGURE 4–2. (A) Placing the younger infant in a small tub makes bath time fun and comforting. The tub should be filled with about 2 in of warm water and placed securely. (B) Later, a baby tub can be used in the bathtub so the older infant can enjoy sitting up and splashing in the water. The bath ring holds the baby securely in place. Older siblings can join the fun and help wash the baby.

immature sweat and oil glands. These spots usually disappear within the first 2 to 3 weeks of life. Newborn acne, which is pimples on the cheeks, chin, and forehead, is caused by maternal hormones, still circulating in the infant, that stimulate the sebaceous glands. It usually disappears within the first few months of life. Parents should not treat the acne except by washing the infant's face two to three times per day with water. Chapter 25 presents a detailed description of both normal and abnormal skin lesions commonly seen in infants and children. Parents will often need reassurance that certain marks present at birth, such as “stork bites”—flat, pink lesions located on the nape of the neck—are benign and will recede.

The infant should not be overexposed to the sun, because infant skin is quite sensitive and can be burned easily. The best sun protection for infants younger than 6 months of age is to dress them in lightweight long pants and long-sleeved shirts, and keep them out of direct sunlight. To prevent eye damage, infants should also wear a hat with a brim and sunglasses designed to block at least 99% of the sun's rays.

Alert! Because the ingredients in sunscreen lotions may cause an allergic skin reaction, sunscreen should not be applied to infants younger than 6 months. If used for children 6 months to 1 year of age sunscreen should be applied sparingly to small areas of skin, such as the face and the backs of the hands. After 1 year of age, sunscreen should always be applied before the child plays in the sun (see Chapter 25 for more information regarding application of sunscreen).

Oral Care

Oral health depends on regular oral care. Performing good oral hygiene at least twice daily prevents oral infections, soothes the gums, and comforts the child while the teething process is occurring. From the time of infancy, the mouth should be cleaned at least twice a day. Gum care should be started soon after birth. The infant's erupting teeth can be brushed with a soft toothbrush or rubbed lightly with the corner of a soft washcloth. This practice accustoms the infant to the daily ritual of dental hygiene (American Academy of Pediatric Dentists, 2004).

Fluoride is important for tooth protection and growth. It is generally provided in sufficient amounts through the community water supply at an optimum level of one part per million (ppm). For children 6 months of age to 3 years, if community water is not fluoridated or is fluoride deficient (<0.3 ppm), the healthcare provider can prescribe fluoride supplementation (American Academy of Pediatric Dentists, 2007a, c). Supplementation can be provided via solution or chewable tablets (for the older child). Children who receive too much fluoride can develop mottled or speckled teeth.

The first visit to a pediatric dentist occurs between 6 and 12 months of age, when the first tooth comes in. Pediatric dentists want to see infants early on to instruct parents on tooth brushing and diet, and to assess for risk of caries. In addition, the American Academy of Pediatric Dentists recommend that this first visit include counseling with the parents about oral hygiene, nonnutritive

habits, speech and language development, diet, oral injury prevention, and fluoride supplementation. All scheduled health care visits to primary care health providers (e.g., those at 6 months, 9 months, and so on) should include oral assessment and health teaching to promote optimum oral health during infancy (American Academy of Pediatric Dentists, 2007b).

The healthcare provider or the dentist may elect to perform a caries risk assessment using a standardized tool such as a caries risk assessment tool to determine whether proactive interventions need to be implemented to protect the child further from tooth decay (see [thePoint](#) for Evidenced-Based Practice Guidelines) (American Academy of Pediatric Dentists, 2006b). Early childhood caries, one of the leading causes of tooth decay in young children, is also known as *nursing bottle caries*, *nursing caries*, and *nursing bottle syndrome*. Early childhood caries occur when carbohydrates in formula, breast milk, and fruit juice are allowed to remain on the teeth for a prolonged period. Strongly encourage parents not to put the child to bed with a bottle at any time. Both the incidence of dental caries and otitis media are elevated in children who are allowed to go to bed with a bottle of milk or juice. Prevention is the key to good dental health. If the child must have a bedtime bottle, it should contain water.

Teething

QUESTION: At her 8-month visit, Lela does not have any teeth. Claudia asks the nurse whether this is normal, because Jose got his first tooth at 6 months. What would you tell Claudia?

The first teeth, usually the lower central incisors, erupt between 6 and 10 months of age, although this event may not occur until the child is a year old. The next teeth to appear are the four upper incisors (central first, then lateral), which are evident at between 8 and 13 months of age, followed by the two lower lateral incisors, and then the first four molars (both upper and lower; see Fig. 3–14) (Hagan et al., 2008). By the time the child is a year old, approximately 10 teeth will have erupted. This is an average number; some children will have more and some children will be just starting to develop teeth.

Teething can be one of the most difficult and exasperating times for new parents, because it is usually associated with some discomfort for the child. Many parents believe that teething elicits signs of illness, including fever, excessive drooling, and crankiness. In most cases, however, these problems arise from other sources. Rubbing the gums where the eruptions are occurring with a clean finger for about 2 minutes reduces the swelling and provides comfort. The use of topical anesthetics or analgesics is not usually very helpful, because saliva washes them away quickly. Additionally, the infant may touch the area with the tongue, thereby numbing the tongue rather than the affected area. Some teething rings can be chilled; rings that are cold, not frozen, also reduce the swelling and the discomfort of teething (Fig. 4–3).

FIGURE 4–3. A cold teething ring can help soothe a baby's discomfort from swollen, inflamed gums during teething.

caREminder

Frozen teething rings can cause frostbite on the gums and are hard enough to cause trauma to the gums. Alcohol spirits (such as whiskey) should never be used on the gums.

Teething biscuits and small bagels are also good for teething infants, depending on the infant's age. The infant should not be given anything that cannot be chewed easily or that could break off into large pieces and cause choking. Many healthcare providers recommend a mild analgesic, such as acetaminophen, for discomfort from teething.

ANSWER: The order that teeth come in is much more predictable than the age babies will get teeth. A few infants are born with teeth and others don't have a tooth in their head until after their first birthday.

Nonnutritive Sucking

The infant receives a great deal of comfort and gratification by nonnutritive sucking. In addition to sucking the mother's nipple or the bottle nipple, the young infant can often be seen sucking parts of the hand. For some infants, this urge to suck is very strong, particularly when they are hungry or tired. Parents generally foster the need for oral stimulation during times of distress by offering a **pacifier** whenever the infant cries. Pacifiers, also known by the terms *dummy* (British), *soother* (Canadian), or *binkie* (American), are rubber or plastic nipples given to the infant to suck upon.

The choice between thumb sucking and a pacifier for nonnutritive sucking is often one a parent cannot make. Although parents may offer the pacifier frequently and

remove the infant's thumb or other fingers from the mouth, the infant is ultimately the one who selects the form of nonnutritive sucking he or she prefers. The thumb is readily available to the infant. The child does not have to have hand–eye coordination to get the thumb to the mouth. Therefore, during the early months, thumb sucking keeps parents from having to assist the child constantly by putting a pacifier in his or her mouth. Nonnutritive sucking reaches its height at 15 to 18 months of age. Nonnutritive sucking can result in long-term dental problems; thus, professional evaluation for children who continue to display persistent nonnutritive sucking beyond age 3 is recommended (American Academy of Pediatric Dentists, 2006a).

The thumb tends to be dirty; wash the child's hands with water before nap time to ensure that the thumb is clean. When soap and water are not available, cleansing wipes can be used to clean the child's hands. Although cleansing wipes are alcohol based and contain perfume, it is better for the thumb to be clean. Weaning the child from the thumb is generally more difficult than weaning the child from the pacifier, because parents cannot regulate the presence of the thumb. If an older child is unable to break the habit of thumb sucking, a dentist may suggest using an intraoral appliance that interferes with putting the finger or thumb in the mouth. Such devices have been successful in stopping thumb sucking in preschool- and school-aged children.

Pacifiers come in a variety of shapes. If the infant is bottle-feeding, the shape of the pacifier should be similar to the shape of the nipple used during feedings.

caREminder

Nipples intended for use with prepared formula bottles should never be used as pacifiers, because they can be aspirated when not attached to a bottle base.

Pacifier use has been associated with an overall decline in breast-feeding duration, although the specific cause of this decline is not known (Callaghan et al., 2005; Howard et al., 1999; Nelson et al., 2005). Some authors recommend restricting or avoiding pacifier use until breast-feeding is well established, usually between 4 to 6 weeks of age (Cornelius, D'Auria, & Wise, 2008).

Pacifier use has also been associated with a reduced risk of sudden infant death syndrome (SIDS), and the American Academy of Pediatrics recommends pacifier use after 4 weeks of age for the prevention of SIDS (American Academy of Pediatrics, 2005c; Cornelius, D'Auria, & Wise, 2008), although the mechanism by which pacifiers reduce the risk of SIDS is unknown (Callaghan et al., 2005; Li et al., 2005; Mitchell, Blair, & L'Hoir, 2006). Last, pacifier use has been associated with a higher risk of otitis media, and thus pacifier use during the second 6 months of life should be reduced (American Academy of Pediatrics, 2004a; Marter & Agruss, 2007). In all of these issues, it is evident that the findings are inconclusive and conflicting with regard to when pacifiers should be introduced and discontinued.

During the early months, an adult must put the pacifier in the infant's mouth. As the infant matures, he or she will be able to find the pacifier in the crib and place it in his or her own mouth. Pacifiers can be just as dirty as thumbs. Pacifier clips can be used to attach the pacifier to the infant's shirt and to prevent the pacifier from constantly falling on the ground. Weaning from the pacifier, as with weaning from the bottle, can start with restricting pacifier use to sleep time.

Sleep

QUESTION: Claudia is concerned because Lela has a bald spot on the back of her head. What questions would you ask Claudia? What suggestions would you make about sleep positions?

The American Academy of Pediatrics (2005c) recommends that all infants without respiratory problems or reflux be placed on a firm mattress, on their backs (supine), without soft objects, a pillow, or other bedding materials, because sleeping in the prone position has been linked to SIDS (Fig. 4-4). According to the Academy of Breastfeeding Medicine (2008, p. 38), “the terms co-sleeping and bed sharing are often used interchangeably. However, bed sharing is only one form of co-sleeping. Co-sleeping, in reality, refers to the diverse ways in which infants sleep in close social and/or physical contact with a caregiver (usually the mother). This operational definition includes an infant sleeping alongside a parent on a different piece of furniture/object, as well as clearly unsafe practices such as sharing a sofa or recliner.” In some parts of the world, co-sleeping may provide a means to protect the infant from environmental hazards. On the other hand, sharing a bed with a parent or another child is generally not recommended, because this practice may increase the risk of infant suffocation. However, bed sharing when practiced in a safe and responsible manner supports infant nutrition and physiology (Academy of Breastfeeding Medicine,

FIGURE 4-4. Infants should be placed on their back to sleep. A pillow or bedroll can be used to keep the baby in place.

2008; Buswell & Spatz, 2007; Morgan, Groer, & Smith, 2006). If parents choose to share a bed with their infant, they should use a firm mattress, sleep in a bed that is not against a wall or that has a headboard or side railing, and should refrain from using heavy blankets on the bed. The parent should be sober and a nonsmoker. The baby should be placed on his or her back when sleeping, and should be placed next to the mother, not between the parents. Parents should not sleep with an infant on a couch or in a water bed, because these surfaces place the infant at even higher risk for suffocation (Morgan, Groer, & Smith, 2006; Thompson, 2005).

During the first month of life, the average sleeping time for an infant is 16 to 20 hours. Some infants sleep as little as 10 hours a day; others sleep as much as 23 hours a day. Not surprisingly, the infant who sleeps very little tends to grow into the child who sleeps very little, and eventually into the adult who requires little sleep. As the child develops during the first year, hours spent sleeping decrease to an average of 14¹/₄ per day at 6 months and 13³/₄ per day by 1 year of age (Davis, Parker, & Montgomery, 2004).

For many parents, a primary goal within the first few months is to have the infant achieve a pattern of sleeping for a 7- to 8-hour period through the night. For the tired and bleary-eyed parent, this extended sleep pattern is a welcome developmental milestone. To achieve this goal, hunger metabolism and sleep-wake cycles must first be stabilized. From birth through the eighth week, the daily routine for most infants is a continual repeat of a 2¹/₄- to 3-hour cycle that starts with the beginning of one feeding and ends with the beginning of the next feeding. Within this cycle, the parent should promote a daytime pattern of eating, followed by wake time, followed by a nap time of approximately 1¹/₄ hours. During the late evening and nighttime hours, the cycle should consist only of eating and sleeping activities. Between the third and fourth months, the infant will extend the nighttime sleep to 10 to 12 hours, continuing this pattern for the rest of the first year.

Concurrently, daytime naps increase in duration to approximately 2 hours; the infant subsequently drops the number of naps and feedings per day, thereby elongating the periods of wakefulness. The newborn who requires six to eight naps a day tapers off to three to four naps a day at 3 months, and to two naps at 6 months. The need for both a morning and afternoon nap, lasting about 2 hours each, continues until the child is approximately 16 months of age.

Parents can follow several guidelines that help foster good sleep habits in children at an early age. The most important guideline is to adhere to the recommended cycle of eating, wake time, and nap time—in that order. Often, the first two activities are reversed, however, creating a situation in which the infant must have a bottle or be breast-fed to go to sleep. It is important for an infant to learn how to self-soothe by thumb sucking, rooting around in bed, head shaking, or listening to soft music or the sound of a parent's voice. Cuddling the infant and then placing the infant in the crib, continuing to talk or sing until the infant falls asleep, teaches the infant how to self-soothe and fall asleep without a bottle or breast (Mindell and Owens, 2003).

Two types of sleep occur: active and quiet (Developmental Considerations 4–3). Active sleep, also known as *rapid eye movement (REM) sleep*, is light sleep during which the infant may cry out or fuss. Waking the infant during this time is easy, but if left alone, the infant can find that a blanket, pacifier, or thumb is quieting. Swaddling and nesting are also helpful; some infants like to sleep tightly swaddled, whereas others prefer to sleep loosely swaddled. Some infants have difficulty settling back down if they awaken during the night. If the infant is older than 4 months, parents should not respond immediately to fussing, but should wait about 10 minutes to determine whether the infant settles down. By 3 months of age, the amount of quiet sleep time nearly doubles. If the infant takes long naps during the day and wakes frequently at night, naps can be shortened to help the child be more tired at night. Deal with reasons for nighttime waking as quickly as possible, lovingly, but without sustained cuddling, which may encourage the infant to repeat the activity.

ANSWER: Ask what position Lela sleeps in and when or if she spends time on her abdomen or on her side. Commend Claudia for using the back as the primary sleeping position and reinforce that this is the safest position. Lela is old enough now to spend more of her awake time on her abdomen. This will help her bald spot and will give her upper body a workout as she pushes up.

Clothing

QUESTION: Lela arrives on a lovely spring day for her 8-month visit at the health department in an outfit, a sweater, and wrapped in a blanket. What would you suggest to Claudia?

Clothing should be loose enough to prevent constricting the child's extremities. Clothing that is tight around the neck, arms, or legs, in addition to being uncomfortable, is a potential safety hazard. Garments with "feet" should be checked periodically for loose threads that could constrict the toes. Encourage parents and friends to buy big sizes and to limit the amount of clothes sized for infants 3 months and younger. Clothing should be durable, easily washable, and machine dried. Washing instructions located on the clothing should be followed to maintain the safety and integrity of the garment (e.g., flame-retardant chemicals are removed if garments are washed with soap and not detergent). Items with snap openers down the legs make dressing and diaper changing much easier (Fig. 4–5). Oval (rather than round) necks are easier to fit over the large, round heads of infants. All sleepwear should be flame retardant.

A common misconception is that infants need to be kept warmer than adults. Parents often overdress infants, making them overheated, uncomfortable, and fussy. In

DEVELOPMENTAL CONSIDERATIONS 4–3

Infant States

The states of arousal that are not optimal times for interacting with infants are

- Quiet or active sleep
- Drowsy
- Opens and closes eyes
- Eyes glazed, with a heavy-lidded look
- Delayed responsiveness
- May occur when arousing from a sleep state
- Crying
- Irregular respirations
- Facial grimaces
- Crying
- Color changes
- Sensitive to stimuli and may respond with crying
- Using self-consoling behaviors

The awake state that is the best time for the family to interact with infants is

- Quiet alert
- Minimal body activity
- Regular respirations
- Face has a bright, shiny look
- Eyes wide and bright
- When they are most attentive to stimuli

The family can also interact with infants during an active alert stage, which is when infants

- Active alert
- Much body activity
- Irregular respirations
- Facial movement
- Eyes open, but not bright
- Fussiness that may indicate need for a change in stimuli, feeding, or consoling

FIGURE 4–5. Disposable diapers make it easy to place the diaper on the infant. Specially made disposable diapers can be worn by the infant or toddler in the water.

the winter, several layers of clothing are warmer than single layers; dress the infant in one more layer than the mother wears in the same environment. One exception is hats, which infants should wear both during the winter and the summer. During the winter hats minimize heat loss (90% of heat loss occurs through the uncovered head), and during the summer they prevent sunburn and overheating. Shoes are not necessary until the infant begins to walk outside and needs foot protection. Socks will keep the feet warm during the winter. When the infant begins to wear shoes, try them on with the infant bearing weight to ensure they are soft and flexible, and fit the foot well. A good shoe fits the toe area well and allows at least half the width of the thumbnail between the longest toe and the end of the shoe.

ANSWER: Reinforce that Lela is comfortable wearing the same number of layers that Claudia is wearing. Many parents worry that the infant needs additional protection from the elements when going out. Suggest that a hat would protect Lela from wind and sun but would not overheat her.

NUTRITION

The infant has unique dietary needs related to physiologic development and the nonnutritive benefits associated with sucking and eating. The energy content of food is called its **kilocalorie (kcal) value**. Estimated energy requirements are based on basic body metabolism, growth, and activity. The average kilocalorie requirements for children up to age 1 year are presented in Table 4–1 (Burns et al., 2008; Butte et al., 2004). Whether breast- or bottle-fed, the infant will want to feed about every 2 hours for the first 2 to 3 weeks, taking about 2 to 3 oz each time. During the first month of life, infants should be awakened to eat if they sleep for more than 4 hours. During the second month, the infant usually develops a more sustained schedule, lasting 4 hours between feedings and taking 3 to 6 oz. This stage lasts until 3 to 4 months of age. At 4 to 5 months of age, the infant will take about 4 to 7 oz of formula at each feeding. By 5 to 6 months of age, the infant is usually taking 6 to 8 oz per feeding. When the infant is able to go longer than 4 hours between feedings, one of the nighttime feedings should be eliminated. Some infants do so naturally as they increase the length of time they sleep at night. Other infants may get into a habit of waking frequently in the night to be fed. In this case, when the infant awakes and indicates wanting to be fed, the infant should be patted and calmed or should be offered a pacifier rather than feeding. After a few nights of not receiving a midnight feeding, the infant may awaken but will learn not to expect food and thus will go back to sleep.

Prior to initiating feeding, the infant should be awake. Infant alertness can be increased by loosening the

TABLE 4 – 1

Nutritional Needs of Infants

Age	Breast Milk or Formula	Solid Foods	Total Caloric Needs
Newborn–3 months	1–6 oz every 2–4 hours (intake varies with age and weight)	No solid foods should be introduced.	$(89 \times \text{weight [kg]} - 100) + 175$
4–6 months	6–8 oz every 4 1/2–6 hours	Introduce solid foods beginning with cereal products. Breast-fed infants can be sustained on mother’s milk alone.	$(89 \times \text{weight [kg]} - 100) + 56$
7–11 months	6–8 oz every 6–8 hours (with a maximum of 32 oz per day)	Introduce solid foods. Introduce the cup. Offer finger foods.	$(89 \times \text{weight [kg]} - 100) + 22$

infant's clothes, rubbing the infant's hands or feet, and talking to the infant. The discussion on breast-feeding and bottle-feeding presents strategies for positioning the child and proper placement of the nipple in the infant's mouth to ensure a good suck. Some infants may be more challenging to feed as a result of poor suck, decreased motor postural control, gastroesophageal reflux, or the presence of cleft lip or palate. Nursing Interventions 4–1 presents strategies to deal with the challenging feeder (see [thePoint](#): Evidenced-Based Practice for more information on feeding children with cleft lip and/or palate).

Breast-Feeding

QUESTION: Lela is a sleepy newborn and is not showing much interest in establishing her nursing skills. This is a new problem for Claudia because her older son, Jose, was born ravenous. Review Teaching Intervention Plan 4–1. What are strategies to share with Claudia that will help wake up Lela and encourage her to breast-feed?

Human milk provides optimal nutritional support for a newborn. Breast-feeding is the feeding method most encouraged by healthcare providers today, resulting from the nutritional composition of the milk, the additional immunity it provides the infant in the form of antibodies, and the fact that it has the most easily digestible form of protein (National Association of Pediatric Nurse Practitioners, 2001; Yasmin, 2005). Human milk is readily available, inexpensive, and encourages bonding between the mother and infant. Ideally, the decision to breast-feed should be made before the child's birth. The American Academy of Pediatrics recommends breast-feeding exclusively (no supplemental formulas or baby foods) for approximately the first 6 months and supports continuing breast-feeding after foods are introduced to serve as the child's milk source for the entire first year, as long as it is mutually desired by the infant and the mother (American Academy of Pediatrics, 2005a). Research indicates that breast-fed children have a lower risk of being overweight or obese than those children fed formula (Arenz et al., 2004; Owen et al., 2005).

Difficulties can arise when the mother does not have the support or instruction she needs when first attempting to breast-feed. She may not have adequate knowledge to prevent problems such as sore nipples and engorgement or know the correct interventions to implement when a problem does occur (TIP 4–1). In her frustration, she may give up trying to breast-feed. The nurse plays an important role in providing the mother with the education she needs to breast-feed successfully (Fig. 4–6). Community resources such as the La Leche League are also available for mothers who experience difficulty with breast-feeding. Before the infant is discharged from the hospital or birthing center, provide the family with a list of resources that can be used

if the need arises (see [thePoint](#) for Organizations and Evidenced-Based Guidelines).

The newborn's first feeding optimally occurs in the delivery room. The first "milk" that is let down is **colostrum**, a substance that is produced for several days until the mother starts producing milk. Colostrum contains more protein, salt, and antibodies than regular milk, but less fat and calories. The newborn is fed when hungry, usually 10 to 12 times per 24 hours. Because of extracellular fluid, meconium loss, and limited initial food intake, infants can lose up to 10% of their birth weight but should start to regain weight by 2 weeks of age.

During the first few days of life, the infant will urinate about three to four times per day and produce stool one to two times per day. As the mother's milk supply increases, the infant will urinate and defecate more frequently. By the end of the first 2 weeks, the infant will create about six to eight wet cloth diapers or five to six wet disposable diapers and three to four stools per day (Story, Holt, & Sofka, 2002).

ANSWER: The first important tactic to teach Claudia is to be watchful of Lela's sleep-wake cycles. Ideally, Lela will be with Claudia throughout the day, so that Claudia can become attuned to the more subtle signs of wakefulness. It is important that nurses do not assume a mother who has successfully breast-fed one child has all the information needed to succeed with a different child. In utero, newborns have a constant source of glucose via the umbilical cord. Although they all swallow amniotic fluid, they have never before experienced "empty stomach" versus "full stomach." Although newborns are also born with a suck reflex, the urge to suck is stronger in some than others. Some newborns figure out pretty quickly that the "empty stomach"/falling glucose level is unpleasant and they vigorously protest their situation. Others seem not to notice until they have more experience with the "full stomach" sensation. Claudia will have to watch for Lela's wakefulness because she is not demanding to be fed. Ways to enhance her wakefulness include unwrapping her, gently washing her face with tepid water, and gentle stroking.

Positioning

Proper positioning during breast-feeding enables the newborn to latch on properly and effectively, and promotes the mother's comfort during feeding. Poor positioning can lead to sore nipples and a frustrated and hungry infant who is not able to suckle and get enough milk (Burns et al., 2008). The newborn should have the entire areola in his or her mouth, not just the nipple (Fig. 4–7).

Three comfortable positions can be used to achieve this goal: side lying, seated or cradle, and football. In the side-lying position, the mother lies on her side in the recumbent position. Pillows can be used to support the mother's back. The infant is placed in a side-lying position, cradled in the mother's arm, with the infant's mouth parallel to the mother's nipple and the feet toward the mother's waist.

NURSING INTERVENTIONS 4–1

Strategies for Dealing With the Challenging Feeder

Problem	Strategy	Rationale
Poor suck	<ol style="list-style-type: none"> 1. Assess if nipple is correct if bottle-fed: too hard, too big, or flow too slow. 2. Assess infant state: <ul style="list-style-type: none"> • If infant is sleepy, talk with the baby, change diaper, gently massage infant awake. • If infant is highly irritable, move to a quiet, dimly lit room. 3. Assess parent's anxiety level. Reassure parent frequently. Provide information materials (booklets, videos). Provide counseling support as needed. 4. Assess infant's hunger level. 	<ol style="list-style-type: none"> 1. Infant may be working too hard to initiate flow or unable to handle amount of flow. 2. Infant may be too sleepy to suck well or may be overstimulated and cannot focus on eating. 3. Anxious parents may transfer anxiety to infant, and infant will not suck well. 4. An overly hungry or satiated infant will not suck well.
Decreased motor postural control (e.g., children with cerebral palsy and neurodisabilities)	<ol style="list-style-type: none"> 1. Ensure child is in upright position with good head–trunk alignment. 2. Use chin–tuck head posture (head is upright and midline with neck flexion so that the chin is directed slightly downward and inward). 	<ol style="list-style-type: none"> 1. Alignment and stability of oral structures for feeding and swallowing may be compromised by abnormal or weak muscle tone.
Gastroesophageal reflux (GER)	<ol style="list-style-type: none"> 1. Assess if and how much infant regurgitates after feedings. 2. Elevate infant's head after every feeding. 3. Monitor amount of formula or breast milk the infant is taking. 4. Ensure the head of the infant is elevated while feeding. 	<ol style="list-style-type: none"> 1. A wet burp occasionally after feeding is normal, but if amount of fluid is significant, projectile, or the occurrence is regular, the baby may have reflux. 2. GER is commonly seen in premature infants. Can be caused by positioning, formula intolerance, or medical conditions. Proper positioning may decrease incidence. 3. It may be necessary to limit amount taken at any one feeding. 4. Proper position can prevent reflux.
Cleft lip or palate	<ol style="list-style-type: none"> 1. Assess extent of cleft lip or palate. If breast-feeding is not possible, modification of a nipple may be needed. 2. Monitor weight gain carefully in an infant with cleft lip or palate. 3. Feed slowly, evaluating child's ability to suck and swallow using modified nipple. 	<ol style="list-style-type: none"> 1. An infant with only a cleft lip may successfully breast-feed, if the mother prefers. If the child also has a cleft palate, breast-feeding may not be possible because of the inability to produce effective suction to extract the breast milk. 2. Ensures good nutrition and hydration. 3. Monitors for potential aspiration during feedings.

TIP 4 –1 A Teaching Intervention Plan to Prevent Breast-Feeding Problems

Nursing Diagnoses and Family Outcomes

- Effective breast-feeding related to adequate knowledge and skills

Outcomes: Mother expresses physical and psychological comfort with breast-feeding.

Mother reports she is able to effectively initiate actions to relieve breast-feeding problems when they occur.

Neonate feeds successfully on both breasts and appears to be satisfied after feeding.

Prevention and Intervention Measures

Painful Nipples

Prevention

- Avoid soaps, oils, lotions, or self-prescribed treatments.
- Position infant properly at breast, ensuring that entire areola is grasped.
- Hold the breast with the thumb above the areola and fingers and palm underneath it and to gently compress the breast and direct it into the infant's mouth; a scissors grasp may also be used compressing the areola between two fingers and supporting the breast to facilitate the infant's ability to grasp the areola properly.
- Apply small amount of breast milk to areola after a feeding and let it dry.
- Change nursing pads frequently; plastic-backed pads trap moisture and should be avoided.
- Expose nipples to air as much as possible; use of hair dryer on low setting may be helpful.

Interventions

- Nurse infant on less affected breast first and affected breast second
- Ensure proper positioning of infant at breast with entire areola grasped.
- Allow let-down reflex before putting infant to breast.
- Take aspirin or acetaminophen 30 minutes before a feeding to relieve excessive discomfort.
- Apply ice to nipples after feeding to decrease discomfort.

Engorgement or mastitis

Prevention

- Frequent nursing (every 2 to 4 hours) on both breasts to promote complete emptying to ducts.
- Provide proper support of breasts with well-fitting nursing bra, worn 24 hours a day.
- Divide feeding time relatively evenly between both breasts.
- Alternate from feeding to feeding the breast that infant nurses at first.

Interventions

- Manually express milk before putting infant to breast to nurse.
- Apply warm compresses or take a warm shower 10 to 15 minutes before feeding.
- If breasts are severely engorged, use cold compresses to decrease vascularity after a feeding.
- Massage breasts to promote emptying.
- If discomfort is excessive, consider taking aspirin or acetaminophen 30 minutes before feeding.
- Treat mastitis with antibiotics per health care provider presentation

Let-Down Reflex

Prevention

- Encourage infant to nurse at both breasts.
- Observe infant to see if he or she is swallowing every few sucks at the start of the feeding.
- Expose the opposite breast while nursing and see if milk flows from it as infant sucks.
- Slide a finger into the corner of the infant's mouth, breaking his or her suction to see if there is flow from that breast.

Interventions

- RELAX! Sit in a comfortable chair with good support for your back and arms.
- Listen to soothing music.
- Minimize distractions by finding a quiet corner.
- Gently massage the breast.
- Apply warmth to breast. Take a warm shower.
- Avoid alcohol, illegal drugs, and smoking because all contain substances that can interfere with let-down and affect the contents of breast milk.

Latching-On

Prevention

- Verify the infant is attaching to the nipple properly. Proper latching-on involves the infant taking the whole breast in his or her mouth, jaws closing around the areola, gums forming a circular seal, and creation of a vacuum effect; as the tongue strokes upward pressing the nipple against the palate, the milk ducts are emptied.
- Avoid bottles or pacifiers until breast-feeding is well established.

Interventions

- Ensure infant's tongue is down with the nipple directly on top of it during the feeding.
- Make sure infant is awake and alert when feeding; unwrap infant from blankets as needed.
- If nipples are partially inverted, use a nipple shield to draw out the nipple.

- Sprinkle glucose water on nipple before feeding. When the infant opens his or her mouth and tastes the glucose, the mouth can be directed and attached to the nipple in the correct fashion.

Inadequate Milk Supply

Interventions

- Encourage nursing at both breasts, six to eight times daily.
- Encourage adequate rest, nutrition, and fluids.
- Avoid use of supplemental formula feedings until breast feeding is well established (usual 3 to 4 weeks after delivery)

Fussy or Gassy Infant

Prevention

- Choose diet with care. What a mother eats and drinks may have some impact on breast milk volume and nutritional content.

- Drink caffeinated beverages in moderation.
- Eliminate foods that appear to irritate the child’s gastrointestinal system.

Contact Healthcare Provider if

- Mother has a fever.
- Infant refuses to eat.
- Infant remains fussy and irritable during 2-hour time increments between feedings.
- Infant is difficult to arouse or appears listless.
- Infant has less than 5 to 6 wet diapers a day.

In the seated or cradle position, which many mothers prefer, the mother sits upright with the infant cradled across her abdomen in a stomach-to-stomach alignment with the infant’s mouth at nipple level. The mother’s back and arms should be supported by a pillow under her knees (if she sits in bed) or a stool for her feet (if she sits in a chair).

The football hold is a variation on the seated position. While sitting, the mother cradles the infant’s body so that the infant is positioned at the mother’s side with

the feet extending toward her back. A pillow or blanket can be used to support the infant as the mother uses her arm and hand to support the baby’s head and neck.

FIGURE 4–6. The nurse can promote a positive experience by demonstrating breast-feeding techniques and encouraging the mother.

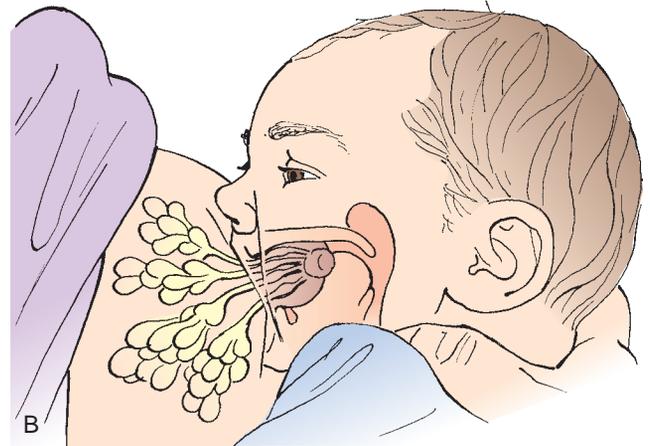

FIGURE 4–7. (A) A newborn with all of the nipple and areola in the mouth. (B) Diagram of newborn on breast correctly compressing milk ducts.

This technique is often used when twins are nursed simultaneously.

Fathers may feel left out of the feeding process. One way to encourage the father's participation is to have him be the "helper." He can get the child and change the diaper if needed while the mother finds a comfortable position. He can also participate when the infant is older by offering the infant water between feedings.

Breast-Feeding Routine

The mother should nurse the infant for 20 to 30 minutes each feeding, starting with 10 minutes on the first breast, burping the infant well, and then alternating to the second breast. The infant will be much more energetic nursing from the first breast and will empty it faster than the second, so it is important with each feeding to alternate which breast the newborn nurses from first. If the infant becomes sleepy after nursing on the first breast, stimulation with a diaper change, burping, or talking may be necessary so the infant will be alert enough to finish nursing on the second breast (Page-Goertz, 2005). To help a mother remember which breast should begin the next feeding, she can place a safety pin on the bra strap on that side. The mother can also wear a ring that she switches from hand to hand to remind her which side to start the next feeding.

Breast-fed newborns do not routinely need water between feedings. Ingestion of water may unintentionally decrease milk production, because the infant will not feel as hungry and will not nurse as vigorously. The well-nourished breast-fed infant does not need supplemental vitamins or minerals. However, iron supplements should be started at 4 to 6 months of age for infants who are exclusively breast-fed, because during this period fetal iron stores are depleted. If the infant is not regularly receiving any iron-fortified formula or iron-fortified cereal, then oral iron supplements, such as ferrous sulfate, may be needed. The breast-fed infant who has deeply pigmented skin or who does not receive enough sunlight (10–15 minutes per day) should be given 200 IU vitamin D daily to prevent the development of rickets.

caREminder

Oral ferrous sulfate can stain the teeth and will cause the infant's stools to be dark green or black. Advise parents to rinse the infant's mouth with a small amount of water after administering the iron supplement and to be aware that the color of their child's stool will change as a result of the iron intake.

Pumping the Breast

If the mother must be away from the infant during feeding times because of work or other activities, she

may elect to pump her breasts to provide milk for her child in her absence. Special bottle nipples are available to make the transition to bottle-feeding much smoother and to avoid nipple confusion. To prepare for returning to work, she should start pumping her breasts about 2 weeks beforehand. The ideal time to begin pumping is between the infant's first two feedings of the day. The volume of a mother's milk production diminishes during the day, so pumping early in the day will enable her to produce a good amount. Pumping can be completed at the workplace as long as the mother has time to pump (10–30 minutes, one to four times per day), privacy, and a place to refrigerate the milk. Many women find breast pumps easier to use than expressing breast milk by hand. Many different pumps are available, and a certified lactation consultant can assist the mother in making a choice. A mother who needs to use a breast pump should do so regularly to stimulate her milk supply.

Storing Breast Milk

Expressed breast milk can be refrigerated up to 8 days in the home refrigerator (33–39.2°F or >0°C to ≤4°C) and up to 12 months in a deep freezer (–4°F or –20°C) (Academy of Breastfeeding Medicine, 2004; Bowden & Greenberg, 2008). Freezing the milk does not harm its nutritional content, but it does destroy some of the antibodies. Breast milk should be stored in plastic or glass containers. If disposable bags are used, the milk should be double-bagged to prevent punctures or splits, and should be closed tightly with a twist tie or rubber band. In the freezer, breast milk in a plastic bag should be stored in a rigid, sealed container to reduce the possibility of freezer burn. Place the container in the back of the freezer to decrease temperature variations caused by frequent opening and closing of the freezer. When cooled, newly expressed breast milk can be added to an existing container of frozen breast milk and placed back in the freezer (see [thePoint](#) for Evidenced-Based Guidelines for additional information on storage and handling of human milk).

To thaw the milk, sit the container at room temperature, move the container to the refrigerator for several hours, or place the container under warm water until it has reached room temperature. Before use, shake the container of breast milk to mix the layers that have separated. The milk should be used within 1 hour of defrosting.

Alert! Never microwave human milk for defrosting or warming. Resultant "hot spots" from the microwave within the milk increases risk of burning the infant. Immunoglobulin A and other anti-infective properties are also reduced when microwaving.

Bottle-Feeding

QUESTION: Claudia is beginning to work at night. This is a time that Lela usually sleeps and only occasionally wakes to nurse a little bit. Claudia would like her to accept an occasional bottle just in case she wakes up. So far, when Claudia tries to give Lela a bottle, she grimaces, gags, and refuses to drink. What suggestions can you give Claudia?

The choice of expressing breast milk or using formula is up to the mother. She may not be able to pump at her place of work or, because of the environment, may not be able to relax enough to let her milk down. Using formula is a supplemental alternative that can be highly successful. As with breast milk, formula will meet the nutritional needs of the infant for the first 4 to 6 months of life (see Table 4-1).

Commercial formulas provide easily digestible protein; calories for energy; and fat, iron, vitamins, and minerals necessary for growth and development. Most formulas are cow's milk based. It is important to discuss with the parents the type of formula to use (see [thePoint](#) for Supplemental Information: Common Formulas for Infants and Young Children). Most infants are started on an iron-fortified formula that provides 20 kcal/oz. Low-iron formulas are not recommended for healthy infants, because most infants tolerate the regular iron-fortified formulas well, without any constipation, gastrointestinal disturbances, or toxic effect. If the family has a history of lactose intolerance, the healthcare provider may recommend a soy formula.

Controlling fluid intake while bottle-feeding is regulated by the softness of the nipple, the size of the nipple hole, and the size of the bottle. For the term newborn, three primary types of nipples are available commercially. The regular nipple is elongated and teat shaped. The NUK nipple has a wide, flat tip that fits below the hard palate. The Playtex nipple is short and has a square shape. For the premature newborn, premature or special care nipples are available, but these types are not recommended, even if the infant has a weak suck. Use of these nipples does not develop the muscles needed to suck, and infants using these nipples have a greater risk for aspiration.

The breast-feeding mother may elect to introduce the bottle for supplemental feedings when she is at work or engaged in other activities that take her away from the infant during feedings. The best time to introduce the bottle for supplemental feedings to the breast-fed child is at 3 to 4 weeks of age. The mother can begin offering the infant a bottle to replace one or more of the feedings from the breast. These bottles can contain breast milk, water, or formula (perhaps just 1 or 2 oz at first). It may take several tries for the infant to accept a rubber nipple, particularly if the infant has never been exposed to a pacifier. After the infant has accepted the bottle, a bottle should be offered at least once a week to maintain the infant's skill in using the nipple.

KidKare ■ If the infant has been breast-fed and balks at taking the bottle, have someone other than the mother offer the bottle (an ideal way for the father to become involved). Also, try bottle-feeding when the infant is sleepy, distracted, or very hungry. Use expressed breast milk at first, because the infant is used to the taste, and spread a little on the rubber nipple. Experiment with different-shaped nipples, and warm the nipple to about body temperature. If the problem seems to be getting the infant to accept an alternate caregiver, have the alternate caregiver use the same perfume as the mother or use a receiving blanket the mother has used, so the infant smells the same scents as when mother is feeding him or her.

ANSWER: The first step in helping Lela accept an occasional bottle is assessment. What type of bottle and nipple is Claudia trying? What type of liquid is in the bottle? Is it always Claudia offering the bottle? Many infants have an exaggerated gag reflex, and the elongated-type nipple may trigger her gag reflex. Suggest the Playtex nipple. If Lela does not like change, suggest using expressed breast milk warmed to body temperature. If Claudia does not have any expressed breast milk, the powdered formula mixed with warm, sterile water is a closer consistency to breast milk than the prepared formulas. Suggest that Selma or Ignacio offer the bottle and that Claudia be out of sight. Make "bottle time" a part of the daily routine so that it becomes more familiar to Lela, even if she does not really drink from it initially.

Preparing Formula

Many of the commercial formulas come premade and ready-to-feed, and simply have to be poured into a sterilized bottle. To provide formula to the infant, select glass bottles or plastic bottles that do not contain bisphenol A in their composition.

Alert! Bisphenol A has been commonly used to make clear polycarbonate plastic for products, such as baby bottles. With as few as 50 to 100 washings, this plastic breaks down and leaches bisphenol into the formula placed in the bottle. Although not labeled as such, many plastic baby bottles are made from polycarbonate plastic containing bisphenol A (Environment California Research & Policy Center, 2007).

Concentrated or powdered formulas should be prepared by carefully following the manufacturer's directions. Bottles and nipples should be cleaned after each feeding using a bottle sterilizer. Electric steam sterilizers are available, as are models that can be used in microwaves. Bottles and nipples can also be sterilized by

boiling them in water for 10 minutes. Cold-water sterilization is commercially available and consists of tablets dissolved in a prescribed amount of water to form a solution that is effective against bacteria.

Alert! Instruct parents not to alter the composition of the formula by adding more or less water than directed in the instructions. Overdiluted formulas can cause water intoxication and lead to malnutrition. Feeding a too-concentrated formula can cause renal problems.

Formula should not be prepared any more than 24 hours in advance and, after it is prepared, should be refrigerated. Discard any refrigerated formula left over after 24 hours, because of the potential for bacterial growth. For feeding, the temperature of the formula should be room or body temperature, although some infants do not mind cold (from the refrigerator) formula, particularly in hot weather. Formula should not be heated in a microwave oven, because doing so often heats formula unevenly and could make portions of the formula exceptionally hot and cause burns. To ensure that the formula is not too hot for the infant, shake the bottle to mix the formula and test the temperature by shaking a few drops onto the inside of the wrist. Formula should feel cool to warm. Bottle-fed infants, like breast-fed infants, should not need supplemental water during the first 6 months, unless the child has a fever or diarrhea, or the weather is very hot. Supplemental vitamins and minerals are generally not necessary for the first 6 months. After the sixth month, fluoride supplements are recommended if local water supplies are not fluoridated or if the infant is given cereals in which fluoridated water is not added. Parents should not offer low-iron milks (e.g., cow, goat, soy) to their child until the child is at least 12 months old. Cow's or goat's milk can contribute to anemia, because both are deficient in iron. Infants should also never receive low-fat or nonfat milk, because these milks do not have the fat, calories, or iron needed to support the rapid growth and development that occurs at this age.

By the time the infant is a year old, his or her body is physiologically ready to digest whole milk, because the gastrointestinal tract is more mature and allergic reactions are less likely. Common gastrointestinal presentations for cow's milk allergy or hypersensitivity include vomiting, diarrhea, wheezing, bloody stools, and colic. Respiratory symptoms may also occur and include rhinitis, coughing, bronchitis, and asthma. Other signs and symptoms include fussiness, eczema, and prolonged crying. Treatment for milk allergy is to switch the infant to a protein hydrolysate formula such as Nutramigen, Alimentum, or Pregestimil. The protein in these formulas has been broken down into amino acids. Healthcare providers may recommend a soy-based formula first, although 50% of infants with cow's milk sensitivity are also sensitive to soy (Sicherer, 2003).

Positioning

Positioning is as important in bottle-feeding as it is in breast-feeding. The infant's head should be elevated, and the infant should be held close to the mother in a semi-Fowler position. The bottle should be tilted so the formula fills the nipple. The nipple is placed on top of the tongue. The hole in the nipple should allow the milk to drop slowly from the bottle, rather than streaming out or having to be squeezed out. Frequently during and after the feeding the infant should be burped. The infant will burp up a little air and possibly a little formula, a very common event known as a *wet burp*. As long as the volume returned is small, and the burp occurs only when air is passing the vocal cords, it is normal. Vomiting large amounts of formula immediately after feeding, or projectile vomiting, is not normal and requires referral to the healthcare provider. Table 18–1 describes abnormal emesis and stool associated with health concerns that must be addressed by the healthcare provider.

Bottles should never be “propped”—that is, the infant should not be laid down with a bottle positioned on a pillow or blanket to hold the bottle to the baby's mouth. When the infant is fed by propping the bottle, risk for aspiration of the formula is substantial, and potential for developing otitis media is increased, because milk pools in the eustachian tubes and contributes to bacterial growth. Furthermore, this method does not encourage maternal bonding with the infant and may cause the child to become uninterested in feeding (Story et al., 2002).

Starting Solid Foods

By 4 to 6 months of age, the infant should be developmentally ready for the introduction of solid foods (Story et al., 2002). The infant's chronologic age is not as meaningful as whether the infant has developed the skills necessary to handle spoon-feeding (Chart 4–2).

CHART 4–2 ASSESSING READINESS TO BEGIN INTRODUCTION OF SOLID FOODS TO THE INFANT

- The tongue-thrust reflex is extinguished.
- Drooling is present.
- Infant is able to sit fairly upright.
- The suck–swallow reflex is present.
- Infant demonstrates sensory readiness cues (mouthing of toys and objects).
- Infant is easily distracted from the bottle or breast-feeding.
- Infant birth weight is doubled and infant weighs about 13 lb.
- Infant demonstrates an interest in table food (e.g., reaching for food or eating utensils, protesting when he or she sees others eat food).

Introducing the Spoon

During the first attempts to feed with a spoon, food with a semiliquid consistency allows the infant to use the suck and swallow reflexes while adjusting to this new food delivery method. Introducing the spoon may cause the infant to turn away, spit out food, or bat it away with the hands, but given patience and perseverance, the infant will eventually accept the spoon. Do not introduce the spoon when the infant is extremely hungry, tired, or ill. The best time to start solids is at the noon or early-evening feeding, when the infant is not sleepy and may be more interested in a new activity. An infant spoon, coated with a pliable plastic and properly sized for the infant's mouth, is used because it feels softer than metal. If a coated spoon is not available, any spoon smaller than a teaspoon will work (Fig. 4–8).

Progression of Food Introduction

QUESTION: At 8 months, Lela can sit well and has sufficient fine motor skills to pick up small objects. Lela does not like to be fed. She turns her head, makes a face, and then spits out the baby food. Jose, her older brother, would open his mouth like a baby bird and let Claudia spoon the food in. Claudia is at a loss what to do. She is tired from working three nightshifts a week in addition to caring for the children and their home, and has just let Lela continue breast-feeding. What can you suggest to Claudia?

The first solid food should be rice cereal mixed with a little breast milk or formula. Rice cereal is very bland, is easily digestible, and rarely causes allergic reactions. Do not mix cereals in the bottle with the formula or breast milk for the infant to drink or offer plunger feedings. These approaches merely increase the calories ingested without enabling the infant to learn the process of meal taking or experience the various consistencies of solid foods, thus placing the infant

FIGURE 4–8. At about 4 to 6 months of age, solid foods are often introduced. The infant soon learns to manipulate the tongue and comes to enjoy this new way of eating.

at risk for obesity. When introducing rice cereal, give a small amount of breast milk or formula to drink before offering the cereal mixed with formula or breast milk. Place a small amount of cereal toward the middle or back of the tongue. The infant most likely will not know what to do with the cereal and may spit it out or make a face. Most of the first feedings will not be swallowed; rather, the food usually ends up all over the child. After the infant grows accustomed to the cereal and has no difficulty swallowing, the amount offered can be increased. After about a week, if feeding is going well, another type of cereal can be introduced. After a careful assessment of family allergies has been done, introduce rice, oats, barley, and wheat, in that order. Before adding another type of solid food, wait 7 days to rule out allergies. Wheat cereals cause the highest rate of allergic reactions in infants (Burns et al., 2008; Yasmin, 2005).

Cereal products can sustain the child's need for solid food up until age 6 months. After cereals, other solid foods are introduced as the child's nutritional needs increase. These foods are introduced very slowly, no more than one per week, again to watch for allergic reactions. The order of introduction should be vegetables, then fruits, and then meats, each pureed and of a very thin consistency. Over-feeding or offering the wrong type of foods, especially high-calorie foods, may cause excessive weight gain, leading to obesity-associated medical problems. Some research studies report a significant association between infant size and childhood and adult obesity (Eriksson et al., 2003). The obesity status of parents of young children is the best predictor of whether a child will be obese (Hoppin & Taveras, 2004; Polhamus et al., 2005).

As teeth erupt and the child gains skills in swallowing and chewing, the texture of the food can be varied and can become thicker and chunkier. Avoid foods that are easily aspirated or choked on. To reduce the risk of choking or other accident, the infant should always be supervised by an adult while eating. At 6 months of age, solid foods are served two to three times per day at family mealtimes. By 9 months, the infant is offered solid foods three to four times a day. It may take 15 to 20 attempts before an infant accepts a particular kind of food (Story et al., 2002).

caREminder

When an infant is hospitalized, it is important to assess which foods the child already eats and to avoid introducing new foods during the illness. Every effort must be made to ensure that an allergic reaction to a food is not triggered during an illness, because then ascertaining the true cause of symptoms, such as a rash, vomiting, or diarrhea, is difficult.

Certain foods are avoided until late in the first year, because they are considered major allergens or because the infant's gastrointestinal system is not adequately mature. These foods include eggs, corn syrup solids, citrus fruits and juices, tomatoes, strawberries, seafood, spices, and chocolate. When introducing vegetables such as peas, beans, or beets, finding some green or red particles in the stool is common for the first day or so after

the food is first given. Because the intestinal tract has not totally matured, it must adapt to a new food, and some of it may be passed undigested.

Alert! To prevent botulism, do not give the infant honey or foods with a low acid content, such as home-canned fruits and vegetables, until after the child's first birthday.

ANSWER: One suggestion when introducing solids is to encourage Claudia to allow Lela to feed herself. It is very messy at first, but some children have a very strong independent streak and will not be passively fed. Encourage her to put food directly on the tray or find a bowl that will stay on the high chair tray, and have a large bib and a spoon that Lela can hold herself. She should start with iron-fortified rice cereal and then progress to vegetables.

Introducing the Cup

At 6 months of age, use of the cup to drink fluids can be started. Instead of giving a bottle, place a small amount of formula or breast milk in a cup (about one-quarter full at first) to help the child become accustomed to and proficient at using a cup. Cups with specialized covers can be used to prevent spills and to regulate the amount of fluid that flows. Handles on the cups enable the infant to grasp the cup easily and stably bring it to the mouth.

With the introduction of the cup comes the introduction of fruit juices (Tradition or Science 4–2). The

TRADITION OR SCIENCE 4–2

Fruit juice often is recommended as a source of vitamin C and an extra source of water for healthy infants and children, but does this recommendation hold water?

EVIDENCE-BASED PRACTICE

Fruit juices taste good and children enjoy the flavor. Fruit juice is a natural source of vitamins, contains no fat or cholesterol, and, unless pulp is included, contains no fiber (Baker, 2007). The American Academy of Pediatrics has concluded that fruit juice offers no nutritional value for children younger than 6 months, nor any nutritional benefits over those of whole fruit for infants older than 6 months and children. Parents should not give infants juice from bottles or easily transportable covered cups that enable the child to consume the juice easily throughout the day. Infants should not be given juice at bedtime. Excessive juice consumption may be associated with malnutrition, diarrhea, flatulence, abdominal distention, and tooth decay (American Academy of Pediatrics, Committee on Nutrition, 2001). In children age 2 to 5 years, excessive fruit juice consumption has been associated with obesity and short stature (Dennison, Rockwell, & Baker, 1997; Faith et al., 2006).

amount of juice is limited to 4 to 6 oz per day so as not to suppress the child's desire to have breast milk or formula. The first fruit juice is usually low in acidity and may be diluted to half strength with water. Low-acidity juices include apple and white grape juices. Orange, grapefruit, and pineapple juices should be avoided until the infant's bowel is more mature (Hagan et al., 2008).

When the infant is able to drink a sufficient amount of fluids from a cup, it is an opportune time for weaning from the bottle or breast. The breast-fed infant who is comfortable using the cup can be weaned directly from breast to cup. Although the infant may tolerate weaning from the breast well, the mother may become depressed as she stops producing milk and feel that she is no longer "needed" for her nutritional support. Supporting the mother through this time is essential, because these feelings may severely affect her relationship with the infant.

A bottle-feeding infant can be weaned by changing the fluid put in the bottle. Formula should be offered only in the cup, and only water should be offered in the bottle. The infant will be attracted to the cup because it contains the more palatable liquid. Weaning can also be completed gradually by eliminating all except the nighttime bottle. If the bottle is not in sight and not accessible during the day, the infant quickly learns that the bottle will be offered only at bedtime.

Elimination

QUESTION: Lela did not have a diaper rash until meat was introduced into her diet. Her stools immediately changed color and odor. If the stool is in contact with her skin for only a few minutes, it turns pink. Fortunately, the strong odor alerts the parents that Lela needs a diaper change. What can you recommend to the family in response to this change in Lela's stools?

If the infant was delivered without complications and did not pass meconium while still in utero (see Chapter 14), the first bowel movement after birth is to pass the meconium. **Meconium** is a sticky, thick, greenish black, tarry stool made up of epithelial cells, salts, bile, and mucus, and usually is without a strong odor. This stool appears within the first 24 hours and may persist for up to 3 days.

The stools of the breast-fed infant are usually yellow and very soft to thick liquid in consistency with little or no unpleasant smell. Breast-fed infants pass less stool than bottle-fed infants do. The bottle-fed infant produces stools that can vary from pale yellow-brown and almost liquid to greenish brown and pasty. When the infant starts feeding, the stools take on a consistency determined by the food ingested. The newborn generally has a bowel movement every time he or she is fed, but if the infant does not have a bowel movement for several days, this pattern, too, is normal. As the infant develops, normal elimination patterns become more rhythmic and individualized; some infants have two or three bowel movements a day, some have only one. Infants usually bear down, grunt, and

appear to strain when having a bowel movement. This behavior is not necessarily a sign of difficulty.

The infant's first urination occurs within the first 24 hours of life. Production of urine is 200 to 300 mL/day, increasing as the infant matures, which can translate into six to eight diapers per day. Healthy urine is clear, colorless to very pale yellow, and does not have a strong odor. If an infant is dehydrated, there will be no wet diaper for several hours; the urine may appear darker in color and smell stronger than normal, indicating that it is concentrated. Although concentration of the urine is not the only indication of dehydration, be alert to the possibility and check other potential signs.

ANSWER: Changes in diet will result in changes in an infant's stool. Infants may initially lack the ability to digest new foods completely. The Diaz family is on the right track in that they change Lela immediately. A barrier cream on her buttocks could also help protect her skin.

Constipation

Constipation is present when an infant produces very hard stools or no stool within the normal schedule. Hard stools are more common with formula feeding, with initiation of solid foods, and during illness. Constipation is usually caused by a change in the amount of water or fluids the infant receives while eating solids, or by a lack of water ingested when ill. Also, if the weather is very hot, the child may need extra water to supply enough water in the stool.

When constipation occurs, offering low-acid fruit juices (such as apple or white grape juice) to infants younger than 4 months up to twice a day can be very effective. Continuing fruit juices beyond this treatment period is not recommended. Enemas and suppositories are not recommended for small infants. If the child is taking solids, increasing the amount of high-fiber baby foods such as cereals, prunes, and peaches may assist in elimination; bananas and carrots should be avoided because they may increase constipation (see Chapter 18 for more information on constipation and diarrhea).

Diarrhea

Although infants normally have very soft to liquid stools, they should not have frequent and extremely watery stools. Diarrhea is usually a sign of illness or intolerance to a specific food or type of formula. Monitoring the infant closely during diarrhea is important, because frequent watery stools can lead to dehydration (see Chapter 17). The infant must continue to ingest formula or human milk to correct the fluid loss. Breast-fed and bottle-fed infants may need extra water (or electrolyte solutions) between feedings. When a formula intolerance is suspected, the infant should be given clear liquids for 4 to 6 hours and then be offered a soy-based or a protein hydrolysate formula (American Academy of Pediatrics, 2004b). Parents should contact the healthcare provider

immediately if the infant refuses to accept the bottle or the breast, cries without tears, does not have a wet diaper for more than 8 hours, has a dry mouth, or if any blood is seen in the diarrhea. The infant with diarrhea also is at risk for diaper rash. Meticulous perineal care, frequent diaper changes, and a barrier agent should be used to prevent skin breakdown (see Chapter 25 for a detailed description of diaper dermatitis).

PERSONAL AND SOCIAL DEVELOPMENT

The maturing infant is not capable of seeking activities that will provide optimal sensory and developmental stimulation; he or she depends on adults to provide meaningful activities that will stimulate development while promoting trust and security. Parents do not automatically understand all of the infant's needs nor have the tools to meet those needs readily. The healthcare provider's responsibility is to provide parents education to augment their knowledge base and to ensure an optimal environment in which the infant can learn and grow. Nursing Interventions Classification (NIC) 4–2 provides an overview of appropriate sensory activities to promote development and movement during the first year of life.

Temperament

Temperament is defined as the combination of intellectual, emotional, ethical, and physical characteristics of an individual. It is the natural inborn style of behavior of each individual. Every infant has his or her own set of temperament traits or characteristics (Turecki, 2003). Nine temperament traits can be used to classify a child from being very easy to raise to being very difficult: activity level, distractibility, intensity, regularity, persistence, sensory threshold, approach/withdrawal, adaptability, and mood (see Chapter 3). By assessing a child for these traits, a professional or a parent can determine to what extent the behaviors associated with each trait may be demonstrated by the child (Turecki, 2003).

Brazelton (1992) identified three types of infant temperaments: the average child, the quiet child, and the active child. Each temperamental category represents a totally normal developmental type, with specific characteristics. These characteristics often are strictly parents' perceptions of what the child is like, and many parents link the personality type to use of drugs during delivery or to parenting skills.

The average child is usually easygoing and is predictable in responses to environmental stimulations. The quiet child is unusually quiet and does not cry as much as the average child, yet does not appear developmentally delayed in any way. The active child can often be referred to as a "difficult" child (Fig. 4–9). These are the children that even as infants are restless, are irritable, cry inconsolably, and often have unpredictable schedules for feeding and sleeping (Turecki, 2003).

NIC 4 –2 Nursing Interventions Classification: Teaching Infant Stimulation

Definition: Teaching parents and caregivers to provide developmentally appropriate sensory activities to promote development and movement during the first year of life

Activities:

Teach normal infant development
 Assist parents to identify infant readiness cues and responses to stimulation
 Protect infant from overstimulation
 Assist parents to set up routine for infant stimulation
 Teach parents/caregivers to perform activities that encourage movement and/or provide sensory stimulation
 Have parents demonstrate techniques learned during teaching

Instruct parents of infants 0–4 months to:

Promote face-to-face interaction with infant
 Talk, sing, and smile at infant while giving care, describing care to infant
 Praise infant for all efforts to respond to stimulation
 Tell infant his/her name frequently
 Whisper to infant
 Touch and hug infant frequently
 Respond to crying by holding, rocking, singing, talking, walking, repositioning, rubbing/massaging back, wrapping, as appropriate
 Rock infant in either an upright or cradle position
 Sponge or tub bath using various massaging strokes with a soft washcloth or sponge and pat dry with soft towel
 Massage infant by rubbing lotion in gentle but firm strokes
 Rub soft toys on infant's body
 Encourage infant to feel different textures and identify them for infant
 Blow air in circles on alert infant's arms, legs, and tummy
 Encourage infant to grasp soft toys or caregiver's fingers
 Promote shaking of raffles, encouraging auditory following
 Provide opportunities for infant to reach for objects
 Encourage visual following of objects
 Reposition infant every hour unless sleeping, placing in infant seat, swing, stroller, as appropriate
 Place infant on tummy while awake to encourage head lifting

Position infant on back under cradle gym
 Play peek-a-boo with infant
 Encourage infant to look in mirror

Instruct parents of infants 5–8 months to:

Place infant on tummy, putting caregiver's palms on soles of infant's feet, and push gently forward
 Stand infant on caregiver's lap, swaying side to side
 Encourage infant to lie on back and kick with feet
 Lay infant on back or tummy and help to roll over
 Provide opportunity for infant to explore cloth or soft plastic books
 Introduce infant to body parts
 Encourage infant to use toys for teething
 Play pot-a-cake with infant
 Hide objects and let infant look for them
 Encourage infant to bang toys together
 Encourage hand transfer of toys
 Place infant in high chair, encouraging infant to feel food and feed self
 Dance with infant while holding infant upright

Instruct parents of infants 9–12 months to:

Pull infant to standing, holding onto hands for stabilization
 Guide infant to walk, holding infant by hands/wrists with arms above head
 Encourage ball play (e.g., rolling, grasping, stopping, retrieving)
 Introduce use of cup at meal times, assisting infant to grasp and put to mouth
 Wave bye-bye to infant, encouraging infant to imitate
 Take infant on a house tour, identifying objects and rooms
 Play follow the leader, practicing imitation of infant noises, animals, or songs
 Say words to infant, encouraging infant to say them back
 Demonstrate how to remove objects from and replace them in a container
 Demonstrate stacking objects

From Bulechek, G., Butcher, H. & McCloskey Dochterman, J. (Eds.). (2008). *Nursing interventions classification (NIC)* (5th ed.). St. Louis, MO: Mosby. Used with permission.

Colic

Infants commonly have a regular “fussy” period during the day (usually around 6 PM to midnight), but if the crying does not stop and continues for more than 3 hours, or the infant appears inconsolable, often pulling up the legs and passing gas, this “fussiness” may reflect **colic** (gastrointestinal pain). In breast-fed infants, colic sometimes

is a reaction to something the mother has eaten. In other infants, colic may result from sensitivity to milk or milk products. Breast-fed infants are just as likely to have colic as those who are bottle-fed (Clifford et al., 2002). Colic may indicate a medical problem, but this circumstance is very rare. Episodes generally peak at about 6 weeks of age and stop at about 3 months of age (Neu & Robinson, 2003; Nield & Kamat, 2003).

FIGURE 4–9. The infant with an “active” temperament may be irritable and cry inconsolably.

Several interventions can alleviate this problem. These interventions are directed toward creating a soothing and restful environment for the infant (Developmental Considerations 4–4) (Neu & Robinson, 2003; Nield & Kamat, 2003). Changing the infant’s formula may also decrease symptoms; soy formula has been helpful in some studies (Campbell, 1989; Garrison & Christakis, 2000; Oggero et al., 1994), although not all. The use of whey hydrolyzated or casein-hydrolyzed formula has been associated with a significant decrease in infant crying (Jakobsson et al., 2000; Lucassen et al., 2000). Although simethicone drops (0.3 mL three times daily) may be recommended, research does not indicate that they are effective (Danielsson & Hwang, 1985; Garrison & Christakis, 2000; Metcalf et al., 1994).

If the mother is breast-feeding, she should eliminate from her diet any foods that produce gas (e.g., cabbage, onions, broccoli) and reduce her caffeine intake. She should also eliminate milk products from her diet, particularly if there is a family history of milk intolerance or other allergies. If the infant is bottle-feeding, a formula that is not based on cow’s milk can be tried. Usually, colic caused by food intolerance will improve in 1 to 2 days.

Other strategies are to use a baby carrier to keep the infant close to the body and in motion or to place the infant near a steady rhythmic sound such as a vacuum cleaner or clothes dryer. Laying the infant on his or her

stomach across the parent’s knees, with a pacifier, while rocking often helps relieve any discomfort. Cuddling and rocking the infant is often helpful. Rocking with a windup swing or cradle often enables the infant to relax and go to sleep. Vibrating chair seats are also helpful. Warm baths may also relax and soothe, creating a more comfortable state and helping to induce sleep.

It is important for the parents to occasionally get away from an incessantly crying infant, just to clear their minds. A trusted sitter or friend can stay with the child for a few hours at least once each week. If this respite is not available, the parents can alternate caregiving activities to give each other a breather. Parents should also be given support and empathy as they cope with this stressful experience.

Relationships

An infant’s first relationships are with his or her family. Through these relationships, the infant learns how to interact with others.

Parent–Child Attachment

Attachment is the affectional bond that creates an important foundation for the relationship between the parent and the infant. Attachment encourages protectiveness and the development of trust and empathy between the parent and child. Healthcare professionals must do as much as possible to encourage attachment, especially if a mother or father does not immediately bond with the infant, as can occur after a particularly difficult delivery.

Certain identifiable behaviors—eye-to-eye contact, physical contact, and communication—indicate that attachment is occurring. The nurse should be concerned if the parent avoids eye contact and physical contact with the infant or if, when contact is unavoidable, the infant is not held close to the parent’s body. By 3 weeks of age, the infant responds to the mother by cooing, making eye contact, sucking, pupil dilation, or face brightening. These behaviors tell the nurse that attachment is occurring normally. Some of these behaviors may be difficult to observe, particularly if birth was by cesarean section and the mother is recovering from anesthesia, or if cultural practices do not allow certain behaviors. Attachment may be delayed if the parent has medical problems or is

DEVELOPMENTAL CONSIDERATIONS 4–4

The REST Regimen for Managing the Child with Colic

- **Regulating** the infant’s state by preventing overarousal calms the infant. Infant states should be learned by parents and modulated (see Developmental Considerations 4–3).
- **Environmental** cues such as light and dark, noise and quiet, help to synchronize the infant’s behavior.
- **Structure** and repetition make events reassuringly predictable for the infant.
- **Touch** (chest-to-chest or skin-to-skin) soothes the child and diminishes stimulation.

ill, or if the infant is removed from the mother immediately after birth because of illness or frailty. Family discord or an ineffective support system can also contribute to poor or inadequate attachment.

To promote attachment, the mother/father and infant should have time together as soon as possible, during which the parents can cuddle, talk to, and examine the infant. Ideally, this attachment will occur within the first hour after delivery, but it can occur later without any problem. If the infant is in an intensive care unit, the parents should be allowed to view the infant and touch or stroke the infant's hand or foot.

After the infant is born, many fathers feel left out and not needed for feeding (particularly with breast-fed infants) or other care. Many fathers want to achieve closeness to the baby but often feel this closeness is not possible because the mother–infant bond is so strong (Nystrom & Ohrling, 2004). Fathers can and should become involved with all aspects of the infant's care and cuddling. Fathers, like mothers, need private time to bond with the infant. This time should be encouraged, but not pushed.

Sibling Adjustment to the Newborn

QUESTION: When Lela was about a month old, Claudia placed her in an infant seat on the floor in the living room where Jose was watching television. A moment later from the kitchen, she heard a thump and then a wail. She ran into the living room. Jose was still on the couch staring hard at the television and Lela was tipped over but still belted in her infant seat, crying. Claudia asked Jose, "How did your sister fall over?" Jose answered, "I pushed her!" How would you recommend that Claudia approach this situation?

How a child experiences a mother's pregnancy and subsequent arrival of a new sibling is affected by three factors:

1. The child's state of emotional and social development
2. The child's cognitive abilities, such as the child's ability to reason and solve problems
3. The child's level of separation and independence from the mother

Some degree of stress resulting from the birth of a younger sibling can be expected. The degree of stress or upset after the birth does not predict the quality of future sibling relationships. Many older children demonstrate substantial developmental gains after the birth of younger siblings. For instance, the child who reverts to thumb sucking may also begin to start dressing himself or herself. Siblings spaced about 2 years apart are likely to experience the greatest degree of stress with the arrival of a new brother or sister, because they must deal with increased separation from the mother at a time when they find separation and the decreased lack of attention especially difficult. In addition, a very young sibling may not have the cognitive and verbal skills to express complex emotions.

There is no "best time" to tell siblings about the pregnancy and impending birth. The timing depends on the age of the older children. Young children (less than

6 years of age) do not need much lead time, because they are not able to measure time in terms of weeks or months. The beginning of the second trimester is a good time to share the news with children, or the point at which the mother's protruding abdomen is evident to the child. School-aged children should hear the news as soon as the family plans to tell friends and other family members. Older siblings should learn the news before it is shared with grandparents or others, so that they do not accidentally hear the information from someone besides the parents.

The news of the pregnancy may not be greeted with joy by the older sibling. The older child may struggle with the new role and worry about the changes that will occur in the family. Providing loving support and developmentally appropriate discussions can help the child to adapt to the changes.

The older child may also feel frustrated because he or she has already noted changes in the home environment during the mother's pregnancy. Many physical and psychological changes occur to the mother during pregnancy. Although the mother may feel physically well, the child may be deprived of the mother's attention as she focuses inward on her pregnancy and the fetus. The normal physiologic changes of pregnancy may cause the mother to be more tired, irritable, and moody. In addition, as her abdomen grows, it may be increasingly more difficult to pick up and carry younger siblings or even to sit with them on her lap.

The arrival of the new family member affects all aspects of family life and all relationships in the family. Not only are the parents welcoming a new child into the home, other children will welcome and need to adjust to a new brother or sister. Having a sibling has been described as the single most beneficial way in which children can learn how to relate and interact appropriately with others (Fig. 4–10). During the pregnancy and after the arrival of the infant, the sibling needs to continue to feel loved, wanted, and valued. This need is important regardless of the child's age or the way he or she may show his or her feelings. To promote successful sibling relationships, a parent should know that the effect on the older child begins during the pregnancy and will continue through the first several months after the newborn's arrival at home. TIP 4–2 summarizes several interventions that can help to alleviate sibling jealousy and promote bonding between siblings (see also discussion in Chapter 5).

ANSWER: As the nurse talking to Claudia, there are several points to make. One is that Claudia must reinforce to Jose that we never, ever hurt our baby. The other is that this is not a good time for spanking. Spanking at this time reinforces the notion that the adult is bigger and can hurt Jose; therefore, Jose is bigger and can hurt the baby. Another issue is that Jose is resenting Lela and may need a little more attention at this time. Reading to a toddler while nursing the baby is a good way to reduce jealousy over the time mommy is spending snuggled with that new baby. Review TIP 4–2 for other ideas to help a sibling accept a new baby.

TIP 4–2 A Teaching Intervention Plan to Prepare Siblings for the Arrival of the Newborn

Nursing Diagnosis and Family Outcomes

- **Interrupted family process related to addition of new members**

Outcomes: Family members will voice realistic expectation of sibling's behavior and reaction to the newborn.

Sibling will experience feelings of support, love, and nurturance from parents.

Sibling will participate in activities to prepare for the arrival of the newborn.

Sibling will participate in age-appropriate care activities and social interactions with the newborn.

Guidance for Family Members

Involve the Sibling in the Pregnancy

Activities for the Child

- Have the sibling attend a doctor's appointment with the mother. If possible, allow the child to be present during the ultrasound examination.
- Let the sibling feel the fetus's movements.
- Visit friends who have a newborn in their home. Discuss what it will be like to have "our baby" at home.
- See if the hospital provides sibling classes in which the older child can learn about newborns.
- Read books together about what happens during pregnancy, what it is like to be a big brother or sister.
- Male and female toddlers and preschoolers can benefit from having a doll to teach sibling about the care of the newborn and to allow the child expression of his or her feelings regarding the arrival of the sibling.

Preparation for the Newcomer

- Encourage the older child to help prepare and decorate the infant's room. Let the sibling be involved in selecting and purchasing clothes for the newborn.
- Encourage the older child to help select the newborn's name.
- Place a picture of the older sibling in the newborn's room.
- Let the older sibling pick the outfit the newborn will wear home from the hospital.

Avoid Pursuing New Developmental Challenges

Change in the Child's Environment and Routines

- Changes in the older child's environment or routine should be made several months before the birth so that the child will not feel pushed out or shoved aside for the newborn.
- If the child will be starting a new daycare or nursery school, do this well in advance of the delivery.

- Do not make any demands for new skills such as toilet training and bottle weaning during the months just preceding the delivery. Even if the child appears ready, wait until after he or she has adjusted to the arrival of the newcomer.

Increase Father's Participation

- Have the father get more involved in the daily activities of the child. The sibling will better tolerate less motherly attention during the mother's hospitalization and after the newborn's arrival if the father or another significant family member has become more involved in the child's care.

The Time of Delivery

Siblings at the Birth

- Some hospitals and birthing centers permit siblings to be included in the birthing process. These children must be prepared in advance for the sights and sounds they will encounter.
- An adult who is emotionally close to the child should be assigned the responsibility of monitoring the child during the birthing process.
- In general, studies have shown that children younger than the age of 4 have difficulty attending the birth. At these ages they are still quite dependent on their mother for emotional support and can become overly concerned and distressed by the mother's physical exertion during the birthing process.

Care of the Sibling Left at Home

- Tell the child where the mother is going and who will care for child where the mother is at the hospital. Optimally, the child should know the "baby-sitter" well and the sitter should have been thoroughly prepared to step in at any time.
- Prepare in advance written instructions of the older children's routines for the baby-sitter to follow.
- Encourage the father, grandparents, or special friends to take the child on a special outing while the mother is in the hospital.

Visiting Mother in the Hospital

- Try to have the older child visit the mother each day.
- If the older sibling cannot visit, send along a picture of mother and baby.
- Call the older children daily from the hospital.
- Take a special gift to the hospital to give to the older child as a present from his or her new sibling.

Welcoming the Newborn Home

- Have the older sibling come to the hospital and join the new family on the trip home.

TIP 4–2 A Teaching Intervention Plan to Prepare Siblings for the Arrival of the Newborn (*Continued*)

- When entering the home, spend the first moment with the older sibling. Let someone else carry the newborn into the house and get the newborn settled.
- Do not give the sibling the impression of always being tired and haggard. The child may think that the mother was hurt by the newborn's birth.
- Have a special party to welcome the infant home. Some suggest doing this 1 week after the newborn comes home. Give the sibling "gifts" from the newborn. Have a cake and make it a real celebration.
- Refer to the newborn "our baby" or "your brother or sister."
- Ask visitors to give some extra attention to the older sibling.
- Allow the older sibling to unwrap the newborn's gifts.

Promoting Positive Sibling Encounters

Encourage Interactions

- Encourage the older sibling to touch and play with the newborn in the presence of an adult. Allow him or her to hold the infant while sitting in a chair or the ground.
- Encourage the sibling to talk or to tell stories to the newborn.
- Teach the sibling to attract the newborn's attention with bright toys.
- Teach the sibling when the best times are to interact with the newborn. This depends on the newborn's states of arousal.

Parents' Reactions

- At certain times the older child's need for parental support may be more important than the need to the newborn.
- Let the sibling play a game of "pretend baby" if his or her desire to be a baby is apparent. A few minutes of being treated like a baby are generally enough, because the child must understand that being the baby means no going outside to play or walking or eating snacks or other "big boy or girl" activities.
- Do not always tell the older sibling to "be quiet" because of the newborn. Most newborns will learn

to sleep through all sorts of noises. Constant silencing of the older child can cause resentment.

- Intervene promptly if the older sibling shows aggressive behavior toward the newborn, such as physical or verbal attacks.
- Teach civil behaviors. Promote sharing, respect for property, and the right to privacy. Teach children to be loyal to one another regardless of the anger they may feel at times.
- Avoid comparing and labeling the siblings.

Enlisting the Older Sibling as a Helper

- As the older child feels comfortable, let him or her help wash or feed the newborn or find toys or the pacifier for the newborn. Emphasize how much the newborn "likes" the older sibling and how it makes the newborn happy to have his or her brother or sister help.
- On the other hand, do not expect the older sibling to shoulder adult responsibilities.

Regressive Behaviors

- Do not criticize the older sibling if he or she begins or display regressive behaviors such as thumb-sucking or bed-wetting. Rather, praise and reward grown-up behaviors in siblings. Be tolerant of regressive behaviors and realize that these symptoms will resolve time.
- If the child is old enough, encourage him or her to talk about his or her feelings about the newborn.
- Explain why the "rules" or what are considered acceptable behaviors are not the same for every child in the family.

Providing the Older Sibling With Extra Attention

- Try to give at least 30 minutes a day of special time or "our time" with just the mother and the older child.
- In the evening, have the father or another family relative or close friend participate in a special activity with the older sibling each day while mother is feeding the newborn.
- Spend some time with the older sibling looking through his or her baby album.

When an Infant Cannot Come Home From the Hospital Immediately

The newborn may experience health problems that require a hospital stay after the mother has been discharged. During the pregnancy, older siblings have been told that their mother would go to the hospital and then

mother and baby would come home from the hospital. The siblings may have difficulty understanding why the newborn cannot come home.

Parents need to provide age-appropriate explanations regarding why the baby needs to be cared for at the hospital by the doctors and nurses. If hospital policy allows, siblings should be encouraged to visit the newborn. If the

FIGURE 4–10. Children learn to relate and interact appropriately with others through the sibling relationship. This older brother likes to hold, cuddle, and protect his newborn sister. A positive sibling bond is being established.

infant is in a newborn intensive care unit, older children may only be allowed to look through a window at their younger sibling. If the newborn is on a ventilator, parents need to determine whether the older sibling will do well seeing the newborn with all of that equipment. In all cases, children should be prepared by their parents for all that they might see in the hospital.

The older sibling can be given pictures of the newborn. If the sibling does visit the newborn in the hospital, a picture of the family can be taped to the baby's bassinet or incubator. The sibling can be told that the newborn likes to look at the family and is excited about coming home.

Notes can be written from the newborn to the sibling, and the sibling can write notes or color pictures to be given to the newborn. The older sibling can be given updates about the infant's progress. If the newborn is not doing well, the sibling should be told. The older child will see the parent's stress and be concerned.

When an Infant Has a Noticeable Physical Defect

If the infant looks or acts differently than other newborns, siblings must be prepared for these differences. The parents should openly discuss how "our baby" is different. Consider the sibling's developmental age when answering the questions he or she may have about why the newborn is different and how this difference may have occurred. Books about "special" babies and "special" children are available to be read to older children. Although the parents may be experiencing grief or a sense of loss, the sibling may not have had expectations about what the newborn would be like. Children can be

very tolerant and accepting of how others look. The sibling's reaction to the newborn will most likely reflect the parents' reactions. Modeling a gentle approach and a loving acceptance of the infant will highly influence the sibling's acceptance of the "special" child.

Play

During the first few weeks of life, neither the newborn nor the exhausted parent is very interested in playtime. During periods of wakefulness, the newborn is bonding with the new parents, eating, and developing a sense of the surrounding environment. At this time the infant is very egocentric; everything revolves around him or her. Ideal play activities should be adjusted to the infant's age and should promote development and movement (see Nursing Interventions Classification 4–2). At 1 month, brightly colored objects hung overhead and musical mobiles, perhaps with high-contrast black-and-white motifs, are good "toys." Being able to watch himself or herself in a mirror or watch other people's faces is an activity that will absorb an infant's attention. Encourage the parents to talk to the infant frequently, from a distance of about 12 to 15 inches from the infant's face so the infant can focus on their faces. By 4 months of age, infants prefer bright colors to pale colors and human faces to any other patterns (Casby, 2003) (Fig. 4–11). During the early months, activities that include cuddling, rocking, massaging, and singing are the most nurturing for the infant. The infant is extraordinarily sensitive to touch and movement. An infant carrier that keeps the infant close to the carrier's body is an excellent method of providing soothing movement. The newborn is also very responsive to sound. A very fussy newborn may quiet by just hearing soft music or a parent's voice. The infant should also be given the opportunity to have "floor time" or "tummy time" when awake to help strengthen abdominal and arm muscles (Fig. 4–12). The infant is placed supine or prone on a blanket on the floor, preferably a carpeted area, where he or she is free to move all body

FIGURE 4–11. The bright colors of a toy provide visual stimulation for the infant.

FIGURE 4-12. During floor time, an infant should be placed on the abdomen and allowed to move the body freely.

parts without being confined by an infant seat or car seat. Placing the child on his or her abdomen is especially important in giving the infant an opportunity to develop head control as he or she lifts the head up and off the blanket. Toys placed close to the child aid in stimulating eye movement and gross motor movement as the child attempts to reach the toys (Patrick et al., 2001).

As the infant matures and developmental milestones progress, he or she will become more sociable, interacting more with surroundings. At about 3 months of age, the child begins to reach for toys and attempt to grasp (a skill that does not mature until about age 6 months). The infant loves sitting up and watching the activities in the environment. Mobiles and mirrors can be continued, “busy boxes” can be introduced to the crib, and play gyms can be used during floor time. This is also a good age to start reading to the infant if this practice has not been started already. Many parents believe they can increase the child’s intelligence if they encourage reading at an early age. Although popular books foster this belief, research is not yet conclusive.

By 6 months, the infant is able to grasp large toys, loves to play peek-a-boo, likes to listen to stories, and usually loves water and water play. In the bath, the infant loves to pour the water in and out of cups, swatting and dunking floating objects, squirting sponges, and so on. Imitation and repetition skills are becoming more defined, and the infant loves games that enable copying what is being done (e.g., making funny faces or noises, clapping, laughing), and repeats it over and over. This is a special time for the infant and parent. The infant experimenting with the environment by banging pots and pans may be annoying, but the 6-month-old is fascinated with the sounds produced.

At 8 to 9 months, the infant’s manual dexterity is improving and is now able to grasp large toys, turn large book pages, and shake a rattle (Fig. 4-13). A large box set up with lots of objects (not always toys) is ideal. The objects can be items such as balls, oatmeal boxes, plastic margarine containers, wooden spoons, and old plastic bowls. During this time, the infant loves to imitate the activities of parents and older children (Fig. 4-14). Care

FIGURE 4-13. This 8-month-old child enjoys picking up and manipulating blocks and other fun toys.

must be taken to ensure that play objects are not too small; do not have parts that can come apart and can be easily lodged in the throat, nose, or ears; lack sharp edges; and are not made of toxic substances. The infant is also usually crawling by now, and may be very fast and curious about his or her surroundings. “Childproofing,” if not already done, is now an absolute necessity (Hagan et al., 2008; Patrick et al., 2001). **Childproofing** is the process by which the parent or other caregivers screen the child’s environment for safety hazards (e.g., stairs, small items that could choke the child) and use measures to eliminate these hazards to protect the child from injury.

By 1 year, the infant has developed enough motor control to coordinate both hands at the same time, which enables him or her to bang things together and operate simple mechanisms. The infant loves to sit in a high chair and drop items to the floor. The infant may seem to be doing this to be mischievous, but in fact is discovering gravity and is amazed that the objects always move in the same direction and that objects of different types, sizes,

FIGURE 4-14. This 10-month-old child imitates the actions of the older child as they play with the drum together.

textures, and shapes all do the same thing—hit the floor. This is usually a favorite game. The infant's manual dexterity has matured enough to pick up small objects from a plate, table, or off the floor.

Daycare and Baby-sitters

Daycare services provide care for the child, in exchange for financial reimbursement, when the parents are not available to do so because they are required to attend work or school. Most parents would agree that selecting a safe and competent daycare facility is a very difficult, stressful task. They must consider such issues as the distance of the center from the parents' place of employment or from the child's home, the hours that daycare services are provided, the numbers and ages of other children being served, and the cost of the services provided (Youngblood & Carter, 2004). Opinions and research findings vary regarding the positive and negative outcomes of placing children in daycare services. Children placed in daycare early in life and for more than 30 hours per week have been noted to be at increased risk for stress-related behavioral problems. On the other hand, children in daycare centers have been noted to have higher language and early school achievement. Factors that influence any outcomes for the child include quality of the child care, number of children in the environment, parenting behaviors, and social interactions among the children at the center (Bradley & Vandell, 2007).

Nurses can help parents select suitable daycare facilities and provide families with suggestions to help all involved parties adjust to the child care arrangements. In addition, child healthcare providers can play a key role in educating daycare staff to ensure a safe environment, and to help prevent and reduce the transmission of infectious diseases.

Types of Daycare Services

There are two basic types of daycare services: in-home care and center-based care. In-home care is services provided in the child's home, the home of a parent, or the home of one of the children within the daycare group. Care providers may live in the home with the family, come to the child's home, or have the children come to their home. Care provided through in-home arrangements may be offered by personnel who are authorized by a state licensing board, in which case the licensing board defines the number and ages of children who can be cared for at any one time. In addition, the board establishes certain environmental and safety criteria to which the caregiver must adhere. In-home daycare can also be provided by individuals who are not licensed, such as family members, friends, baby-sitters, or au pairs.

Center-based care is provided in a licensed daycare facility that may be privately owned, federally funded, or associated with a neighborhood project or workplace facility. In these settings, six or more children receive care for several hours a day. The ratio of parents to children is determined by the state for licensed daycare centers and licensed family daycare homes. All ages of children may

be served, with children of similar ages generally grouped together.

Choosing a Daycare Provider

Selecting a daycare provider is one of the more complex tasks facing new parents. The considerations that must be addressed when choosing a child care provider are location, hours of service, cost, religious or cultural beliefs, and characteristics of the individual care provider. Are both parents working full-time, or is this a single-parent family? Is it better to have the child care provider closer to a workplace or closer to home? How much can the family afford for child care? After these questions are answered, parents must choose in-home or center-based care (Table 4–2).

When parents decide to use an in-home provider, they need to advertise and interview prospective care providers, unless they use an agency placement service. In either case, interviews should be conducted face to face, preferably with the child available to ascertain the potential care provider's interaction and the child's acceptance of the care provider. A list of interview questions is provided in Community Care 4–1 as a guideline to help new parents decide what to evaluate when selecting a daycare setting.

Choosing a Baby-sitter

Selecting the infant's first baby-sitter can be a difficult and sometimes scary task. This person may be a teenager within the neighborhood, a relative, or a close friend. Many of the guidelines covered earlier for hiring any daycare provider can be used to choose a good baby-sitter. Parents should leave the baby-sitter a list of emergency phone numbers, and the name and phone number of the nearest available neighbor in case an emergency arises. Parents should notify the sitter where they will be, how they can be contacted, and how long they will be gone. Separation anxiety is common for a child around 9 months of age. Parents should not attempt to sneak out the door when the sitter arrives to avoid a crying scene with the infant. The child needs to learn that the parents may leave, but they will come back. Creating some ritual behaviors surrounding the parents' good-bye is preferable to having the child worry that his or her parents will simply disappear whenever a certain individual comes to the home. Inform the sitter of the child's routines (e.g., bedtime, favorite book, comforting toy). Set clear guidelines with regard to handling emergency situations and disciplinary methods. Last, ensure the sitter is aware of the "house rules" regarding their personal activities while in the home (e.g., phone calls, viewing television, restrictions on other guests in the home). Babysitters.com is an excellent resource for tips for parents and baby-sitters, and sitter profiles and report cards across the nation.

Daycare for Sick or Medically Fragile Children

When the infant or child is sick, the parent may be unable to stay home with that child. Yet, few daycare providers appreciate having the sick child brought to them with the potential of infecting other children. To assist parents in

TABLE 4 – 2
Types of Care Providers: Advantages and Disadvantages

Type	Advantages	Disadvantages
In-Home Care Providers		
Sitter (nonfamily member hired to come to house) Family member Au pair (young person sponsored from foreign country)	Very convenient location One-on-one attention for the child Secure, comfortable surroundings for child When the child is ill, care continues to be provided Consistent care provided by one person Caregiver knows child's moods, habits, and likes/dislikes Meals are prepared for the child's specific tastes Some sitters and au pairs will do laundry and light housework Cultural and religious beliefs are easier to implement Less frequent exposure to illness	When caregiver is ill, replacement is needed or parent must remain at home No group or social interaction between peer groups Could be expensive Rivalry could develop between caregiver and parent Privacy may be invaded by caregiver (particularly live-in caregivers) Caregiver may leave suddenly, leaving parents without any care provider Parents must do interviewing and reference checks of potential applicants If care is provided by family member, this could cause tension within the family May lack wide variety of age-appropriate toys and activities
Center-Based Care Providers		
Institutional, community based, family home based	Regulated and inspected by licensing agency Required to follow specific regulations regarding provider ratio, cleanliness, and qualifications of staff Often teachers have degrees or the corporation provides training in early childhood education Children get to interact with peers and develop peer relationships Usually have structured programs designed to meet developmental needs of children Exposed to wide variety of age-appropriate toys, educational materials, and activities If a teacher is sick, off, or on vacation, the child still receives care (may not be true in family home-based care) If center-based care is provided by a parent's workplace, location is usually convenient and hours are usually flexible to the parent's schedule Usually less expensive than in-home care	May not be conveniently located Hours may be rigid Children are exposed to illness Potential for less individual attention May not respect individual religious or cultural beliefs Meals are prepared for large groups and are not altered for specific tastes (although allergies are considered)

coping with this type of situation, daycare centers for sick children have emerged. Some of these centers may have a “spots” room, where they accept children with rashes, fevers, and other potentially contagious diseases as well as children recuperating from surgeries or with noncontagious illness. It is wise to investigate the availability of such services before they are needed, because centers often have a registration fee and a processing procedure that must take place before placing the child.

For those infants and toddlers with handicaps or long-term medical conditions requiring specialized care,

daycare centers for the medically fragile child may be available. Because these children need nursing care; developmental stimulation; physical, occupational, or speech therapy; and special feeding or routine care, the staff consists of registered nurses and other allied healthcare personnel, along with childhood educators. Admission to these programs is generally reserved for children who cannot be served by other “regular” daycare programs, preschools, or specialized healthcare services. Care is provided at the level the parent can give at home.

COMMUNITY CARE 4–1

Interview Questions and Tour Tips for Evaluating Daycare Options

Administration and Operations

- Is the program licensed or registered?
- What are the hours?
- Is the location convenient?
- What is the cost (or, for in home, what is the rate)?
- What days of the year is service not provided? Is tuition paid for these days?
- What meals will be provided and at what times?
- Will the child leave the facility on field trips or other excursions with the care provider?
- Are unannounced visits okay?
- How does the center communicate with the parents regarding activities, the child's progress, and any problems?

Request at least two references from parents with a similar-aged child.

Staffing

- What is the ratio of staff to child?
- What is the education of the staff?
- How often does the staff turn over?

Tour the facility to observe

- Interaction among the children and the teachers. Are teachers truly familiar with the children, knowing each child's likes and dislikes, and personality? How do they handle discipline? Do they interact with the children on their level, eye to eye?
- Toys and activities. Are there enough? Are they age appropriate? Are the teachers using the instruments creatively?

- Characteristics of the environment. Is it friendly or sterile, is it cluttered or clean (perhaps too clean and neat)? Are there indications in view of the children's activities (e.g., paintings, crafts, writing)? Are the infants all in swings or cribs, or on the floor with toys and gyms?

Cleanliness

- What are the cleaning protocols for toys and equipment?
- What products are used?

Tour the facility to observe

- Are the diaper-changing areas clean?
- Does the staff wash their hands after changing diapers or wiping up messes?
- Are the eating areas clean?
- Is all food in the kitchen covered?

Safety

Tour the facility to observe

- Are all the outlets covered?
- Are stairs covered with carpet?
- Are gates in place where necessary?
- Is the facility well lit?

Food

- Is it nutritious?
- Is the amount appropriate?
- Do the meals include age-appropriate foods?

Request a sample menu.

Alert! In any daycare environment, parents must address concerns about the potential for neglect or abuse. If a child's personality suddenly changes, and no other outside causes (e.g., recent move, divorce, death of a family member) are apparent, a look at the child care provider may be indicated. Clinging behavior, excessive crying when dropping a child off with the care provider, or more subtle signs such as a child not looking at an adult in the face, weight loss, refusing to eat, a sad and worried look, withdrawal, and inability to be comforted are potentially signs of neglect or abuse.

INJURY AND ILLNESS PREVENTION

One of the first priorities of new parents is to babyproof or childproof the home to prevent injury or even death. Although most parents think of babyproofing after the infant is crawling, it is never too early to start thinking of safety in cribs, car seats, and the newborn's immediate

environment, whether in the home or outdoors (Community Care 4–2).

Home Safety

To prepare the home environment, start with general home safety issues. Ideally, all parents should know cardiopulmonary resuscitation (CPR) and first aid, and should make emergency plans for accidents and fires, including escape route planning. Emergency numbers should be posted near the telephone along with the address and phone number of the residence. This information is helpful to the parent, who in times of emergency may temporarily be unable to recall his or her own address and phone number.

Smoke alarms should be installed on every level of the home, and carbon monoxide detectors are recommended

COMMUNITY CARE 4–2

Injury Prevention Guidelines for the Family With an Infant

Home Safety

- Ensure that the crib is safe. The slats should be no more than $2\frac{3}{8}$ inches apart, and the mattress should be firm and fit snugly. The side rails should be all the way up when the child is sleeping. As the child learns to sit and stand the mattress should be lowered.
- Do not use soft bedding or soft toys.
- Put the infant to sleep on his or her back or side (back preferred) to reduce the risk of SIDs.
- Do not drink hot liquids or smoke while holding the infant.
- Keep all poisonous substances, cleaning agents, health and beauty supplies, medicines, and home improvement materials in a locked safe place out of sight and reach of the infant.
- Use safety locks on cabinets.
- Keep sharp objects (e.g., scissors, knives) out of reach.
- Get down on the floor and check for hazards at the infant's eye level.
- Place plastic plugs in electrical sockets.
- Do not leave heavy objects or containers of hot liquids on tables with tablecloths that the infant may pull down.
- Install gates at the top and bottom of stairs.
- Place safety devices on windows and make sure screens are secure.
- Avoid dangling electrical and drapery cords.
- Install/check smoke alarms.
- Avoid “choke” foods (e.g., nuts, carrot sticks, large pieces of fruits or vegetables).

Play Safety

- Keep toys with small parts or other small objects out of infant's reach.
- Do not use baby walkers at any age.
- Do not give the infant plastic bags, latex balloons, or small objects such as marbles.
- Teach siblings which of their toys are unsafe for the infant to play with.

Water Safety

- Set hot water thermostat at less than 120°F (48.9°C).
- Test the temperature of the batch water with your wrist to make sure it is not too hot for the infant.

- Never leave the infant alone in a tub of water or on high places; always keep a hand on the baby.
- Empty buckets, tubs, or small pools immediately after use.
- Ensure that swimming pools are enclosed by a four-sided fence with a self-closing, self-latching gate.

Car Safety

- Use an infant seat that is properly secured at all times.
- Place the car seat in the back seat of the car, facing backward toward the backrest of the car.
- Never place baby in front seat with a passenger air bag.

Safety with Others

- Never leave the infant alone or with a young sibling or pet.
- Keep the infant away from cigarette smoke. Do not allow people to smoke around the infant.
- Use baby-sitters who have received CPR training.
- Provide the baby-sitter with a list of emergency phone numbers, the home address and phone number, your location, and how you can be reached.
- Keep food for animals out of child's reach. Do not let the child approach an animal that is eating.
- Never shake the baby.

Outdoor Safety

- Avoid overexposure to the sun.
- Use straps in strollers to contain the child.
- Do not allow the child to be outdoors unattended.

Emergency Preparation

- Keep own address and phone number posted near the phone.
- Keep list of emergency numbers (doctor, hospital, nearest neighbor, poison control center) near the phone.
- Learn first aid and infant CPR.
- Know signs of illness: fever $>100.4^{\circ}\text{F}$ (38°C), seizure, rash, unusual irritability, lethargy, failure to eat, vomiting, diarrhea, dehydration, or jaundice.

Adapted from Green, M., & Palfrey, J. (2002). (Ed.). *Bright futures: Guidelines for supervision of infants, children, and adolescents* (2nd ed., rev.). Arlington, VA: National Center of Education in Maternal and Child Health.

near sleeping quarters (or elsewhere according to the manufacturer's directions). Every home should be equipped with a working flashlight in case of electrical failure, and a fire extinguisher should be kept near the kitchen.

Hot-water heaters should be turned down to 120°F (48.9°C) to prevent scalding the child's skin. The cords of lamps and appliances should be shortened and covered or hidden out of the child's view to prevent the child from chewing them or getting them wrapped around the neck. Electrical outlets should be covered to prevent the child from inserting keys or other metal objects in the outlet and causing electric shock and burns on the child. Windows should have locks and screens that are securely attached to keep the child from falling out the window. The window cords should be rolled up or placed out of reach with the use of rubber bands or twist ties so the child does not become entangled in the cords, causing suffocation. As the infant begins to crawl, safety gates should be installed to prevent entrance up or down stairs and in rooms with computer or office equipment.

Two areas that are especially hazardous are the kitchen and the bathroom, because of the types of activities and equipment that are available. Babyproof locks should be installed on all kitchen cabinets. One or two cabinets can be left open if they contain items for the child to play with, such as plastic bowls, spoons, and pan lids. All sharp scissors and knives should be kept in drawers or cupboards with childproof latches. When cooking, pot handles should be turned away from the front of the range so the child cannot grab them and pull hot liquids off the stove onto himself or herself. All cleaning supplies should be placed up high, out of reach, or kept in a childproof cupboard to prevent the child from ingesting them.

In the bathroom, the toilet lid should be kept lowered to prevent drowning. Safety latches are available to prevent the child from opening the lid. Medications and toiletries should not be kept out where a child could get to them. Nonskid strips installed in the bathtub help prevent falls. A cushioned cover on the faucet will keep the child from being injured by the faucet. When bathing the infant or child, parents must never leave the child unattended.

The infant spends a lot of time unsupervised in his or her bedroom, so the nursery must be inspected carefully for any hazards. Encourage the parents to get down on their hands and knees and see the environment from the perspective of the child. All potential hazards must be removed from this level. Next, other areas of the child's environment must be evaluated for safety. Crib mobiles and monitors should be out of reach. The infant should never be left unattended on a changing table, even if strapped in place, because of the danger of falling.

Crib Safety

Safety should be addressed even before the infant is born, when the parents-to-be are beginning to purchase the equipment an infant will use. Cribs are usually the first

item that is either purchased or obtained through a friend or family. All cribs manufactured since 1973 in the United States are required to meet stringent federal regulations for safety to prevent infant entrapment and suffocation. If a crib is borrowed or purchased secondhand, the following checklist should be used: the side slats should be no less than $2\frac{3}{8}$ in apart, decorative cutouts should be avoided, the mattress must fit snugly on all sides, and drop sides must have safety latches and lower only part of the way. No bumper pads, pillows, or fluffy blankets should be in the crib, because they increase the danger of suffocation. The mattress should be firm, not soft, and no pillow is needed for an infant. If an older crib is obtained that has been painted, the paint should be stripped off (not sanded) because the paint may be lead-based and, if inhaled, could cause lead poisoning. The crib should be repainted with high-quality enamel paint. Some new parents are opting for cribs with mesh sides rather than wooden ones. In this situation, the sides must be kept raised, because the mesh causes pockets that can trap an infant and can be hazardous when they are lowered.

Play Safety

All children need toys to learn from and to help them meet developmental milestones. Toys are the tools of play for children. But, as with any tool, they must be appropriate for the job, and they must be safe. Toys must match the child's age and development. Manufacturer's guidelines may help, but the parents know whether their child is mature and skilled enough for a particular toy.

caREminder

Many children's toys are made of plastic that contain bisphenol A, a toxic substance that can lead to impaired brain development in exposed infants and children. Encourage parents to buy wooden toys or those labeled "PVC-free" (Environment California Research & Policy Center, 2007).

Rattles should be at least $1\frac{5}{8}$ in in diameter to prevent them from becoming lodged in the child's throat. All toys should be well constructed, with no loose pieces that can be removed and potentially swallowed or aspirated. This precaution is particularly important with stuffed animals or dolls, because some have eyes or noses that can be pulled off and possibly swallowed. Small toys should be avoided until the child is at least 3 years old. A small cylinder, approximately the size of a child's throat, has been developed to assist parents and healthcare professionals in determining what toy or toy part is too small. If the object can fit into the cylinder, do not allow the child to play with the object (see [thePoint](#) for Organizations).

Balloons, although they are fun to look at and part of many birthday parties, should not be blown up or played with by children younger than 5 years old. If a balloon pops, be sure all the pieces are collected, because a crawling infant can pick up a loose piece and choke on or aspirate it. Latex balloons should not be used around children, because many children are allergic to latex or

have choked on an uninflated balloon. Mylar balloons are considered safe for children.

Toys must be inspected periodically to be sure they remain in good condition; if they become broken or overly worn, they should be repaired or discarded. Projectile toys should be avoided as well as toys that produce loud noises. Noise levels at or about 100 dB (the sound of a typical cap gun at close range) can damage an infant's hearing. A quick clue to a safe toy is to look for the letters ASTM, which indicate that the product meets the national safety standards for the American Society for Testing and Materials.

Water Safety

Drowning remains a leading cause of death in the pediatric population. Although many parents may not consider drowning a risk during the neonatal and infant periods, drowning can easily occur if the infant is left unattended in the bathtub or wanders into areas with easy access to swimming pools or hot tubs. Many parents respond to this safety hazard by enrolling their child in a swimming program specially designed to introduce infants and toddlers to the joy and risks of being in and around water (Tradition or Science 4–3). These programs cannot be used as a substitute for common water safety practices (e.g., the child must never be left alone in the tub, pools must be enclosed by a fence).

Water safety also includes ensuring the hot-water temperature used in the home is set less than 120°F (48.9°C) to prevent burns and scalding of the infant during bath time.

Car Safety

Talk with parents about temperatures inside their car. A temperature that is comfortable for the parent would be appropriate for the infant. Parents must ensure that the sun is not shining in the infant's eyes or directly on

the infant. They must never leave the infant in the car alone, even to run into the store quickly. To help protect the infant, parents should observe traffic rules more carefully and be watchful for reckless drivers.

Car Seat Safety

QUESTION: Lela will use the crib that the Diaz family bought new for Jose, and the home has been baby-proofed. They have a convertible car seat, but Jose does not yet meet state requirements for weight, height, or age to move to a booster seat, so he is still using it. What could you recommend to this family?

Most hospitals will not discharge an infant home unless there is a car seat available to transport the child. Many acute care facilities have a car seat loan program or other means to provide car seats to those who are unable to purchase their own. Car seats that were manufactured before January 1981 should not be used because more stringent safety standards were implemented at that time (Fig. 4–15). Parents should look at all types of car seats and decide on one that fits their usage style and the size of their car (Community Care 4–3). Car seat laws vary from state to state and between the United States and Canada. Parents should review state laws to determine the specific legal requirements. Some states require car seats until age 4, others up until 8 years of age. States may also have a weight or height requirement that supersedes the age requirement—that is, a child who meets the age requirement but does not meet the height or weight requirement must continue to be restrained in a car seat. In general, after the child is heavier than 80 lb and taller than 48 in, the regular automobile seat with a lap belt may be used with the addition of a shoulder harness. Some states have enacted booster seat laws to protect children up to 8 years old. Belt-positioning booster seats cannot be used safely with lap-only belts. Caution parents to always follow the manufacturer's directions regarding installation and proper use.

TRADITION OR SCIENCE 4–3

Do aquatic programs for young children help prevent drowning in their age group?

MORE INQUIRY NEEDED

No research has demonstrated an association between aquatic programs for infants and toddlers and a decreased risk of drowning. Parents should not feel secure that their child is safe from drowning and water injury after the child has participated in an aquatic program. Until after their fourth birthday, children are not generally ready developmentally for formal swimming lessons. (American Academy of Pediatrics, Committee on Sports Medicine and Fitness, and Committee on Injury and Poison Prevention, 2000).

FIGURE 4–15. Infants should be restrained in a car seat in a rear-facing position in the backseat of the car.

COMMUNITY CARE 4–3

Types of Car Seats

Infant-Only Seats

Installed in a rear-facing position only; used until the infant is about 20 lb. These seats come with a three-point or five-point harness.

Convertible Seats

Can be used in both rear-facing and front-facing positions. Used to seat infants facing the rear of the car until they have reached at least 1 year of age and weigh at least 20 lb. These car seats have a five-point or six-point harness, a T-shield, or an overhead shield to secure the child in place.

Booster Seats

Forward facing only, have a removable shield; for children who have reached the top weight or height allowed for the convertible car seat. Children 40 lb or heavier are best secured in a booster seat with a full harness. Seats with boosters and shields have not been certified by manufacturers for use by children who weigh less than 40 lb (American Academy of Pediatricians, 2005b).

caREminder

Car seats should be placed in the center of the backseat of the automobile, because this location is much safer than the front seat, where the child could be injured by rapid inflation of airbags during a collision. No child younger than 12 years should be in the front passenger seat, because the way the airbag would hit the child in the event of an accident would cause injury or death.

ANSWER: The Diaz family needs two car seats. The hospital nurses caring for the Diaz family should give Ignacio the resources for community loan programs before the day of discharge. Almost all communities have car seat loan programs.

Outdoor Safety

Outside areas must be policed with the same rigorous attention to safety afforded in the home. Playgrounds can provide a tremendous opportunity for children to explore and expand their physical capabilities. Risks can be minimized if the equipment is kept in good condition and the area is appropriately designed. The area must be arranged to allow enough room between equipment to prevent collision with other equipment or interference with other play areas. The equipment should be placed far enough away from off-limit areas such as trafficked streets and railroad tracks, and it should be in good condition (e.g., no broken pieces, rusted or exposed bolts, or splinters). A soft, shock-absorbing material under the equipment (at least 6 in of sand, mulch, or bark or rubberized matting) is required by many building codes. The area must be well maintained, with no overgrown bushes interfering with the equipment. Overgrown grass or an

abundance of leaves can cause slippery areas. Cleanliness must be maintained, with no broken glass or trash accessible to children, who are prone to putting foreign objects in their mouth. These guidelines can be applied to both public and home playgrounds. Home playgrounds may have additional issues to be assessed, such as whether they are fenced, what kind of vegetation is being grown around the yard (poisonous or not), whether pesticides or herbicides have been used in proximity to the play environment, and whether there are animals in the neighborhood that might present a hazard to children playing in the yard.

See [thePoint](#) for a summary of Key Concepts.

5

Early Childhood (1–4 Years)

Case History

B. J. and J. D. are 2½-year-old fraternal twins in an African American family. They have an older sister, Shawanda, who is 6. All three children live with their mother. Their parents, James and Lanese Johnson, divorced about a year ago. Now their father visits on the weekends. He takes Shawanda and the twins out to do special things, but he does not keep the three of them overnight. Lanese's mother lives in the same town and comes over to watch the kids. The family consensus is that the twins are exhausting!

The boys are big for their age, sturdy and strong. They are very physically active and love to run, climb, and tumble. When Shawanda was their age, she loved to scribble with crayons and paint at the easel at day-care, but these activities only hold the boys' attention for a few minutes, and then it is back to exploring and practicing their gross motor skills. Shawanda also began speaking much earlier than the twins. She said many words clearly by the time she turned 2. The twins, on the other hand, babble and seem to understand each other, but even their mother is not sure what they are saying.

The twins have recently moved into low toddler beds because they kept escaping from their cribs. One evening before the transition,

Lanese put them both in their cribs and went to take her shower. When she got out of the shower, she heard a noise in the kitchen. When she walked into the kitchen she found that the twins had both gotten out of their cribs and pushed a chair over to the kitchen counter. J. D. was on the counter handing down a box of breakfast cereal from the top of the refrigerator to B. J.

B. J. and J. D. have very different preferences in food. B. J. loves colorful food, especially red. He will eat tomatoes, strawberries, and watermelon. J. D. is fixated on macaroni and cheese. Every time he climbs in his booster seat he bellows, "Roni!" Lanese is trying to use "roni" as dessert; if J. D. eats his other food, he can have "roni." The boys are using a sippy cup at meals. At their 24-month appointment, the pediatrician strongly urged Lanese to get the boys off the bottle completely, but especially at night.

Lanese is a little frustrated at the twin's lack of interest in potty training. When Shawanda turned 2, she wanted to wear pretty panties and thus potty trained easily. The boys don't seem to notice or care if they are wet, whether in big boy pants or in diapers.

Lanese went to high school with the nurse in her pediatrician's office and is comfortable calling her for advice about the twins.

CHAPTER OBJECTIVES

1. State the developmental surveillance and milestone concerns of children aged 1 to 4.
2. Discuss nutrition, elimination, hygiene, and personal care needs during the early childhood years.
3. Select age-appropriate interventions to promote healthy personal and social development of the child aged 1 to 4.
4. Select interventions to promote illness and injury prevention for the young child and the family.

See [thePoint](#) for a list of Key Terms.

Bright Futures defines early childhood as the period from 1 to 4 years of age (Hagan, Shaw, & Duncan, 2008). The term *toddler* is also used to describe children from 12 months old to the third birthday and the term *preschooler* is often used to describe the child from 3 to 5 years of age. During this time, the child's rate of growth slows compared with the growth that occurred during infancy; however, many physical and developmental changes can still be expected. The child starts to walk and talk, and begins to test boundaries and assert some independence. Language acquisition accelerates, and the young child is able to express desires more clearly, and sometimes in a rather loud and theatric manner. The young child has seemingly endless energy to explore the world, make new friends, and test new skills. Parents must respond by being ever diligent about the child's safety, ensuring that the young child begins to develop a sense of caution and control. This chapter reviews the unique needs of early childhood, the challenges faced by parents, and the nurse's role in promoting healthy and safe growth and development.

DEVELOPMENTAL ASSESSMENT AND SURVEILLANCE

Developmental changes during early childhood are more subtle than those that occur during infancy, but are just as important for healthcare providers to monitor on an ongoing basis. Toddlers refine skills that have already been acquired during infancy and develop new skills that foster their curious and active personalities. As with toddlers, developmental changes during the preschool years are more subtle than those during infancy, but should be considered just as important. Preschoolers refine abilities, acquire new skills, become bigger and stronger, increase communication skills, and grow socially and emotionally (Murphy, 2004). Speech development and the ability to communicate are especially important during this time. Developmental assessment and surveillance remain an important part of the nurse's role, especially because the number of well-child visits decreases during early childhood compared with the infancy period (Fig. 5–1).

Developmental Considerations 5–1 summarizes the developmental milestones that are accomplished during early childhood. This information provides the nurse

FIGURE 5–1. During the health examination, a young child may sit on a parent's lap to help him or her feel more safe and secure.

with direction for specific trigger questions to ask the parents to determine the child's developmental progress. Questions about how the child communicates and comprehends instructions, how the child crawls or walks, and whether the child is toilet trained should be as open-ended as possible to elicit more information. Missing or delayed milestones must be identified so that the child can be referred to early intervention or early education services. Referrals to early education services may be indicated. Early childhood education services for children ages 3 to 5 years old are widely available. Legislative changes have supported early identification of delays, so that interventions may start earlier. The nurse plays a role in teaching parents about growth and development so that they can become partners with healthcare team providers in identifying developmental delays and in identifying medical, genetic, and environmental factors that place the child at risk for developmental delays.

Health supervision interventions are presented in Appendix G. Visits to the healthcare provider should be scheduled at 12, 15, and 18 months of age and at 2, 2½, 3, and 4 years of age. Vision and hearing testing, and screening for anemia are especially important during these years (see Chapters 8 and 28). The nurse also participates in screening the child for oral health, communicable diseases, learning disabilities, and child abuse. Selective screening of at-risk children may be needed for lead poisoning, tuberculosis, and dyslipidemia (elevation of plasma cholesterol). Chart 5–1 presents a quick reference overview for many of the conditions and illnesses that may affect the child age 1 to 4 years.

DEVELOPMENTAL CONSIDERATIONS 5–1

Milestones of Early Childhood (1–4 years)

Physical

12 Months

Head circumference equals chest circumference
 Birth weight triples to 20 lb
 Half of adult height
 Height increases 3 in/year for the next 7 years
 Weight increases 4 to 6 lb/year

18–24 Months

Has from 10 to 14 temporary teeth
 Anterior fontanelle closes
 Cuspids and first and second molars appear
 Toilet training may be initiated
 Chest circumference exceeds head circumference

24 Months

Has 16 temporary teeth
 Average weight is 30 lb
 Toilet training may begin; voluntary control of anal and urethral sphincters occurs
 Average of 10 to 14 hours of sleep, including afternoon naps

36 Months

Nighttime control of bowel and bladder may be achieved
 Weight increases 4 to 6 lb/year
 Height increases 3 in/year

Sexual

1–4 Years

Anal stage (Freud)
 Sensual pleasure shifts to anal and urethral areas
 Identifies with male/female sex roles

3 Years

Knows own gender

Language

12–18 Months

Beginning of spoken language; may occur at same time as walking, although concentration on one or the other may occur
 Recognizes nouns that stand for objects
 Uses gestures to make needs known
 Develops from 3 to 20 words
 Uses telegraphic speech, uses noun and verb to convey meaning
 Uses words that may be quite inconsistent

18 Months to 2 Years

Follows directions

Points to nose, hair, eye, and so forth, on demand
 Comprehends “give me that” when accompanied by a gesture

2 Years

Has a 50-word expressive vocabulary
 Has a 300-word receptive vocabulary
 Gives first and last name
 Demonstrates progressive comprehension of speech
 Talks without trying to convey ideas

3 to 4 Years

Has a 900–1,500 word vocabulary
 Uses complete sentences of three to four words
 Talks incessantly
 Asks many questions

Vision

18 Months

Displays interest in pictures

2 Years

Identifies forms
 Has 20/40 vision

3 years

Has 20/30 vision

Gross Motor

12 to 18 Months

Walks well
 Throws ball
 Stoops and recovers
 Walks up stairs with help
 Begins to run
 Walks sideways and backward for 10 ft
 Stands on one foot with help
 Sits down from standing by self
 Falls frequently, often used as a way of sitting down
 Rolls large ball on floor

18 Months to 2 Years

Kicks ball forward
 Throws overhand
 Walks down stairs, one at a time, with help
 Climbs
 Sits self in a small chair

2 to 3 Years

Jumps and runs well
 Jumps from bottom step
 Jumps in place
 Balances on one foot for 1 second
 Walks on a straight line
 Walks on tiptoes

Broad jumps 4 to 14 in
Can pick up objects on floor without losing balance

3 to 4 Years

Rides tricycle

Fine Motor

12 to 18 Months

Scribbles spontaneously
Builds tower of two blocks, then four blocks
Dumps raisins from container after demonstration, then spontaneously
May untie shoes
Uses opposable thumb well (prehension)
Shows preference for one hand or the other
Turns pages in a book
Uses spoon with frequent spills when getting food to mouth

18 Months to 2 Years

May remove articles of clothing
Holds pencil well enough for scribbling
Builds tower of four cubes
Imitates drawing a vertical line within 30 degrees
Turns doorknobs within reach

3 to 4 Years

Unbuttons large buttons
Builds tower of six to eight cubes
Can use a paintbrush
Imitates scribble
Copies a circle
Begins to wash and dry hands
Drinks from a cup
Can begin brushing teeth one to two times a day
Can take off socks and other easy-to-manipulate clothing
Snaps large snaps
Zips large zippers with help
Twists caps off bottles
Places simple shapes in correct holes
Will disassemble objects

Play

1 to 2 Years

Engages in parallel play
Imitates adult roles
Imitates housework
Will do simple household tasks

2 to 3 Years

Engages in parallel and associative play
Uses colors
Begins to play interactive games, such as tag
Plays with sand, clay, puzzles
Plays fantasy and make-believe
Plays action/ritualistic games such as tag or hide-and-seek

Cognitive

12 to 18 Months (Preoperational and Sensorimotor: Piaget)

Uses imitation to discover new ways of acting
Experiments to discover how objects behave and how they can be manipulated

18 Months to 2 Years (Sensorimotor: Piaget)

Concept of object permanency is fully achieved
Symbolic plane
Has a limited concept of time (no “tomorrow”)
Is very egocentric
Talks to stuffed animals
Has imaginary playmates
Has a premature sense of cause/effect
Demonstrates goal-directed behavior
Believes death is reversible; a temporary restriction, departure, or sleep
Bedtime becomes very ritualistic

2 to 4 Years (Preoperational: Piaget)

Forms symbolic thought
Is egocentric in thoughts, feelings, and experiences
Understands instructions literally
Imitates others' behavior at later time

Social

12 to 18 Months

Responds to limit setting

18 Months to 4 Years

Attempts to please parents and conform to their expectations
Aware of family relationships and roles

Interpersonal

1 to 4 Years (Autonomy versus Shame and Doubt: Erikson)

Differentiates between “good mother/bad mother” to “good me/bad me” or “not me”
Swings from love to hate

3 to 4 Years

Self-concept begins
Egocentric in thought and behavior

Emotional

1 to 2 Years

Shares emotions based on immediate needs (e.g., crying, screaming)
Learns how emotional reactions affect behavior of others

3 to 4 Years

Uses symbolic communication to convey ideas in terms of complex intentions
Explores different emotions in pretend play
Can communicate and comprehend emotions of self and others

DEVELOPMENTAL CONSIDERATIONS 5–1

Milestones of Early Childhood (1–4 years) (Continued)

Moral/Spiritual

1 to 4 Years

Moral: Stage 2: Preconventional Level (Kohlberg)

Detects concepts of fairness and sharing
Has an instrumental–relationistic orientation
Satisfies own needs
Is at a conventional level, beginning “good girl/nice boy”
Demonstrates approval-seeking behavior coupled with a desire to please

Spiritual: Stage I: Intuitive/Projective (Fowler)

Learns to imitate the religious affect and behavior of parents
Mimics religious gestures, although does not comprehend meaning
Formulates own conceptions and explanations of faith and belief
Cannot separate feelings from intellect
Formulates imagined descriptions of God (angel, friend child can communicate with)

HYGIENE AND PERSONAL CARE

Children age 1 to 4 years are still too young to manage their own hygiene and personal care needs. However, their inquisitive nature will ensure that they want to actively engage in learning new skills related to bathing, brushing their teeth, toileting, and dressing. Parents will need to curb their child’s enthusiasm and exploration only to the extent that the parent ensures that a safe environment for learning is provided at all times. Young children should not complete hygiene and personal care activities beyond the watchful eyes or outside the reach of their parents. Adolescent siblings may help to monitor the activities of the young child; however, siblings of younger ages should not be given the responsibility for monitoring the safety of the child, because their own lack of knowledge and experience will most likely prevent them from being able to anticipate hazards and prevent injury.

Bathing

The young child’s increased activity level necessitates bathing daily or every other day. Bath water should be between 98.6°F or 37°C and 100.4°F or 38°C. Wash the child’s hair two to three times per week with a mild shampoo. Assess the child’s scalp for scaly and crusty skin (seborrheic dermatitis), and the presence of lice or scabies. A good time to bathe the child is after eating, either after breakfast or in the evening. During the meal, the child may have spread food in the hair as well as all over his or her clothing. By the evening, the child is fairly dirty from a full day of play. Evening bath time provides an opportunity for cleansing and a way to relax the child in preparation for bedtime.

A young child usually views bath time as another opportunity for play. However, some children may have

fears associated with bathing, such as being afraid of being sucked down the drain. In this case, do not drain the tub until the child is out of the room. Use nonskid mats or gripping tape on the bottom of the tub to prevent the child from slipping. Provide plastic bath toys of appropriate size and without removable parts for water play. During rinsing of the hair, a washcloth placed over the child’s eyes can prevent the shampoo from irritating the eyes. Bubble baths should be avoided to prevent urethral irritation and possible development of cystitis.

Alert! The young child should never be left alone or be monitored by young siblings while bathing. Placing a young sibling in the bathtub with the child while the parent leaves the room does not guarantee the safety of either child (Fig. 5–2).

The young child is becoming more self-aware of body parts and spends time in the bath exploring his or her naked body and enjoying the unencumbered feeling of being without clothing. Young children usually have discovered their genitalia and may touch themselves frequently when the diaper or underpants are removed (Hagan, Shaw, & Duncan, 2008). The child should not be punished for exploring the body in this fashion, because such exploration is a normal part of development. Ask the parents in a nonjudgmental manner how they feel about this behavior and how they react to it. If parents are uncomfortable with this behavior, explain that it is normal and common among most children this age (see further discussion later in the chapter).

During bath time, the parents should observe the condition of the child’s skin and examine the symmetry of body parts. Any unusual findings should be reported to a healthcare provider. When examining a child, note

CHART 5-1 QUICK REFERENCE TO CONDITIONS COMMON DURING EARLY CHILDHOOD (1–4 YEARS)

Condition	Chapter
Autism	30: The Child With a Developmental or Learning Disorder
Breath-holding spells	21: The Child With Altered Neurologic Status
Bronchiolitis	16: The Child With Altered Respiratory Status
Child abuse	29: The Child With a Mental Health Condition
Cognitive challenge	30: The Child With a Developmental or Learning Disorder
Common cold (nasopharyngitis)	16: The Child With Altered Respiratory Status
Communicable diseases	24: The Child With an Infection
Conjunctivitis	28: The Child With Sensory Alterations
Constipation	18: The Child With Altered Gastrointestinal Status
Croup	16: The Child With Altered Respiratory Status
Epiglottitis	16: The Child With Altered Respiratory Status
Hemolytic uremic syndrome	19: The Child With Altered Genitourinary Status
Intussusception	18: The Child With Altered Gastrointestinal Status
Laryngotracheobronchitis	16: The Child With Altered Respiratory Status

especially bruises or other unusual marks around the genitalia and buttocks area. These marks may be signs of physical or sexual abuse.

FIGURE 5-2. Bath time can be an enjoyable experience for the child, but safety is always a priority. Parents should closely monitor the child throughout the bath.

Oral Care

QUESTION: Lanese calls the nurse at the pediatrician's office. She is frustrated with the struggle of putting the boys to bed. "Why can't I give them a bottle of milk to lie down with?" she asks. If you were the nurse in the office, what information could you share with her?

During the toddler period, the child gains a full set of 20 primary teeth (see Fig. 3-14). While the teeth continue to erupt, the toddler may experience discomfort similar to that experienced during infancy when the teeth started to come in. Chewing food brings comfort to the toddler's gums, just as biting on a teething ring did for the infant. Drooling may increase when teeth are erupting.

It is recommended that the first oral examination occur at the eruption of the first tooth and no later than 12 months of age (American Academy of Pediatric Dentists, 2007b). The dentist checks the child's mouth for placement of the teeth, notes any problems with initial eruption of the teeth, assesses the size of the jaw for future molars, and gives recommendations for follow-up visits and fluoride treatments (American Academy of Pediatric Dentists, 2004). Also, the dentist educates the parent about dental care, including tooth-brushing technique and dietary guidelines to prevent caries. The first trip to the dentist should be a nonthreatening experience. Pediatric dentists are very sensitive to the needs and fears of children and usually go very slowly, allowing the child to become familiar with the equipment and procedures.

FIGURE 5-3. To promote good oral hygiene, encourage the child to brush his or her teeth once in the morning and once in the evening.

KidKare ■ Children's books that have stories about trips to both the doctor and the dentist are good tools to help the child prepare for the visit. After the visit, the books can be read again to compare the child's experience with that discussed in the story and allow the child to verbalize feelings about the visit.

Help young children brush their teeth using a child-sized soft toothbrush and a pea-sized amount of fluoridated toothpaste. Young children do not possess the manual dexterity needed to brush their own teeth effectively. Although the parent still must assume complete responsibility for dental hygiene, encouraging the child to participate in this routine develops good habits (Milgrom et al., 2009) (Fig. 5-3). A good starting point is to brush in front of a mirror or allow the child to sit with his or her head in the parent's lap so the parent can brush the child's teeth and then have the child "brush" the parent's teeth. The easiest technique to teach at this age is the horizontal brushing technique. As the child matures, a more sophisticated up-and-down technique can be taught. The child's teeth should be brushed at least twice daily: after meals and before bedtime. After the child has had the opportunity to brush, the parent should finish brushing to ensure that all areas of the mouth are cleansed. Flossing may be introduced at this time, although the child does not have the manual dexterity to accomplish flossing and thus needs a parent's assistance.

Many types of toothpaste have been developed just for children, made with appealing colors and flavors. A potential problem with these toothpastes is that the flavors are so good that the child wants to eat the paste off the brush rather than brush with it. The toothpaste should be kept out of reach, so that the child does not try to eat the paste directly from the tube.

Even in communities with fluoridated water, dentists may recommend fluoride treatments or fluoride supplements, according to the level of fluoride in the drinking water and the amount of water the child ingests each day. Water sources that should be evaluated include municipal water supplies, wells, and commercial and home-system processed water (Story, Hold, and Sofka, 2002). If community water is not fluoridated or is fluoride deficient (<0.3 ppm), the healthcare provider can prescribe fluoride supplementation, treating the child until approximately 3 years of age (American Academy of Pediatric Dentists, 2007a, c). Supplementation can be provided via solution or chewable tablets (for the older child). Monitor the use of fluoride supplements, because excessive ingestion of fluoride can cause **fluorosis**, a condition characterized by staining of the teeth. Also monitor young children to prevent them from swallowing excessive amounts of fluoridated toothpaste.

If the enamel of a child's tooth is impaired, the dentist may recommend coating the child's teeth with a plastic occlusal sealant to prevent tooth decay. Although the procedure is entirely painless, it does require the child's cooperation; thus, attempting to coat the teeth of a young child may not be successful.

Early-childhood caries (see Chapter 4) continue to be a concern at this age. When a child is put to bed with milk or juice in a bottle or sippy cup and does not rinse the teeth, the sugars in the milk or juice settle on the teeth for the night and promote development of caries. Discuss this concern with parents and remind them of the risk. Monitoring the amount of sweets that the child eats is also important. Fresh fruits and vegetables are good for healthy teeth, but candy is a real culprit in tooth decay. If children do eat sweets, they should brush their teeth immediately afterward to remove the sugars and prevent them from remaining in the mouth. If brushing is not feasible, they can at least rinse the mouth with plain water.

Many parents also find that this is the time to encourage weaning from pacifiers to coincide with weaning from the bottle (see Chapter 4). Offering the child a low-cariogenic diet, which is low in concentrated sugars and high-carbohydrate snacks, will help to decrease the incidence of cavities. Sweets should be offered after a meal, because they are less cariogenic to the teeth if eaten then than if eaten between meals. Cleaning a child's teeth after sweets are eaten at the end of the meal is easier (and more likely to be done) than trying to brush them both after meals and after snacks. Foods that are hard and sticky are more cariogenic, because they stay in the mouth and coat the teeth longer than soft, nonsticky foods. Eating a piece of hard candy is more damaging to the teeth than eating a candy bar. Advise parents which foods are healthiest for the teeth, so that they can incorporate those suggestions into the child's diet.

ANSWER: Make sure Lanese understands that when children fall asleep with milk in their mouth, the sugars in the milk sit on the teeth and eat away at the teeth. Ask if she has ever seen young children with rotten teeth. Explain that this is usually from falling asleep with a bottle and is called *early childhood caries*.

Sleep

The active and exuberant young child requires 8 to 13 or more hours of sleep each day. The exact duration of a child's daily sleep patterns varies based on temperament, activity levels, and overall health. The 1-year-old spends approximately 13³/₄ hours a day sleeping. This time is slowly tapered to 13 hours a day by age 2 and to 12 hours a day by age 3. Around the age of 4, many children discontinue the afternoon nap (Davis, Parker, and Montgomery, 2004). Children age 1 to 4 years of age should sleep through the night without any need for a nighttime feeding. There is no “magic hour” at which the child should be placed in bed for the night. Eight o'clock in the evening is a reasonable time that allows parents to have some time to themselves before they retire for the evening. Most parents gauge bedtime based on their own routines: Parents who like to retire very late often enjoy having their children stay awake until 10:00 or 11:00 pm. When the parents must rise early to take the children to daycare, however, managing a late night–early morning schedule deprives the child of some much-needed hours of sleep. Young children need a bedtime routine such as bathing, reading a story, getting a kiss goodnight, having a favorite toy or security object such as a blanket or teddy bear placed next to them, and then having the main lights turned off. Rowdy play should be avoided close to bedtime, because it tends to excite the child and makes it more difficult to get the child to bed, let alone to sleep. Many children like a night-light. A routine enables children to know what will happen next and gives them a sense of security. After the routine is established, the child is less resistant to bedtime (Fig. 5–4).

Sleep Disturbances

It is not uncommon for young children to have night terrors or nightmares. **Night terrors** occur during the early hours of sleep. The child does not fully awaken and rarely remembers the night terror in the morning. For night terrors, instruct parents to let these episodes take their course, while providing a safe environment and making sure the child does not harm himself or herself in any way. They should not interact with the child, because the child will not have any understanding of who or what is around him or her. Because full consciousness has not been reached, the child may interpret a helpful action as a harmful one and may strike out or hurt himself or herself during the process.

Nightmares occur during the second half of sleep. The child awakes afraid, has difficulty falling back to sleep, and usually remembers the episode in the morning (Richardson, 2006). Nightmares are common during the toddler and preschool years because of the child's active imagination and increased dream state. Although an occasional nightmare is normal, an increase in the number of nightmares can be a response to stress or to the child being anxious about something. Other triggers can be a change in normal routine, such as moving, starting a new school, or a death or divorce in the family.

FIGURE 5–4. This young child finds security and comfort in her favorite blanket.

Nightmares may also be a response to a violent or scary movie, television show, or story.

When the child has an occasional nightmare, parents should reassure the child that it was just a dream and was not real. Giving lots of hugs and words of reassurance can be supportive. The child may want the parent to search the room to ensure that there are no monsters about. Advise parents to wait until the next morning to talk about the details of the dream, at which time the child should be calmer. The parent should try to determine whether there was a specific event or stressor that may have triggered the nightmare. In addition, to decrease nightmares, parents should avoid having the child watch television in the hour before bedtime, avoid telling scary bedtime stories, let the child sleep with a night-light, and examine how to decrease perceived stress in the child's life.

Naps

Naps continue to be an essential component of the young child's daily routine. Until about the 16th month, the toddler generally takes two naps a day—one in the morning and one in the afternoon—each of which lasts about 2 hours. Between the 16th and 20th month, the morning nap is usually eliminated, leaving one afternoon nap that lasts 1 to 3 hours. All children are different. Some might still want and need an afternoon nap, whereas others just need an afternoon rest period to reenergize. Many children resist ceasing all play activities, but after quiet time has been imposed, these same children are often the first to fall asleep. For the child who will not sleep, an extended period of quiet activity, such as looking at books, can be beneficial as a structured period of rest

before the busy activities of the evening, when all the family members gather at home. Nap time should be set at a consistent time each day. The afternoon nap will benefit the child most when taken after lunch and when completed before 3:00 or 4:00 pm. This allows at least 3 hours between the nap and evening bedtime. Naps taken later in the afternoon and extending past 4:00 pm might cause problems when the child is then unable to fall asleep at the regular bedtime hour (Mindell & Owens, 2003). In many daycare centers and preschools, the afternoon nap period is continued, because a great number of children can still benefit from a scheduled period of rest in the middle of the day. During this time, many preschoolers do not actually sleep, but are encouraged to remain on a mat or blanket, quietly playing, to develop the ability to relax or unwind from the tension of the day's activities.

Clothing

During early childhood, the child begins to participate in dressing and undressing. Participation may begin with the child simply lifting a foot to have a shoe put on or learning to slip an arm in a sleeve hole. By age 3, the child is able to undress without assistance (except for removing shoes) and may be able to put on most simple pieces of clothing (Fig. 5-5). Clothes should be easy for the child to put on (e.g., shirts with large neck openings and pants made of stretchy fabrics). Velcro closures on shoes and clothes are easier for the young child than buttons, zippers, snaps, and shoelaces. Items that close in the back should be avoided. Also avoid clothes with drawstrings,

FIGURE 5-5. This young child is proud of her ability to dress herself.

because drawstrings can get caught on furniture or playground equipment, and can lead to strangulation. When drawstrings are present in pants, jackets, and hoods, they should be cut out. Sleepwear should be flame retardant.

The child often chooses clothes based on visual appeal, regardless of whether the socks match or if layering a skirt over pants looks appropriate. A way to avoid arguments about outfits is to keep everything as color coordinated as possible. Many clothing manufacturers develop clothing lines with interchangeable components. The order in which clothing is put on is very confusing to preschoolers, so the parent can help the child by placing the clothes out in the order in which they are to be put on. Shoes need to be fitted correctly and checked periodically for fit. At this age, the child may grow out of shoes faster than any other clothing item.

Toilet Training

QUESTION: Lanese calls the nurse about toilet training. "Shawanda was so good about pee-peeing in the potty, but those boys don't care if they wear a wet diaper for hours." Review Nursing Interventions Classification 5-1. What pertinent information can you share with Lanese?

As the child approaches the second birthday, parents may start thinking about toilet training (Fig. 5-6). The key to toilet training is the readiness of the child. Parents usually find that the older child (2-3 years) is more successful. Some of the signals that indicate a child is ready for toilet training are

- A predictable bowel movement schedule
- Diapers remaining dry for periods of 2 hours or more
- Ability to follow instructions
- An interest in imitating family members in the bathroom
- An indication (either by a facial expression or some other change in activity) that the bladder is full or the bowel needs to be evacuated
- The ability to pull pants up and down

FIGURE 5-6. The young child might be encouraged to sit on the potty chair by using books to keep her still.

NIC 5–1 Teaching: Toilet Training

Definition: Instruction on determining the child's readiness and strategies to assist the child to learn independent toileting skills

Activities:

Instruct parent about how to determine the child's physical readiness for toilet training (e.g., child is at least 18 to 24 months of age; evidence of being able to hold urine before void; recognizes urge to go or that he/she has just voided or defecated; shows some regularity in elimination patterns; ability to navigate to the toilet/potty, sit on it, and get off when completed; ability to remove and replace clothing before and after elimination; ability to wipe self and wash hands after elimination)

Instruct parent about how to determine the child's psychosocial readiness for toilet training (e.g., child expresses interest in and desire to participate/cooperate in toileting; has vocabulary to communicate need to eliminate; is anxious to please parents; imitates the behaviors of others)

Instruct parent about how to determine parental/family readiness for toilet training (e.g., parent has knowledge and time to devote to training process; parent/family is experiencing no major transitions during or shortly after the process such as change of job or residence, divorce, birth of another child; has realistic expectations about child development and the time and energy needed to successfully complete the process; understands child may regress during times of stress or illness)

Provide information on strategies to promote toilet training

Provide information on how to dress the child in loose, easy-to-remove clothing

Provide information on how to agree on vocabulary to be used during training process

Provide information on opportunities for child to observe others during the toileting process

Provide information on how to take the child to the potty to introduce him/her to the equipment and process

Provide information on how to take the child to the potty on a regular basis and encourage him/her to sit

Provide information on how to reinforce the child's success with any part of the process

Provide information on how to consider the child's temperament or behavior style when planning strategies

Provide information on how to expect and ignore accidents

Provide information on how to communicate strategies, expectations, and progress to other care providers

Support parents throughout this process

Encourage parents to be flexible and creative in developing and implementing training strategies

Provide additional information, as requested or needed

From Bulechek, G., Butcher, H., & McCloskey Dochterman, J. (Eds.). (2008). *Nursing interventions classification (NIC)* (5th ed.). St. Louis: Mosby. Used with permission.

These readiness signals may occur at the age of 2, but more commonly are seen at 2½ to 3 years of age (Graham & Uphold, 2003). Daytime control is usually achieved before nighttime control. Bowel control is usually completely achieved by age 3. Bed-wetting (nocturnal enuresis) is a common problem in this age group. It is seen more frequently in boys and those who are deep sleepers. If a child continues to wet the bed after age 7, or if infection or anatomic abnormalities are suspected, referral to a healthcare provider is needed (Hagan, Shaw, & Duncan, 2008). Even after toilet training has been successful, accidents are common. Strategies to promote toilet training are presented in Nursing Interventions Classification 5–1.

ANSWER: The following are signs of readiness for toilet training according to Nursing Interventions Classification 5–1: Determining the child's physical readiness includes the child's recognition that he or she has just voided or defecated. Determining the psychosocial readiness includes the child expressing an interest in toilet training. To prevent Lanese from becoming overly frustrated, it is important that she

understands that children are ready for toilet training at different ages and the boys just might not be ready. The nurse's role is to share the signs of readiness with the parent.

NUTRITION

QUESTION: Lanese wants to know whether it is normal for the boys to have such strong opinions about their food. Give an example of an appropriate response. How can you further assess the boys' eating habits and what information can you share that may improve the boys' nutritional intake and eating habits?

By the first birthday, the young child should have already started eating solid food. Because the rapid growth rate of infancy has slowed, the toddler needs fewer calories per day (1,100–1,550 cal/day) than needed in infancy. After gaining 3 to 4 lb every 2 to 3 months during the first year, the child now gains an average of 4½ to 6½ pounds per year and grows 2½ to 3½ in per year (Patrick et al., 2001).

Introduce the child to a schedule revolving around three meals per day, with snacks midmorning and midafternoon. The young child's stomach is small, so frequent, small meals are appropriate. The diet should consist of the five basic food groups, with a variety of foods with different textures and tastes (Table 5-1). Before the age of 2, fat is needed for brain development and should not be restricted unless the child has an underlying medical condition, such as diabetes. Avoid "diet" food and drinks (e.g., nonfat milk, diet soda). After the age of 2, high-fat foods should be gradually restricted, so that by 5 years of age the child is consuming no more than 30% to 35% of their daily calories from fat (Giddings et al., 2006). Because parents choose which foods to feed their children and role-model these same practices, teaching about nutritious foods is an important role for nurses. For example, one study found that mothers who consumed more than 12 fl oz of soft drinks per day were nearly four times as likely to have a child with poor dietary intake and high average intakes of milk, fruit juice, and sweetened beverages (Hoerr et al., 2006). Teach parents that young children should have the same foods that the rest of the family is eating, but in portions about one fourth of the amount an adult would be served. Foods offered to the child should be of high nutrient density, so that the child develops good eating habits. Good eating habits and food preferences developed early will help prevent chronic health conditions such as type 2 diabetes, heart disease, and obesity, which result in part from poor eating habits. Avoid fruit drinks, flavored milk, and sodas; encourage drinking water for thirst. Heavily spiced or salted foods should be avoided, because young children may not find them palatable. Refer

parents to the U.S. Department of Agriculture website (www.MyPyramid.gov). At the website, parents can type in information specific to the child and receive individualized nutrition information.

A 1- to 2-year-old has not yet mastered the use of the spoon or fork; therefore, finger foods are highly recommended. A plastic mat placed underneath a high chair and use of bibs help contain some of the mess the child makes as hands are used to experiment with food and attempts are begun to use the spoon. By 18 months, the child has enough control over the hands and fingers to navigate food to the mouth consistently using a spoon (Carruth et al., 2004) (Fig. 5-7A). Child-sized utensils are offered for use to the 3- and 4-year-old, such as chunky handled spoons and forks that fit his or her hands, and allow the child to feed himself or herself (Fig. 5-7B). Age-appropriate foods include those that enable the preschooler to perfect these newly developed skills. Finger foods such as diced fruit, steamed diced vegetables, shredded cheese, or cereals are ideal for the young child. Foods should be mashed or cut into small pieces to prevent choking.

caREminder

To prevent a young child from choking, never give small, hard foods such as peanuts or hard candies. Even soft small foods such as grapes could be a hazard. Carrots and hot dogs should be cut in half lengthwise and then quartered to prevent choking.

TABLE 5-1

Nutrition Guide for Early Childhood

Number of meals: three meals and two snacks per day		
Same number of servings as for a 4- to 6-year-old, but smaller portions (about $\frac{2}{3}$ of a serving)		
Range of calories: 1,100–1,550/day		
Calories/kg/day: 102		
Food Category	No. of servings per day	Recommendations
Grain	6 servings	Servings include 1 slice of bread, $\frac{1}{2}$ cup of cooked rice or pasta, $\frac{1}{2}$ cup of cooked cereal, or 1 oz of ready-to-eat cereal.
Vegetables	3 servings	Servings include $\frac{1}{2}$ cup of chopped or raw vegetables, or 1 cup of raw leafy vegetables.
Fruits (may include 100% fruit juice)	2 servings	Servings include 1 piece of fruit or melon wedge, $\frac{3}{4}$ cup of 100% fruit juice, $\frac{1}{2}$ cup of canned fruit, or $\frac{1}{4}$ cup of dried fruit. Limit fruit juice to 4 to 6 oz each day.
Dairy products (including yogurt, cheese products)	2 servings	Servings include 1 cup of milk or yogurt or 2 oz of cheese. Need 500 mg calcium each day (about 2 glasses of milk). Age 2 may begin to use 2%, low fat, or skim milk.
Meats/poultry/beans/nuts	2 servings	Servings include 2 to 3 oz of cooked lean meat, poultry, or fish; $\frac{1}{2}$ cup of cooked dry beans. You can substitute 2 tbl of peanut butter or 1 egg for 1 oz of meat.
Fats, oils, and sweets		No more than 30% of calories should be from fat. Limit saturated fats to no more than 10% of daily calories.

FIGURE 5-7. (A) This young child enjoys feeding himself! Self-feeding allows the child to investigate the different textures and tastes of foods. (B) As the child matures, she develops the manual dexterity to handle utensils.

Young children are at risk for choking, because of the small size of the airways, poor chewing ability, and a tendency to put things in the mouth (U.S. Food and Drug Administration, 2005). To prevent choking, parents should stay with a child who is eating to help monitor how much food is placed in the mouth at one time. The young child should always sit while eating and not be allowed to walk or run while chewing food. In addition, keeping children calm at mealtime can minimize the risk of choking caused by overexcitement.

At 1 year of age, the child can begin drinking whole cow's milk instead of formula or breast milk. Some mothers may continue breast-feeding at bedtime. A young child should receive at least two servings of milk and other dairy products a day, and take milk primarily from a cup. More than 16 oz of milk per day will interfere with the amount of solid food that a child can eat and can also contribute to iron-deficiency anemia. During young childhood, iron-rich foods (e.g., meats, fish, poultry), iron-fortified cereals, and foods that contain vitamin C should be consumed to enhance iron absorption (Story, Hold, & Sofka, 2002). Iron supplements may also be needed to ensure that the child is receiving adequate iron.

Alert! Instruct parents to store iron supplements out of reach of children and to reinforce that they are medicine, not candy, because some preparations look like candy.

Mealtimes can become a power struggle between parents and the young child. Reassure parents that toddlers and preschoolers go through periods during which they are very particular about food. **Food jags**, periods when a child will eat only a few foods, may occur. Young children also begin to be attracted by the color, smell, and shape of food. Foods that look like or smell like other foods they enjoy are most likely to be eaten. Never force a child to eat. Children may resist trying new foods and

10 to 15 attempts may be necessary before a child will try a new food. When introducing a new food, the parents can encourage the child to taste it or combine a new food with an old favorite. Parents should not assume that initial refusal of a new food represents a permanent dislike and thus label the child as a picky eater. The child will have personal likes and dislikes, as all individuals do, but these may change. The food should be offered again in a few days; if the child is not forced to eat it, often it will be accepted. If the child consistently refuses a particular food or food group, one can become creative. For instance, if the child refuses to eat raw apples, steaming, baking, or grating them onto a plate with a dip are alternative ways to serve the snack. Do not negotiate what the child eats, reward the child with treats, or threaten punishment. Mealtimes should be nonstressful but not “play” times. Family mealtimes enable the parents to role-model healthy eating behaviors and also promote social interaction (Giddings et al., 2006). Meals or snacks, therefore, should not be eaten while watching television.

ANSWER: When Lanese asks about the boys' food preferences, you might respond, “It is common for toddlers to choose a taste or a color of food for a time.” Assess specific information by asking, “What do the boys eat during a typical day?” Another tactic is to ask, “What did the boys have yesterday for each meal and snacks?” Toddlers need small quantities of all the food groups. Be sure that Lanese has an understanding of the food pyramid and that she is offering the boys a variety of foods at each meal. Reassure her that it is okay for J. D. to have a small serving of macaroni and cheese often if he is also eating fruits, vegetables, and meats.

PHYSICAL FITNESS

Activities for the young child are selected based on emerging cognitive, linguistic, and fine and gross motor

skills. Many variations exist regarding when children will master these skills during the preschool years. Parents should not be discouraged or concerned because their child is not reading or coloring within the lines like another child of the same age. The Denver II (see Appendix B and discussion in Chapter 3) and other developmental measures can be used to assess the child's skills and to provide reassurance to the family that the child is performing within the normal range for his or her age.

At 1 year of age, mastery of gross motor activities takes precedence. One of the major accomplishments of the second year of life is learning to walk. By 2 years of age, the toddler is able to walk, run, carry several large objects while walking, and go up and down stairs. This accomplishment occurs over several months, beginning with the toddler placing the feet far apart, for a wide base of support, and using the hands and arms for balance. Toddlers often "cruise" furniture, using tables, sofas, and chairs as crutches to assist with their balancing act. Falls are frequent at this stage, and parents must be aware of sharp table edges that may cause injury to the toddler and of small wrinkles in carpets or rugs that could cause them to fall. As gross motor skills become more developed, the child will be interested in a riding a tricycle, kicking a ball, and playing running games.

Fine motor skills are also being perfected. At 1 year of age, using a pincer grasp to pick up small items (between thumb and forefinger) is still very difficult. As the toddler matures during the second year, these fine motor skills become easier. The child's fine motor skills are developed enough to color with crayons, turn pages in books, and operate small toys that produce action or sounds. Because attention spans are still short, toddlers need a wide variety of objects to play with and touch; they prefer objects that make noise in response to playing and touching them. Filling containers with objects and dumping them out, stacking blocks and knocking them over, scribbling, and painting are favorite activities at this age (Fig. 5–8). Games

FIGURE 5–8. Activities such as stacking blocks help toddlers refine their fine motor skills.

TRADITION OR SCIENCE 5–1

Does television viewing have a negative impact on young children?

EVIDENCE-BASED PRACTICE

Providing the child (age 1–12 years) with time during the day to watch television is one method to help the child calm down and allow parents time to attend to their personal activities. The deleterious effects of television viewing include weight gain, exposure to violence, and the development of attentional problems. Several studies have found a relationship in young children between television viewing and weight gain over time. That is, the more television that is viewed by the child, the greater the increase in body mass index (Iago et al., 2005; Proctor et al., 2003; Robinson, 1999; Saelens et al., 2002; van Zutphen et al., 2007). Christakis et al. (2004) found that the more television children viewed at young ages, the more likely they are to have attention problems at age 7. This finding has been debated by Miller et al. (2007), who also found a correlation between television exposure and attention-deficit/hyperactivity disorder (ADHD), yet could not conclude whether levels of television viewing were the cause or result of ADHD symptoms. Children watching greater amounts of television (more than 6 hours per week) have also been reported to have higher levels of violent behavior, higher levels of posttraumatic stress syndrome (after watching traumatic life events on television), and are more likely to engage in risk-taking behaviors than children who watch less television (Bernstein et al., 2007; Singer et al., 1998). Yet, these studies also question whether children with preexisting psychological or behavioral problems tend to watch more television than children without these problems.

In both Australia and the United States, it is recommended that television viewing should be discouraged in children younger than 2 years of age, and should be limited to 1 to 2 hours per day for older children (American Academy of Pediatrics, 2001; Commonwealth of Australia, Department of Health and Ageing, 2004). More interactive activities, such as reading stories, talking, and singing, are encouraged to promote appropriate brain development. It is recognized that children's and adolescents' TV viewing time is influenced by parental rules limiting the time spent watching TV and by parental TV viewing (Barradas et al., 2007; Yalcin et al., 2002), thus suggesting that it is important to set rules to limit television viewing, monitor what is being viewed, and having parents role-model good television viewing behaviors.

that also teach spatial concepts such as under, in, over, and so on, help the child develop skills. The cause-and-effect mechanisms of mechanical toys give 2-year-olds a sense of accomplishment; something happens because they cause it to happen. All toys still need to meet the appropriate safety standards. Tradition or Science 5–1 explores the impact of television on young children.

Play

The play interactions of an infant occur primarily between the parent and the infant. As the infant matures into early childhood and becomes more social, play interaction with peers evolves into several different types of play styles (Fig. 5–9). Play is critical to the child’s social and emotional development, helping the child to learn to get along well with others. Although there may seem to be a push to increase academics in early childhood education settings, the value of play in developing the child’s ability to communicate and enhance other developmental skills should not be overlooked (Ashiabi, 2007).

Onlooker play is when the child observes the actions of other children and does not attempt to interact with them. **Solitary play** is when a child plays alone, absorbed

in an activity and uninterested in the play of other children. **Parallel play** occurs when children play with similar toys, beside other children, but are not influenced by other children’s play activities. The child may have an identical toy, but may play with it in a different manner. **Associative play** occurs when children are playing together in a group without organization or leadership; however, they may share materials or follow one another. For example, two children draw pictures, share paper and crayons, and discuss what they are drawing, but neither suggests that they draw the same thing. When the play is organized, with a leader–follower type of relationship established, it is considered **cooperative play**.

The young child participates in onlooker, solitary, and parallel play. Piaget described the development of play as two stages: **Practice play** occurs between the ages of

FIGURE 5–9. (A) Young children (e.g., the boy in the red shirt) participate in onlooker play. (B) During parallel play, children may play side by side, but do not influence each other’s play activities. (C) During associative play, children play together, although there is no specific organization to, nor leader guiding, their activities.

2 and 18 months. Practice play is followed by **symbolic play**, which occurs between the ages of 18 months and 4 years. During the practice play period, the infant or young child engages in sensorimotor activities, out of which the infant gains the pleasure of being the cause. As time passes, the child tries out the same patterns of action on different objects and begins to define objects by their use and begins to relate one object to another (Casby, 2003). During the period of symbolic play, the child transitions from sensorimotor schemes to mental operations. During this type of play, children apply a familiar action pattern they have previously applied to themselves to other people and objects. As symbolic play progresses, the child begins to demonstrate the ability to anticipate outcomes and to adapt actions accordingly (Casby, 2003).

Age-Appropriate Activities

By age 3 years, the child has understandable speech, a vocabulary of about 900 words, and a beginning concept of time. He or she has also learned some self-control. Gross motor skills have developed to allow the child to jump, kick a ball, ride a tricycle, and walk up stairs with alternating steps, although the child may still lead with the same foot to come down stairs. Play must expand on these skills. The child should have a tricycle; large, sturdy toys such as big blocks; active toys like a pounding bench; and musical toys that encourage rhythmic movement. The preschooler also likes show-and-tell, guessing games (because his or her memory is improving), and big-pieced jigsaw puzzles (Fig. 5–10). At age 3 years, play is still ego-centric, but the child is becoming more tolerant of play companions.

By the age of 4, the child's receptive vocabulary has expanded to between 900 and 1,500 words, and he or she

uses full sentences and can understand simple analogies. The child is now able to jump on one foot, skip, walk down the stairs with alternating feet, and throw a ball overhand. The preschooler is able to use scissors well, and fine manual dexterity is improving. Construction toys, jigsaw puzzles, memory games, and fantasy play are favorites. The child will tell family secrets and exaggerate stories. Children at this age love to listen to audible books and music. During ages 3 to 4 years, the child has an insatiable curiosity and will constantly ask “why” questions. These children are developing a sense of their world around them. Their play is now becoming interactive, and the child can obey limits, but still does not have a sense of true right or wrong. Imaginary friends are very common among children this age.

Generally, toys for the young child must be sturdy, with no sharp edges or small pieces. Preschoolers learn many things by doing (Fig. 5–11). This is an age when they will pretend to be a mother or father, doctor or nurse, which is why pretend play and dress-up are so important. They have a lot of energy and, as their manual dexterity improves, they need large balls to bounce and tricycles to ride. Electric toys should be avoided unless they are battery operated and used under adult supervision only.

caREminder

Toys should always be chosen according to the child's age and size, and should be checked often to be sure that they have not become broken or developed a dangerous, sharp edge. Children should not be allowed to place toys in their mouth, nor should they run with toys that are large, easily breakable, or have sharp, accentuated borders or ends.

FIGURE 5–10. This young child enjoys playing with puzzles as she gains an ability to learn simple sequences, develops fine motor skills, and has good eye–hand coordination.

FIGURE 5–11. Young children are encourage to use gross and fine motor skills in their play activity. This little worker is busy digging in sand.

Exposing the child to a wide variety of interactions (playing alone, in peer groups, or with older children or adults), locations for play (home, friend's home, parks, libraries), and activities (structured, group, quiet, spontaneous) is beneficial. Because young children are very active, parents must be sure to provide enough physical space for play. Tactile exploration is important. Water tables, sand, soap bubbles, and clay provide excellent opportunities for the child to explore different textures and to develop creativity (Fig. 5–12). Safety must always be considered, and toys must be appropriate, with no sharp edges.

Developing a healthy exercise habit during the child's early years to improve general well-being throughout life and to help prevent obesity is important. Parents should promote daily activity such as walking, running, riding a tricycle or bicycle, or playing with a ball (Fig. 5–13). Organized activities provided by qualified and experienced teachers, such as tumbling, gymnastics, and dancing, are recommended because these activities enhance balance and coordination (Patrick et al., 2001). Encourage the parents to set an example by being active and encouraging parent–child activities.

Television

Many of today's television programs are not appropriate for younger viewers (Shelov & Hanneman, 2004). Young children believe that everything they see on TV is real. They develop a distorted view of how to deal with problems, because their favorite cartoon character uses violence as a method to cope with anger and frustration. Cartoons can contain much more violence than adult programming. Television can contribute to many psychological and physical problems, because it lessens the child's creative ability and can undermine the capacity for independent thinking. Children who watch a great deal of television are also more likely than others to become obese (Shelov & Hanneman, 2004) (Tradition or Science 5–1).

Banning television completely from a child's life is almost impossible, but parents should monitor carefully

FIGURE 5–12. Playing with modeling clay allows for hands-on learning and tactile exploration.

FIGURE 5–13. Young children love outdoor physical play, such as riding a tricycle. The child should always wear a proper safety helmet when riding a bike.

what a child watches and how often. Electronic devices can be used to limit a child's TV watching. These devices are installed between the TV set and the cable input or the antenna to prevent unauthorized watching. As a general rule, 1 to 2 hours of quality television per day should be the limit (American Academy of Pediatrics, 2001). The parent should watch with the child to explain that commercials are advertisements, not a part of the program, and to talk with the child about the program and what the message of the program was. This practice helps the child develop critical viewing skills and enables better choices about television programming when the child is older (Developmental Considerations 5–2). Early TV exposure and watching for prolonged periods contributes to attention problems by 7 years of age (Christakis et al. 2004).

PERSONAL AND SOCIAL DEVELOPMENT

During the early childhood years, the child gains independence, and developing social competence becomes increasingly important.

Personality Development

As the child transitions from infancy to early childhood, the child acquires a sense of autonomy and independence through the mastery of various specialized tasks, such as the control of bodily functions, refinement of motor and language skills, and acquisition of socially acceptable behaviors (Fig. 5–14).

Self-esteem is a realistic, positive sense of self-worth and identity. Developing self-esteem is a lifelong task that

DEVELOPMENTAL CONSIDERATIONS 5–2

Guidelines for Television and Video Viewing

- Advise parents to limit children’s television viewing time to no more than 1 to 2 hours per day.
- Encourage parents to control which shows their children watch.
- Encourage parents to watch television with their children, especially if the children are viewing a new show or a new videotape.
- If children are allowed to watch television while parents cook dinner, shower, or engage in other activities during which play activities cannot be adequately supervised, encourage parents to select videotapes for the child to view.
- Advise parents and daycare providers to familiarize themselves with high-quality, low-cost videotapes that are available from the library or for purchase.
- Caution parents not to assume that videotapes produced by a major “family” entertainment company are appropriate for children of all age levels. Fighting scenes or death of a mother or father may be very disturbing for the young child.
- Encourage parents to provide feedback to the networks regarding the quality of programming for children.

begins at birth but is truly fostered during early childhood (see Developmental Considerations 5–1). Young children love to pretend they are adults and do appear very grown up at times. Their self-esteem is strongly tied to learning new skills. They are developing an awareness of their own skills and interests. As young children become more self-aware, and aware of peers, parents may hear them express a lot of dissatisfaction with their own achievements. They may want their drawing to look like another child’s drawing or to look like a “real” flower. Parents can nourish feelings of self-esteem by praising the child’s achievements, showing respect and support to the child, allowing the child to make decisions, listening to the child, and spending time with the child. The parent needs to be a coach to the child rather than just a cheerleader who merely praises accomplishments. A coach uses praise to instill feelings of self-worth and teaches the skills the child needs by reinforcing specific actions (“You did such a good job setting the table by putting the napkins and forks in exactly the right place!”).

Building self-esteem in a child is quite challenging, because the child can display a lot of negativism. This negativism is expressed through the tendency to say no to most questions. The child also acts on the impulse of the moment and may not completely understand what the parent wants. Nonetheless, positive comments should

FIGURE 5–14. Young children enjoy being outside with their parents, exploring the world.

outweigh criticisms. Keep the rules to a minimum if possible.

Another way to foster self-esteem is to provide opportunities for the child to make choices and decisions, thus allowing the child some control over his or her life. Children should then be given encouragement and positive feedback (when appropriate) for the decisions they have made. The child should be allowed to begin to establish self-discipline so that he or she understands logical consequences and can make appropriate choices. The parent should help the child learn how to deal with mistakes and failures so the child will not avoid attempting new things. Spending a few minutes each day talking with the child about the events of the day, or praising the child for accomplishments (with specific examples), or providing an environment where the child can play without being restrained by “no,” “don’t touch,” and so on, will do much to foster healthy self-esteem (Developmental Considerations 5–3).

Temperament

How the young child adapts to life’s new challenges and meets developmental milestones may be determined by the child’s temperament. An “easy” child with high adaptability will accept new activities and experiences easily. A “difficult” child is the exact opposite, will not make these transitions easily, and may be very loud and vocal regarding these changes. The “slow-to-warm-up” child initially will react with some negativity, but will respond more positively with repeated exposures (see Chapter 3 and 4 for more information on temperament).

Temper Tantrums

The young child becomes frustrated easily and wants to do as much as possible for himself or herself as part of

DEVELOPMENTAL CONSIDERATIONS 5–3

Strategies for Enhancing Self-Esteem

- Help the child build a healthy relationship with peers, because children are sensitive to evaluation of peers.
- Treat the child with respect. Ask the child's views and opinions, and respond seriously.
- Use physical contact to communicate feelings of love and acceptance.
- Talk to the child (even as an infant or toddler), using the child's name frequently; give hugs, smile, and use eye contact.
- Applaud unsuccessful attempts as well as successes.
- Develop a positive, nurturing environment.
- Do not belittle the child.
- Use positive reinforcement whenever possible and avoid negative criticism.
- Include the child in activities that interest the adult.

asserting independence. Temper tantrums are a common way of dealing with this frustration (Ateah, Secco, & Woodgate, 2003). Young children often throw themselves on the floor, kick their feet, and scream. Some children will hold their breath or bang their heads. If the child holds his or her breath until he or she faints, this behavior (although it is not pleasant to watch) does not cause any permanent damage. As the oxygen level decreases and the carbon dioxide level rises, respiration is stimulated. Head banging can cause permanent injury, however, so children who have this kind of tantrum need to be protected by being held so they cannot bang their heads. Tantrums may not have stopped by the time the child is 3 years old, but by the time the child is 5 years old, tantrums should be rare.

When dealing with temper tantrums, it is important to remain calm. The best technique is to avert the tantrum altogether, if at all possible (Developmental Considerations 5–4). If tantrums are dealt with in a controlled manner, they may actually diminish over time. Humor is sometimes effective at redirecting the tantrum. A funny face or a joke may distract the child.

Relationships

Close relational bonds continue to exist between parents and the young child. One of the child's greatest fears is separation from parents and other family members. Parents provide safety and security to the young child as they explore their expanding world. Young children mimic parents' actions, doing so because they want parental approval and they want to be like mom or dad (Fig. 5–15).

DEVELOPMENTAL CONSIDERATIONS 5–4

Managing Temper Tantrums

- “Childproof” the home to reduce the number of times the parent must say no to the child's actions and activities.
- Allow the young children to make frequent small choices, providing clearly defined, acceptable parameters.
- Evaluate the child's temperament and changes that occur in temperament throughout the course of the day. Plan activities accordingly.
- Make sure no really means “no” and not “well, maybe.” Even if the child protests vehemently, the parent should not back down from his or her stand; otherwise, the child learns that if he or she protests enough, mom or dad will give in.
- When a tantrum has started, parents should
 - Ignore the child's behavior
 - Stand about 5 ft away from the child and keep doing the activity they were previously engaged in or leave the room, as long as the child is safe
 - Do not speak to the child and avoid eye contact until the child has calmed down
 - Move objects out of the way or move the child, if necessary, to prevent injury
 - Do not let the child hurt him- or herself or others
- After the tantrum, discuss the child's behavior with him or her in a calm, neutral tone. Discuss ways the child can get “in control.” Do not talk excessively about the tantrum, because this can negatively affect the child's self-esteem.

During early childhood it is not uncommon for the child to be introduced to a new brother or sister. Giving a new older brother or sister the support needed is important during this time, when much parental attention is going to the new sibling. **Sibling rivalry**, the feelings of jealousy and resentment when someone new joins the family, is very normal (see TIP 4–2). It commonly occurs at this age because of the change in the child's routine and general changes in the environment.

When the young child does something that causes the newborn to cry, many parents discipline the older child and comfort the infant. This reaction may lead to further jealousy on the part of the child. A better reaction is to investigate the reason behind the action and talk to the preschooler about alternatives. If the child acted out of jealousy, the parents need to look at the type of time they are spending with each child. One parent could spend quality time with the older child while the other parent cares for the newborn. When the children are old enough to play together, they should be allowed to work out differences themselves. Parents who do not take sides, but instead help the children to work out their differences,

FIGURE 5–15. Cognitive development is promoted by allowing the child an opportunity to observe and imitate. Cooking is a favorite adult role to mimic.

can turn sibling rivalry into a positive advantage (Shelov & Hanneman, 2004).

Young children who are involved in a newborn's care adapt better than those who are not and thus have fewer feelings of sibling rivalry. During this time, it is wise not to introduce any new developmental tasks such as toilet training, weaning from a nighttime bottle, or changing from a crib to a toddler bed. Encourage parents to spend extra alone time with the child to decrease sibling rivalry. The older child is used to having all of his or her time spent with the parents and will miss this greatly.

Friendships with other children are developed during early childhood; however, these friendships are not expressed in the same manner as those developed by older children and adolescents. Friends enable children to learn from what other children do, and to note how other children's actions affect the environment and the people in the environment. Young children have short attention spans and thus are likely not to carry a grudge when a friend has mistreated them or ignored them. Young children are most likely to seek friendship without constraints of ethnicity, age, or gender. Friendships are a means to have a playmate and to learn how to socialize in a manner that is acceptable to other children and adults.

By the age of 3, the child is less egocentric than before and will actively engage in interaction with other children. Preschoolers play interactively rather than side by side. During this time, children may also start to develop friendships, and by the age of 4 they will have a very active social life and possibly even "best" friends. Friendships are easily established but may vary in expression; for example, periods of laughter and joy may be followed by episodes of aggression and arguing. Children want to please friends and show off to them. These friendships are often based on frequency of contact with one another. That is, at this age it would not be expected that the child would initiate a request to see or play with another child, as would happen in middle childhood. Preschoolers will find friends or make friends in whatever circumstance they find themselves to ensure that they have a playmate.

Around age 3, children are cognitively involved with fantasy and will drift from reality to fantasy often. At times, they may have imaginary friends. After the child turns 4 years old, he or she focuses more on reality. Children at this age can distinguish that they are not a superhero or storybook princess.

During early childhood, the child initially identifies more with one parent than another, as if to learn all he or she can about his or her parents one at a time. It is important that the parents understand that this bonding is a normal part of development, and the parents should not display disappointment or jealousy when it occurs.

Language Development

QUESTION: Lanese asks the nurse, "Should I be worried that the twins are not speaking as clearly as Shawanda did?" What areas of language development can you identify for Lanese that need further assessment?

A major accomplishment affecting a young child's social development is the acquisition of language. By the end of the first year, the child has a vocabulary of about 50 words and is using pronouns; by the time the child is 3 years old, he or she has a vocabulary of hundreds of words, speaks sentences of two and three words, understands most of what is said, and can follow short, easy directions. Now parents may find that they need to spell out words that they would rather the child not hear (e.g., "Should we buy some C-A-N-D-Y?"). The child is increasingly responsive and attentive to conversations, so songs, music, and nursery rhymes are good games. Children enjoy examining pictures in books and having stories read to them (Fig. 5–16). These activities promote *early literacy* (early introduction of behaviors that foster eventual acquisition of reading and writing skills). Early literacy is discussed later in this chapter, including age-appropriate methods to encourage early literacy behaviors (Developmental Considerations 5–5). Memory

FIGURE 5–16. The young child enjoys examining pictures in books and listening as stories are read.

DEVELOPMENTAL CONSIDERATIONS 5–5

Promoting Early Literacy

Age	Types of Reading Materials	Parent Activities	Skills You Are Promoting
6 to 12 months	Small, hand-sized, board books with pictures of faces and only a few words per page	Read aloud to the child. Hold the book so that the child can see the words and pictures.	Physical manipulation or handling of books Behaviors related to how children pay attention to and interact with pictures in books, such as gazing at pictures or laughing at a favorite picture Hand-eye coordination as the child learns to point to specific objects in the books
12 months to 2 years	Small board books with pictures of family life, animals, and common household items Simple stories with rhymes and repetition that concentrate on particular sounds	Same as above. Follow the words with a finger to show how to read from left to right or assist the child to follow the words with a finger. Repeat reading the same book, letting the child finish familiar sentences and pointing to the words that the child can “read” as the child says the words. Ask questions while reading about the pictures, the story, and the words, such as, “Show me the horse.” “Where is the cow?” “Can you find the letter ‘c’? The letter ‘r’?” Sound out letters and talk about the story, making predictions about what will happen next.	Physical manipulation or handling of books Behaviors, such as pointing to pictures of familiar objects, that show recognition of and a beginning understanding of pictures in books Picture and story comprehension behaviors that show a child’s understanding of pictures and events in a book, such as imitating an action seen in a picture or talking about the events in a story Behaviors that include children’s verbal interactions with books and their increasing understanding of print in books, such as imitating reading or running fingers along printed words
3 to 6 years	Alphabet and number books that the child and parent make to read together Books that are well written and illustrated for young children	Do “picture walks” before starting to read aloud. Review the pictures in the book and discuss the meaning or interpretation of the picture. Let the child tell the story just by looking at the pictures. Take time to talk about the book and concepts. Buy books with the child (e.g., from stores, garage sales, book clubs). Help the child to start building a personal library. Get the child a library card and make frequent trips to the library. Let the child see parents reading. Invite the child to sit beside adults and read a book while they are also reading.	Same as above Behaviors that show an emerging association between written words and visual images Behaviors that role-model a love for books and a desire to use free time to entertain oneself by reading

games, matching games, hide-and-seek, pretend games, and “Simon Says” are great fun to the child, who is the center of attention.

ANSWER: Further assessment of the boys’ language development is important. Determine whether the boys have had their hearing tested. Altered hearing can impair the development of clear speech. Also determine the actual level of the boy’s language development. How large is their vocabulary? Are they combining words and using phrases? Share with Lanese that if the boys have had their hearing tested and their vocabulary is continuing to grow, it may be that they are putting their energy into their physical skills at this time, and language skills will catch up. Note to follow up on the boys’ language skills the next time they are in the office.

Fears

The most common fears in early childhood are the fear of separation from the parent and fear of loud noises. Fears are common in children of all ages, and they change as the child matures and obtains a more concrete level of cognitive ability. For some fears, such as the fear of dogs or the fear of falling, there is usually a triggering event. Because of the limited cognitive understanding of the child, some fears that surface are irrational, because the child does not have enough information to self-reassure and thus allay the fears (Chart 5–2).

The young child is still learning to differentiate between reality and fantasy. Because of very vivid imaginations, 3- and 4 year-olds can have some strong fears. These fears may be of real objects (e.g., dogs) as well as imaginary things (e.g., monsters in the dark). Three-year-olds have visual fears associated with burglars, and people with deformities, scars, and masks. Children 4 years of age and older have more auditory fears, such as imaginary creatures and sounds heard in the dark. When a child experiences a fear, the parent must take it seri-

CHART 5–2 COMMON FEARS OF THE YOUNG CHILD

- Abandonment or separation from parents/family members
- Animals
- Bath/toilet
- Becoming lost
- Costumed characters (e.g., Easter Bunny, Santa Claus)
- Dark
- Falling
- Nightmares (monsters)
- Noises (e.g., loud noises associated with another fearful event)
- Strangers

ously, comfort the child, and then discuss the fear with the child.

KidKare ■ The parent should not belittle the fear and should never use it as a threat, because doing so could exacerbate the fear. Sometimes the parent may need to use concrete actions to remove an imaginary fear, such as “monsterproofing” the bedroom.

Most childhood fears are a perfectly normal part of development and will disappear as the child matures. Some situations, such as a move to a new house, divorce, death in the family, or a serious accident or illness, may exacerbate a child’s fears. Reading books about scary situations may help a child regain control and understand that the situation is not to be feared. Another common technique to deal with a child’s fears is **desensitization**, during which a fear is conquered by approaching it little by little. For example, a fear of water can be conquered by playing with water in a basin, then in a sink, then from the side of the tub (always with adult supervision) until enough confidence is obtained to get into the tub. If a fear becomes a phobia, then the healthcare team must be consulted. Emphasize to parents that providing reassurance and comfort will help children face fears.

Regression, a change from current behaviors to past developmental levels of behavior, may occur in young children in response to sibling rivalry, fears, or stress. For example, a child who has achieved toilet training may have accidents or refuse to use the potty. Caution parents to ignore the regressed behavior, praise the correct behavior, and not introduce new expectations during this time.

Sexuality

The young child develops an emerging awareness of his or her body. Parents may find young children examining each other’s genitalia or laughing about a “bathroom” joke. Masturbation (deliberate self-stimulation that results in self-comfort or sexual arousal) also begins at this age. Many parents are alarmed to find their young children engaged in such activities. An adult may be shocked to discover a 3-year-old child masturbating, but such actions should not be handled in a punitive manner. Reprimanding the child or forbidding these actions could lead to unwanted consequences later, because such reactions will produce guilt and remorse. Therefore, parents should strive to present a casual response.

Children at this age have normal curiosity about their bodies. Questions asked should be answered simply and honestly. Young children have active imaginations, and if they are told not to ask such questions, they will come up with their own answers, which may not be totally accurate. The parents should investigate the actual intention behind the question. Most have heard the old joke in which the child asks where he or she came from, and the parents go into a long detailed explanation of childbirth, only to discover that the child wanted to know the town where he or she was born. Parents must not let their own

biases or prejudices influence their answers. A 3-year-old girl is very curious about the “thing” that the 3-year-old boy has that she does not; the 3-year-old boy is just as mystified that the girl can urinate without having a penis. When children ask about sexual issues, parents should use the correct terms for all body parts, including genitalia. This is also a good time to introduce the idea that certain body parts are private and should not be touched by strangers (Hagan, Shaw, & Duncan, 2008).

Discipline and Limit Setting

Limits are needed to define acceptable behaviors during early childhood. These limits will be tested in many ways. At the age of 3, the child is unable to verbalize many feelings and easily becomes frustrated. The child exhibits frustration by acting out or perhaps by hitting. A child welcomes the setting of limits, because it defines expected boundaries of behavior. When boundaries are crossed, parents must take disciplinary action. **Positive redirection**—verbally guiding the child toward the accepted behavior—may be effective. Establishing a consistent routine is helpful in preventing children from becoming frustrated because they are unprepared to move to a new activity. When a child misbehaves, demonstrating natural or logical consequences helps the child understand the association between an action and its result (Developmental Considerations 5–6).

If these measures are not effective, time-outs may be. Time-outs can be an extremely effective disciplinary tool, but to be effective, this tool must be used appropriately. A child should not stay in a time-out until he or she does what the parent wants done. Rather, time-outs should be

FIGURE 5–17. The *time-out* is a disciplinary measure used to remove a child from an activity; this allows him or her to calm down and consider what behavior was wrong.

used to teach the child how to regain self-control and calm down (Fig. 5–17). Therefore, a time-out is appropriate when a preschooler hits or screams, but is not appropriate when he or she will not pick up his or her toys. A time-out should be timed appropriately. The time-out should occur at the time the offense happened to ensure the child relates the offense (the behavioral problem) to the time-out period. Brief time-outs are more effective than very long ones, because a long time-out enables the child to redirect attention from calming down to being resentful. The maximum time-out duration should be 1 minute for each year of age, but it may be necessary to start with much shorter time-outs. A time-out should end as soon as the child is calm. Time-outs do not have to occur in the child’s room; any location where the child is removed from activity and has an opportunity to become calm will do. The nurse or parent must explain to the child why the child is receiving the time-out.

Parents should pick their battles. If the issue is not life endangering, unsafe, or amoral, let it go (e.g., allow the child to wear one red shoe and one blue shoe). Do not allow the child to become overtired, which often causes many more arguments than necessary. Never argue with a child; doing so brings the parent or nurse down to the child’s level. The child is too young to say, “I’ve had a really busy day and need to relax for a while.” Allow toddlers and preschoolers times when they can learn how to occupy themselves for short periods of quiet time. Alerting children to transition times is very important. Many daycare settings use songs to let young children know that it is time to clean up and start doing something different. Parents can use a similar technique by giving children 5-minute notices that a new activity is about to start. Giving toddlers and preschoolers attractive options also

DEVELOPMENTAL CONSIDERATIONS 5–6

Strategies for Effective Discipline

- Set realistic limits.
- Be consistent with consequences.
- Do not be overly negative.
- Use positive redirection whenever possible, distracting the child toward a more positive action.
- Selectively ignore situations if the behavior is not a major issue; ignore it, but compliment and reward the more positive behavior.
- Use time-outs when appropriate (when the child is 18–24 months old): 1 minute of time out for each year of age. Time-outs should be used to allow both the adult and the child cooling off time.
- The use of corporal punishment (spanking, hitting) reinforces violent behavior and may confuse the child.
- Role-model appropriate behaviors and ensure older children in the family role-model appropriate behaviors.

helps with transition. A choice between just leaving or going home to something the child enjoys (e.g., a bath, play with the pet) is much easier to negotiate than a flat demand, but parents should not overnegotiate; pleading and expecting the child to understand and agree are unrealistic. Sometimes, even when parents have negotiated, have not allowed the child to become overly tired, and have offered appealing options, the child is still uncooperative and needs to be gently but physically moved to the next task or place.

Parents may not realize that a child younger than 18 months of age is unable to make a connection between unacceptable behavior and being spanked; they experience only the pain. The American Academy of Pediatrics (1998) has voiced concerns that spanking children younger than 18 months of age increases the chance of physical injury to the child. In addition, spanking models aggressive behavior, and has not been proved any more effective than other disciplinary strategies at producing long-term changes in the child's behavior (Tradition or Science 5–2). Young children start to make the connection between behavior and consequences. Encourage parents to communicate the rules to the child, and the consequences for breaking them, consistently. Make sure the child knows a rule before being punished for breaking it (see Developmental Considerations 5–6).

Schooling and Child Care

Early childhood education programs include preschools, daycare centers, Head Start programs, nursery schools,

prekindergarten programs, and other early childhood learning programs (National Center for Education Statistics, 2008). In 2005, approximately 57% of children age 3 to 5 years in the United States attended some form of an early childhood education program (National Center for Education Statistics, 2008). The documented benefits of early childhood education, especially for at-risk children, include better language and cognitive skills during the first few years of elementary school than those children who did not attend similar education programs. In addition, children who have attended early childhood education programs tend to score higher on math and reading tests, and they are less likely to repeat a grade, drop out of school, need special education or remedial services, or get into trouble with the law in the future. Studies show these children also tend to complete more years of education and are more likely to attend a 4-year college. In these studies, the most significant benefits occurred to low-income and minority children, and those whose mothers had a high school education or less (American Educational Research Association, 2005).

If the child has never attended out-of-home daycare, the initial strategy is to allow the child to adjust to the transition from parents to center, so that he or she is comfortable with a few hours of separation, and observes group activities and the learning process. Monitoring the child's behavior when he or she starts preschool is important, because some children may be too young to adapt to a very structured environment and may show signs of stress. To make goodbyes easier, the parent should develop a morning routine, prepare as much as possible the night before, and avoid rushing in the morning. Rushing tends to cause stress for the parents, and the child feels the tension and may become upset when the parent leaves, thinking that he or she did something wrong. When the parent and child arrive at the center, the parent can spend a few minutes to settle the child in, perhaps by reading a book or starting a group activity. The ultimate goodbye should be short; the parent should not linger as if unsure whether to leave. If it is the first time the child and parent have been separated, a few days of adjustment may be necessary. The parent might stay longer at the center the first day and decrease the length of stay each day. When the day is over, the parent should not be surprised if the child appears preoccupied and ignores him or her; alternately, the child might burst into tears because he or she really missed the parent.

Early education programs are designed to offer the building blocks to prepare for learning in kindergarten and to provide an opportunity to develop and build age-appropriate developmental skills and abilities. Early education programs can be extremely important to the child's overall development because the child receives stimulation in areas that are not ordinarily addressed in the home environment. These programs are also valuable as a resource for discovering potential learning disabilities at a very early age (Shelov & Hanneman, 2004).

A good early education program encourages children to gain independence and self-confidence, and to develop interpersonal skills (Fig. 5–18). The program should have

TRADITION OR SCIENCE 5–2

Does spanking, used as a disciplinary measure on children younger than 2 years, have any association with behavioral problems after the child enters school?

MORE RESEARCH NEEDED

Slade and Wissow (2004) used a sample of 1966 children who were younger than 2 years to evaluate spanking frequency and other characteristics. Approximately 4 years later, these children were evaluated for behavioral problems in school using parent reports and documented visits by the parent with a school administrator. Among white non-Hispanic children, but not among black and Hispanic children, spanking frequency before age 2 was significantly and positively associated with behavior problems at school age. These findings suggest that some infants and young toddlers are vulnerable to emotional trauma and stress as a result of this type of discipline. These children are believed to be too young to understand punishment and to change their behavior to comply with their parent's expectations (Slade & Wissow, 2004, p. 1321). More research is needed to explore ethnic differences and, ultimately, whether this form of corporal punishment results in long-term behavioral consequences for the child.

FIGURE 5–18. In the preschool setting, children are exposed to a variety of activities to enhance development of multiple types of intelligence.

the resources to identify any learning disorders. If a special need has already been identified, the preschool should have the appropriate resources in place to implement necessary interventions. Many community programs are not equipped to accommodate special needs students, and parents should speak with the director for advice and referral.

Many of the questions that are asked when a daycare center is chosen are the same questions that must be asked when a formal preschool or other type of education program is chosen (see Chapter 4). Besides location, hours the center is open, numbers and ages of the other children, cost, and the “instructional” capacities of the program need to be evaluated.

Early education programs have relatively small class sizes, about 10 children or fewer per one adult, and the “teacher” or aides should have experience with early childhood development or education. In many states, this experience is mandated by daycare or preschool regulations. Advise parents to investigate disciplinary methods used and be sure they are in line with home discipline techniques. The entire center and grounds should be childproofed and under adult supervision at all times. Encourage parents to visit the center whenever they like and be suspicious of centers that have very strict visiting procedures.

Investigate healthcare issues such as what happens when a child becomes ill at the center and what the center’s policies are for accepting children with apparent illness. Policies regarding infectious diseases should be strict and should emphasize handwashing by both staff and children. Child-sized sinks should be available, and toilet-trained children should be expected to wash their hands after using the restroom. If children attend who are still in diapers, the center should have a separate diaper station that is cleaned with disinfectant after each use.

Parents must agree with the overall theory of the program. Although some children thrive in a structured environment, many need opportunities to socialize, learn to control emotions, and explore their own ideas. Encourage parents to investigate all available programs to find the type that may be the most suitable for their child.

Promoting Early Literacy

Engaging in **early literacy** activities, which promote learning to read and write, is important during early childhood (Fig. 5–19). Early literacy does not mean teaching young children to read before they start kindergarten. Doing so would not be developmentally appropriate, and such activities can be counterproductive if they create a situation in which the child associates reading with failure and parental disappointment. Rather, early literacy emphasizes pairing the enjoyment of books with the child’s emerging developmental skills (e.g., hand-eye coordination, language acquisition). These activities will promote early familiarity and comfort with the skills that are used later to teach reading and writing. In the past, it was believed that children should learn all reading and writing skills when they entered elementary schools. The formal instruction to these skills would begin at this time, and beginning these processes earlier in the child’s development was unnecessary. Language skills were thought to develop first, followed by reading and then writing. It is now known that language, reading, and writing skills develop at the same time and are intimately linked. Literacy development is a continuous developmental process that begins during the first years of

FIGURE 5–19. When an older sibling reads to a younger sibling, both children increase their literacy skills.

life, using real-life settings and positive interactions with people and literacy materials.

Children who are not read to while they are growing up and who have little exposure to books are at increased risk for reading failure after they enter and progress through elementary school. The Early Childhood Longitudinal Study found that children whose family members read to them at least three times a week were almost twice as likely to score in the top 25% on measures of reading proficiency than children who were read to fewer than three times a week. Children who were read to three times a week as they entered kindergarten demonstrated increased mastery of letter–sound relationships at the beginning and end of words, sight–word recognition skills, and understanding words in context (National Institute for Literacy, 2006).

Provide parents with information about age-appropriate reading materials and the developmental skills that are enhanced through early literacy activities (Developmental Considerations 5–5). Many healthcare facilities are taking an active role in literacy promotion by providing reading

materials for children in the waiting areas and by distributing free books (Tradition or Science 5–3).

Ask about the child’s language skills and whether parents are reading to their young child. If the parents’ ability to read is limited or access to books in the appropriate language for the family is lacking, the child may be in a position that does not foster early literacy. Parents may feel uncomfortable and perhaps may be unwilling to try to “read” with the child, given their own lack of literacy skills. Parents in this situation still can be encouraged to share books with children by examining the pictures and telling stories about the pictures. If parents express a desire to improve their own literacy skills, provide referrals to adult or family literacy programs. Help parents understand that the child greatly enjoys the parental attention associated with sharing books and will benefit in later years from this early exposure to reading materials.

PREVENTING INJURY AND ILLNESS

Injuries pose a major threat to health during early childhood. Unintentional injuries are the leading cause of death for children age 1 to 4 years (Centers for Disease Control, 2008). The child’s inquisitive nature and expanding motor and developmental abilities combine to increase the risk. Although young children experience most injuries in and around their own homes, parents need to be informed of the potential for injury at homes of relatives and friends that they visit. Approximately 2,000 children age 14 and younger are fatally injured from accidents that occur in their own home (Safe Kids Worldwide, 2008). The four leading causes of unintentional injury in early childhood include motor vehicle/traffic accidents, drowning, fires and burn injury, and unintentional suffocation (Centers for Disease Control, 2008).

QUESTION: Lanese asks, “Ever since the boys could get out of their cribs, they occasionally surprise me by getting into mischief when I think they are in bed. What can I do about the boys roaming around when I think they have gone to sleep?” What suggestions can you offer to Lanese to help prevent injury to the twins?

Even if the home has already been babyproofed, it is now time to childproof the environment based on the unique developmental abilities of this age group. See Community Care 5–1 for a review of injury prevention guidelines. **Childproofing** the house helps keep the child safe, and removes temptations and the need for the parents to restrict activities and access to parts of the home. Childproofing involves parents actively searching the indoor and outdoor environment of the home and other areas where the child may frequently spend time (e.g., daycare provider’s home, house of worship) to ensure that the area is safe for the child in relation to age-related safety

TRADITION OR SCIENCE 5–3

Do clinic- and or hospital-based literacy promotion programs positively affect literacy skills in young children?

EVIDENCE-BASED PRACTICE

Several institutions have used programs to educate parents about the importance of reading to their young children. The interventions in these programs have included providing parent handouts about early literacy, ensuring that primary healthcare providers are trained to assess for literacy activities in the home and able to provide strategies to enhance literacy activities, and ensuring that each child leaves the health visit with a developmentally appropriate book (Golova et al., 1999; High et al., 2000; McCall, 2005; Silverstein et al., 2005). Results of these interventions included significant increases over time in the frequency with which parents read to their children, an increase in the number of parents who read to their children, and an increase in children’s personal libraries at home. Participating families had children who ranged in age from 5 months to 6 years, and most families were identified as low-income. A study by Nagamine et al. (2001) that used a literacy intervention program in the emergency department was not associated with any measurable changes in family literacy behaviors. This environment is likely not the most effective place to promote literacy, given concerns over the child’s immediate medical needs, parents’ information overload at the time, or both.

Clearly, healthcare providers can positively affect early childhood literacy by providing parent education and the resources (e.g., actual books) for parents to implement reading activities with their child. Books can be purchased at low cost by the facility or donated by volunteer groups interested in supporting literacy programs.

COMMUNITY CARE 5–1

Injury Prevention Guidelines for the Family During Early Childhood (1–4 Years)

Home Safety

- Get down on the floor and check for safety hazards the child may encounter as they begin walking.
- Test smoke detectors to ensure that they work properly. Change batteries yearly.
- Do not leave heavy objects or containers of hot liquids on tables with tablecloths that the child may pull down.
- Place safety locks on cupboards and toilet seats.
- Use doorknob covers and childproof locks on all doors, sliding doors, and windows. Make sure screens are secure.
- Turn pan handles toward the back of the stove. Place knives and sharp objects toward the back of counters, cabinets, and drawers.
- Keep the child away from hot stoves, fireplaces, irons, curling irons, and space heaters.
- Ensure that all electric wires, outlets, and appliances are inaccessible or protected.
- Keep all poisonous substances, cleaning agents, alcohol, health and beauty supplies, medicines, and home improvement materials in a locked, safe place out of sight and reach. Never store poisonous substances in empty jars or soda bottles.
- Ensure houseplants are not toxic if they are consumed by the child.
- Keep cigarettes, lighters, matches, and alcohol out of the child's sight and reach.
- Use safety gates at the top and bottom of stairs. Supervise the child closely when he or she is on stairs.
- Tie blind and drapery cords out of the child's reach.
- Avoid placing furniture the child can climb on near windows and balconies.
- Ensure that guns, if they are in the home, are locked up and that ammunition is stored separately. A trigger lock is an additional important precaution.

Play Safety

- Do not give the child plastic bags, latex balloons, or small objects such as marbles.
- Teach older siblings which of their toys are unsafe for the younger child to play with.
- Discard toys with sharp edges or broken pieces. Ensure all toys selected are approved by the manufacturer for that child's age group.
- Confine the child's outdoor play to areas with fences and gates, especially at a child care facility, unless he or she is under close supervision.
- Ensure that playgrounds are safe. Check for impact- or energy-absorbing surfaces under playground equipment. Make sure playground equipment is not more

than 3 ft tall and not made of pressure-treated wood.

Water Safety

- Ensure that the hot water heater is set at less than 120°F or 48.9°C.
- Test the bath water temperature with your wrist to make sure it is not hot before bathing your child. Supervise the child constantly whenever he or she is around water, buckets, the toilet, or the bathtub. Empty buckets, tubs, or small pools immediately after use.
- Ensure that swimming pools are enclosed by a four-sided fence with a self-closing, self-latching gate. Ensure that the child wears a life vest if boating.
- Use flotation devices on the child when he or she is in the pool or hot tub. Note that inflatable flotation devices or "knowing how to swim" do not make a child safe in the water.
- Keep U.S. Coast Guard-approved life jackets and preservers and a shepherd's crook at the poolside.

Car Safety

- Change to a toddler care seat. Make sure it is properly secured at all times. The car seat should face toward the front of the car, but remain in the backseat.
- Never leave the child alone in the car or in the house.

Safety With Others

- Do not leave young siblings alone to supervise the child (e.g., in the bathtub or in the house).
- Keep the infant away from cigarette smoke. Do not allow people to smoke around the child.
- Choose caregivers carefully. Discuss with them their attitudes about behavior in relation to discipline. Prohibit corporal punishment.
- Teach the child to use caution when approaching animals, especially if the animals are unknown or eating.
- Teach the child not to talk to strangers.

Outdoor Safety

- Put sunscreen on the child before he or she goes out to play.
- Keep the child away from moving machinery, lawn mowers, overhead garage doors, driveways, and streets.
- Ensure that a child riding in a seat on an adult's bicycle is wearing a helmet. Wear a helmet yourself.
- Supervise the child whenever he or she is outside. Know where your child is at all times. A child age

(Continued)

COMMUNITY CARE 5-1 (CONTINUED)

1 to 4 years is too young to be roaming the neighborhood alone.
Teach the child pedestrian safety skills.

Emergency Preparation

Keep your address and phone number posted near the phone.

Keep a list of emergency numbers (doctor, hospital, nearest neighbor, poison control center) near the phone.

Enroll in a child CPR course.

Discuss with the healthcare professional what to do for falls, cuts, puncture wounds, bites, bumps on the head, bleeding, and broken bones.

Adapted from Hagan, J., Shaw, J., & Duncan, P. (Eds.). (2008). *Bright futures: Guidelines for health supervision of infants, children, and adolescents* (3rd ed.). Elk Grove, IL: American Academy of Pediatrics.

concerns. This precaution keeps the environment “explorable,” prevents conflicts, and enables the child to expand on skills that need mastering (e.g., fine and gross motor skills). In addition, when grandparents, baby-sitters, or other friends are in the home to watch the child, safety issues must be reviewed. Although parents may have a complete understanding of the hazards in the environment that trigger the child’s curiosity, other adults may not be as well informed or maintain the same degree of vigilance regarding the child’s safety.

Automobile accidents are a leading cause of death in this age group as a result of the number of children not restrained in car seats and as a result of unsafe driving practices around areas in which small children are present. Advise parents to check whether car seats and other restraints (see Chapter 4) still fit the growing child prop-

erly. All states and Canadian provinces require young children to be restrained in a forward-facing car seat when the vehicle is in motion (Fig. 5-20). The car seat should be placed in the backseat. All harness straps on child safety seats should be fastened snugly to the body so the child cannot slip out. The seat’s base is attached to the vehicle by a lap belt and, for optimum security, the top is fastened to the vehicle with a tether strap (Fig. 5-21). Transition from a car seat to a belt-positioning booster seat should be made if the child weighs more than 40 lb (Hagan, Shaw, & Duncan, 2008). The child should never be placed in the front seat of a vehicle with passenger airbags. The parent should not start the car unless everybody (including the parent) is buckled up. The child will follow the parent’s lead; if the parent buckles up, the child will imitate this behavior. If the child unbuckles during the car ride, the parent should pull over and stop the car until the child is rerestrained.

Children ages 4 years and younger have the highest drowning death rate (two times greater than other age groups) and account for 80% of home drownings (Safe Kids Worldwide, 2008; Somers, Chiasson, & Smith, 2005). Drownings often occur because secure fencing is not in place to separate the pool from easy access by the

FIGURE 5-20. All young children must be placed in the backseat of a car, strapped into a front-facing car seat.

FIGURE 5-21. Many injuries resulting from motor vehicle accidents can be prevented by proper use of car restraints.

child. In addition, drowning can occur when supervising adults are preoccupied and not closely attending to children playing in the water. Concern for young children is especially important when the pool is occupied by large groups of children. Although teaching young children to swim helps, children should never be around water without adult supervision (Fig. 5–22), and all pools should be surrounded by a fence at least 5 ft high. Swimming in partially covered pools should be avoided, because the child may become trapped underneath the cover. When an aboveground pool is not in use, the stairs should be removed. Local codes usually require a latched and locked gate to gain access to a pool. When boating, every person in the craft is required to have a flotation device and to be wearing it at all times.

Young children have thinner and much more sensitive skin than adults do. When a young child will be out in the sun for a prolonged period, sunscreen of at least a sun-protective factor of 15 to 30 should be applied frequently and liberally. If the weather is hot, children should be sure to drink plenty of fluids, because they tend to become dehydrated easily.

Fire-related injuries in the home can be prevented by installation of smoke detectors/alarms on every level of the home and in every sleeping area. In addition, keeping matches, lighters, and other heat sources out of the reach of young children will help prevent needless injuries or death from home fires.

Suffocation is the fourth leading cause of unintentional deaths in early childhood. Suffocation can occur if the child is allowed to sleep with adults, sleep in a water bed, or sleep in a bed where too much space exists between the mattress and the crib or bed slats (this space should not be more than the width of two adult fingers). Suffocation can also occur if a child becomes locked in a cabinet, toy chest, or car trunk and has no means to escape and get fresh air. Strangulation can occur from drapery and miniblind cords, hood cords, and drawstrings on clothes and hammocks to name a few items.

FIGURE 5–22. Assist the young child to wear safety equipment while swimming and ensure the child is accompanied by an adult when in or around a pool or other swimming area.

Encourage parents to remain vigilant about hazards in the home, the school, and the child's play area that may be a source of injury. The child's increasing vocabulary and overall comprehension can be misinterpreted as an ability to make choices to prevent self-harm. The young child's curiosity and inquisitiveness are likely to result in high-risk behavior. The child does not recognize the activity (e.g., playing near a pool) as "high risk," but such activity unmonitored by parents and caregivers can have dire consequences for the child. Provide anticipatory guidance to parents regarding the unintentional injuries that may occur in the home. Encourage parents to use Internet sites such as Safe Kids Worldwide (<http://www.USA.safekids.org>) to review the variety of measures that can be used in their home to protect their child.

ANSWER: In response to Lanese's concerns, you might say, "You are right to be worried. When children this age get up and out of their rooms unsupervised, it is dangerous. You might want to consider a doorknob cover for the inside of their bedroom door so they cannot let themselves out. You could also try putting the baby monitor back in their rooms so that you can hear them if they are awake and 'plotting.' You also should go through your home and double-check that there are no products under the sink or in the medicine cabinet that they can get to."

See [thePoint](#) for a summary of Key Concepts.

6

Middle Childhood (5–10 Years)

Case History

Cory Whitworth is the youngest of six children. He just turned 5 years old and is ready to start kindergarten. He has never attended preschool or daycare. His parents, John and Wendy Whitworth, have five boys and one girl between the ages of 5 and 20. The oldest four boys are each about a year and a half apart. The sister, Clarissa, is 3 years younger than the fourth son, Chase. Then there is a 6-year space between Clarissa and Cory, the baby of the family. Cory has significant household status as the baby of the family. They are members of the Church of Latter-day Saints.

Cory did not receive the hepatitis B vaccine as an infant. In the state in which he lives, hepatitis A and B vaccinations are mandatory for kindergarten attendance; therefore, Wendy has several appointments scheduled during the spring and summer with their pediatrician. At the spring appointment, the nurse in the doctor's office weighs and measures Cory and asks Wendy about Cory's eating habits, dental hygiene, and sleep patterns. According to the Centers for Disease Control growth chart,

his stature-for-age is greater than 97% and his weight-for-age is less than the 25th percentile. The office nurse asks Wendy to go through a typical day and relate what Cory eats throughout the day. Wendy states, "Cory is not a good eater; he won't eat meat, for instance. He won't eat most of the food that the rest of the family eats, so I prepare special meals for him that he eats at the breakfast bar. He doesn't like to eat unless I am eating with him or I feed him. But I do give him a nutritional shake almost every day." When asked about Cory's oral hygiene, Wendy replies that she brushes Cory's teeth every morning and evening and that he has seen a dentist. The nurse also asked about Cory's sleeping habits. Wendy answers, "We just converted the study into Cory's room. He has a bed that looks like a blue race car. He never takes a nap now and he usually sleeps through the night. He usually falls asleep in the living room while the older kids are watching TV. I let him stay up because that is about the only time the whole family is together."

CHAPTER OBJECTIVES

1. State the developmental surveillance concerns and milestone accomplishments of middle childhood.
2. Discuss the abilities of the school-aged child related to managing hygiene and personal care.
3. Describe the nutritional requirements to promote optimum growth during middle childhood.
4. Discuss the importance of engaging the child in physical activity with regard to developing lifelong health patterns of behavior.
5. Select age-appropriate interventions to promote healthy personal and social development of the child.
6. Describe strategies to help the child be successful in school.
7. Select interventions to prevent illness and injury among children age 5 to 10 years and their families.

See **thePoint** for a list of Key Terms.

Middle childhood, also referred to as the *school-aged years*, is designated as ages 5 to 10 years (Hagan, Shaw, & Duncan, 2008). Both parents and child anticipate a tremendous change in the child's life with the dawning of the school-aged years, marked by the child's entrance into full-time schooling. For the child, increased exposure to peers and constant exposure to new skills and knowledge bring feelings of both excitement and fear. For the parent, new schedules and routines must be developed to ensure the child's success as he or she learns to balance physical needs with the demands of schoolwork, homework, and extracurricular activities. Middle childhood represents a time of tremendous developmental changes.

During this time of the child's development, the child's primary role is that of student, with the goal of gaining grade-level mastery of established educational standards. The parents' primary role is to serve as advocates for their children as they interact with the school and community. Optimally, family and home serve as secure environments for children to renew and refresh themselves each day, and are places of solace where children's sense of self can be bolstered and individually encouraged. This chapter addresses various practical aspects of development during middle childhood.

DEVELOPMENTAL ASSESSMENT AND SURVEILLANCE

QUESTION: Cory sees his pediatrician regularly. What other healthcare professional should Cory see this year?

Before the child can enter kindergarten or the first year of formal public or private education, a visit to the healthcare provider is required. Parents must show the school evidence that the child has had a physical examination

and that all immunizations are up to date. States and countries vary regarding which vaccinations are required prior to school entrance. Some include tuberculosis screening in these requirements (Hagan, Shaw, & Duncan, 2008).

During the middle childhood years, healthcare visits are recommended every 2 years to complete developmental assessments and to screen for conditions common to this age group (Chart 6–1). Health visits include blood pressure screening; vision and hearing screening; and assessment for height, weight, and body mass indices (BMIs) that would alert the healthcare provider to childhood obesity (Fig. 6–1). Scoliosis screening begins around 8 years of age. Issues discussed during health visits with children and their parents include nutrition and eating behaviors, oral health, parent–child relationships, school concerns, media use and access to the Internet, violence, and environmental exposures that may be unhealthy for the child (e.g., smoke, sun, play equipment; See Appendix G) (Hagan, Shaw, & Duncan, 2008).

An essential component of the health visit is assessing acquisition of developmental milestones. Developmental Considerations 6–1 presents a summary of the developmental milestones that are accomplished during middle childhood. This information is useful to provide the nurse with direction for specific trigger questions that can be asked of the parents to determine the child's developmental progress. Trigger questions should also include school performance as well as the usual concerns regarding general developmental issues.

ANSWER: All school-aged children should be examined by a dentist every year and an ophthalmologist every few years. Cory should visit a dentist to examine his teeth and identify any dental caries. He should also visit an ophthalmologist to examine his eyes and check his vision prior to entering school.

HYGIENE AND PERSONAL CARE

Preparing for school each day provides the opportunity for the child to develop good hygiene and personal care habits that include oral care, choosing appropriate clothing based on environmental conditions, ensuring adequate sleep, and making healthy food choices. The child is still too young and not knowledgeable enough to make decisions about these issues totally independent of parental supervision. The child will certainly challenge the parents' authority and respective "house rules" about bedtime, snack choices, and clothing choices. As children move through middle childhood, they are cognitively able to understand and appreciate these rules and the ways that these rules affect their personal health. As children move into adolescence, teachers, peers, and the media will have increasing influence on the child's behaviors. Ongoing parental guidance provided during middle childhood can help children in their decision-making processes.

CHART 6–1 QUICK REFERENCE TO CONDITIONS COMMON DURING MIDDLE CHILDHOOD

Condition	Chapter
Allergic rhinitis	16: The Child With Altered Respiratory Status
Appendicitis	18: The Child With Altered Gastrointestinal Status
Asthma	16: The Child With Altered Respiratory Status
Attention-deficit hyperactivity disorder	29: The Child With a Mental Health Condition
Celiac disease	18: The Child With Altered Gastrointestinal Status
Childhood depression	29: The Child With a Mental Health Condition
Childhood schizophrenia	29: The Child With a Mental Health Condition
Cognitive challenge	30: The Child With a Developmental or Learning Disorder
Common cold (nasopharyngitis)	16: The Child With Altered Respiratory Status
Contact dermatitis	25: The Child With Altered Skin Integrity
Diabetes	26: The Child With Altered Endocrine Status
Encopresis	18: The Child With Altered Gastrointestinal Status
Enuresis	19: The Child With Altered Genitourinary Status
Epistaxis	31: Pediatric Emergencies
Functional abdominal pain and irritable bowel syndrome	18: The Child With Altered Gastrointestinal Status
Growth hormone deficiency	26: The Child With Altered Endocrine Status
Hypertension	15: The Child with Altered Cardiovascular Status
Learning disorders	30 The Child With a Developmental or Learning Disorder
Pediculosis	25: The Child With Altered Skin Integrity
Pharyngitis	16: The Child With Altered Respiratory Status
Precocious puberty	26: The Child With Altered Endocrine Status
Scabies	25 The Child With Altered Skin Integrity
School phobia	29: The Child With a Mental Health Condition
Tonsillitis	16: The Child With Altered Respiratory Status
Tuberculosis	24: The Child With an Infection

FIGURE 6–1. The school-aged child is likely to willingly cooperate during healthcare screening examinations.

Oral Care

QUESTION: Because of the emerging independence seen in children during middle childhood, many activities of daily living may be performed solely by the child, jointly by the parent and child, or solely by the parent. How would you assess the extent of the Cory's autonomy and his development of health maintenance behaviors? How do you respond to Wendy's information?

By the time the child is 5 years old, some of the permanent teeth may start to erupt, and preventive care at an early age will forestall any problems. The number one dental problem in middle childhood is tooth decay. Because some of the cavities are in the baby teeth, which will be lost,

DEVELOPMENTAL CONSIDERATIONS 6–1

Milestones of Middle Childhood (6–11 Years)

Physical Development

- Girls: by age 11 years have achieved 90% of adult height and 50% of adult weight
- Boys: at age 12 years have achieved 80% of adult height and 50% of adult weight

All School-Aged Children

- Acceleration of growth of long bones
- Beginning of Tanner stages of prepubertal development
- By 12 years of age, have all permanent teeth except second and third molars

6 to 9 Years

- Sleep 10 to 12 hours per day
- Gain 3 to 5 lb per year
- Have 10 to 11 permanent teeth
- Arms grow longer in proportion to body

10 to 11 Years

- Sleep 8 to 10 hours per day
- Need 1,600 to 2,600 calories a day
- 12-year molars erupt

Sexual Development

- Girls: some have menarche as early as 10 years of age

All School-Aged Children

- Normal interest in same-sex relationships
- Interest in heterosexual relationships more pronounced in later school-aged years
- Latency years; sex drives repressed (Freud)

Language Development

All School-Aged Children

- By 5, vocabulary of 1,500 to 2,000 words
- Know coin exchange

Vision Development

All School-Aged Children

- Have 20/20 vision

Gross Motor Development

6 Years

- Walk a straight line
- Have mastered all skills on the Denver II (see Chapter 3)

8 Years

- Crouch on tiptoes
- Put right or left foot forward on command

9 to 11 Years

- Balance on one leg with eyes closed
- Catch tennis ball with one hand

Fine Motor Development

All School-Aged Children

- Continually refine and improve previously learned skills
- Move more gracefully
- Bathe unassisted
- Use tools

Play Development

All School-Aged Children

- Engage in cooperative “team” play
- Engage in skill play (jump rope, skating)
- Enjoy testing, model building, exploration
- Collect things and classify them as hobbies
- Play board games
- Read for pleasure
- Become engrossed easily in long hours of TV watching

Cognitive Development

All School-Aged Children

Concrete Operations (Piaget)

- Gain ability to reason
- Grasp concept of reversibility
- Classify objects according to their characteristics
- Understand concept of conservation
- Understand concept of relativism
- Can place self in another’s situation
- Understand serialization, master the ordinal number line; can group and sort/place in logical order
- Develop fundamental skills of reading, writing, and grammar
- Understand concept of reciprocity
- Understand concept of identity
- Gain greater ability to calculate distances and use directions
- Tell time
- Acquire decentration; able to focus on many aspects of experience

11 Years

- Capable of abstract and deductive reasoning
- Consider death irreversible, but capricious
- Use external/internal physiologic explanations

Social Development

All School-Aged Children

- Initiate social participation in school, neighborhood, scouting groups

- Begin to manage cooperative and competitive relationships

Interpersonal Development

All School-Aged Children

- Gain independence within family
- Learn to self-regulate behavior
- Navigate issues of industry versus inferiority (Erikson)

Emotional Development

All School-Aged Children

- Use coping behaviors (strategies): avoidant coping, active coping, avoidant–active coping

Moral/Spiritual Development

All School-Aged Children

Moral—Stage 4: Conventional (Kohlberg)

- Concerned with authority figures, fixed rules in moral decisions

- Concerned with obligation to duty
- Understand that a “bad” act breaks a rule or does harm
- May interpret accidents or misfortunes as punishment
- Develop a conscience and sense of values

Spiritual—Stage 2: Mythical/Literal (Fowler)

- Distinguish religious fact from fantasy
- Respect and rely on authoritative figures such as parents, priest, rabbi
- Influenced by attitude of peers toward faith
- Have monomythic attitude; use fantasies to explain events or facts they do not understand
- Learn to differentiate between natural and supernatural
- Perceive God in anthropomorphic imagery, with human qualities
- Describe God in a way that implies formation of a reciprocal relationship

parents may assume that it is nothing to worry about (U.S. Preventive Services Task Force, 2004). However, premature loss of baby teeth may cause other baby teeth to shift and not allow the permanent teeth room to come in later. Until the age of 7 years, children may need assistance brushing their teeth. Children who develop good oral hygiene habits do not run the risk of developing dental caries and other problems that cause premature tooth loss (Fig. 6–2). The best method of preventive care is to foster good dental hygiene habits at an early age.

FIGURE 6–2. The school-aged child needs encouragement to brush after meals and at bedtime as part of a good dental hygiene program.

A child-sized, soft-bristled toothbrush with a dab of fluoride toothpaste is recommended. Caution the parent not to overuse fluoride toothpaste, because the child may swallow it in amounts that can cause dental fluorosis, a condition that produces staining on the permanent teeth. For many years, dentists recommended only brushing up and down, but now any direction of brushing is considered fine, as long as each tooth is thoroughly brushed from the gum line to the crown, and plaque is removed daily. Children usually concentrate on the front teeth, because they can see them easily, and “forget” about the teeth in the back. Parental oversight is needed to be sure those overlooked teeth are brushed as carefully.

Children should have their teeth checked by a dentist and cleaned by a dental hygienist twice a year. Chapter 3 describes the sequence in which the primary (deciduous) and secondary (permanent teeth) erupt (see Fig. 3–14). Eruption of secondary teeth, which begins around age 6, is not associated with the same amount of fussiness or discomfort as the eruption of primary teeth. If a primary tooth is lost before the permanent tooth erupts, parents should consult the dentist to determine whether a space retainer is needed to keep the teeth in appropriate alignment until the permanent tooth erupts (Casamassimo & Holt, 2004).

Early orthodontic intervention may mean less extensive treatment later, because young teeth are easier to move. Early treatment may also reduce the risk of relapse. If a child needs orthodontic intervention, the child must adhere to the care regimen that is needed for the braces (e.g., keeping them clean, wearing retainers). Selecting an orthodontist who is knowledgeable and will establish a good rapport with the child and family is essential, because treatment will include dental visits every 4 to 6 weeks for a 2- to 4-year treatment period (Fig. 6–3).

FIGURE 6–3. Orthodontics may be initiated in middle childhood to prevent malocclusion of the permanent teeth.

ANSWER: Wendy has already stated that she brushes Cory's teeth. Follow up with another question to determine whether Cory is learning to brush his own teeth. An example of a response to Wendy is, "Brushing his teeth twice a day is excellent. When he turns 5, he should start brushing the front teeth and you can still make sure the molars are brushed." With parents as well as with children, it is more effective and less a matter of personal opinion to say "Now it is time . . ." rather than "I think you should . . ."

Sleep

QUESTION: How would you elicit more information regarding Cory's sleep habits? How could you respond to Wendy's information about Cory falling asleep in front of the television?

During middle childhood, sleep disturbances may be a common factor related to changes in cognitive function and behavior (Carno, Hoffman, Carcillo, & Sanders, 2003). The amount of time the child sleeps will vary with the day of the week (school day vs. weekend) and time of the year (school year vs. vacation). On average, children spend 8 to 10 hours per night sleeping, although sleep duration can vary considerably and still be considered normal. During vacations and weekends, the child is likely to sleep longer because the child's schedule is not dictated by school start times. Most children experience two awakenings per night, and approximately 20% to 41% of children experience substantial sleep problems (Carno et al., 2003).

The most common sleep disturbances at this age can be traced to several origins: general behavioral problems, separation anxiety, desire to have special time with a parent without sibling interruptions, or an altered sleep cycle that may need some adjustment (e.g., the child may go to bed too late or may have a different bedtime at one parent's home than at the other parent's home).

Some other causes of sleep disturbances can be nightmares, fears of the dark, night terrors, or sleepwalking. Health factors such as chronic cough, snoring, chronic rhinitis, and eczema also contribute to sleep problems during middle childhood (Desager, Nelen, Weyler, & De Backer, 2005). Although the child may not waken in the night from these problems, the child may be less alert in the morning. Children who have difficulty with initiating sleep or staying asleep may also have subsequent problems in school as a result of the cumulative patterns of disordered sleep (Tradition or Science 6–1).

Most sleep disturbances are of limited duration and resolve without intervention (Hoban, 2004). If a child continues to have sleep disturbances, a healthcare provider should be consulted to recommend interventions. Medical interventions may be needed if the sleep disturbance is related to a health problem (e.g., snoring related to enlarged tonsils).

A consistent bedtime will help ensure that the child gets adequate sleep. Parents should encourage children to have a consistent bedtime routine that may include quiet reading time and time for nonstressful family talk. Homework should be stopped early enough to allow the child to have some quiet time to relax before slumber. A well-darkened room can also facilitate good sleep. Keeping pets away from the room may also be helpful, especially if the pets are likely to jump on and off of the child's bed during the night and thus awaken the child.

ANSWER: To elicit more information regarding Cory's sleep habits, follow an open-ended question with specific questions. You could ask, "What time does Cory usually fall asleep and when does he wake up?" Although Cory may be getting enough sleep, Wendy's answer alerts the nurse to ask more questions about TV viewing. Although many Americans fall asleep in front of the television, sleep experts strongly discourage this practice. Explain that for Cory to learn to fall asleep by himself in his own bed is a learned skill just like riding a bike is a learned skill.

NUTRITION

QUESTION: What information and strategies could you share with Wendy that might affect Cory's eating behaviors and nutritional intake?

By middle childhood, the child's diet should be a healthy combination of the foods made up from the U.S. Department

TRADITION OR SCIENCE 6–1

Do most children with ongoing sleep problems have attention-deficit hyperactivity disorder (ADHD)?

EVIDENCE-BASED PRACTICE

An estimated 25% to 50% of children with ADHD experience problems with sleep, particularly in initiating and maintaining sleep. At one point, restless and disturbed sleep was a part of the *Diagnostic and Statistical Manual of Mental Disorders IV* (DSM-IV) diagnostic criteria for ADHD. These problems, subsequently considered nonspecific criteria, have been eliminated as defining characteristics of the condition. A literature review by Owens (2005) describes the complexity associated with defining the relationship between sleep disorders and ADHD. Sleep problems may mimic ADHD symptoms, may exacerbate underlying ADHD symptoms, or may be associated with or be exacerbated by ADHD and the psychotropic medications used to treat it.

Researchers have found that sleep-related breathing disorders (including snoring), periodic limb movement disorder, and restless legs syndrome are highly associated with inattention and hyperactivity among general pediatric patients (Chervin et al., 1997, 2002). Some have suggested that treating these causal effects effectively could eliminate the child's ADHD. Chervin et al. (2002) suggest that ADHD could be eliminated in 81% of habitually snoring children (which is approximately 25% of the ADHD population) if their snoring and other sleep-related breathing problems were effectively treated. The consensus among researchers is that ADHD may be overdiagnosed, and that daytime inattentiveness and attentional difficulties may in fact arise from underlying sleep disorders that are not being managed appropriately. Further investigation is warranted, and every child who presents with ADHD and sleep problems should be evaluated to ensure that no underlying factor is accentuating the child's sleeping problems (Owens, 2005).

of Agriculture food pyramid (Chart 6–2) (American Heart Association, 2006; U.S. Department of Agriculture, 2005). The amount of food that the child eats is still not equivalent to the amounts in an adult portion. Because this is the age when most food preferences are determined, the parents should offer the child a wide variety of foods. Family food habits influence children the most during this time.

For a child eating a well-balanced diet, the American Academy of Pediatrics does not recommend the use of vitamin supplements. All the nutrients a child needs should come from the food eaten. The most recent recommendation for this age group (Story, Holt, & Sofka, 2002) is to introduce a low-fat diet (less than 30% of calories should come from fat). This measure helps the child start a lifelong habit of healthy eating.

CHART 6–2 NUTRITIONAL RECOMMENDATIONS DURING MIDDLE CHILDHOOD

Calories per Day	Age	Not Active	Active
	Females 5 to 8 years	1,200	1,800
	Females 9 to 13 years	1,600	2,200
	Males 5 to 8 years	1,400	2,200
	Males 9 to 13 years	1,800	2,600

Food Group Recommendations**Grains**

- Make half your grains whole.
- Eat at least 3 oz of whole grain cereals, breads, crackers, rice, or pasta every day.

Vegetables

- Vary vegetable intake.
- Eat more dark-green vegetables like broccoli and spinach.
- Eat more orange vegetables like carrots and sweet potatoes.
- Eat more dry beans and peas like pinto beans, kidney beans, and lentils.

Fruits

- Eat a variety of fruit.
- Choose fresh, frozen, canned, or dried fruit.
- Go easy on fruit juices.

Milk

- Choose low-fat or fat-free milk, yogurt, and other milk products.

Meat and Beans

- Choose low-fat or lean meats and poultry.
- Eat meat that is baked, broiled, or grilled; stay away from fried meats.
- Choose varieties of protein sources; eat fish, beans, nuts, and seeds.

Fats, Sugars, and Salt

- Make most of your fat sources from fish, nuts, and vegetable oils.
- Limit solid fats (e.g., butter, margarine, lard).
- Keep intake of saturated fats, trans fats, and sodium low.
- Choose food and beverages low in added sugar.

From U.S. Department of Agriculture. (2005). *New 2005 food guide pyramid information*. Retrieved April 8, 2009 from <http://www.usaring.com/health/food//food.htm>

As the child enters school and begins eating lunch there, monitoring what the child is eating away from home becomes difficult. Many children participate in a school lunch program or may “brown bag” their lunch from home. If the child brings a lunch from home, it should be varied, with interesting, tasty foods that the child likes. School cafeteria lunches have been a focus of media scrutiny because of a belief that they do not offer enough healthy choices for children. The National School Lunch Act stipulates that the lunches provided by schools contain one third of the daily recommended amounts of key nutrients and include a meat (or meat substitute), vegetable, fruit, bread, and milk. The law does not address the freshness of food, cooking methods, or fat content. One of the disadvantages of school lunch programs is that the children may pass up the school lunch altogether if it is not appealing and buy a “vending machine lunch” or trade with friends, making nonnutritious choices. One of the successful strategies offered by schools today is to teach children about healthy food at an early grade level and to elicit their help in making appropriate menu choices (Fig. 6-4).

This is also an ideal age at which to encourage children to help prepare meals (Fig. 6-5). Adult supervision is needed when the child is 5 to 8 years old, but by the time the child is 12, the child should be able to prepare a simple meal without assistance. Allowing children to prepare their own school lunches encourages them to make choices of foods that they will eat and not discard or trade.

ANSWER: Eating is a significant part of a family culture and is difficult to change. Wendy is feeding six children, four of whom are athletic teenage boys. Their nutritional needs and their schedules are different from Cory's. In addition, Cory and Wendy are perpetuating Cory's baby status. Although there are many changes that can be recommended, it may be most effective to suggest one or two at a time. Give Wendy specific examples of appropriate meals for Cory that include small portions of a variety of foods. Strongly encourage Wendy to stop feeding Cory separately from the older children. Suggest that Wendy tell the family, “Now that Cory will be starting school, it is time for him to join the older children at the table and feed himself.”

Obesity

Obesity is the epidemic of the childhood years. Since 1971, the proportion of overweight children has more than doubled for children age 6 through 11 years and has more than tripled among children age 12 through 19. An estimated 30% of children age 6 through 19 years are affected by this epidemic (Kaiser Family Foundation, 2004; Miller, Grunwald, Johnson, & Krebs, 2002; Shelov & Hanneman, 2004). Obesity is defined as body weight more than 20% above the ideal weight; for children and adolescents, age and gender are also considered (see Chapter 7 for more information about obesity). Inherited factors may play a role in obesity, but the rapid increase in obesity rates during the past 20 years indicates that

FIGURE 6-4. School lunches should provide a balanced, nutritious midday meal for the child. Lunchtime provides both an opportunity for physical renewal and social exchange with friends.

changes in behavior are a more likely cause. Food convenience, large intake of sodas and juices, decreased physical activity, and a hurried lifestyle contribute to the epidemic. Guide parents in assisting their children to make correct choices of healthy foods and to stay away from excessive salt or sugar consumption. Nursing Interventions 6-1 summarizes some of the recommendations for evaluating and treating childhood obesity. Several organizations have developed position statements and extensive materials to assist practitioners to use strategies to prevent, screen, and treat pediatric overweight and obesity (Community Care 6-1). Bariatric surgery is showing promise as a treatment option for adolescents age 13 and older who are severely obese (BMI \geq 40), with severe obesity-related comorbidities (hypertension,

FIGURE 6-5. Learning to cook can be an enjoyable activity for the school-aged child.

NURSING INTERVENTIONS 6–1

Recommendations for Assessment and Treatment of Obesity

Assessment

- Screen children for overweight by checking BMI at every healthcare encounter.
- Rule out secondary causes of obesity (e.g., genetic causes, endocrine causes).
- Assess for psychological causes of obesity.
- Assess for complications of obesity, such as sleep apnea, type 2 diabetes, and slipped capital femoral epiphysis.
- Assess family readiness for change.

Treatment

- Provide family education about medical complications (e.g., hypertension, dyslipidemia, heart disease, and diabetes) and psychosocial complications (e.g., depression, poor self-esteem) related to obesity.
- Involve the entire family in developing and implementing the program.
- Emphasize long-term permanent changes, not rapid weight loss or short-term diets.
- Support family activities that promote having everyone exercise moderately at least 30 to 60 minutes most days of the week.
- Encourage a low-fat, low-cholesterol, reduced-sugar diet appropriate for the age and weight of family members. Encourage dietary practices that foster moderation rather than overconsumption.
- Encourage meal planning; discourage skipping meals.
- Counsel the family to avoid using food as a punishment or reward.

type 2 diabetes, obstructive sleep apnea), and who have completed 6 months or more of organized attempts at weight management under the supervision of primary healthcare providers (Haynes, 2005; Henry, 2005).

A primary role of the nurse is to work with school programs to ensure that healthy foods are being provided. For instance, the American Academy of Pediatrics endorses a policy that restricts the sale of soft drinks in schools (American Academy of Pediatrics, 2004). The nurse can use this policy as a springboard to implement schoolwide change to ensure that sweetened, carbonated,

and caffeinated drinks are eliminated on school campuses and are replaced with real fruit and vegetable juices, water, and low-fat white or flavored milk. The nurse must also campaign for an ongoing plan to ensure that physical activity is a part of each child's daily school schedule. Last, every campaign to support good nutrition and daily physical activity must include parents and their children as active members of the learning community. Programs implemented without a family-centered approach are doomed to fail when the child's home life and school life are disconnected.

PHYSICAL FITNESS

The American College of Sports Medicine and the American Academy of Pediatrics recommend that health-care professionals actively promote physical fitness in children (American Academy of Pediatrics, 2000, 2001c; Luebbers, 2003). Physical fitness programs help to start behavioral habits that will promote a child to be a healthy and fit adult. School-aged children should be encouraged to participate in 20 to 30 minutes of vigorous physical activity at least three times per week. Exercise should consist of activities that the child enjoys, which can be incorporated easily into the child's routine, and could be continued into adulthood. These activities can include bicycling, walking, running, or swimming.

Team sports such as baseball, basketball, soccer, or football enable the child to develop group play skills. For children from 5 to 8 years old, team sports that are loosely structured and not too aggressively focused toward winning are good options. From years 8 to 10, trying a variety of sports, both team and individual, is a good way for a child to find something that he or she enjoys (Fig. 6–6). After age 10, with the onset of puberty and the accompanying changes in physique and coordination, sports must be matched to the physical and emotional development of the child (Patrick, Spear, Holt, & Sofka, 2001). Organized sports programs should not replace regular physical activity, but rather should serve as complementary activities to enhance the child's physical abilities, knowledge of team skills, and knowledge of new sports.

Children will not benefit from sports unless they are suited for the sport in both age and temperament. The parent needs to work hard to find the right sport for the child and make the experience a positive one. A parent should not be as concerned with who won the game as with how the game was played and whether everyone had a good time. Praising the child's efforts and not giving tips on how the child could have done something better or differently is more positive and is what the child needs at this age. The child should be allowed to quit a sport he or she does not care for or finds too difficult. Many parents believe that doing so allows the child to become a "quitter," but a bad experience with a coach or someone

FIGURE 6–6. Girls and boys enjoy participating in team sports and can benefit from physical activity.

else on the team can cause permanent repercussions, and the child may never again participate in a sport.

Physical fitness activities also place the child at risk for injury. In 2001 and 2002, an estimated 15 million school-aged children (ages 5–19 years) made emergency room visits because of injuries. Approximately 1.8 million of those visits (16.5%) were for injuries that occurred while the child was at school. Middle school children (ages 10–14 years) accounted for a significantly greater proportion of injuries (46%) than did primary (ages 5–9 years, 24%) or secondary (ages 15–19 years, 30%) school children. In contrast, for injuries that occurred outside of school, secondary school children were injured most often (40%), followed by middle (32%) and primary school-aged children (27%). Sports injuries were significantly more common at school (53% of injuries) than outside of school (32.9%) (Linakis, Amanullah, & Mello, 2006). Most injuries occur as a result of falls, being struck by an object, collisions, and overexertion during unorganized or informal sports activities. Most injuries during team events occur during practices rather than during games. Death from a sports injury is rare; the leading cause of death from a sports-related injury is a brain injury. Sports and recreational activities contribute to approximately 21% of all traumatic brain injuries among American children and adolescents. Most head injuries sustained during sports or recreational activities occur during bicycling, skateboarding, or skating incidents.

Children need to be monitored during physical activities to ensure they are incorporating proper body mechanics and safety precautions. When learning a new sport, children should always be supervised and given instruction regarding proper use of sport equipment, rules regarding body contact with other children, and safety precautions that must be used during participation in the sport. Chapter 7 presents a discussion about sport activities and the adolescent, and suggests ways to prevent sports injury (see Community Care 7–1 and Developmental Considerations 7–4).

Age-Appropriate Activities

By the time the child reaches age 5, vocabulary is about 1,500 to 2,000 words, and speech is almost 100% understood, even by strangers. He or she has developed very good balance and coordination. This child can hop and skip on alternate feet, throw and catch a ball, dress himself or herself, and complete total self-care. Pretend play, playing with puppets, and dressing up in clothes are added to the list of favorite games. This is the age when the child starts to mimic his or her parents and behave in a gender-specific fashion (Fig. 6–7).

“Play” in the traditional sense has become a declining focus of activity during middle childhood. Indoor and outdoor recreation is being replaced by computer play, television, and video games. Recreational activity (recess and physical education classes) at elementary schools has been minimized by the elimination of trained physical education teachers from the school staff and by the increased focus on mandated testing in the educational system. Increased homework affects children's ability to

FIGURE 6–7. Dressing up and pretending to be different real and make-believe characters is fun for children. Here, this little girl enjoys dressing up as “Mommy”.

get out and play, as do the busy schedules of children and parents as they race from one planned activity to another (Frost, 2004). Children need time to play, however, because play helps them to develop cognitively, socially, physically, and emotionally.

Middle childhood is characterized by play that embodies the need for rules and structure. This need for rituals and rules translates well into team sports and other activities that have rules and structure. The group the child participates with may actually develop very rigid and outlandish rules for some group games. This is also the time that many children enjoy being part of a social group, such as Girl Scouts or Boy Scouts, which has a structured set of guidelines for behavior and achievements. These groups provide many opportunities for activities such as camping, making crafts, completing service projects, and participating in fund-raising promotions (Fig. 6–8).

Team play is a more complex version of group play and is an ideal model for children to learn the importance of being a team player and achieving goals set for the team, not just the individual. They also learn how to handle competition, and work cooperatively in a group to achieve a common goal—skills that later can be transferred to other situations. Through these accomplishments, they develop self-esteem, physical skills, and improved manual dexterity.

Another focus of the ritualistic behavior common at this age is collecting and hobbies. The school-aged child may develop the desire to collect all sorts of matching and nonmatching items (Fig. 6–9A). School-aged children have developed the ability to concentrate and participate in self-initiated quiet activities that challenge their cognitive skills, such as reading or playing computer and board games (Fig. 6–9B and C). This is an ideal age to introduce musical instrument instruction. The child has the manual dexterity, attention span, and

the rule rigidity to make this experience a positive one (Fig. 6–9D).

One type of play activity that must be approached cautiously during middle childhood is the use of trampolines at home, school, and recreation centers. The American Academy of Pediatrics (1999) does not recommend trampoline use except under the direct supervision of a physical therapist, athletic trainer, or other appropriately trained individual. Concerns have been raised regarding

FIGURE 6–8. Scouting groups can expose the child to community service activities. This young scout is participating in a community canned food drive.

FIGURE 6-9. The refinement of fine motor and cognitive skills allows the child to enjoy many new activities. (A) The ability to classify objects increases the child's interest in collecting insects, rocks, stickers, or anything that strikes his or her fancy. (B) Computer games and research require the ability to read, add, critically think, and manipulate the mouse and keyboard. (C) Board games can be used to sharpen the child's cognitive skills. (D) With increased dexterity and higher level thinking, the child can learn the complexities of playing an instrument.

trampoline safety because of the number of cervical spine injuries associated with this activity. In 2004, approximately 84,000 injuries were associated with trampoline use (Thompson, 2005). Despite use of side safety pads and nets, the way children land on their heads, arms, and other parts leads to fractures of upper and lower extremities, and to cervical spine injury (Toth, McNeil, and Feasby, 2005). When trampolines are used, no child younger than 6 years should be allowed to use the equipment, only one person should be allowed to use the trampoline at a time, and personnel trained in trampoline safety should be present at all times.

Television and Other Electronic Entertainment

QUESTION: Wendy has mentioned that Cory watches TV or plays in the room with the TV on while Cory's teenage brothers are watching TV. Wendy states she doesn't think Cory is paying much attention to what is on the TV. What do you think is appropriate to say to Wendy?

Television viewing by children and adolescents has increasingly displaced other activities in the child's life, such as reading, exercising, and playing with friends. The average child or adolescent watches an average of 3 hours of television a day (American Academy of Pediatrics, 2001b). This figure does not represent the number of additional hours (approximately 2 per day) spent watching videos or playing video games (Christakis, et al., 2004). One study has indicated that 32% of children 2 to 7 years of age and 65% of children 8 to 18 years of age have TV sets in their bedrooms (Roberts et al., 1999). Television viewing hours and the number of televisions in the home increases with the child's age, as reported by a study following children from ages 6 to 12 (Saelens et al., 2002). These statistics are in sharp contrast to the number of minutes daily that a child spends in meaningful conversation with his or her parents (3.5 minutes/day) and the number of minutes a child spends reading daily (41 minutes/day) (TV-Turnoff Network, 2005).

Television viewing and video game participation by school-aged children raise several concerns. The first relates to the content, which increasingly emphasizes violence (Tradition or Science 6-2). The National Television Violence Study (Center for Communication and Social

TRADITION OR SCIENCE 6–2

Do violent games increase children’s aggressive behaviors?

EVIDENCE-BASED PRACTICE

Recent data indicate that boys spend an average of 13 hours per week and girls spend an average of 5 hours per week playing violent video games (Gentile et al., 2004). Most video games include violence, even between cartoon characters. Playing a lot of violent video games has been associated with having aggressive thoughts, feelings, and behaviors. Playing video games is also related to children being less willing to be caring and helpful toward peers. These effects are seen as often among nonaggressive children as among children with documented aggressive tendencies (Anderson & Bushman, 2001; Anderson et al., 2003; Gentile et al., 2004; Robinson et al., 2001). Children are in a critical period for learning and developing healthy ways to relate to other people and to resolve conflicts peacefully, and playing violent video games has been demonstrated to have harmful effects on children’s social relationships.

Policy, 1998) found that nearly two thirds of all programs contain violence and that children’s shows contain the most violence. In these shows, violence is often glamorized, and the perpetrators of crime and violence go unpunished. As much as 10% to 20% of real-life violence is believed to be attributable to media violence (Kaiser Family Foundation, 2003). Viewing frightening or violent scenes on television can cause children to experience unrealistic fears, bad dreams, anxious feelings, and the fear of being alone.

A second concern is the relation between television viewing and childhood obesity. Studies have concluded that a child’s weight increases with the number of hours he or she spends watching television each day (Robinson, 1998; Saelens et al., 2002). As television viewing time increases, the time spent exercising and engaging in other active pursuits declines. Additionally, while children watch television, they frequently snack on high-calorie and high-fat foods or are encouraged to do so by the commercials they view.

A third area of concern is the many references to, and depictions of, cigarette, alcohol, and illicit drug use; dangerous stunts; and irresponsible sexual behavior in television programming. MTV’s programming is watched by 73% of boys and 78% of girls age 12 to 19. An analysis of MTV coverage noted that the programs averaged 13 sexual scenes per hour and 32 uses of foul language (LifeSiteNews.com, 2005). Although no recent studies substantiate the effect of this exposure on actual childhood or adolescent behaviors, concern remains that this highly influential medium promotes risky behaviors with little emphasis on consequences.

Television viewing has potential benefits for children if viewing is monitored and exposure time is balanced with other family and personal activities (see Developmental Considerations 5–2). Essential guidelines for parents to follow include limiting total media time, removing

televisions from children’s bedrooms, and monitoring the types of shows being viewed (American Academy of Pediatrics, 2001b).

ANSWER: The first step is assessment. Ask specific questions such as, “What do the other children watch?” Determine whether it is TV shows or movies. The difference is twofold: exposure to commercials and length of programming. Sometimes it is difficult to initiate a conversation when you perceive that your values are different than those of the client family. Approach the subject in a factual and non-judgmental way. An example of an appropriate statement is: “The healthcare community has studied a number of issues related to TV exposure including violent behavior, attention problems, and obesity. Would you like more information about television viewing and children?”

PERSONAL AND SOCIAL DEVELOPMENT

The social environment of the school provides opportunities for children to develop personally and to begin to discriminate who they are as unique individuals. Social relations with peers can be quite challenging as the child learns to form bonds of friendship and learns the nuances of gender relations. Adults play an important part in the child’s development of self. Teachers role-model behaviors that affect the choices that school-aged children make in their own behavior. Parental support and encouragement has been shown to be an important factor in increasing the resiliency of school-aged children and adolescents, including protecting them from engaging in high-risk behaviors (Loewenson & Blum, 2001).

Personality and Temperament

As described in Chapters 4 and 5, the temperament of the child—whether “easy,” “difficult,” or “slow to warm up”—helps to determine how a child adjusts to the environment and influences his or her personality. The “difficult” child is usually the child who is most challenging to live with. The nurse may need to assist the parents in determining good strategies to use when dealing with a “difficult” child. The nurse can coach the parents to remain neutral or objective in emotional situations and to not take the child’s behavior personally. Parents need to learn to anticipate high-risk situations and to strategize how to deal with them effectively to avoid potential disasters. Parents may need to consider their own temperaments when dealing with children (i.e., whether their temperament is “difficult,” “high maintenance,” or “easy”). Effective parenting entails recognizing both the child’s unique temperament and one’s own, and considering how they interact. Parenting goals should include strategies to manage parental expectations, help the child be successful, and enhance positive developmental outcomes. Healthcare professionals may find it necessary to counsel parents to adjust their behavior and expectations to allow their children to

succeed in ways appropriate to their unique temperaments (McClowry, 2002; Shelov & Hanneman, 2004).

Middle childhood is a period when individuality is being sought and children begin to develop their own sense of personhood. Children seek to determine how they “fit” into their families, and to decipher their roles in the school environment and in relationships with peers. A stimulating environment in which children can invent, create, experiment, and “grow” will assist in building self-confidence. As children approach their teen years, they are likely to seek more independence in decision making. Youths may push to gain more responsibility and have opportunities to achieve more autonomy. Interactions with adults can help build children’s sense of self-esteem and self-worth, and enhance their understanding of personal success. Children may often challenge the rules and limits set by parents, finding many faults in their parents and other family members. A common statement may be “you’re not my boss” or “you can’t make me” as children test their limits and boundaries. Setting fair, firm, consistent limits is the most successful strategy. This is a critical stage during which the child needs mature, compassionate adults as role models, because these adults can be a positive influence on the child’s future life.

Relationships

During middle childhood, making friends and sustaining those relationships is one of the most important social accomplishments. The school-aged child is able to form complex relationships, and communication has developed to a point that the child can share feelings with friends and family (Fig. 6–10). A child may develop a “best”

FIGURE 6–10. In middle childhood, same-sex activities are customary.

friend, usually someone who complements him or her and with whom he or she can feel completely comfortable. As the child moves to more independent activities, parents need to understand that it is necessary for the child to differentiate himself or herself from parents and siblings. Help parents develop a good relationship with the child by serving as a “sounding board,” by listening to the child as they work through various concerns and issues, and by ensuring that even with the most hectic schedule, the parent is available to talk and listen to the child.

Bullying is aggressive behavior carried out repeatedly and over time, with one or more children targeting someone perceived as less powerful. Bullying is a common experience for many children. At least half of all children have been bullied at some time in their lives, and more than 10% are bullied on a regular basis (Chart 6–3). Children who are bullied tend to be insecure and cautious, have low self-esteem, and lack social skills and friends, all of which makes them easy targets. Boys tend to be more involved in bullying others than girls (Nansel et al., 2001; Stop Bullying Now, 2005).

CHART 6–3 MANIFESTATIONS OF BULLYING

Physical Bullying

- Actions that cause physical injury (hitting, punching, kicking, tripping)
- Taking items that belong to the bullied youth (money, lunch, homework)
- Damaging the belongings of others
- Engaging in extortion

Inappropriate grabbing at youths and pulling at their clothes (snapping the bra, pulling down pants)

Verbal Bullying

- Teasing
- Name calling, insults, threats
- Spreading rumors about the youth or his or her family
- Humiliating the youth in front of peers

Nonverbal or Emotional Bullying

- Intimidation through gestures
- Social exclusion, shunning

Cyber Bullying

- Sending insulting messages by e-mail or instant messaging
- Sending threatening messages by e-mail or instant messaging
- Posting insults or threats on Web-based community sites or pages

Bullying by Proxy

- Coercing others to steal from or bully a victim

(Selekman & Vessey, 2004, 246–249.)

Many children who are bullied have psychosomatic complaints such as headaches, stomachaches, dizziness, sleeping problems, anxiety, abdominal pain, and feel unhappy. These children are at higher risk than others for depression and poor psychosocial adjustment (AMA, 2003; Due et al., 2005; Fekkes, Pijpers, & Verloove-Vanhorick, 2004). They often come from homes where aggressive measures are used to handle discipline and difficult situations (Selekman & Vessey, 2004).

Counsel parents who think their child might be a victim of bullying to discuss this possibility with the child's teacher or school counselor (Nursing Interventions 6–2). Encourage the child not to fight back but to walk away from the situation or seek help from someone he or she trusts. Some children need psychological counseling to avoid long-term emotional consequences of bullying.

Fears

The most common fears identified during middle childhood are still some of the same fears experienced during early childhood, such as a fear of darkness, separation, and injury. Some newer fears that are now expressed have to do with failure at school and peer relationships (not being liked, fear of being bullied). These fears are a normal part of childhood, and most will subside on their own. Some may persist as ongoing stressors for the child, whereas others may develop into phobias. Changes in children's stressors have emerged during the past 30 years. In the 1970s, children reported worrying about such issues as being poor, bad dreams, getting into trouble, and family fighting. Today, children report that their biggest stressors include

- Fighting among family members
- Homework
- Liking someone or girlfriend–boyfriend issues
- Playing sports and games
- Too many things to do (Ryan-Wenger, Sharrer, & Campbell, 2005)

Many parents may seek professional assistance to determine whether a fear has become a persistent stressor or a phobia (a fear that reaches abnormal proportions and becomes irrational).

caREminder

The child's fears may be based on real-life trauma and threats the child has received. The parent and child need to determine the rationale for the specific fear. For instance, if the child has fear of a specific classmate, further investigation is warranted to determine whether the child has been a target of harassment and bullying. If the child is afraid of a particular adult, exploration of the child's relationship with that adult is warranted to ensure that the child has not experienced any abuse from this adult.

Nurses can assist parents in dealing with the fears and stressors of their children by helping parents to understand which fears and stressors are normal at each age, and by encouraging them to use sympathy, empathy, and open communication to allow their children to express their concerns. The child should never be ridiculed, told they “worry too much,” or be forced to “be brave,” because these techniques could cause the fears and personal stress to increase, rather than diminish, and ultimately manifest as true phobias or physical symptomology (e.g., headaches, stomachaches, or skin disorders).

Sexuality

QUESTION: Throughout the course of the spring and summer healthcare appointments, you notice that whenever Cory is nervous he holds his penis. Wendy asks, “I have four other sons, but Cory touches his penis more than any of my other boys. What do you recommend?” What would you say to Wendy?

NURSING INTERVENTIONS 6–2

Roles for Healthcare Professionals in Bullying Prevention and Intervention

Assess for signs of bullying behaviors and victimization. To limit adverse influences on children, intervene early in situations of peer bullying.

Engage youths in discussions about solutions to bullying, encouraging youth-led dialogue and support groups.

Assist parents in responding to signs of bullying and in identifying support and resources for those involved and affected by bullying behaviors.

Recommend appropriate treatment, referral, and management protocols for children who exhibit antisocial and deviant behaviors.

Partner with schools to implement comprehensive bullying prevention programs.

Oversee implementation of antibullying policies and practices, including “safe school” policies that specifically address bullying behaviors.

Promote training and continuing education in strategies to prevent bullying.

Participate in political action to increase resources to prevent bullying and to ensure sustained funds for programs aimed at intervention and prevention.

During middle childhood, the child's curiosity about his or her sexuality is greater than has been previously displayed. This is a critical time for discussions to begin about sexual development. These discussions should include sex's social implications as well as the biologic factors associated with sex. It is important that parents be involved in delivering the information about sexuality and sharing their values about sex. Parents may be uncomfortable discussing certain aspects of sexuality with their children and may seek the healthcare professional's advice about how to answer the questions presented to them. Sex education in the school environment varies in each state, although most states offer classes in the fifth or sixth grade. If parents have established open lines of communication about sex from an early age, children will find it easier to approach them with questions and will not be as likely to ask peers, who may misinform them. Encourage parents to use correct terminology for the sexual organs and to provide simple but honest explanations of the functions of the body parts and the actions that cause pregnancy.

Parents and healthcare providers are encouraged to discuss sexuality and to integrate sexuality education as part of the ongoing discussions held with the child or adolescent about relationships (see Chapter 7). Parents sharing the family's attitudes, values, and beliefs strongly influences children's and adolescents' behavior. Nurses might help provide developmentally appropriate material. School programs vary considerably in the information provided. Nurses might help parents be aware of the community's school policies regarding sexuality education. Children might share information with the physician or nurse regarding sexual activity or sexual concerns that they are hesitant to discuss with parents. The child may require counseling to prevent pregnancy and acquiring sexually transmitted infections. In all discussions with the child, encourage open discourse between parents and the child, providing all parties with accurate information about sexuality while supporting parental values.

ANSWER: A favorite piece of advice recommends teaching a child that touching "private parts" in public is like picking your nose in public; we just don't do it! Do not try to make it a moral issue; keep it an issue of manners. When Cory touches himself, tell Wendy to tell him, "Not here, Cory."

SCHOOLING AND CHILD CARE

The biggest transition for every child and their family during middle childhood is the entrance in to a full-time formal education environment. Whether parents choose to homeschool their children or have their children attend private or public schools, the child must now adapt to new rules, learn to concentrate for extended periods of time, and adjust to the varying personalities of other children in the classroom.

Preparation for School

QUESTION: Wendy indicates that Cory expresses a lot of ambivalence about school. One day he seems very excited; the next day he says he won't go. What would you tell Wendy?

Kindergarten is the child's first "real" school experience (Fig. 6-11). Kindergarten is either a half day or a full day. The kindergarten is usually centered in the elementary school and focuses on social skills and elementary academics. Before the child enters kindergarten, many school districts require testing to assess the child's readiness or to determine whether the child has the skills necessary to succeed.

Parents can prepare their children by talking to them about kindergarten. They can explain how it will differ from the preschool experience, with new children to meet and different activities. The children will have more independence and more responsibilities (Shelov & Hanneman, 2004). The teacher will expect the children to have more self-control, particularly if they have attended preschool.

Even for children who have attended preschool, kindergarten is a big step. Parents may approach the healthcare provider to determine whether the child is "ready" for kindergarten. No formal statewide definition of **school readiness** exists other than an age of eligibility requirement. In most states, children are allowed to enter kindergarten in the fall of the school year if they have turned or will turn 5 years old by a certain preestablished date. Cutoff dates vary by state (Saluja, Scott-Little, & Clifford, 2000).

FIGURE 6-11. For the first day of kindergarten, this child has been prepared with a new backpack and clothes.

In addition to meeting the age requirements for school, a child should be able to play well with others; be toilet trained; have fine manual dexterity adequate to use a crayon or to fasten buttons; be able to sit quietly and listen to a story; and have enough memory skills to memorize his or her name, address, and phone number (Shelov & Hanneman, 2004). School personnel may conduct readiness testing that assesses academic readiness, fine and gross motor skills, and attention span. None of these “tests” is infallible, and the child who may not do well when tested still may be very successful in the kindergarten environment, particularly with the right teacher. Readiness tests are also used for instructional purposes. The data are given to the kindergarten teacher to inform them about the incoming class and to assist the teacher to prepare an educational plan that meets the needs of the incoming students (Saluja et al., 2000).

ANSWER: Once again, it is best to get more information before giving advice. Ask, “What worries you most?” Is Wendy more concerned about separation from her or is she worried about his readiness for kindergarten? Cory has an August birthday and therefore will probably be one of the youngest in his class. The nurse could perform a Denver II assessment to give Wendy an idea of his developmental level. The nurse could also remind Wendy that school personnel can conduct assessments to determine Cory’s readiness for school.

School

The best teacher that a child can have is his or her parent. A parent can do many things at home to enhance a child’s learning skills for school, such as allowing the child to assist in the kitchen to learn fractions (e.g., using $\frac{1}{4}$ cup, $\frac{1}{2}$ cup); giving the child the opportunity to add and subtract the money in a wallet or coin purse; and encouraging the child to read an article from a child’s magazine, a recipe, or a billboard to enhance reading skills.

After the child has started school and is attending on a regular basis, each new year should be approached with positive feelings. The parents should not allow any negative experiences from a previous school year or from their own personal background to influence the child’s expectations of the new year.

Promotion to the next school grade level requires that the child attain grade-specific learning goals (Fig. 6–12). If these goals are not attained, the child may have to repeat the grade. Although research shows that attempts to relate future success to repeating a school grade are problematic, and that retention may reduce the chances of graduation by as much as 50%, the process continues to be widely used and even mandated by some states. Strategic intervention before the end of the year would be a better alternative; however, most schools still follow an industrial model, and the shift to meeting individual needs has not yet been fully supported by the funding sources.

FIGURE 6–12. Specific learning goals during middle childhood include counting, sequencing, recognizing letters and simple words, and basic writing. Math and reading skills emerge during this period as well.

The Gifted Child

Although parents may be aware that their child attains some developmental milestones unusually early or possesses extraordinary capabilities (e.g., early advanced language development, unusually retentive memories), it is usually the school system that identifies a child as being potentially gifted. The definition of “gifted” varies with each source. Initially, simply a high IQ (top 1%) was thought adequate to define a child as gifted. More recently, the definition has been expanded to include three areas: an above-average intelligence, a high level of creativity, and a high level of task commitment.

Gifted children may experience social challenges. Many children who have been identified as gifted have difficulties relating with peers because of the contrast between their chronologic age and their intelligence. Also, siblings who are not gifted often feel inferior to their gifted brother or sister. Occasionally, academic or behavioral problems may be attributed to boredom with the school curriculum.

Schools often provide testing for such children and offer special programs to enhance learning capabilities and expand areas of potential. Parents and teachers can find gifted children challenging to deal with, because they often have a habit of questioning traditional facts and conclusions, and have an insatiable curiosity that can be irritating to authority figures. Although gifted children need to be challenged in their areas of excellence, they also should be offered the basic instruction that all children receive, although possibly to an accelerated degree (Community Care 6–2).

COMMUNITY CARE 6–2

Responsibilities of the Healthcare Team to Gifted Children and Their Families

- Assess for achievement of normal developmental milestones and identify indicators of developmental precocity.
- Identify resources within the community to help evaluate gifted children.
- Help children and families understand the concept of giftedness.
- Help parents prevent creating excessive vulnerability or privilege in the identified child.
- Help the family deal with siblings of the identified child who may feel inferior and less appreciated than the gifted child.
- Help the family avoid overstimulation of the child or the desire to push their child into too many activities.
- Advocate for appropriate educational resources in the school system.
- Help identify gifted children who may have behavioral and learning problems that require intervention.
- Foster communication between school personnel and the family.

Children With Learning Disorders

Children who fail to reach academic or behavioral standards appropriate to their grade level may be recognized by the school or their parents as needing some additional attention to ensure success. Chapter 30 provides an in-depth discussion of those conditions referred to as *intellectual disability*, *cognitive disability*, *cognitive deficit*, *intellectual deficiency*, and *mental retardation*. Most schools have screening procedures in place, often called *student study teams*, to bring together all people involved with the child in a problem-solving meeting. This team approach ensures that all perspectives are considered and allows for input from all involved parties. Student study teams frequently bring together the child's teacher, the school resource specialist, the school psychologist, the school speech therapist, a school administrator, and, of course, the parents. The first time a student study team meeting is held for a child, all team members contribute input to determine the child's current performance level and the kinds of support that have already been provided.

Potential solutions can include suggesting that the parents seek medical or psychological attention for the child, or that the school provide academic and psychological testing to determine whether a learning disability is present. Many times, learning disabilities are identified by looking for discrepancies between academic performance (current level of performance) and IQ score (innate ability). Additionally, schools may give behavior assessments to determine whether evidence exists of ADHD. Schools do not make medical diagnoses, however, and are required to respond only to issues that affect student learning.

If testing is determined to be appropriate, the parents are offered this option, and the process begins. Schools have 15 days to respond to parents' requests for assessment, and must complete the testing and report back to parents within 60 working days. At the posttest meeting, results from all the tests are reviewed to determine

whether the child meets the qualifications for special programs. Potential outcomes of this meeting include several conclusions: the child is delayed but within normal developmental limits, so no further action is required; the child has ADHD-like symptoms that affect his or her functioning in the classroom, so the opportunity to develop an Individuals with Disabilities Education Act Section 504 modification plan is offered; and the child has a learning disability, so placement in a special education program is offered. The decision is based on the parents' desires, because they have the right either to take advantage of the programs offered or to decline services. Chapter 2 provides a thorough discussion of the educational programs available for children with special needs; TIP 30–1 provides guidance to help parents advocate for the educational needs of a child with a developmental or learning disorder.

Learning-disabled children are typically placed in a special resource program, because federal guidelines require placing all children in the "least restrictive" educational environment. As a result of federal directives, many students with conditions such as Asperger's syndrome, autism, and even Down syndrome may now be included in the regular education program as "full-inclusion" students. These children create severe burdens on the public education system, which by federal law must provide a "free and appropriate education" to each child. See Chapters 2, 12, and 30 for more information regarding programs for children with chronic conditions or learning disorders who may benefit from special educational programs provided through the public school system.

Homework

Homework is a natural consequence of school. Homework usually starts at the third-grade level at about 15 to 30 minutes several times per week, increasing to up to 2 hours each night by the time the child is in high school. The time required to complete assignments varies, based

on the child's ability to focus on the task, the child's comprehension of the assignment, and the presence of any learning disorder. Homework should not be a power struggle between the parent and the child. Parents need to allow the child to complete the homework with assistance and support. Good homework habits should be developed at an early age, and the child should have a specific time, place, and tools to complete the assignments. The decision regarding where and when a child does homework must be determined by family dynamics. Some children do best by doing the homework immediately after school, whereas others have too many distractions at that time and do better when they do homework after dinner. Both are acceptable, as long as the child develops the habit of completing the homework (Paulu, 2004) (Fig. 6–13).

Parents may seek advice from the healthcare professional if the child experiences school problems—particularly, incomplete homework. The healthcare professional should encourage parents to allow the child to suffer the natural consequences of not doing homework. Rather than engaging in a power struggle, parents can be supportive and open, and show interest, but should not insist the homework be completed perfectly, do the homework themselves, argue with the child about homework, or criticize the child about homework. Encourage the parents to meet with school personnel regarding the problems of homework and to work with the school and coordinate with the teacher to delineate the responsibilities of the school and the child.

After-School Care

A parent is usually somewhat relieved when a child starts school on a full-day schedule. If the parent has not been working, now may be an opportunity to return to work, although usually school is 5 to 6 hours long and not the 8 to 10 hours that a parent needs for work and commuting. Until children are 12 or 13 years old, they should continue to have some after-school care. Latch-key kids (children who are unsupervised at home after school at an early age) are common in today's society. Most children younger than 13 do not have the maturity to make decisions in an emergency. Some children as young as

FIGURE 6–13. The child attending school is encouraged to establish homework routines. A quiet place without distractions helps the child focus.

8 years old may have the skills needed to make these decisions, but legal authorities usually do not allow a parent to leave the child in an unstructured environment until the age of at least 12 or 13. Children who are allowed to be home after school by themselves may develop fears or anxieties because they feel isolated and lonely. Nurses should be aware of the resources in the community that assist families in locating programs to care for children after school. The nurse may also help families to develop rules for children to follow when they must stay at home alone, such as locking doors, never opening the door to strangers, and having a neighbor or close friend available by phone if a question or problem arises (Community Care 6–3). Children should be taught how to use the telephone, and a list of emergency phone numbers should be posted next to the telephone, including the home address and telephone number, because a child can easily forget his or her own address and phone number in an emergency.

When the parents are looking for a baby-sitter, they must take care to select the appropriate individual to provide care for the child at home. They should interview caregivers and ask appropriate questions about their approach to discipline, general child-rearing beliefs, activities considered appropriate for the child, and so on. The ideal candidate will have local references and be a person with whom the parents feel they can develop an open relationship.

PREVENTING INJURY AND ILLNESS

As the child's independence increases, the potential for accidents is also increased. A high incidence of accidents occurs while children are at school playing with friends (Fig. 6–14). Children do not yet have the maturity to accurately judge speeds or distances and may also accept dares to play unsafe "games" with matches or loaded firearms. Most of these accidents are preventable, and with a little forethought the child will not be at risk for death or injuries with lifelong consequences.

KidKare ■ Many children want cell phones. Although parents may be hesitant to purchase one for the child, the device may serve as a safety support for the family. Cell phones can be purchased that have limited minutes and usage requirement. Features such as limited minutes and usage enable parents to use cell phones to keep tabs on their children, while limiting others' access to the child. Educate parents that children who have cell phones still require monitoring by their parents regarding where they are going and with whom. Remind children that having a cell phone does not mean that they no longer have to follow family safety rules.

By implementing simple routines and enforcing rules, children can be kept reasonably safe. Teach parents to lock the car doors at all times and remind them that a child

COMMUNITY CARE 6–3

Injury Prevention Guidelines for the Family During Middle Childhood

General Safety

Reinforce important safety considerations. Anticipate that the child may make errors in judgment because he or she is trying to imitate peers. Anticipate providing less supervision.

Home Safety

Establish and enforce consistent, explicit, and firm rules for safe behavior.
 Test smoke detectors to ensure that they work properly. Change batteries yearly.
 Lock up poisons, matches, and electric tools.
 Ensure that guns, if in the home, are locked up and that ammunition is stored separately. A trigger lock is an additional important precaution.
 Reinforce the child safety rules for the home, including what to do when home alone. Remind the child not to answer the door or to invite visitors into the house when no parent is present.
 Discuss telephone rules and the importance of not tying up the telephone for long periods of time. Keep emergency phone numbers available for easy use.
 Discuss what to do in case of fire or other emergencies. Conduct fire drills at home.

Activity Safety

Reinforce sports safety with the child, including the need to wear protective sports gear.
 Teach the child to avoid high noise levels, especially when using music headsets.

Water Safety

Ensure that home and neighborhood swimming pools are enclosed by a four-sided fence with a self-closing, self-latching gate. Children should be supervised by an adult whenever they are in or around water.

Teach the child how to swim.
 Reinforce safety rules for swimming pools.

Car Safety

Based on the child's age and size, ensure that the child uses appropriate restraint and seat belt devices in the car at all times.
 Prohibit children from sitting in the front seats of cars with passenger air bag devices.

Safety With Others

Keep the child away from cigarette smoke. Do not allow smoking in the home.
 Teach the child safety rules regarding interacting with strangers. Ensure that the child's school curriculum has information on how to deal with strangers.
 Ensure that the child is supervised before and after school in a safe environment.

Outdoor Safety

Teach the child to put on sunscreen (SPF 15 or higher) before he or she goes outside for long periods.
 Reinforce the child's knowledge of neighborhood safety skills.
 Reinforce child safety rules for bicycles, including use of proper traffic signals.
 Ensure that the child wears a bicycle helmet when riding a bicycle.
 Do not allow the child to operate a power lawn mower or motorized farm equipment.

Emergency Preparation

Keep your address and phone number posted near the phone.
 Keep list of emergency numbers (doctor, hospital, nearest neighbor, poison control center) near the phone.
 Learn first aid and CPR techniques.

Adapted from Hagan, J., Shaw, J., & Duncan, P. (Eds.). (2008). *Bright futures: Guidelines for health supervision of infants, children, and adolescents* (3rd ed.). Elk Grove, IL: American Academy of Pediatrics.

should never be allowed to be alone in the car. Educate parents to use the appropriate type of car seat and consistently enforce the rule that seat belts always be worn when the child is in the car (Community Care 6–4). The safest place for a child younger than 12 years and weighing less than 100 lb is in the backseat. Only older and heavier children should be in the front seat of a vehicle with a passenger airbag. States and provinces vary in car safety requirements for children. Most states have laws that

require a child to be placed in a booster seat until certain age, height, or weight requirements are met. Prior to providing information to parents, review your state or province laws to ensure that you give accurate information.

Crossing the street may also be a challenge for the 6- to 10-year-old who is still unable to judge the speed of an oncoming car or its distance from the intersection. Adult supervision should be used until the child is older than 10 years of age. The bicycle is one of the most popular

FIGURE 6–14. Injuries on playground equipment can occur when children do not follow safety precautions and are allowed to play unsupervised.

“toys” during middle childhood. Mastering the skill of riding a two-wheeled bicycle means independence, a mode of independent transportation, and freedom. Because bicycles can pose serious risks to safety, a child must learn the rules of the road and abide by them (Clinical Judgment 6–1). Most of the accidents between bicycles and automobiles are caused when a child does not obey the rules and darts out in front of a car or rides against traffic.

A properly fitted bicycle helmet that can absorb the impact of a crash should be worn at all times the child is on a bicycle (Community Care 6–5). A helmet should be worn squarely on top of the head, covering the top of the

forehead. If it is tipped back, it will not protect the forehead. The helmet fits well if it does not move around on the head or slide down over the wearer’s eyes when pushed or pulled. The chin strap should be adjusted to fit snugly (American Academy of Pediatrics, 2001a).

Alert! A helmet worn during a serious fall or accident should no longer be used. The helmet has served its purpose and may have been damaged so that it will not be able to provide adequate protection in another crash. If any uncertainty exists about whether a helmet is still usable, throw the helmet away and replace it with a new one.

Many communities do not require helmets even though helmet use can reduce the risk of head injury (Clements, 2005). Helmets also should be worn when a child is using a skateboard or skates. In addition, the child should have protective knee and elbow pads as well as wrist guards to prevent serious injury during falls off the skateboard or skates. When purchasing a bicycle or skates for a child, parents should also purchase a proper-fitting helmet with a Consumer Product Safety Commission sticker (Fig. 6–15). The child needs to start learning the laws of the road. Children who ride bikes should understand that it is necessary to follow the same types of traffic laws that cars do and to go with the flow of traffic, signal when stopping or turning, and obey stop signs and stoplights. Light-colored or reflective clothing is recommended when riding at dusk. Cyclists should be encouraged to ride on paths as much as possible and to avoid the streets.

Although the number one cause of death in middle childhood is accidental injury, the second most common

COMMUNITY CARE 6–4

Seat Belt Safety for Children

Ensure that lap and shoulder seat belts fit properly.

- The shoulder belt lies across the middle of the chest and shoulder, not the neck or throat.
- The lap belt is low and snug across the thighs, not the stomach.
- The child is tall enough to sit against the vehicle seat back with her legs bent without slouching and can stay in this position comfortably throughout the trip.

Use a booster seat until the adult seat belt fits correctly.

- Seat belts are made for adults.
- The child should reach about 4 ft 9 in in height and be between 8 and 12 years of age before quitting the use of a booster seat.

Use seat belts as intended by the manufacturer.

- Do not tuck the shoulder belt under the child’s arm or behind the back.
- If there is only a lap belt, make sure it is snug and low on the child’s thighs, not across the stomach.
- When purchasing a new or used car, try to get a lap and shoulder belt installed in the car by a dealer.
- Do not allow children or other passengers to “share” seat belts. All passengers must have their own car safety seats or seat belts.
- Do not use seat belt adjuster products that attach to the seat belt but are not part of the original belt. These products actually interfere with proper fit of the lap and shoulder belt.

CLINICAL JUDGMENT 6–1

An Injury at School

The bike rodeo at the elementary school brings about 75 fifth and sixth graders together to learn about bike safety. The children bring their bikes from home, and with assistance from a local bike shop, they learn a few tips on bike maintenance. Police officers are on hand to teach bike safety and to monitor the children as they complete a bicycle obstacle course. Although the event has not officially started, fifth grader Ernie has been brought to the nurse's station with severe lacerations to his arms and knees. He fell off of his bike while on his way to school. You have seen him in your office several times related to complaints of a stomachache. He is a shy boy, new to the school, and is easily upset when things do not go his way.

Questions

1. What is your first assessment priority?
2. What are the issues you need to consider as you manage Ernie's injuries?
3. Although there was a lot of blood, the wounds will not require stitches. You are able to cleanse and bandage the wounds at your office. As you talk with Ernie, you learn that he was injured while trying to race away from some boys who were teasing him. You also note that Ernie is wearing shorts and has no bike helmet with him. What additional issues do you need to address with Ernie?
4. How would you proceed with Ernie after his injuries have been assessed?
5. As the bike rodeo event begins and the day progresses, how would you determine that Ernie is benefiting from the activities and is feeling better?

Answers

1. Assess Ernie's injuries to his legs and arms. Complete a neurologic assessment and brief head-to-

toe assessment to ensure he has not sustained injury elsewhere and that there is no change in level of consciousness.

2. Evaluate the wounds to determine whether more extensive care is required in a more comprehensively equipped setting. Review Ernie's medical record to ensure he has no bleeding issues and to determine his immunization status.
3. During the time you are caring for Ernie, explore why he does not have a helmet and whether he knows what other clothes he can wear to protect his body while biking. You would also want to elicit from Ernie his perception of the exchange he had with the other boys who caused him to have the accident.
4. Contact Ernie's parents to let them know what happened. Ask permission to administer Tylenol if needed for pain and swelling at the site. Walk Ernie back to the event area. Ernie would benefit from having a "friend" paired with him for the activities. You might ask another boy to be Ernie's "special friend" for the day and be sure to include him in activities as the day progresses. Introduce Ernie to the police officers and determine whether he can get a "loaner" helmet for the day. Ask a particular officer to keep an eye on Ernie, and request that if there is some way to involve him in a special task that would make him feel important, to please do so.
5. Periodically check on Ernie to ensure the dressing is dry and intact, and he is free from pain. Use these contacts to further note his general affect and his interactions with other children. Later in the week, make contact with Ernie to assess his wounds and to ask him about the bike rodeo and how the day went for him. Follow up with teachers regarding the concerns you have about Ernie and his "fitting in" at school.

cause of death is drowning. Children older than 5 years of age are most likely to drown in natural sites such as rivers and lakes (Brenner, 2003). As parents see the child mature, their confidence in allowing the child more independence may increase to the point that they overestimate the child's survival skills. Children must have adult supervision whenever they are around water. Swimming instruction from a qualified instructor is important, but should not take the place of adult supervision. Specific rules should be strongly enforced whenever a child is to be around water, such as never swim alone, do not dive unless the depth of the water is known, and wear a personal flotation device when riding in a boat.

School-aged children are often fascinated by guns, but children should never be allowed access to firearms. Even with instruction, they are not mature enough to handle a potentially lethal weapon. A loaded gun should never be kept in a car or a home. The gun should be kept unloaded and the ammunition should be stored in another location under lock and key.

Even with all these precautions, many children are allowed access to firearms through friends or family members. Parents must discuss with their children tactics to use if they are approached by a friend with a gun or encounter a gun in another home or at school. They should be encouraged to stay away from it, not to touch

COMMUNITY CARE 6–5

Promoting Helmet Use

- Establish the habit of wearing helmets at an early age, even before children are riding tricycles in public areas.
- Allow children to help choose their helmets, selecting a design and a fit that is comfortable to them.
- Instruct parents to be role models by wearing helmets themselves.
- Explain to children why they need to protect their heads.
- Use the media to show examples of professional athletes wearing helmets (e.g., skateboarders, race car drivers).
- Give children special treats when they remember to wear their helmets.
- Encourage children's friends to wear helmets. Have extra helmets available so that wearing helmets becomes a "house rule" that everyone can follow.
- Do not let children ride without wearing a helmet. Be consistent in enforcing this rule.

it, and to report it to their parents. In television and movies, handgun violence does not appear as devastating as it actually is, which may mislead children about its dangers. Frequent discussions with children about what is observed on television and comparisons with real life will

FIGURE 6–15. Helmets are an important aspect of bike safety. Parents can be role models for their children by also wearing bike helmets.

help them understand that guns are not toys and must remain with adults.

Adolescence (11–21 Years)

Case History

Ashley Tran is a 16-year-old Vietnamese American attending public high school in her junior year. She is the oldest child in her family and at home she is called *Chi Lon* (which means “oldest sister” in Vietnamese). She has a younger brother, George. Both children were born in the United States. Her father, Tung Tran, and her mother, Loan Pham, were both born in Vietnam and immigrated to the United States. Her father now speaks English fairly well, but her mother does not. Her mother, Loan, has three sisters who live nearby. Ashley is closest to her Aunt Ha, her mother’s youngest sister who attended high school in the United States. Ashley’s grandparents on her mother’s side are deceased and her paternal grandparents are still in Vietnam. Everyone in their family is Roman Catholic.

Ashley’s parents have very high academic expectations and professional expectations for their daughter. It is expected that she will attend to her studies and bring home all As. They would like her to be a doctor. Ashley, however, is more of a B student. She does try hard; she just doesn’t care that much and she definitely does not want to be a doctor. Her brother George, on the other hand, is a very conscientious student and very bright. Ashley’s parents frequently ask why she is not doing as well in school as her brother.

It is also an expectation that she would only date Vietnamese young men. Ashley has a boyfriend, Eric, who is not Vietnamese. Eric is a senior at Ashley’s school. To see each other outside of school Ashley has to lie about where she is going. Eric doesn’t really understand why they cannot just tell her parents, but Ashley is adamant they would not understand. Eric and Ashley have had occasional, unplanned sexual intercourse without protection. Eric has urged Ashley to get on “the pill,” but Ashley insists “good Catholic girls” don’t do that and they must not have intercourse again.

Ashley is very thin and complains that she is not sleeping well. Her conflict with her parents has reached such a level of tension that she is avoiding meals at home. She is aware she is disappointing her parents, but at the same time she feels that their wishes and expectations are not her own. One evening, Ashley’s parents discover she has lied to them in order to see Eric, and they have an extensive argument. That same week, Ashley’s report card comes home from school. Ashley thinks her parents do not understand what it is like to be a teenager in the United States today, and she talks to her Aunt Ha about moving in with her. Ashley’s story continues in Chapter 29: The Child With a Mental Health Condition. When Ashley does not feel well at school, she visits the school nurse.

CHAPTER OBJECTIVES

1. State the age-appropriate developmental milestones of the adolescent years.
2. Distinguish components of developmental surveillance unique to the adolescent population.
3. Discuss the concerns of the adolescent related to hygiene and personal care.
4. Describe challenges to maintaining optimum nutrition in the adolescent years.
5. Describe activities that promote physical fitness in adolescents.
6. Select age-appropriate interventions to promote healthy personal and social development of the adolescent.
7. Select interventions to promote illness and injury prevention for the adolescent and the family.

See **thePoint** for a list of Key Terms.

The **adolescent** years begin with the onset of physiologically normal **puberty** (the sequence of events by which a child becomes a young adult) and ends when an adult identity and behavior are accepted. This stage of development corresponds roughly to the period between the ages of 11 and 21 years (Hagan, Shaw, & Duncan, 2008). The patient population seen by child healthcare providers includes all children from birth through age 21, and in some cases, may extend beyond the age of 21 (American Academy of Pediatrics, 1998; National Association of Pediatric Nurse Practitioners, 2002). Clearly, those providing healthcare to adolescents must allow sufficient flexibility in defining this age span to encompass special situations, such as the emancipated minor (see Chapter 2) or the young person with a chronic condition that causes delayed development, prolonged dependency, or a need for continuity of healthcare services for pediatric acquired chronic conditions. This chapter covers healthy lifestyles of adolescents and young people to the age of 21.

Adolescence is a critical growth period for young people, during which they form their own identities, develop independence from their parents, and prepare to become members of society. Protective nurturing factors that can strengthen adolescents and help them resist problem behaviors include individual, family, peer, and environmental influences. Risk factors that may limit adolescents' success vary widely, and include such factors as poverty, a history of mental illness in the family, use of alcohol and other substances, and lack of parental supervision and guidance. The healthcare provider plays an important role in promoting factors that will assist the adolescent to be resilient when facing daily challenges associated with school, family issues, and peers.

DEVELOPMENTAL ASSESSMENT AND SURVEILLANCE

Developmental Considerations 7–1 presents a summary of the developmental milestones that are accomplished

during adolescence. This information can provide the nurse with direction for specific trigger questions to ask the parents or child to determine the adolescent's developmental progress. Variances in attainment of developmental milestones will be affected by physical change related to the onset of puberty, and by influences from family, school, and social (peer) groups. Trigger questions will elicit information about social and sexual activities, and school and vocational performance, as well as health maintenance activities for this age. During the adolescent years, annual healthcare visits are recommended to complete developmental assessments and to screen for conditions common to the adolescent years (Chart 7–1). The physical examination includes assessment of blood pressure, height, weight, body mass index (BMI), skin (acne, piercings, tattoos, abuse, and so forth), breast examination, pelvic examination, and inspection for sexual maturity. Health screening of the adolescent includes several assessments not incorporated in health visits of younger children. Some of these assessments are completed based upon the risk assessment screening criteria. Scoliosis screening, alcohol or drug use screening, evaluating anemia in the young girl with a heavy menstrual bleeding, tuberculosis screening, and testing for sexually transmitted infections and cervical dysplasia in all sexually active young people are essential components of surveillance and screening in this age group (Hagan, Shaw, & Duncan, 2008).

A primary goal of developmental surveillance is to promote adolescent self-advocacy—that is, to assist the adolescent in seeking out, evaluating, and using information to promote his or her own health. Prepare adolescents for self-advocacy by teaching the adolescent to ask for information and to make decisions about his or her own care by encouraging health promotion activities, and by providing the adolescent with age-appropriate and correct healthcare information (Nursing Interventions Classification [NIC] 7–1). Older adolescents may no longer be living at home. Parental promoting to maintain regular healthcare visits and medical insurance coverage may be absent. Both factors may affect the health promotion and prevention activities of the young adult.

caREminder

Adolescents report that they desire to receive healthcare from competent professionals who demonstrate warmth and compassion, and communicate in a straightforward, understandable fashion. Concerns about confidentiality can be a major barrier to healthcare for the adolescent (Brindis et al., 2002). The healthcare provider who interacts in a sensitive manner, providing respect and compassion, is likely to develop a strong relationship with the adolescent that will provide a foundation for promoting ongoing access to preventive healthcare.

Healthcare providers also play an important role in helping parents better understand and support their teenagers during these challenging years. Parent education includes information about the normal characteristics of

DEVELOPMENTAL CONSIDERATIONS 7–1

Milestones of the Adolescent Years

Physical

- Full height not attained until age 20 to 24 years, when epiphyseal plates close
- Marked increase in muscle mass in males related to increase androgen production (up to 20 times greater than previous levels)
- Muscle mass two times greater in males than in females by age 17, resulting in strength two to four times greater in males
- Adult cardiovascular rhythms achieved by age 16

Nutritional needs greater than at other times of life:

- Pregrowth spurt, 1,500–2,400 cal/day; pubertal girls, 2,000–2,500 cal/day; pubertal boys, 2,500–3,000 cal/day
- Male basal metabolic rate about 10% greater at end of adolescence than that of females

Sexual

- Genital stage (Freud)
- Learning appropriate outlets for sexual drives
- Female attains menarche at 10 to 15 years
- Usually cannot reproduce for 1 to 2 years after menarche because of anovulation
- Early use of oral contraceptives limits potential height
- Male attains puberty between 12 to 16 years
- Tanner stages I through V usually attained between early and late adolescence

Approximate sequence of appearance of sexual characteristics in adolescence:

Females

8 to 9 Years

- Hormones begin to release, sometimes causing moodiness and skin sensitivity

9 to 10 Years

- Hips start rounding out
- Breast nipples start to grow

10 to 11 Years

- Breast tissues around and under nipples begin to grow
- Downy hair near labia
- Growth spurt may begin

11 to 12 Years

- Internal and external organs continue growing (vagina, uterus, breasts, ovaries)
- Pubic hair becomes darker, coarser, and curlier

12 to 13 Years

- Underarm hair growth

- Onset of menstruation (average age 12.8 years and approximately 2 years after breasts start growing)
- Pregnancy is now possible

13 to 14 Years

- Underpants may be wet at times with a clear mucus; flow is often heavier in teen years and will continue naturally during adulthood, especially with ovulation and sexual arousal

14 to 15 Years

- Most of growth spurt complete (height)

15 to 16 Years

- Acne
- Voice deepens, although not as much as males'

16 to 17 Years

- Full height achieved

Males

9 to 10 Years

- Hormones begin to release, sometimes causing moodiness and skin sensitivity

10 to 11 Years

- Testes become larger
- Scrotal skin becomes redder and coarser

11 to 12 Years

- Prostate begins functioning
- Penis begins to lengthen

12 to 13 Years

- Pubic hair grows
- May experience wet dreams, spontaneous erections, ejaculations (about 1 year after testes begin to grow)
- Growth spurt may begin

13 to 14 Years

- Rapid growth of the penis, especially enlargement occurring about 1 year after testes begin to grow
- Testes color deepens
- Two thirds of boys may experience slight growth of their breast tissue, which generally subsides within 1 year but may last 3 years

14 to 15 Years

- Underarm hair
- Mustache begins as fine hair starting at outside lip edges about 2 years after pubic hair starts to grow
- Voice change begins

(Continued)

DEVELOPMENTAL CONSIDERATIONS 7–1

Milestones of the Adolescent Years (*Continued*)

15 to 16 Years

- Average age that sperm matures and can cause pregnancy; average age, 14.6 years; 50% of boys reach this stage within the past 2 years
- Majority of growth spurt complete (height)

16 to 17 Years

- Chest and shoulders fill out
- Facial and body hair becomes heavier
- Acne

21 Years

- Full height achieved

Play

- Group/peer activities such as sports, academic teams
- Seeks parental/adult “limit setting”
- Thrill-seeking behaviors

Cognitive

- Pseudo-stupidity: asks “dumb” questions (Elkind)
- Difficulty reconciling concrete and formal operations
- Imaginary audience: superself-consciousness; believes everybody is watching and evaluating (Elkind)
- Personal fable: belief of being special and not subject to rational laws (Elkind)
- Apparent hypocrisy: act of expressing an idea tantamount to working for and attaining it (Elkind)
- Formal operations (Piaget)
- Abstraction and hypothetical/deductive reasoning (Piaget)
- Adaptability and flexibility
- Thinking in abstract terms
- Use of abstract symbols
- Conclusions drawn from set of observations
- Development of hypotheses and testing of them
- Considerations of abstract, theoretic, and philosophical matters
- Problem solving
- Ability to comprehend purely abstract or symbolic content exists
- Ability to solve math and logic problems
- Comprehension of value and belief systems in the philosophical, moral, and political realms
- Reality versus possibility views only one arrangement of the possible
- Combinational reasoning
- Propositional thinking
- Hypothetic–deductive reasoning
- Death is irreversible, universal, personal, but distant

- Uses natural, physiologic, and theologic explanations of death

Social

- Capable of sharing self with others to foster intimate relationship
- Inability to form intimate relationships may lead to sense of isolation

Interpersonal

- Identity versus role confusion (Erikson)

Moral/Spiritual

Moral

Stage 4: Conventional (12–16 Years [Kohlberg])

- Fixed rules in moral decisions
- Obligation to do no harm and to do duty

Stage 5: Postconventional (16 Years [Kohlberg])

- Social contracts understood and formulated
- Laws recognized as changeable
- Correct actions depend on standards and individual rights

Stage 6: Adulthood (Kohlberg)

- Abstract moral principles govern behavior
- Morality is easily separated from legality
- Orientation is based on universal, ethical orientation
- Able to apply situational ethics

Spiritual

Stage 3: Synthetic/Invention (Preadolescent [Fowler])

- Reflections and questioning of religious beliefs as gains more contact with people whose values and beliefs are different
- Seeking to resolve moral conflicts by appealing to outside authority figures rather than using own inner resources
- Learning to distinguish more clearly between supernatural versus natural
- Perceiving God as a spirit
- Beginning to understand spiritual component of individuals

Stage 4: Individuating/Reflexive (Adolescent [Fowler])

- Seeking to establish and maintain balance regarding religious/spiritual questions and beliefs; adapting “devil-may-care” attitude or going to other extreme and joining zealous religious group, or may suspend effort to resolve conflict

CHART 7-1 QUICK REFERENCE TO CONDITIONS COMMON DURING ADOLESCENCE

Condition	Chapter
Acne	25: The Child With Altered Skin Integrity
Alcohol and substance abuse	29: The Child With a Mental Health Condition
Anorexia/bulimia	29: The Child With a Mental Health Condition
Depression	29: The Child With a Mental Health Condition
Diabetes type 2	26: The Child With Altered Endocrine Status

adolescents, strategies to assist adolescents to manage changes in their life, and methods to manage family conflict (NIC 7–2).

Changes Related to Puberty

Puberty encompasses the changes following gonadarche (sexual maturation) and adrenarche (maturation of the cortex of the adrenal glands). Puberty is considered “as an interconnected suite of changes with wide variations in the sequence and timing of its components” (Patton & Viner, 2007, p. 369). Biologic changes include the maturation of the growth hormone insulinlike growth factor and thyroid axes. These lead to a pubertal growth spurt; maturation of many organ systems; and changes in blood

lipids, hematologic indices, and enzyme systems (Patton & Viner, 2007). The onset of puberty occurs in boys at about 13 to 15 years of age and in girls as early as 9 to 16 years of age. During this period, the child may become very modest and self-conscious. Adults must avoid even “good-natured” teasing, because it may cause embarrassment as the child becomes extremely sensitive about his or her body image.

As the teenager reaches puberty, many physical changes occur. In females, the earliest sign is usually thelarche, or the development of breast tissue, followed by the development of pubic hair and then the ultimate hallmark of late puberty, **menarche**, the first menstruation. Menarche usually occurs at about 12 years of age, although menarche at any time within the range of 9 to 16 years of age is not abnormal. This event is a symbolic achievement of womanhood in a young girl’s life, and it should be accompanied by open discussion and accurate information about the normal changes the body undergoes. Girls will have questions about exercise, hygiene, sanitary protection, and pain. Encourage parents to be supportive and understanding with the changes, both physical and emotional, that their daughter is experiencing.

In males, the earliest sign of puberty is testicular enlargement, followed by some penile growth and the development of pubic hair. Boys experience their voices “cracking” as the larynx and vocal cords grow to their full size and the voice becomes deeper and more resonant. Boys also experience growth spurts, and possibly “wet dreams” or spontaneous erections. Neither the spontaneous erections nor the wet dreams (nocturnal seminal emissions) mean that the child is sexually active or having overactive sexual thoughts. Parents may need to be instructed that these occurrences are spontaneous and that the child is not doing anything to cause them.

Both boys and girls usually experience a growth spurt of 3 to 4 in during the next 2 years. Body composition changes include an increase in total body fat and fat-free mass, with a greater increase in fat-free mass in boys than in girls (Biro & Dorn, 2005). **Tanner staging** is a method used to determine the adolescent’s stage of growth according to established parameters of physical development (see Figs. 3–16 and 3–17).

Although many adolescents are physically mature, research indicates that brain growth continues during the adolescent years, extending well into the 20s. Therefore, when interacting with a physically mature adolescent it is easy to treat the individual as a young adult, when in fact thinking patterns, processing abilities, and reactions to stressful stimuli are not the same as those in the mature adult brain. For instance, the last part of the brain to mature is the prefrontal cortex, responsible for rational, executive brain functions. When this frontal section is not fully developed, adolescents use the temporal lobe to interpret and act on emotional stimuli. This immature brain function means they are likely to behave more impulsively, misread emotional cues, and lack emotional insight (Herrman, 2005). In addition, hormones are believed to affect brain development and behavior. Increased dopamine and decreased serotonin levels are

NIC 7–1 Nursing Interventions Classification: Developmental Enhancement: Adolescent

Definition: Facilitating optimal physical, cognitive, social, and emotional growth of individuals during the transition from childhood to adulthood

Activities:

- Build a trusting relationship with adolescent and adolescent caregivers
- Encourage adolescents to be actively involved in decisions regarding their own healthcare
- Discuss normal developmental milestones and associated behaviors with adolescent and caregivers
- Screen for health problems relevant to the adolescent and/or suggested by patient history (e.g., anemia, hypertension, hearing and vision disorders, hyperlipidemia, oral health problems, abnormal sexual maturation, abnormal physical growth, body image disturbances, eating disorders, poor nutrition, alcohol, tobacco or drug use, unhealthy sexual behavior, infectious disease, poor self-concept, low self-esteem, depression, difficult relationships, abuse, learning problems, or work problems)
- Provide appropriate immunizations (e.g., measles, mumps, rubella, diphtheria, tetanus, hepatitis B)
- Provide health counseling and guidance to adolescent and adolescent's caregivers

- Promote personal hygiene and grooming
- Encourage participation in safe exercise on a regular basis
- Promote a healthy diet
- Facilitate development of sexual identity
- Encourage responsible sexual behavior
- Provide contraceptives with instruction for use, if needed
- Promote avoidance of alcohol, tobacco, and drugs
- Promote vehicle safety
- Facilitate decision-making ability
- Enhance communication skills
- Enhance assertiveness skills
- Facilitate a sense of responsibility for self and others
- Encourage nonviolent responses to conflict resolution
- Encourage adolescents to set goals
- Encourage development and maintenance of social relationships
- Encourage participation in school, extracurricular, and community activities
- Enhance parental effectiveness of adolescents
- Refer for counseling, as needed

From Bulechek, G., Butcher, H., & McCloskey Dochterman, J. (Eds.). (2008). *Nursing interventions classification (NIC)* (5th ed.). St. Louis: Mosby. Reprinted with permission.

known to lead to a desire for novel, risky, and intense stimuli (Wallis, 2004). Although much research still is needed to explore the relationship between changing hormone levels, brain development, and adolescent behavior, healthcare providers must remember to intervene with teens as teens, and not as young adults. As Herrman (2005, p. 147) states, “understanding of the cognitive abilities of teens, which may be constrained by physiological function, is integral in creating individually based, developmentally appropriate strategies.”

HYGIENE AND PERSONAL CARE

Most parents feel that by the adolescent years they have provided their children with the skills to manage personal hygiene (bathing, hair, teeth), to dress themselves, and to make good choices when balancing day and nighttime activities. Not surprisingly, these same parents are befuddled by the 13-year-old who stays up until midnight, then complains of being “so tired” the next day; the 15-year-old who wears one set of clothes when leaving the house, only to change into another set at school; and the 17-year-old who insists on two to three showers a day. During the time teenagers are developing pubic hair, the

males are also developing some chest hair, and both sexes are developing axillary hair. This is a time to discuss the use of deodorants and regular bathing schedules. As boys develop facial hair, they will need to be taught how to shave.

Hygiene and personal care can become sources of family arguments as the young person develops their own style of personal care. Parents need to maintain family rules and boundaries regarding aspects of personal care, while at the same time providing adolescents the latitude to develop their own personal care standards and daily patterns (Fig. 7–1).

Acne

A common occurrence during the teenage years is the appearance of acne vulgaris or common acne. Acne vulgaris is an inflammation of the sebaceous glands and hair follicles of the skin, characterized by comedones, papules, and pustules. Cysts and nodules may develop, and scarring is a common occurrence. Acne appears in both males and females, but more predominantly in males. It usually occurs on the face, neck, back, and upper chest. Although it may last into adulthood, it is usually most severe during adolescence. Chapter 25 discusses care management for

NIC 7–2 Nursing Interventions Classifications: Parent Education: Adolescent

Definition: Assisting parents to understand and help their adolescent children

Activities:

Ask parents to describe the characteristics of their adolescent child

Discuss parent–child relationship during earlier, school-aged years

Discuss disciplining of parents themselves when they were adolescents

Teach normal physiologic, emotional, and cognitive characteristics of adolescents

Identify developmental tasks or goals of the adolescent period of life

Identify defense mechanisms used most commonly by adolescents, such as denial and intellectualization

Address the effects of adolescent cognitive development on information processing

Address the effects of adolescent cognitive development on decision making

Have parents describe methods of discipline used before adolescent years and their feelings of success with these measures

Describe the importance of power/control issues for both parents and adolescents during adolescent years

Teach parents essential communication skills that will increase their ability to empathize with their adolescent and assist their adolescent to solve problems

Teach parents methods of communicating their love to adolescents

Explore parallels between school-aged dependency on parents and adolescent dependency on peer groups

Reinforce normalcy of adolescent vacillation between desire for independence and regression to dependence

Discuss effects of adolescent separation from parents on spousal relationships

Share strategies for managing adolescent's perception of parental rejection

Facilitate expression of parental feelings

Assist parents to identify reasons for their responses to adolescents

Identify avenues to assist adolescent to manage anger

Teach parents how to use conflict for mutual understanding and family growth

Role-play strategies for managing family conflict

Discuss with parents issues over which they will accept compromise and issues over which they cannot compromise

Discuss necessity and legitimacy of limit setting for adolescents

Address strategies for limit setting for adolescents

Teach parents to use reality and consequences to manage adolescent behavior

From Bulechek, G., Butcher, H., & McCloskey Dochterman, J. (Eds.). (2008). *Nursing interventions classification (NIC)* (5th ed.). St. Louis: Mosby. Reprinted with permission.

the youth with acne. The presence of acne can be very distressing and can affect self-esteem. Pharmacologic, nutritional, and skin care interventions can be implemented to help treat acne vulgaris.

Body Shaving

Body hair removal has been done for years by both adolescents and adults. Hair typically removed has included facial hair on men, and leg and underarm hair for women. Removal of hair on other parts of the body has become more popular in recent years and is being seen more often in the adolescent population. The extent of hair removal may be localized (e.g., the pubic area) or may encompass all areas of the body, including head, chest, arms, and legs.

Health concerns have escalated with these shaving practices, because they have been associated in the adolescent population with an increased incidence of folliculitis caused by *Staphylococcus aureus*. Concerns also exist about adolescents sharing razors when participating in shaving parties. Blood-borne pathogens and infectious

agents can be transferred when shaving supplies are shared. In addition, shaving in any area can cause skin irritation and increases the skin's exposure to ultraviolet rays. Discuss safe shaving practices with the adolescent and ensure that any rashes or reddened areas that develop on the skin are evaluated by a healthcare prescriber. Topical or oral antibiotics may be needed. Skin irritation can be minimized by applying soothing ointments (prescribed by the healthcare provider), wearing loose clothing, and ensuring that good skin care practices are maintained.

Tattooing, Body Piercing, and Branding

Adolescents make deliberate decisions to engage in body ornamentation for the purposes of self-expression, sexual expression, and to exert a sense of control (Armstrong, Caliendo, and Roberts, 2006; Elkind, 2001; Gold et al., 2005) (Fig. 7–2). According to some studies, between 10% to 15% of adolescents have a tattoo, and more than 25% of adolescents have at least one piercing (Carroll et al., 2002; Martel and Anderson, 2002; Sweeney, 2006).

FIGURE 7-1. Adolescents can be very concerned about personal appearance.

Piercings are most commonly performed in the earlobe and ear cartilage; yet may be frequently performed on the nose, nipples, and genital sites (foreskin, penis, scrotum, clitoris, perineum, and labia). Branding is another form of body art that may be seen in the adolescent population. It is a form of scarification done with a third-degree burn to the skin. After the burn heals, a design of scar tissue is left behind on the skin surface.

Encourage the adolescent to seek the expertise of a trained technician, doctor, or nurse to have the piercing, tattooing, or branding done. Although states vary in their approaches to licensing these technicians, the Association of Professional Piercers and the Alliance of Professional Tattooists (see [thePoint](#) for Organizations) have devel-

FIGURE 7-2. Having multiple piercings and tattoos can lead to certain health risks.

oped safety rules for those who do piercings and tattoos. Branding has not yet been regulated. Adolescents younger than 18 must be accompanied by a parent or guardian to grant permission to the salon and to sign a consent form before piercing or tattooing is done.

Tattoos, body piercings, and brandings can be painful. They carry risks of complications such as infection, blood-borne diseases, keloid and/or granulomas, allergic reactions, excessive bleeding, nerve damage, or damage to the piercing site (Levin, Zadik, and Becker, 2005). Complications are more likely when an adolescent does his or her own.

KidKare ■ Before getting a piercing or a tattoo, adolescents should verify with their healthcare providers that their tetanus shots are current.

Posttattoo care includes wearing a bandage over the area for the first 2 to 13 hours. The site needs to be washed gently with mild soap and warm water, patted dry, and allowed to air-dry for 10 minutes. Apply Polysporin, Bacitracin, or A&D ointment sparingly a few times each day for 3 to 14 days. Use of petroleum jelly will drain the color from the tattoo, and use of alcohol will interfere with healing. The tattooed area should not be soaked in water or shaved until healing is complete. The goal of posttattoo care is to prevent scab formation and allergic reaction.

Alert! Because tattoos are associated with risk for blood-borne diseases, the American Red Cross requires a person to wait 1 year after getting a tattoo before donating blood.

Healing time for piercings varies from 1 to 6 months, based on the location of the piercing. If adolescents tire of their piercings, the jewelry can be removed and the pierced opening will close. Some scarring may remain. If an allergic reaction occurs, the piercing should be removed. For a comprehensive teaching plan to be implemented when an adolescent chooses to have a piercing see [thePoint](#) for Supplemental Information: Teaching Intervention Plan.

Branding aftercare involves cleaning the area with soap and water, and applying a bandage until the wound is healed.

Body Modification

Adolescents are becoming increasingly more interested in body modification surgery—that is, plastic surgery as a means to change body appearance. Perceived or real physical defects may be the driving motivation for an adolescent trying to establish self-image and adjust socially to change his or her body appearance. These body image concerns can erode self-esteem and have severe consequences on an adolescent's development.

As the adolescent explores surgery options, learning what the adolescent wants and what they perceive the plastic surgery may have to offer is essential. Ensure that adolescents have realistic goals and that the outcomes are something that they want, not something a parent or another influential person wants for them. When educating adolescents, ensure that they understand the part of the body that will be involved and how that body part may change as the body matures. As with tattoos and body piercings, the adolescent must have parental consent and be fully aware of associated risks before undergoing the surgery.

Oral Care

By the time the child has reached adolescence, ensure that twice-a-year dental checkups have been established, as well as good oral hygiene habits. By 12 years of age, most, if not all, of the primary teeth have been shed. Eruption of permanent teeth is generally completed between the ages of 11 and 13, except for the wisdom teeth, which do not complete eruption until between the ages of 17 and 21. Orthodontics may be needed for oral malocclusions or to improve aesthetic appearance of the teeth. If the teenager has orthodontic appliances, reinforce the need to provide enhanced dental hygiene, because such appliances increase the opportunity for dental caries if dental hygiene is poor. The incidence of dental caries usually declines as the child matures; however, the risk of gingivitis and caries can increase during adolescence resulting from such factors as poor oral hygiene, frequent exposure to natural and refined sugar in the adolescent diet, immature enamel present on newly erupted teeth, and erosion of the dental enamel from eating disorders such as bulimia (Hagan et al., 2008).

Many of the high-risk behaviors that adolescents participate in can affect oral health. For instance, adolescents who use smokeless tobacco are at a risk of developing gingivitis, gum recession, stained teeth, or halitosis. Substance use can affect soft and hard tissues of the oral cavity and lead to oral cancer. Oral piercings can cause local infections in the oral cavity, tooth fractures, and hemorrhage. Sexual activities can lead to oral infections and trauma (Hagan et al., 2008).

Sleep

QUESTION: Ashley frequently complains that she is tired and does not sleep well. If you were the school nurse, what might you further assess related to Ashley's sleep pattern?

The teenager needs about 8½ to 10 hours of sleep per night. Sleep patterns experience a normal phase delay, with a shift occurring from the early bedtime hours and early rising of childhood to late-night slumber and (when given the opportunity) late-morning rising (Durmer & Chervin, 2007). During this age, with the increase in

social and school activities, homework requirements, and possibly work activities, ensuring that the adolescent receives enough sleep at night is important. Between 25% and 40% of adolescents complain of sleep problems, with at least 4% diagnosed as having clinically relevant **insomnia** disorder (inability to sleep) (Ohayon et al., 2000; Wolfson & Carskadon, 2005). Parents and healthcare professionals need to be alert to abnormal sleep patterns, because they could indicate some other underlying problem, such as sleep apnea, drug abuse, or depression. Teenagers should be sleeping uninterrupted through the night, without nightmares or sleepwalking. If any of these aberrations is present, the teen should be seen by a healthcare provider to determine whether an underlying cause exists.

Insufficient sleep has been linked to impaired daytime functioning, depressed mood, and poor school performance (Eliasson et al., 2002; Fuligni & Hardway, 2006). The challenge confronting many teenagers is that they are not behaviorally or psychologically ready to sleep until 11:00 PM or later. Many schools start classes too early for the adolescent to get adequate sleep. Start times generally range between 7:30 and 8:15 AM. High schools in Minneapolis changed their start times from 7:15 to 8:40 AM. Attendance, enrollment, grades, and sleep patterns were evaluated before and after the change for the 18,000 high school students affected by this change. Significant results of the later school start time included improved attendance rates, slight improvements in grades, and student reports of getting more sleep (Wahlstrom, 2002). Other studies have confirmed that early school start times are associated with daytime sleepiness, dozing in class, attention difficulties, and poorer academic performance (Baroni et al., 2004; Wahlstrom, 2002).

Clearly, many factors affect the amount of sleep a teenager receives each night. Creative changes in scheduling school, practice times (which often start before school), late-evening activities (including work), and homework can be implemented by parents and school officials to assist teenagers to get the daily rest they need.

ANSWER: Further assess her sleep habits but also consider the possibility that she may be sleeping poorly because of underlying depression or anxiety. Given the tension between Ashley and her parents, it is a possibility that these emotions are affecting her sleep.

NUTRITION

QUESTION: Ashley is very thin and tells you that she is avoiding eating at home. She reports that she mostly eats small quantities of junk food and she almost never drinks milk. What information can you share with Ashley to help her make better nutritional choices and establish better nutritional habits?

The growth rate during adolescence is second only to what occurs during infancy. Typically, the adolescent's

weight doubles, and height increases by about 25%. Heredity, nutrition, and general health influence the teen's eventual stature.

Teenagers are growing quickly and use enormous amounts of energy. This internal blast furnace keeps them hungry most of the time, and as they test their independence, food choices may be one of the areas of conflict between adolescents and parents. Allowing the teen to make some choices is important, so that food does not become a battleground. Many teenagers do not eat a good breakfast. They may even skip breakfast because they tend to be in a hurry in the morning or believe that it is not important. A nutritious breakfast gives the teenager energy for a good day at school or to accomplish athletics before school. Ensure the teenager is receiving a balanced diet based on the U.S. Department of Agriculture food pyramid, with a caloric intake of 1,500 to 2,400 calories, although some athletes may need substantially more. Dietary strategies for adolescents include the following approaches (American Academy of Pediatrics, 2005a; Hagan et al., 2008):

- Balance calorie intake with physical activity.
- Ensure daily physical activity lasting 60 minutes or longer.
- Eat fruits and vegetables liberally; limit juice intake.
- Use vegetable oils and margarines low in saturated fats and trans fatty acids.
- Eat whole grain products (bread, cereals).
- Reduce intake of sugar-sweetened beverages (e.g., sodas) and foods.
- Drink non-fat or low-fat milk.
- Reduce salt intake.
- Eat more legumes and tofu instead of meats.
- Limit snacking during sedentary activity.
- Take a supplemental daily vitamin.

In addition, several nutrients may need to be added to the adolescent's diet including folate, iron, and calcium. Folate is recommended for all female adolescents who are capable of becoming pregnant to reduce the risk of giving birth to a child with a neural tube defect. A total of 400 μg folate per day should be ingested from fortified foods and/or a supplement (Hagan et al., 2008).

Rapid growth during the adolescent years leads to an increase need for iron. Females have an increased need and are at risk for iron-deficiency anemia as a result of blood loss through menstruation. Boys (and to some extent girls) require increased iron to manufacture myoglobin for expanding muscle mass and hemoglobin for expanding blood volume (Hagan et al., 2008). The recommended iron intakes for adolescents are

- Age 9 to 13 (females and males): 8 mg/day
- Age 14 to 18 (females): 15 mg/day
- Age 14 to 18 (males): 11 mg/day

Last, calcium intake needs to be increased as a result of the bone mass development that occurs during adolescence. Dietary requirements are as follows:

- Age 9 to 18 years: 1,300 mg/day
- Age 19 years and older: 1,000 mg/day

Overeating comes naturally for adolescents pressured by peers to participate in activities that involve food consumption and is driven by the media to consume fast-food products. Media and peer pressure may also contribute the development of anorexia nervosa or bulimia. Both of these conditions are psychological illnesses that present as physical symptoms. For further discussion, see Chapter 29: The Child With a Mental Health Condition. Parental role modeling of good nutritional habits is essential. Continuing to plan for regular family mealtime will both promote social interaction and will role-model food-related behaviors for the teen.

ANSWER: Share with Ashley the food pyramid, but keep in mind that the number of servings identified may seem like a lot to her. To further assess what Ashley is eating you could ask her to keep a food diary for several days to a week. Encourage Ashley that making better food choices will also make her feel better. Review her food diary with her and, in particular, encourage her to think of fruits and vegetables that she could substitute for the processed snack she is currently eating. For example, apples are great "to go" food. If Ashley is not drinking milk, discuss alternative sources for vitamin D and calcium. Be sure to follow up with Ashley. Your concern at this stressful time is very therapeutic.

It is estimated that 24% to 29% of the entire adolescent population uses dietary supplements (Dorsch & Bell, 2005). Dietary supplement are those products intended to supplement the diet that contain one or more of the following dietary ingredients: a vitamin, mineral, amino acid, herb or other botanical; a dietary substance for use to supplement the diet by increasing the total dietary intake; or a concentrate, metabolite, constituent, extract, or combination of any ingredient just mentioned (Dorsch & Bell, 2005, p. 653). Dietary substances are ingested in the form of a capsule, powder, softgel, or gelcap, and are not represented as a conventional food or as a sole item of a meal or the individual's diet. Adolescents may choose to use these supplements to maintain or improve their health, increase energy, build muscle, increase or decrease weight, supplement an adequate dietary intake, or help healing during an illness or injury. Energy drinks are beverages that, when consumed, promise to deliver a burst of energy, and are among the most popular type of dietary supplement consumed by adolescents. The drinks contain caffeine, sugar, and other ingredients such as ginseng, taurine, guarana, and B-complex vitamins. Sale of these beverages has been aimed at students, athletes, and active individuals age 21 to 35. However, younger individuals are consuming these products to give them stamina, physical endurance, mental alertness, and an overall sense of well-being. Energy drinks have many adverse effects, especially when taken after exercise or mixed with alcohol. Deleterious effects include insomnia, headaches, nervousness, nosebleeds, vomiting, seizures, heart arrhythmias, and even death (Braganza & Larkin, 2007; Kapner, 2004).

Most dietary supplements, although safe and effective for adult populations, may have adverse side effects for adolescents, and the actual effectiveness of these supplements on

adolescents is unknown (Dorsch & Bell, 2005). The safety, purity, potency, and efficacy of dietary supplements have not been regulated. Given this information, caution adolescents about dietary supplement use and encourage healthy dietary intake instead of using products to supplement the vitamins and other health ingredients found in food on the food pyramid.

Obesity

Obesity (body weight more than 20% more than the ideal weight) is of some concern at this age. Preserving self-esteem is crucial for teens, and obesity carries with it a stigma in today's society. Adolescents with a BMI that is at or above the 85th percentile and below the 95th percentile for age and gender are classified as being *at risk for overweight*; those above the 95th percentile for age and gender are classified as **overweight** (Durant & Cox, 2005; Reilly, 2007). BMI categories for children and adolescents are age and sex specific, and do not correspond precisely to adult BMI categories; however, a BMI in the highest percentile, whether it is defined as “obese” or “overweight,” represents unhealthy excess weight. The prevalence of overweight youths ranges from 15% to 20% among 12- to 19-year-olds (Calderon et al., 2005; Durant & Cox, 2005). The primary health-related consequences include type 2 diabetes and hypertension. Causes of adolescent obesity include lack of physical activity, frequent television watching, and high consumption of fat calories (Calderon et al., 2005; Regber et al., 2007).

Intervention plans for both preventing and treating adolescent obesity must include dietary adjustments, regular physical activity, and behavioral change. Childhood and adolescent obesity is considered an epidemic. Adolescents must work in collaboration with the healthcare team, parents, the school, and the community to implement the strategies that will help youths successfully manage their weight and provide opportunities for engaging in physical activity.

PHYSICAL FITNESS

If physical fitness has been introduced at an early age, and if parents are role models, most likely the adolescent exercises regularly through competitive or individual sports. Many adolescents still are not as physically active as they should be. Encourage adolescents to develop a habit of exercising. The positive benefits of physical activity for the adolescent include

- Fosters a feeling of accomplishment
- Reduces the risk of certain diseases (e.g., coronary heart disease, diabetes mellitus)
- Promotes mental health
- Assists in achieving healthy body weight and composition, reducing the risk of obesity
- Promotes a healthy lifestyle throughout life

Provide the adolescent with many opportunities to engage in physical activity while in school and through community organizations. In these venues, a positive

approach to physical activity is essential (Community Care 7–1). Hazards can occur from rough physical contact while engaging in a sport, from predisposing health issues of participating adolescents, from environmental factors (e.g., rain, lightning), and from malfunctioning equipment. The physical and social environment in the school and community should encourage participation in physical activity in a safe setting, under the supervision of adults trained in physical education, health education, and safety standards for athletes (American Academy of Pediatrics, 2000; Patrick, Spear, Holt, & Sofka, 2001; Walsh et al., 2000) (Fig. 7–3).

Enjoyment of the particular activity appears to enhance the motivation to participate in that activity. The adolescent with a medical condition need not necessarily be restricted from sports participation. Sickle-cell disease, HIV infection, and diabetes are examples of chronic conditions that should not prohibit participation in sports activities. In contrast, youths with fever or carditis are considered to be at too high of a cardiopulmonary risk to participate in sports activities. The American Academy of Pediatrics (2001b) provides recommendations for sports participation for more than 35 medical conditions. In general, for most chronic health conditions, the American Academy of Pediatrics supports participation by affected youths in sports activities (American Academy of Pediatrics, 2001b).

Teenagers need to develop their coordination and are still gaining muscle strength. Female adolescents stop increasing muscle strength at the time of their first menses, but males continue to increase their strength until they reach adulthood. A safe and structured regimen of daily physical activity will enhance coordination and normal adolescent development. However, physical and physiologic changes in the growing adolescent also place the youth at high risk for injury when engaging in physical activity. **Strength training**, the use of resistance methods to increase muscle ability to exert or resist force, is popular among adolescents and is often required in sports training programs. Strength training can be beneficial for youths to improve sports performance, rehabilitate after injury, prevent injuries, and enhance long-term health. No detrimental effects have been documented on cardiovascular health or linear growth of adolescents participating in weightlifting (American Academy of Pediatrics, 2001d). Strength training may cause injury, however, when improper lifting techniques are used, too much weight is lifted, or lifts are improperly supervised. Adolescents should avoid competitive weightlifting, power lifting, body building, and maximal lifts until they have reached full skeletal and physical maturity (American Academy of Pediatrics, 2001d) (see Tradition or Science 7–1).

PERSONAL AND SOCIAL DEVELOPMENT

The emerging identity of the adolescent is strongly affected by family and peer relationships. Parents will want to continue to monitor the youth's choice of friends,

COMMUNITY CARE 7-1

Components of an Adolescent's Physical Fitness Program

Goal: Develop a Positive Attitude About Fitness

- Enjoy participating in physical activities.
- Recognize positive outcomes of regular physical activity.
- Feel competent when participating in physical activity.
- Have positive role models for physical activity.
- Select activities that reflect individual needs and interests, and that can be continued into adulthood.
- Incorporate physical activity into daily life.

Goal: Participate in Physical Activity on a Regular Basis

- Be physically active every day or nearly every day through planned activities within context of the family, school, or community.
- Engage in moderate physical activities (e.g., brisk walk) or shorter, more intense activity (e.g., basketball) daily for 60 minutes.
- Participate in a variety of noncompetitive sports (e.g., skating, biking).
- Participate in competitive, organized sports as desired.

Goal: Meet Age-Appropriate Nutritional Requirements

- Practice healthy eating behaviors that help achieve healthy body weight and composition, and provide sufficient energy to engage in physical activity.

- Abstain from using alcohol, tobacco, drugs, and ergogenic aids.

Goal: Engage in Cooperative and Team-Building Experiences

- Engage in physical activities with family members.
- Seek opportunities for team sports, ensuring that all players are given equal opportunity for participation and skill building.

Goal: Prevent Injury

- Ensure the use of appropriate safety equipment (e.g., helmet, knee pads, and wrist guards) during physical activity.
- Ensure appropriate supervision during physical activity (e.g., monitoring during use of weights or gymnastic equipment).
- Ensure that the environment is safe for the indoor or outdoor activity selected (e.g., bike paths, well-maintained recreation centers).
- Monitor pacing of activity to ensure injury does not occur from overexertion.
- Reduce exposure to the sun by appropriate use of sunscreen, clothing, and hats to protect the skin.

From Patrick, K., Spear, B., Holt, K., & Sofka, D. (Eds.). (2001). *Bright futures in practice: Physical activity*. Arlington, VA: National Center for Education in Maternal and Child Health.

including those associations developed at school and social venues (e.g., church, sports teams) and even through online communications.

FIGURE 7-3. Basketball is an example of an activity that promotes physical fitness and helps the adolescent learn to work with others in a small group.

Temperament

QUESTION: Which aspects of Ashley's behavior might be affected by the conflict of cultural norms between her and her parents?

Temperament has been defined as the inherent way a person responds to environmental stimuli (see Chapter 4). Although temperaments are evident from infancy, the clash of temperaments between the child and that of his or her parent may seem to be at its greatest state of disconnect during the adolescent years. The “fit” between the adolescent's temperament and the parenting style is further challenged by adolescents' need to distance themselves from their parents emotionally, intellectually, and physically. As youths progress through the adolescent years, they challenge parental norms by testing behavior limits and by testing parents' beliefs and values. Parents can easily perceive that the child is “out of control.”

TRADITION OR SCIENCE 7–1

Are any potential dangers associated with backpack use in children and adolescents?

EVIDENCE-BASED PRACTICE

Backpack use has become an effective method of carrying school supplies in an era when lockers have been banned from many campuses. Research has concluded that when children or adolescents carry more than 10% of their body weight, they experience kyphotic postures that diminish lung capacity. Backpacks that weigh more than 15% of body weight are too heavy for a child or adolescent to maintain a standing posture. Carrying a backpack with one strap changes posture and gait. Over a prolonged period, children may experience back pain, exacerbation of functional scoliosis, and stress on the spine and surrounding muscles (Chansirakorn et al., 2001; Chow et al., 2005; Grimmer, Williams & Gill, 1999; Lai & Jones, 2001; Navuluri & Navuluri, 2006; Pascoe et al., 1997; Rateau, 2004; Sheir-Neiss, et al., 2003). To prevent injury, it is recommended that backpacks be weighed and that children and adolescents carry only 5% to 15% of their total body weight. Adolescents should be made aware of their posture and should be discouraged from leaning forward to correct for the heavy weight in their backpacks. Both shoulder straps should always be used when carrying the pack; incorporating hip or pelvic straps may further eliminate back strain. Weight in the pack should be evenly distributed. Backpacks on wheels, although not viewed as fashionable, are an excellent alternative to a conventional backpack (Brackley & Stevenson, 2004; Rateau, 2004).

Young adolescents demonstrate a need to be separate from parents by establishing same-sex peer groups. These young teens vacillate from being clingy and infantile at one moment to being distinctly uncomfortable in the presence of their parents in the next. During middle adolescence, the teenager may spend more time ignoring adult authority and become much more reliant on peer relationships. During this period, the adolescent might choose a stance directly opposite that of their parents and use peer support to back their ideas. Mood swings, a common occurrence during the early adolescent period, tend to smooth out during the middle adolescent period, when the teen will become more introspective. By late adolescence, emotions smooth out and become more consistent. The adolescent who has navigated successfully through early and middle adolescence usually comes to understand that their parents are “fine folks” and that they actually agree with their parents’ standards and values (Brown & Friedman, 2001).

Successful adaptation during the adolescent years does not depend on the presence or absence of certain temperament styles. Parents and children need to understand and accept that adolescents will at times be sullen, verbally defiant, moody, and oppositional. These behaviors are normal expressions of adolescents striving to separate from their parents. To alleviate parental anxiety and to

assist in reducing hostilities in the home, educate parents about normal adolescent separation behavior. Further assistance can be given through counseling and support groups to seek a better fit between the parenting style and the child’s temperament, and to develop strategies to help both parent and child traverse the stages of normal development.

WORLDVIEW: A conflict of cultural norms may create situations in which parents consider a youth to be “out of control” (i.e., oppositional, exhibiting conduct and behavioral problems). Immigrant parents from a traditional, patriarchal parenting style may believe their adolescent is out of control when the teen is behaving in a fashion typical of adolescents in today’s American society.

ANSWER: The conflict with Ashley’s parents affects many aspects of her health. Consider the following questions: Do you think the additional stress from cultural conflicts is affecting Ashley’s sleep and nutritional behaviors? Do you think there might be a relationship between Ashley’s desire to fit in American culture and her sexual behaviors with her boyfriend Eric?

Relationships

This is the time that adolescents establish an identity for themselves outside the family. They use their friends to elicit responses to their ideas and actions as they evolve into adults. During the early part of adolescence, teenagers usually are preoccupied with what is happening to themselves physically. They use peer groups to stabilize themselves emotionally while entering puberty. Young adolescents usually have one very “best” friend of the same sex. Parents are still important to them, even though they are trying to separate from the family.

As youths enter middle adolescence, making friends becomes easier as adolescents develop a greater repertoire of social skills and have expanded social opportunities through school and extracurricular activities. Teenagers use peers for the validation and approval they sought from their parents during earlier years. Peer relationships are extremely important, because the group forms formal and informal standards that teens use to measure themselves (Fig. 7–4). This stage is usually the low point in parental relationships, as adolescents push for independence and separation. Major conflicts may erupt as teens detach themselves from parental bonds.

By late adolescence, the teenager is less dependent on peer groups and develops more individual relationships, including romantic or intimate relationships. The emancipation from the parental bond is complete, and the young adult tends to have far less conflict with the family.

Despite the changing dynamics between parent and adolescent during this time, research indicates that adolescents who perceive that at least one parent cares about them and loves them are less likely to participate in risk-taking behaviors. Parent and family connectedness is a strong protective factor in helping youths to remain

FIGURE 7–4. Adolescents develop relationships with their peers that provide a source of support and companionship.

resilient when faced with adversity and challenges during the adolescent years (Loewenson & Blum, 2001). Parental presence and monitoring (i.e., at least one parent is home at specific times, such as before or after school, dinnertime, or bedtime) is perceived by adolescents as evidence that a parent cares about them. The perception that school achievement is important to the parent is another factor that reassures adolescents they are loved (Devore and Ginsburg, 2005; Loewenson and Blum, 2001). Parenting practices and parent–child relationships have a profound effect on adolescent development. Although healthcare providers continue to emphasize good nutrition and exercise, adequate sleep, and a balance of work and play to maintain adolescent health, the protective effects of good parenting should not be overlooked. The parent–adolescent relationship must be fostered to promote optimal adolescent health and resiliency.

Sexuality

QUESTION: Ashley confides to you that she and Eric have had unplanned and unprotected sex, but she doesn't think it will happen again. What should you say to Ashley?

During early adolescence, some self-exploration occurs, and adolescents might ask many questions about what is happening to them physically. As teenagers enter puberty, nurses should share correct information regarding the physical changes that will occur and what are normal physical changes and sexual desires during the adolescent years. Because of the influence of television and movies, many teenagers have an idealized body image or misinformation about sex. In many cases, excellent information is provided by a school health education course, but teenagers may still need answers about certain issues that they may be reluctant to discuss in a classroom setting. Encourage parents to share family values regarding sexual activity. Parents generally seem to shy away from discussing anything about sex with the teenager as a

result of discomfort or lack of information. Promote open lines of communication between parents and teens, so the teenager can go to the parent with problems or questions. Encourage parents to listen to their teens, rather than lecture them.

Initiation of sexual activity may begin during the latter school-aged years. Early initiation of sexual activity is most likely to occur in children with learning problems or low academic attainment, children with behavioral or emotional problems (including mental health and substance abuse), children from low-income families, victims of physical and sexual abuse, and children in families with marital discord and low levels of parental supervision (American Academy of Pediatrics, 2001c). Parental supervision has been demonstrated to have a significant affect on the initiation of early sexual activities. Close parental monitoring of the activities of children and adolescents has been shown to delay the onset of sexual activity (Wilder & Watt, 2002). Concern is raised because sexual activity before age 15 is also associated with other high-risk behaviors, including having sex with more than one partner, having intercourse without the use of contraception or use of latex condoms, having sex with strangers, and sexual activity associated with alcohol consumption (American Academy of Pediatrics, 2001c).

By middle adolescence, pairing off in couples is common. These relationships help the teenager develop emotional and behavioral autonomy (Fig. 7–5). The type and depth of the relationships vary, but as the teenager experiences his or her first “love,” sexual activity becomes more likely. Increased sexual activity has been found to be more likely in adolescents who look more physically mature, teens who have engaged in multiple romantic relationships, and in teens who report frequent alcohol or drug use (Siebenbrunner, Zimmer-Gembeck, & Egeland, 2007).

Around the age of 13 or 14, adolescents might question their social–sexual role identity. Homosexual orientation may develop as the adolescent's definition of his or her sexual attractions, thoughts, fantasies, behaviors, and lifestyles emerge to become more solidified toward same-sex attractions (Auslander, Rosenthal, & Blythe, 2005; Selekman, 2007). However, adolescent behavior might also just be exploratory or reflect peer pressure; therefore, do not make assumptions regarding the sexual orientation of any adolescent. Assist the adolescent to understand both the physical and psychosocial dimensions of their sexual development (NIC 7–3). By late adolescence, a consolidated sexual identity has developed, and the teenager is more comfortable in developing opposite-sex relationships that have no sexual element to them (see Tradition or Science 7–2). As the sexual identity of an adolescent emerges, sexual desires change and evolve. The adolescent may choose to become sexually active. With appropriate information regarding prevention of sexually transmitted infections and pregnancy, a teen might choose to delay sexual activity. However, education does not always mean that a teen will choose abstinence. Often, peer pressure and self-esteem influence adolescents in their actions more than education does. The nurse

FIGURE 7–5. Dating becomes an important aspect of teenage life.

interacting with the adolescent, either in the physician’s office or in the school, frequently is the professional who explains the teen’s responsibilities regarding sexual intercourse. Pregnancy and sexually transmitted infections are potential health risks for the adolescent engaging in

sexual activity. These health risks are discussed later in the chapter.

ANSWER: As important as the information you share is the attitude with which it is given. It must be nonjudgmental. State that you understand the conflict she is facing. Adolescents often perceive that they are the only ones who have ever had their feelings or experiences. Rather than using text as references (e.g., “Teenagers often . . .”), it is effective to personalize advice: “Another student told me that she did not realize how strong sexual feelings can be and that she used to really struggle because she believed good girls don’t need birth control or protection from sexually transmitted infections.” Emphasize to Ashley that it is important to have a plan that would protect her from pregnancy and STDs. Share current information regarding STDs in adolescents and give Ashley sources to review on her own. Emphasize her adult role in taking responsibility for her health and her behavior. Strongly recommend that she find a healthcare provider who she likes and trusts that can provide complete sexual health services.

NIC 7–3 Nursing Interventions Classification: Teaching Sexuality

Definition: Assisting individuals to understand physical and psychosocial dimensions of sexual growth and development

Activities:

- Create an accepting, nonjudgmental atmosphere
- Explain human anatomy and physiology of the male and female bodies
- Explain the anatomy and physiology of human reproduction
- Discuss signs of fertility (related to ovulation and the menstrual cycle)
- Explain emotional development during childhood and adolescence
- Facilitate communication between the child, adolescent, and parent
- Support parents’ role as the primary sexuality educator of their children
- Educate parents on sexual growth and development through the life span
- Provide parents with a bibliography of sexuality education materials
- Discuss what values are, how we obtain them, and their effect on our choices in life
- Facilitate the child’s and adolescent’s awareness of family, peer, societal, and media influence on values
- Use appropriate questions to assist the child and adolescent to reflect on what is important personally

- Discuss peer and social pressures on sexual activity
- Explore the meaning of sexual roles
- Discuss sexual behavior and appropriate ways to express one’s feelings and needs
- Inform children and adolescents of the benefits to postponing sexual activity
- Educate children and adolescents on the negative consequences of early childbearing (e.g., poverty and loss of education and career opportunities)
- Teach children and adolescents about sexually transmitted diseases (STDs) and AIDS
- Promote responsibility for sexual behavior
- Discuss benefits of abstinence
- Inform children and adolescents about effective contraceptives
- Instruct accessibility of contraceptives and how to obtain them
- Assist adolescents in choosing an appropriate contraceptive, as appropriate
- Facilitate role playing when decision making and assertive communication skills may be practiced to resist peer and social pressures of sexual activity
- Enhance self-esteem through peer role modeling and role playing

TRADITION OR SCIENCE 7–2

Does viewing television with sexual content affect adolescent sexual behavior?

MORE INQUIRY NEEDED

The American Academy of Pediatrics conducted a longitudinal survey of 1,762 youths age 12 to 17 about their viewing habits, sexual knowledge, attitudes, and behaviors. Adolescents who viewed sexual content more often were more likely than others to initiate intercourse and to progress to more advanced, noncoital sexual activities. Those who watched the greatest amounts of sexual content were twice as likely to initiate intercourse than those who watched the least. Exposure to talk about sex (only) was associated with the same risks as programs depicting sexual behavior (Collins et al., 2004). Similar findings were made by Brown et al. (2006) in a longitudinal study of 1,017 black and white adolescents. The teens' *sexual media diet* (SMD) was first evaluated when he or she was 12 to 14 years old. Two years later, the assessment was repeated. White adolescents with the highest SMD scores were 2.2 times more likely to have had sexual intercourse at the ages of 14 to 16 years than those with the lowest SMD scores. Sexual activity by black adolescents was found to be more influenced by parents' expectations and their friends' sexual behavior than by their SMD score. Clearly, exposure to sexual content in music, movies, television, and magazines may be a factor that strongly influences initiation of sexual activity in the adolescent population.

FIGURE 7–6. School is the center of learning as well as socialization for many teens. School classes, clubs, sports, and activities help shape their identity.

Homework may also be an issue for the teenager, because in high school and college, homework is usually more intense than in lower grades (Clinical Judgment 7–1). Parents are often not as involved with homework as they were when the child was school aged. Basic study habits should have been developed at an early age and may just need to be reinforced. Arrangements for homework, such as when it will be done and where, and the consequences that will occur if it is not completed, should be worked out at the beginning of the school year. Nagging, threats, and bribery do not appear to be effective with teenagers; occasional monitoring and negotiations usually produce better results.

As adolescents consider the next stage of their academic career, parents and school officials can provide guidance in completing applications and testing for college entrance. Many youths may choose not to pursue further academic studies at this point in their life. Career counseling can benefit both college-bound and work-bound youths. Whatever choices adolescents make for their post-high school years, ensuring that their choices reflect their unique skills and gifts is important.

School

QUESTION: Identify aspects of Ashley's case study that lead you to believe that the pressure Ashley feels to perform well in school is affecting her health. Do you think it is appropriate for Ashley to be assessed for depression?

School for the adolescent is very important. It is a center for socialization as well as learning (Fig. 7–6). High school is sometimes intimidating for the student coming from an elementary or middle school, so many schools are preparing their students with orientation days and visits before admission to high school. The high school is responsible for counseling the student to prepare for higher learning or vocational training. High school today is usually not the end of formal education. Most students are at least encouraged to apply to colleges. Sometimes teenagers feel a great deal of pressure to achieve high academic or athletic accomplishments, and this pressure can produce bouts of depression. When persistent depressive moods interfere with the adolescent's normal functioning, encourage the family to seek healthcare assistance (see Chapter 29).

ANSWER: The case history states that Ashley is avoiding meals at home, is very thin, and is not sleeping well. These indicate that the stress she is feeling both from pressure to perform well in school and the conflict with her parents is affecting her health. Yes, Ashley has several symptoms of depression and it warrants further assessment.

Internet Use

Computer use, at both home and school, has increased adolescent comfort in gaining access to and using the Internet to complete school projects, chat with friends, and seek personal entertainment. At the same time, this technology has introduced youths to an array of risks. These risks include exposure to inappropriate materials, exposure to harassment or threats through e-mail or chat rooms, safety concerns from sharing personal information, and even the potential for physical molestation or

CLINICAL JUDGMENT 7–1

The Student Failing in School

Brock is a 17-year-old junior in high school who has come to the school health office because he fell asleep in class and injured his head when he (and his desk) fell over, hitting a nearby table. The teacher accompanies Brock to the office and shares with you his concerns regarding this seemingly minor injury. He has noticed that Brock has been falling asleep a lot in his afternoon class and that his grades have deteriorated considerably. Once a very reliable student, Brock is now inconsistent in completing homework, and his test scores have declined.

After Brock leaves the office, you review his school file. You note that, indeed, his A average has dropped to a C average during the past school year. You casually ask other teachers how Brock is performing in their classes, and their answers reveal a consistent pattern of tardiness, falling asleep in class, and apathy about school performance. The teaching staff agree that a meeting with Brock and his parents might be helpful to determine the cause for these dramatic changes in Brock's academic performance.

Brock is informed of the meeting and becomes very angry, demanding, "Why the heck can't you guys just leave me alone? I am passing in all of my classes, so what's the big deal?" Brock's mother is surprised that a meeting has been called, because she is unaware of any problems with Brock's school performance. She is able to come to the meeting if it is scheduled late in the afternoon. She works nights and needs to sleep during the day. She reports that Brock's father will not be present, because he is in the military and was deployed overseas 4 months ago.

Questions

1. What questions would you ask Brock at the meeting about his activities?
2. What are the presenting issues that you would share with Brock to support the concerns regarding his declining academic performance and his increased fatigue?
3. During the discussion with Brock, he reveals that he has taken on a part-time job that his mother did not know about. How would you proceed at this point?
4. The meeting yields several concerns regarding how Brock spends and uses his time outside of school. How should you proceed with Brock and his mother?
5. What additional support can you provide this family as Brock makes a plan to refocus on his school activities?

Answers

1. Ask Brock to describe a typical week's schedule, detailing where and how he spends his time. Ask Brock specific questions about extracurricular activities, work, girlfriend, and peer group activities. Determine whether Brock has been involved in substance use and is receiving adequate nutrition. Determine his sleeping patterns. Ask Brock what he considers to be stressors in his life at this time.
2. Fatigue, decline in academic performance, tardiness.
3. Give Brock the opportunity to tell his mother about the job and the reason he chose to take it without her knowledge or permission. Provide support for both parties, should the discussion become loud or hostile.
4. Brock has shared that he is playing on the school baseball team and he leaves practice three or four days a week to go to his job until 11 PM. His mother works a 12-hour shift from 7 PM until 7 AM; thus, she had no idea he was not at home during these hours. He has been lying to her about where he is and what he has been doing. When she has called him on his cell phone, he always answered and said he was doing homework and had eaten dinner. Brock felt he had to work because he needed extra money to pay for his school activities but did not want to burden his mother. All members at the meeting need to develop a plan of action to support Brock's primary role—that of a student—while seeking means to assist the family if they are in financial crisis.
5. Brock and his mother may benefit from counseling, because they are dealing with issues of loss (father's absence), trust (Brock's lying), and stress, and need to discuss these issues at length. Brock must consider quitting his job or reducing the number of hours he works each week. He must also develop a plan with his parents and teachers to ensure his accountability in completing schoolwork. If his grades continue to drop, he should be prohibited from participating in extracurricular sports. Ensuring that Brock understands this consequence, and the potential harm he may incur from lack of sleep and poor nutrition (e.g., work injury, falling asleep while driving) may help him understand why such concern exists about the demands he has been placing on his time.

other injury (McColgan and Giardino, 2005). In addition, time spent at the computer is time that youths are not engaged in physical activity. Because youths commonly consume snacks and sodas while using the computer, Internet use has contributed to the epidemic of adolescent obesity.

Supervising Internet use is primarily a parental responsibility (Fig. 7-7). As with the use of other electronic media (television, music players, and handheld gaming devices), the adolescent will pursue these activities for endless hours, given the opportunity. Parental supervision is a key factor in maintaining safe use of all electronic media. The parent must first establish criteria for use of the computer, including when, where, and why it will be used (Developmental Considerations 7-2). Specific hours of the day can be selected for use in addition to delineating the amount of time used. Encourage youths and their parents to communicate about privacy issues, the appropriateness of the media, and the financial risks associated with Internet use. Lenhart, Raine, and Lewis (2001) found that although 69% of parents said they had rules about Internet use, only 37% of the teens in those same families reported being subject to any Internet use rules.

Computer and Internet use have tremendous benefits in terms of education, communication, and recreation. Providing computer use rules will give adolescents guidance in using the computer as a tool to benefit their education and relationships with others (Developmental Considerations 7-3). Diligent monitoring by parents will assist in maintaining the child's safety and will promote opportunities for ongoing discussion of information gleaned from Internet sites.

Work

In today's American society, it has become common for adolescents to hold part-time jobs during nonschool hours. The time spent in these part-time jobs can vary from a few weekend hours to daily work hours. That includes weekend commitments. The U.S. Department

FIGURE 7-7. Computer use should be monitored by parents to ensure the adolescent is safely accessing the Internet.

DEVELOPMENTAL CONSIDERATIONS 7-2

Guidelines for Parents Regarding Child and Adolescent Internet Use

- Discuss with the child or adolescent potential online dangers (e.g., access to violent or sexual images, sexual victimization, unwanted solicitations, scams).
- Keep the computer in a common area of the house, where computer activity can be viewed by other household members.
- If the youth has a computer in the bedroom, do not allow access to the Internet through that computer.
- Use parental control software to filter search results, block unsupervised surfing and chat room access, and turn off the computer after a specified time.
- Maintain access to the child's online accounts and periodically check the history of websites that the child accesses. Be honest with the child about your online activities.
- Limit children's and adolescents' participation in online shopping, trading, or auctioning. If such activities are permitted, establish ground rules and boundaries for such use and continue to monitor use of these activities.
- Be aware of other places where the child may have access to the Internet (e.g., friends, school, library). Ensure that these places have safeguards in place to filter or monitor use of the Internet.
- Report the presence of any illegal material online, unwanted sexual solicitations, and exposure to inappropriate material to the National Center for Missing and Exploited Children (see [thePoint](#) for Organizations).

of Labor (2003) estimates that about more than 50% of 16- to 18-year-olds work at some time during the year. This estimate includes both part-time work during the school year and work during vacations. These statistics likely underestimate the adolescent workforce, because the numbers are reported by parents and other adults in the household. When high school students are interviewed through research surveys, as many as 80% report that they have held a job sometime during the year (Centers for Disease Control and Prevention, 2003).

Both positive and negative consequences have been associated with adolescents participating in paid work experiences. Personal benefits include raising self-esteem, building personal responsibility, and developing teamwork. Of greater concern are the negative health consequences for youths that can arise from work conditions, including insufficient sleep from working too many hours, lack of exercise, interference with schoolwork, and time away from family and friends. In the work setting, teens can be exposed to multiple hazards, use dangerous

DEVELOPMENTAL CONSIDERATIONS 7–3

Internet Use Rules for Children and Adolescents

- Never reveal your password to anyone online, not even to online service staff members.
- Never reveal identifying information (e.g., real name, phone number) or credit card numbers in a chat room, message board, or other online forum. Never give this information by e-mail to someone you don't know.
- Never accept offers of merchandise or information, or give out your street address for deliveries without getting permission from a parent or guardian.
- Never send a photograph or offer a physical description of yourself or your family members over the Internet. Never share personal pictures on the Internet with people you do not know personally.
- Never download pictures from an unknown source, because they may contain sexually explicit or other inappropriate images.
- Never continue a conversation that makes you feel uncomfortable or becomes personal. Just “hang up” on the conversation by going to another area of the Internet. Tell an adult what happened.
- Never respond to e-mail, message board, or instant messenger items that are suggestive, obscene, or rude, or that make you feel uncomfortable in any way. Tell an adult if you come across such messages; they should be forwarded to reporting agencies for investigation.
- Never arrange to meet someone in person whom you've met online. If a meeting is arranged, it is of paramount importance that a parent or guardian be present and the meeting be arranged in a public spot.
- Be careful when responding to e-mail. Return addresses can be falsified to make the message look innocent. Such messages may contain viruses. If you cannot verify or do not recognize who it came from, do not answer it.
- Check what you are sending before you send it and think about it from the recipient's point of view.
- Do not download music or copy downloaded music from a friend. Verify with an adult that the sites used for downloading music are following copyright laws.
- Understand that what you are told or what you read online may or may not be true. Learn how to distinguish authoritative sources from others.
- Talk with your parents about their expectations and ground rules for going online.

Adapted from Giardino, A. (2005). Internet poses multiple risks to children and adolescents. *Pediatric Annals*, 34(5), 405–413. Reprinted with permission.

equipment (despite regulations prohibiting such actions), and work long hours during the school week. Adolescent workers report a lack of consistent job training and adult supervision on the job (Runyan et al., 2007).

From 1992 to 2002, an average of 64 workers younger than 18 died each year from work-related injuries. In 1999, an estimated 84,000 work-related injuries and illnesses among youths less than 18 years of age were treated in hospital emergency departments. It is known that only about one third of work-related injuries are seen in emergency departments; therefore, approximately 250,000 youths likely incur work-related injuries and illnesses each year. Work has been associated with musculoskeletal pain in adolescents and increases in worker compensation claims in this age group (Breslin et al., 2003; Feldman et al., 2002). Healthy People 2010 includes an objective to reduce the rate of youth injuries treated in emergency departments, from 5.2 injuries per 100 people in 1999 to 3.4 injuries per 100 people by 2010 (Centers for Disease Control and Prevention, 2003; U.S. Department of Health and Human Services, 2005).

Nurses can assist the adolescent in making wise decisions regarding work activities. Apprise the adolescent of the laws that govern work rules for youths (Department

of Health and Human Services, 1997). Furthermore, discussions with parents can yield information regarding whether work has affected adolescents' grades, attitudes, or behavior. Encourage parents to limit work hours, and have the youth maintain a schedule that allows 8 to 9 hours of sleep a night while also accommodating work and school.

PREVENTING INJURY AND ILLNESS

Adolescents are known for their daring and fun-loving approach to life. This approach may translate into engaging in high-risk activities without considering the immediate and long-term consequences of these behaviors. Guidelines for preventing injury and violence serve as the template for ongoing discussions between youths and healthcare providers to promote healthy growth and development during the adolescent years (Community Care 7–2). In addition, the healthcare provider should be vigilant with regard to adolescents' emotional and mental state of health. Chapter 29 provides a thorough review of mental health conditions that may affect adolescents, including depression and suicide.

FIGURE 7–8. Driving safety education is one part of the injury and illness prevention plan for the adolescent population.

Driving

Learning to drive and acquiring a driver's license are true rites of passage during the adolescent years. Yet, these accomplishments that best illustrate the adolescent's independence and maturity can also clearly demonstrate the ongoing need to temper independence with caution. Encourage the adolescent to participate in a driver's education course to learn the basic skills of driving (Fig. 7–8). In some states these courses are required to be completed when teens have their driver's permit and prior to receiving their license. When operating a vehicle, states vary on regulations regarding who may accompany the teen in the car, night driving, and use of electronic equipment (e.g., cell phones, iPod) while driving. Encourage parents to familiarize themselves with the driving laws in their state and to model good driving behaviors to their

COMMUNITY CARE 7–2

Injury and Violence Prevention Guidelines for the Adolescent

Home Safety

- Check smoke detectors to ensure that they are working properly; change batteries yearly.
- Discuss safety rules for the home, including those about visitors, use of the telephone, and what to do in case of fire or other emergencies. Conduct fire drills at home.

Activity Safety

- Wear protective sports gear.
- Wear appropriate protective gear at work and follow job safety procedures.
- Avoid high noise levels, especially when using music headsets.
- Always wear a helmet when riding a motorcycle, an all-terrain vehicle, or a bicycle. Even with a helmet, motorcycles and all-terrain vehicles are very dangerous.

Water Safety

- Learn how to swim.
- Do not swim alone.
- Do not drink alcohol while boating or swimming.

Car Safety

- Wear a seat belt in the car at all times.
- If you are driving, insist that your passengers wear seat belts.
- Follow the speed limit and traffic rules.
- Do not drink alcohol and drive. Plan to have a designated driver if drinking.

Outdoor Safety

- Protect yourself from skin cancer by applying sunscreen before you go outside for long periods.
- Do not use tanning salons.
- Use insect repellent to prevent insect-borne diseases.

Emergency Preparation

- Make sure your address and phone number are posted near a phone at your house.
- Know where the list of emergency numbers (doctor, hospital, nearest neighbor, poison control center) is kept in your home.
- Know how to contact your parents in case of an emergency. Keep their work phone numbers in your purse, wallet, or school notebook.
- Keep a cell phone or some loose change with you at all times so that you can make an emergency call if needed.

Violence Prevention

- Do not carry or use a weapon of any kind.
- Develop skills in conflict resolution, negotiation, and dealing with anger constructively.
- Learn techniques to protect yourself from physical, emotional, and sexual abuse, including rape by either strangers or acquaintances.
- Seek help if you are physically or sexually abused, or fear that you are in danger.

Adapted from Hagan, J., Shaw, J., & Duncan P. (Eds.). (2008). *Bright futures: Guidelines for health supervision of infants, children, and adolescents (3rd ed.)*. Elk Grove, IL: American Academy of Pediatrics.

child. Speak frankly with the adolescent about use of safety belts and the risks (both legal and physical) of driving while under the influence of alcohol or drugs.

Alert! Children younger than 16 year of age should not drive or ride an all-terrain vehicle because they do not have the physical coordination and mental judgment to handle these types of vehicles (Hagan et al., 2008).

Sports Injuries

An estimated 30 million children and adolescents participate in organized sports programs across the United States (Adirim & Cheng, 2003; Ganley et al., 2001). Although such programs provide enjoyment and camaraderie, and promote the value of teamwork and exercising, they also place young persons at risk for physical injury. Sports injuries account for a quarter of all injuries among children and adolescents, and account for approximately 55% of all nonfatal injuries that occur at school. Most organized sports-related injuries (62%) occur during practices rather than games (Adirim & Cheng, 2003; Ganley et al., 2001). Contact sports with the highest fatality rates include baseball (highest), basketball, football, soccer, and gymnastics. Damore et al. (2003) found that 41% of all musculoskeletal injuries seen in one emergency department were caused by sports injuries. An estimated 38% of high school students and 34% of middle school students

seek treatment by a healthcare prescriber for injuries sustained during sports activities. The yearly costs of medical treatment for these injured children is estimated to be as high as \$1.8 billion in the United States (Adirim & Cheng, 2003; Ganley et al., 2001; Safe Kids, 2005).

The most commonly injured areas of the body include the ankle and knee, followed by the hand, wrist, elbow, shin and calf, head, neck, and clavicle (Adirim & Cheng, 2003). Eye injury is also a common problem, with baseball and basketball associated with the highest number of eye injuries (American Academy of Pediatrics & American Academy of Ophthalmology, 2004). The primary factors that influence the high rate of sports-related injuries include

- Lack of safety precautions implemented during practices and games (e.g., safe environment, safe equipment, use of protective gear)
- Poor health of the athlete as a result of obesity, improper nutrition and fluid intake, or use of ergogenic aids
- Long practice periods, with increasing intensity and shorter rest periods, causing repetitive stress without adequate recovery time
- Anatomic and physiologic changes of growth (especially during puberty)

The young athlete has several physical and physiologic differences that place them at higher risk for injury when compared with adult athletes (Developmental Considerations 7–4). Both short- and long-term sequelae can result

DEVELOPMENTAL CONSIDERATIONS 7–4

Physical and Physiologic Attributes of Young Athletes That Make Them Vulnerable to Sport-Related Injuries

Attribute	Implications
Large body surface area-to-mass ratio	Absorbs heat more quickly when the ambient temperature exceeds skin temperature
Larger head compared with rest of body	Greater likelihood of head injury
Smaller body size than adults, with more variation in size even within same age groups	Protective gear may not be appropriately sized
Physes (growth plates) still open	Possibility of damage to plates with certain activities (e.g., weightlifting); damage to plates can lead to early closure
Cartilage still developing	More susceptible to overuse injuries
Motor skills have not reached full maturity and mastery of complex motor skills not complete; during puberty, coordination and balance decline	Coordination and response time diminished when injury risk is evident
Higher threshold before beginning to sweat; lower sweat volume	More likely to sustain heat injuries
Produce more heat relative to body mass for the same exercise completed by an adult	Predisposed to dehydration and heat illness

from improper attention to these differences when designing sports training programs. In addition, lack of attention to the general safety, nutrition, and health practices of youths participating in sports activities can have deleterious effects on the adolescent's well-being. These negative effects include severe dyspnea, syncope, cramps, heat syncope, heat exhaustion, heat stroke, dehydration, bone injury, and mental stress (Gomez, 2002; McLain, 2003).

Nurses providing care for adolescents should be aware of weight gain and weight loss methods being used by young people, and sports that have a greater risk of unhealthy weight management practices. Typically, athletes in sports that put the adolescent's body on display, such as gymnastics, ice skating, swimming, and dance, are at risk. Sports in which the athlete must weigh in before competing, such as wrestling, also put the athlete at risk. Adolescents might engage in unhealthy weight control practices (both weight loss and weight gain methods) as a means to improve performance, improve appearance, or meet weight expectations of the sport. These practices may occur during the sports season only or year-round.

Alert! Although young male athletes are encouraged to “bulk up” and increase their body mass, female athletes are often encouraged to maintain a low body weight. Female athletes are at risk for developing eating disorders, amenorrhea, and osteoporosis (contributing to stress fractures) (Rackoff & Honig, 2007; Torstveit & Sundgot-Borgen, 2005). This clinical problem is called the *female athlete triad*, and all young women engaged in intense physical activity are at risk. All adolescent athletes should be carefully monitored and counseled as necessary to ensure that dietary extremes are not used to enhance the teen's competitive edge.

Weight loss methods include food restriction, vomiting, overexercising, voluntary dehydration, and use of over-the-counter and prescribed substances such as diet pills, nicotine, and stimulants. Voluntary dehydration practices are said to include fluid restriction, spitting, and the use of laxatives, diuretics, rubber suits, steam baths, and saunas to dehydrate the body and produce the desired weight loss (American Academy of Pediatrics, 2005b).

Gaining weight might also be a goal of some athletes. Sports such as football, rugby, and weightlifting encourage weight gain to enhance body composition. Supplements or anabolic steroids may be used to gain weight and improve physique. In most cases, these substances have unproved value and potentially are harmful to the child or adolescent (Gardiner, Dvorkin, & Kemper, 2004; Griesemer, 2003; Metz, 2002) (Table 7-1). The use of androgenic-anabolic steroids by adolescents is of primary concern. Athletes and others abuse anabolic steroids to enhance athletic performance and to improve physical appearance. Taken orally or injected, anabolic steroids are typically ingested in cycles of weeks or months (*cycling*), rather than ingested on a continual basis. When the adolescent engages in cycling, this involves taking multiple doses of steroids over a specific period of time, stopping for a period, and starting again. In addition, the adolescent will often combine several different types of steroids to maximize their effectiveness while

minimizing negative effects (*stacking*) (National Institute on Drug Abuse, 2007). Use of anabolic steroids among adolescents is not considered high, ranging from 1.6% of 8th graders to 2.7% of 12th graders reporting use (National Institute on Drug Abuse, 2007). However, the side effects of these substances place these youth at risk for serious health problems, some of which may be irreversible. These side effects include liver and kidney tumors, high blood pressure, high cholesterol levels, jaundice, cancer, and premature skeletal maturation (Hartgens & Kuipers, 2004). Careful monitoring of athletes' weight, eating patterns, hydration practices, heat illnesses, and general health are important to ensure that adolescents are not at risk for injury. Recognizing the signs and symptoms of an eating disorder (see Chapter 29), with prompt referral for medical, nutritional, and psychological intervention, is an important responsibility of the healthcare provider. A key American Academy of Pediatrics recommendation focuses on the need to provide individual, family, and team counseling to promote healthy weight gain and weight loss practices. Such counseling should review optimal growth parameters for the adolescent; discuss both healthy and unhealthy practices for weight gain and loss; and discuss measures to prevent dehydration, overhydration, and related injury attributable to improper dietary practices.

Tobacco, Alcohol, and Substance Use

One of the foremost concerns for adolescents is to prevent the use of drugs and alcohol. Tobacco and alcohol symbolize adult status to the adolescent, and parental warnings can be perceived as a mechanism to block them from achieving independence. Education about drugs and alcohol has a strong effect on adolescent attitudes. The best time to start this education is when the child is still school aged, and if it is reinforced during adolescence, it is even more effective. Positive parental role modeling is one of the best ways to prevent drug and alcohol use among adolescents. For example, several studies have shown that parental provision of alcohol, home alcohol accessibility, and the lack of parental alcohol-specific rules increase the initiation and use of alcohol by adolescents (Komro et al., 2007; van der Vorst et al., 2005, 2007).

Tobacco Use

Despite regulatory efforts to restrict advertising of tobacco products and banning the sale of tobacco products for those younger than 18 years of age, the current rate of adolescents who report using cigarettes one or more times during the past 30 days is 23%, and 8% for smokeless tobacco (Centers for Disease Control and Prevention, 2005). Smoking and other forms of tobacco use affect every organ system in the body, and are major causes of cancer, heart disease, stroke, chronic obstructive pulmonary disease, and fetal damage. Five million deaths occur worldwide each year as a result of tobacco use (World Medical Association, 2007). For many years, tobacco

TABLE 7 – 1
Ergogenic Aids Used by Young Athletes

Type	Use	Comments
Dietary supplements (e.g., protein, creatine, nucleic acid and amino acid components)	Vitamin, mineral, herb, other botanical, or amino acid used to supplement the total dietary intake. May produce brief explosive power or muscle strength that may enhance competitive results. Promoted as producing weight loss, and enhancing athletic and school performance and physical appearance.	Readily available without prescription or parental consent. Marketed as “safe” and endorsed by professional athletes who are compensated for their endorsement. Long-term health consequences of use are unknown. Supplements do not increase endurance; incremental gain in power is only 5% to 7%. High osmotic load of these products can increase risks of dehydration and heat-related illness.
Caffeine	Stimulant effective in endurance sports because of effect on central nervous system, fatty acid metabolism, and muscle contraction.	Readily available and widely used. Limited performance enhancement benefits when weighed against potential for serious complications. Powerful diuretic that places athlete at risk for dehydration and sudden death from heat-related illness.
Diuretics (e.g., furosemide, hydrochlorothiazide)	Induce rapid weight loss for a short time.	Causes diuresis and substantial electrolyte abnormalities, which can lead to fatal cardiac arrhythmia. Can cause syncope from orthostatic hypertension.
Ephedra	Used to reduce weight in weight-categorized sports. Used to reduce total body fat and improve fat-free mass to enhance physique for purely cosmetic purposes.	Often added to dietary supplements. Sale of ephedra and ephedra-containing products is banned except as Food and Drug Administration approved. High morbidity and mortality rates associated with youth use related to heat-related injury and cardiac arrhythmias.
Methamphetamines	Stimulant that can substantially improve athletic performance.	Increased availability seen as major concern. Rate of cardiac related sudden death from arrhythmias is high. Youths treated with this substance for ADHD are at high risk for heat-related injury and should refrain from combining ADHD medication with other stimulant products.
Androgenic–anabolic steroids	Produce increased levels of testosterone. Increase muscle mass and increased strength. Effects also include increased facial and body hair, deepened voice, acne, and psychological lability (testosterone rage).	Cardiac-related sudden death, most commonly related to cardiomyopathy, structural anomalies of the coronary arteries, direct trauma to the chest, or infectious myocarditis.
Blood doping	Enhance competitive edge through use of autologous blood transfusions and/or erythropoietin. Increases hematocrit above level of 60% when erythropoietin is used.	Used more by older athletes. Complication is hyperviscosity syndrome, which may result in stroke, increased rate of heat-related morbidity and mortality, and increased risk of renal damage.

Data from Gardiner, Dvorkin, and Kemper (2004); Griesemer (2003); and Metz (2002).

companies have asserted that smoking tobacco is not addictive and does not cause cancer, lung disease, or other terminal conditions. These claims have been repeatedly refuted by the medical profession and shared in numerous educational campaigns with children and adolescents. Although many youth understand the risks associated with smoking tobacco, they may be uninformed about the hazards associated with smokeless tobacco. The two types of smokeless tobacco, snuff and chewing tobacco, contain 28 carcinogens. The nicotine delivered by smokeless tobacco use is three to four times higher per dose than smoking a cigarette and stays in the bloodstream for a longer time, thus it leads to nicotine addiction just as cigarette smoking does. Smokeless tobacco use increases significantly the user's risk of cancer of the lip, tongue, cheeks, gums, and the floor and roof of the mouth.

Even though the long-term consequences of tobacco products are known, adolescents appear to have little concern about the outcomes that might occur 20 or 30 years from now. Peer pressure and the belief that tobacco use is enjoyable are the most influential factors among teens who initiate use of tobacco substances. Conversely, having favorable attitudes toward remaining tobacco free and perceiving that friends would not be supportive of smoking have been associated with decreased likelihood of intending to smoke by adolescents (Smith et al., 2007).

Nurses should assess for tobacco and smokeless tobacco use. Ask adolescents whether they or their friends have ever tried or used tobacco products. Assess the oral mucosa for oral leukoplakia (white mouth lesions that can become cancerous). Determine whether the youth has any respiratory condition, such as asthma, that may be exacerbated by tobacco use. Provide education about the health risks of tobacco products and how to quit. Teenagers also need to know that smokeless tobacco is not a safer alternative to cigarette smoking and that cancers can develop in as few as 6 to 7 years. Excellent references for nurses working with teenagers include the National Institute of Dental and Craniofacial Research, Office on Smoking and Health at the Centers for Disease Control and Prevention, the National Spit Tobacco Education Program, the American Cancer Society, and the American Academy of Family Physicians (see [thePoint](#) for Organizations).

Alcohol Use

Underage drinking affects adolescent health risk behaviors and has the potential for addiction. In a national study, 43% of high school students report having one or more drinks of alcohol during the past 30 days of the assessment. In the same study, 25% of students report engaging in more heavy use of alcohol as defined by five or more drinks of alcohol in a row, within a couple of hours within the past 30 days. Twenty-five percent of the students stated that they had their first drink of alcohol (other than sips) before the age of 13 (Centers for Disease Control and Prevention, 2005).

Parental alcohol use rules and modeling appear to be the most effective methods of establishing appropriate standards regarding drinking (Komro et al., 2007; van der

Vorst et al., 2005, 2007). Many parents do not take drinking as seriously as drug abuse because they perceive it as the “lesser of two evils” because alcohol is a legal substance. Many teenagers actually obtain their alcohol from their parents, either directly or indirectly (Komro et al., 2007). Adolescents report that the reasons they engage in occasional or regular drinking include the pleasures derived from the effects of alcohol and from the social interactions associated with the drinking activities, and the thrill of risk taking. Boredom is also a motivating factor (McIntosh, MacDonald, & Mc Keganey, 2008). Children who begin to drink at an early age have also been shown to have similar personality characteristics that make them more likely to start drinking. These characteristics include young people who are hyperactive, disruptive, and aggressive; as well as those who are depressed, withdrawn, or anxious. Last, tolerance to alcohol may be directly linked to genetics. Thus, being a child of an alcoholic or having several family members who are alcoholics may place the young person at increased risk for alcohol abuse themselves (Department of Health and Human Services, 2006).

The negative effects of alcohol can be devastating when teens mix drinking and driving. Approximately 10% of high school students state they have been drunk while driving, and 29% report they have ridden in a vehicle operated by someone who had been drinking alcohol (Centers for Disease Control and Prevention, 2005). The leading causes of adolescent death are automobile accidents, homicides, and suicides (see Chapters 29 and 31); alcohol is a major factor in all three (National Clearinghouse for Alcohol and Drug Information, Center for Substance Abuse Prevention, 2006).

Although teenagers drink less often than adults, they drink more than adults and they have a tendency to combine different types of alcohol during the same session (Department of Health and Human Services, 2007; McIntosh et al., 2008). Teenagers generally consume five or more drinks at a time. This is called *binge drinking*. Approximately 40% of adults who began drinking before the age of 15 report having signs of alcohol dependence (Department of Health and Human Services, 2007). There are four stages of becoming dependent on alcohol:

1. Experimental stage: when the teenager tries out alcohol and likes its effect
2. Seeking-out stage: when the teen seeks out opportunities to drink
3. Dependency stage: when the alcohol-induced high becomes top priority for the teen
4. Addiction stage: when the teenager needs alcohol just to feel “normal”

Alcohol dependence is difficult to treat but cannot be ignored. Adolescent who engage in ongoing alcohol consumption are at high risk for injury while inebriated. Alcohol consumption impairs judgment and the ability to make sound decisions. In addition, underage alcohol use increases the risks of carrying out or being the victim of physical or sexual assault, and increases the likelihood of engaging in risky sexual activity that may lead to pregnancy or sexually transmitted infections (Department of Health and Human Services, 2007). Professional

intervention and programs developed to treat alcoholic adolescents can be of assistance. During healthcare encounters, observe the adolescent for potential alcohol abuse. Common signs to indicate physiologic dependence or withdrawal include craving alcohol, compulsive alcohol-seeking behaviors, tremulousness, agitation, weight loss, headaches, and changes in mental status. Ask adolescents about their use of alcohol and their activities with friends who may be drinking. Talk with teens about alcohol use and teach them the hazards of underage drinking. Assist the teenager to make good decisions about alcohol use, including seeking ways to resist consuming alcohol when offered by friends or at parties. Discuss with parents the strong influence they impart upon their child's decision to consume alcohol. Ensure that family rules have been communicated to the adolescent, and encourage parents not to purchase or offer alcohol to their underage child. Last, assist school officials and teachers to create a school environment that does not tolerate alcohol use and that encourages students to have a positive sense of attachment to school (e.g., active engagement in academics and social activities, attachment to teachers, respect for school rules). School attachment has been consistently identified in the literature as a positive factor to prevent and/or delay adolescent use of alcohol (Henry & Slater, 2007).

Illicit Drug Use

The use of alcohol and tobacco products by teenagers may be followed or accompanied by the use of illicit drugs. Marijuana is the most commonly used illicit drug, with 38.4% of high school students stating they have used marijuana one or more times. In contrast, other substances have less reported use by high school students: cocaine, 7.6%; inhalants, 12.4%; heroin, 2.4%; methamphetamines, 6.2%; and Ecstasy, 6.3% (Centers for Disease Control and Prevention, 2005). Of primary concern to school nurses, school officials, and parents is that 25% of high school students state they have been offered, sold, or given an illegal drug on school property by someone during the past 12 months (Centers for Disease Control and Prevention, 2005).

Alert! Nonmedical use of prescription stimulants (such as methylphenidate, which is used for the treatment of ADHD) is seen in approximately 2.5% of the adolescent population. These substances are used to stay awake longer to party, study, or drink more. Problems associated with taking someone else's medication may include cardiovascular effects, insomnia, psychosis, precipitation or worsening of other disorders, and potential promotion of, or worsening of, substance abuse. Assessment of adolescent substance use should include the abuse of prescription stimulants (Arria & Wish, 2006; Croft, 2006).

Clearly, healthcare providers need to meet the goal of diminishing adolescent substance use (including alcohol and tobacco) through several different avenues. Nurses can collaborate with schools to foster environments in which offering, sharing, and using substances of all kinds

is not tolerated. Additionally, teens need to be given resources and strategies to say no to an offer of an illicit drug. Education that includes parental involvement is essential. For adolescents who participate in heavy and harmful patterns of substance use, harm reduction interventions have been reported to be an effective strategy to reduce harm and save lives. These interventions aim to prevent problems by targeting risky contexts or patterns of use, or by affecting the relationship between use and problem outcomes (Toumbourou et al., 2007). Interventions include improved enforcement of drunk-driving laws to decrease motor vehicle injury, providing needle and syringe exchange programs to prevent HIV infection, and serving alcohol in shatter-resistant glasses to prevent alcohol-related injuries. If an adolescent is suspected of using some type of substance, the nurse may be among the first to identify the problem by putting together the pieces of history, activity, and physical signs and symptoms (see Chart 7–2). If a potential overdose occurs, the adolescent must seek medical treatment as soon as possible, because to delay may be fatal. Long-term management is more complex, and requires physical and psychological support systems for both the adolescent and the family. Referrals for adolescents to engage in substance abuse treatment may come from the criminal justice system, self-referral, school counselors and nurses, community organizations, family members, and other healthcare providers. Chapter 29 provides an in-depth discussion of substance abuse, including assessment and interdisciplinary interventions to assist the adolescent with these addictions.

CHART 7–2 WARNING SIGNS OF SUBSTANCE USE

- Reddened eyes
- Pinpoint pupils
- Runny or stuffy nose (constant)
- Gastrointestinal upset (diarrhea)
- Weight loss or gain; change in eating habits
- Signs of needle tracks
- Loss of coordination
- Tremors
- Unusual sleep patterns
- Diminished academic performance
- Withdrawal from friends, activities, and family
- Rapid mood swings
- History of bizarre behavior
- Depression or agitation
- Hallucinations or disorientation
- Smell of smoke

Youths and Violence

Problem behaviors in adolescents include engaging in fighting and initiating other acts of violence upon other youths and individuals. Surveys indicate that around 21% to 33% of adolescents report taking part in a group fight, 21% to 34% report having been in a serious physical fight, and 8% to 19% of adolescents report they have seriously injured someone else (Centers for Disease Control and Prevention, 2004b; Udry, 2003). Bullying (discussed in Chapter 6) can be considered a problem behavior that may lead to further acts of violence. It is bullying when another student or group of students says or does nasty things to another boy or girl. It is bullying when a youth is teased repeatedly in a way he or she does not like. Some argue that bullying, gossiping, stealing another's boyfriend/girlfriend, name calling, or other types of verbal abuse are also forms of violence (Bartlett et al., 2007; Srabstein et al., 2006). Adolescents are also at risk for violence from involvement in relationships that are physically abusive. Chapter 31 discusses abuse, including sexual abuse. The literature reports that dating violence (verbal aggression and physical abuse) among adolescents ranges from 10% to 35% (Close, 2005).

A number of intervention programs have been initiated across the country that are aimed at preventing adolescent violence and recognizing adolescents at risk for violent behavior. The most effective programs combine strategies that address both individual risks and environmental conditions. In particular, approaches aimed at building individual skills and competencies, providing parent effectiveness training, improving the social climate of the school, and effecting changes in type and level of involvement in peer groups have shown to be effective (Department of Health and Human Services, 2001). For example, dating violence prevention programs are recommended at the middle school level to help these young teens to manage relationships before they become abusive and violent. Programs aimed at high school and college students focus more on intervention, promoting nonviolent conflict resolution and healthy partner behaviors (Close, 2005).

Gangs

Youth gangs exist all over the country, in cities large and small, and are major contributors to the rate of violent crimes seen among adolescents. Gangs are not new to the United States; they have been around since the 18th century. As of 2005, at least 21,500 gangs were active in the United States, with more than 731,000 active gang members (U.S. Department of Justice, 2005). Easy access to guns makes gangs of today especially dangerous.

Gangs come in all sizes: very large, with subdivisions; and very small, with just a few members. If a group or clique meets the three following criteria, according to experts, it can be defined as a **gang**:

1. There must be distinct group recognition by the members (e.g., use of signs, colors).
2. The group must be identified by the community as a gang.
3. The group must be involved in some illegal activities and have a negative reputation within the community.

Usually, gangs develop from a group of adolescents who share a common neighborhood, school, or interest. Traditionally, gang members were exclusively male, but now a gang might recruit female members as well. Most common, recruits are from the inner city, the poor, and they are adolescents with low self-esteem, gathering together for mutual support and understanding. Usually these adolescents have little family support (U.S. Department of Justice, 2005). The feelings of poor self-esteem are negated by being accepted by a group that has “power” (and money). Gangs group together adolescents of similar cultural backgrounds and usually exclude anyone who is not the same. Gang association has been highly correlated to an increase in violent behavior by adolescent members. Gangs use violence in retaliation for real or perceived disrespect. Gang members might carry weapons and use those weapons for illegal activity, including violence against others. Arrest, prison, injury, and possibly death all are very likely outcomes of gang membership.

Unfortunately, physicians and nurses usually do not see gang members until they arrive in the emergency department after a violent confrontation. The professional should not sugarcoat the possibilities of what will occur if the adolescent joins a gang or remains in a gang. Getting out of gangs can be very difficult, however. Many ex-gang members state that the easiest way is just to “fade” away, by not attending the activities as often and not being part of the crowd. After a while, the gang member is “forgotten.”

Education is one of the best tools to prevent adolescents from joining gangs. The healthcare professional can talk to the teenager about alternatives to a gang lifestyle and can assist the teen in finding nongang role models. Group counseling with the parents may assist in the development of a stronger family relationship. Programs can be offered to keep the teenagers busy after school, perhaps allowing them to develop other peer relationships outside of gangs, within sports, art, music, and so on. Teenagers can be encouraged to plan their future.

PREGNANCY

QUESTION: Is Ashley at risk for becoming unintentionally pregnant? What health information should a nurse share with Ashley to help her prevent a pregnancy?

During the past decade, the incidence of teenage pregnancy has decreased, along with the percentage of high school students who report having participated in sexual intercourse. The Youth Risk Behavior Survey published by the Centers for Disease Control and Prevention (2004b) reports less than half of 9th to 12th graders had sexual intercourse in 2003. In 2005, it was reported that the percentage of students having intercourse before age 13 had decreased in boys from 12.7% in 1995 to 8.8%.

For girls, the percentage decline was 4.9% in 1995 to 3.7% in 2005 (Hagan et al., 2008). Nevertheless, in 2003, 134,617 births were reported to mothers younger than 19 (American Academy of Pediatrics, 2001a). Although the incidence of teenage pregnancy has decreased overall, the rate varies with racial/ethnic background. Data based on the National Center for Health Statistics show the overall teen pregnancy rate from 2000 is 84 per 1,000 females between the ages of 15 and 19. However, the rate for African Americans is 154 per 1,000 and the rate for Latinas is 140 per 1,000. Adolescents who become pregnant are at risk for not completing high school, holding low-income jobs, living in poverty, and becoming pregnant again during the adolescent years (Montgomery, 2002). Children of single adolescent mothers are at greater risk than children of adult mothers for health problems associated with prematurity, displaying lower levels of cognitive development during infancy, and lower academic achievement. A particularly vulnerable group are those girls who become sexually active before age 14. The younger a girl is when she has sexual intercourse for the first time, the more likely her partner is 4 years or more older than she, the less likely she is to use contraception, and the more likely she is to have an unintended pregnancy (Montgomery, 2002).

Current data indicate that about 46% of both adolescent females and males have had sexual intercourse by age 18. Among females younger than 15, these first sexual

experiences often are coercive. About 75% of first intercourse experiences for females occur with contraception, compared with 82% for males. In 2003, 134,617 births were reported to mothers younger than 19, a steady decline from the peak during the 1990s. In 1997, there were 489,210 live births to 15- to 19-year-old females in the United States (American Academy of Pediatrics, 2001a). Adolescent pregnancy, although it is primarily unplanned, may also be planned. An estimated 1% to 15% of adolescent pregnancies are planned, with the female actively trying to conceive (Montgomery, 2002). Adolescents who become pregnant are at risk for not completing high school, holding low-income jobs, living in poverty, and becoming pregnant again during the adolescent years. Children of single adolescent mothers are at greater risk than children of adult mothers for health problems associated with prematurity, displaying lower levels of cognitive development during infancy, and lower academic achievement (Montgomery, 2002) (see Chapter 1 for more discussion about single parenting).

Teaching safe sex practices is an essential component of adolescent healthcare (NIC 7–4). Comprehensive sexual education, education that promotes abstinence but includes information about contraception, condoms, and sexually transmitted infections, has been effective in both delaying the age of sexual intercourse and increasing the use of contraception and condoms to protect from STDs.

NIC 7–4 Nursing Interventions Classification: Teaching Safe Sex

Definition: Providing instruction concerning sexual protection during sexual activity

Activities:

- Discuss patient's attitudes about various birth control methods
- Instruct patient on the use of effective birth control methods, as appropriate
- Incorporate religious beliefs into discussions of birth control, as appropriate
- Discuss abstinence as a means of birth control, as appropriate
- Encourage patient to be selective when choosing sexual partners, as appropriate
- Stress the importance of knowing the partner's sexual history, as appropriate
- Instruct patient on low-risk sexual practices, such as those that avoid bodily penetration or the exchange of body fluids, as appropriate
- Instruct patient on the importance of good hygiene, lubrication, and voiding after intercourse, to decrease the susceptibility to infections

- Endorse use of condoms, as appropriate
- Instruct patient on how to choose condoms and keep them intact, as appropriate
- Instruct patient on proper application and removal of condoms, as appropriate
- Discuss with patient ways to convince partners to use condoms
- Instruct patient on spermicidal products that can stop STDs, as appropriate
- Provide patient with condoms/spermicidal products, as appropriate
- Encourage patient at high risk for STDs to seek regular examinations
- Refer patient with sexual problem or questions to appropriate healthcare provider, as appropriate
- Plan sex education classes for group of patients, as appropriate

From Bulechek, G., Butcher, H., & McCloskey Dochterman, J. (Eds.). (2008). *Nursing interventions classification (NIC)* (5th ed.). St. Louis: Mosby. Reprinted with permission.

Adolescent decision making about using protection during intercourse is a complex fabric of many threads, including socioeconomic conditions, psychological factors, race, peer relationships, and family values (Clinical Judgment 7–2). The form of **contraception** (pregnancy prevention) most commonly used among adolescents is condoms, and the second most favored is low-dose oral contraceptive pills (OCPs). Condoms offer protection from sexually transmitted infections, but their effectiveness in preventing pregnancy is directly related to the consistency and correctness of use. The effectiveness of condoms ranges from 85% effective with “typical” use to 97% with “perfect” use. Adolescents do not require a healthcare provider to obtain condoms. Through a healthcare provider, a number of contraceptives are available (Table 7–2). Oral contraceptive pills are commonly used, but alternative means of hormonal contraception are available. Depo-Provera is an injectable progestin that is given every 12 weeks. Ortho-Evra is a combination hormone transdermal patch that is applied weekly for 3 weeks and the fourth week a patch is not used. Nuva Ring is a flexible ring worn in the vagina for 3 weeks that

releases combination hormones; the ring is removed during the fourth week. All these hormonal methods of contraception have very high effectiveness rates and are appropriate for adolescents. Another contraception method available is prescription barrier methods, including the diaphragm, the FemCap, and Lea’s Shield. A barrier method may be preferable to the hormone methods if the adolescent is only participating in sexual intercourse occasionally. Several methods of contraception that are used by adults are not appropriate for adolescents. An obvious method is sterilization, which is permanent. It is recommended that withdrawal before ejaculation is not appropriate for adolescents, because it requires experience and self control over ejaculation. It also has a low effectiveness rate as a result of leaking of seminal fluid prior to ejaculation. Fertility awareness-based methods or “rhythm” methods are not recommended for adolescents because they require mature, trusting, and cooperative partnerships to be effective. The fourth method that is not appropriate for most adolescents is an intrauterine device (or IUD), which is only recommended after the birth of a child.

CLINICAL JUDGMENT 7–2

The Sleepy Adolescent

Sixteen-year-old Rochelle and her mother are meeting with the school nurse and the school counselor. The meeting was called by the school staff because Rochelle has been having trouble staying awake in class. Her mother is equally concerned because Rochelle struggles to get up in the morning and “spends way too much time in the bathroom getting ready.” In the evening when Rochelle is supposed to be helping her mother prepare dinner, Rochelle can be found napping on the couch. Rochelle is thin and pale. During the interview she appears sullen and does not speak unless asked a specific question. When queried, she agrees that she has been rather tired the past 3 weeks. Further questions from the nurse elicit that her last menstrual cycle was about 4 weeks ago. She denies having sexual activity. She admits to having feelings of nausea every morning and has been unwilling to eat breakfast for fear of throwing up.

Questions

1. What additional questions would you ask Rochelle at this time?
2. What are the presenting symptoms that you would share with Rochelle that would indicate she could be pregnant?
3. During your private discussion with Rochelle, she shares information about her sexual activity. How would you proceed at this point?
4. The diagnostic test confirms pregnancy. How should you proceed with Rochelle and her mother?
5. Rochelle decides to tell her mother. What additional support can you provide this family?

Answers

1. With the mother out of the room, ask Rochelle if there is any possibility she may be pregnant. Ask her about her dating practices and sexual activity. Ask about relationships with parents.
2. Nausea, fatigue, missed periods, and, if revealed by Rochelle, participating in sexual activity.
3. Explain that a urine test can rule out or confirm the possibility of pregnancy. Gain Rochelle’s consent for this test.
4. Encourage Rochelle to tell her mother, but inform her that, according to state statutes, her pregnancy status is confidential, as are all related decisions. Discuss pregnancy options with Rochelle. Encourage her to be tested for HIV and other STDs.
5. Be present during the discussion between Rochelle and her mother. Answer questions and provide information on options. Arrange for counseling. Arrange a follow-up appointment to further discuss options and provide disclosure of HIV and STD results.

TABLE 7–2

Contraception Methods

Method	Healthcare Considerations
Abstinence	Peer pressure may change desire to maintain abstinence. Ongoing assessment and information about birth control methods should be provided should the adolescent choose to engage in sexual activity.
Oral contraceptive pills	Some medications can decrease the efficacy of birth control pills. During use of rifampin, penicillin, tetracycline, phenobarbital, and other drugs, women need an alternative/additional method of protection. Birth control pills can potentiate the action of some antianxiety, antidepressant, and asthma medications. Women who are currently taking any type of antianxiety, antidepressant, asthma, or antibiotic drug need to inform their healthcare providers and use an additional method of protection.
Condoms (both male and female)	Educate about proper application and removal from male penis. Should not be used if partner is allergic to latex. Female condom can be inserted up to 8 hours prior to intercourse. Both condoms are intended for one-time-only use, and the male and female condom should not be used in conjunction with one another.
Spermicides	Needs to be placed high in vagina to make contact with cervix. Application should be no more than 1 hour prior to intercourse.
Norplant	Return to fertility is prompt after removal. May be left in place for as long as 5 years, then must be removed and replaced.
Depo-Provera	May be a delay in fertility for up to 18 months after discontinuance. Injection must be given within first 5 days of menstrual cycle, or an additional method of protection must be used.
Rhythm method	Patient needs to be aware of potential fertile days of cycle. Physical, psychological, nutritional, and health state may affect cycle and alter cycle observations.
Withdrawal	Patient needs to be aware that there is high risk for pregnancy and high risk for sexually transmitted infections using this method.
“Morning after” pill (combination of estrogen and progestin with ethinyl estradiol)	Menstruation can be expected 7 to 9 days posttreatment. Not intended as a method of family planning.

ANSWER: Ashley is at risk for becoming pregnant because she is participating in unprotected sexual intercourse. She is also denying her responsibility to protect herself from pregnancy and sexually transmitted infections. Nurses working with adolescent girls cannot separate pregnancy and sexually transmitted infections, because they are both an inherent risk of sexual activity. Nurses should ensure that the adolescent has an understanding of her own body: her anatomy, and the physiology of ovulation, menstruation, and conception. The most effective methods of birth control do not protect her against sexually transmitted infections. Ashley needs protection from both. The most effective methods of birth control that are advocated for adolescents are The Pill, The Patch (Ortho-Evra), The Shot (Depo Provera), and The Ring (Nuva Ring).

Whether a pregnancy is planned or unplanned, the goals of the healthcare provider include helping the adolescent have a healthy pregnancy and ensuring that the child has a healthy future (Fig. 7–9). Pregnant adolescents should be directed toward specific healthcare providers for specific healthcare concerns, childbirth and child-rearing classes, and government resources such as Women, Infants, and Children programs (see Chapter 2). In addition, contraceptive counseling should be reinforced, or if not previously introduced, then initiated during pregnancy and continued after pregnancy. Use of both long-acting contraceptives and condoms should be encouraged. Ongoing healthcare interventions supported by the American Academy of Pediatrics and other organizations aimed at supporting adolescent parents and their children are presented in Community Care 7–3 (American Academy of Pediatrics, 2001a).

FIGURE 7–9. The adolescent should be encouraged to receive prenatal care and childbirth/child-rearing education.

SEXUALLY TRANSMITTED INFECTIONS

QUESTION: Is Ashley at risk for a sexually transmitted infection? What health information should a nurse share with Ashley to prevent her from contracting a sexually transmitted infection?

Adolescents are at greater risk for sexually transmitted infections than adults, and one in four sexually active adolescents acquire a sexually transmitted infection each year. The rates of sexually transmitted infections in the United States are significantly higher than any other developed nation. Adolescent girls represent one of the fastest growing groups of persons with HIV infection (Morrison-Beedy & Nelson, 2004). Girls represented 51% of HIV cases reported among 13- to 19-year-olds in 2002. This age category is the only one in which females have higher incidence rates than males (Centers for Disease Control and Prevention, 2004a). Minorities are at even greater risk. Among AIDS cases reported in 13- to 19-year-olds in 2002, African Americans represent 65% and Latino adolescents represent 20% (Centers for Disease Control and Prevention, 2004a). Anatomic differences between adolescents and adult women contribute to the increased susceptibility of younger females. The columnar epithelial cells that are particularly sensitive to invasion by organisms extend over the surface of the cervix in adolescents; as a woman matures, these cells recede to a more protected position.

In addition to HIV/AIDS, adolescents are also at risk for other sexually transmitted infections. Common

COMMUNITY CARE 7–3

Interventions for Adolescent Parents and Their Children

- Ensure that adolescents and their children have a “medical home” (see Chapter 2).
- Connect families with community resources (e.g., WIC, EPSDT) (see Chapter 2).
- Promote breast-feeding.
- Provide contraceptive use counseling.
- Emphasize importance of completing high school.
- Encourage continuation of healthy lifestyles, including abstinence from alcohol, cigarette, and substance use.
- Assess risk for domestic violence during and after pregnancy.
- Encourage adolescents to serve as primary caregivers for their children, even if other family members are available to assist.
- Encourage joint participation of both the mother and father (if present) in the child’s care.
- Provide developmentally appropriate parenting information on infant care, infant development, child discipline, and child safety.
- Attend to adolescents’ developmental needs, providing education and support systems as needed.
- Provide positive reinforcement, praising adolescents’ successes with their children and with personal accomplishments.

sexually transmitted infections include vaginosis, *Chlamydia*, genital warts, gonorrhea, hepatitis, herpes, and human papilloma virus (HPV). Data from the Centers for Disease Control STD surveillance from 2001 found the following rates of infection in adolescents. The highest age-specific *Chlamydia* rates occurred among women ages 15 to 19. Gonorrhea rates were higher among women ages 15 to 19. For example, the overall U.S. rate was 129 per 100,000 population; yet, among 15- to 19-year-old women, the rate was 703 per 100,000. Once again, minorities are at disproportionate risk, with African Americans having much higher rates of infection for *Chlamydia* and gonorrhea. Perhaps the most common sexually transmitted infection among sexually active adolescents is genital HPV, commonly known as *genital warts*. HPV is usually transient, has no symptoms, and clears itself. However, in a small percentage of women, HPV leads to cervical cancer. Although HPV is considered the cause of cervical cancer, only 1 in 1,000 women with HPV develop cervical cancer (Centers for Disease Control and Prevention, 2004a).

The most effective way to prevent sexually transmitted infection is abstinence; the second most effective method of protection is to use condoms. Condoms have been proved to be effective against many sexually transmitted

infections, including HIV, *Chlamydia*, and gonorrhea. In 2006, *The New England Journal of Medicine* published a study demonstrating that condoms also protect against HPV. Although condom use has increased, with 63% of sexually active 9th through 12th graders reporting they used a condom the last time they had sexual intercourse, many teenagers are not aware of how these diseases are transmitted and do not effectively protect themselves against exposure (Winer, et al., 2006).

In addition to anatomic, educational, and behavioral risks for sexually transmitted infections, adolescents have less access to healthcare services. In a large collaborative survey completed by the Kaiser Family Foundation (2001) and *Seventeen* magazine, about half the teenagers (age 12–17 years) identified that they did want more information about sexual health. Among teens age 15 to 17 years who had engaged in sexual intercourse, only 6 of 10 had seen a healthcare provider. Reasons identified for decreased use of healthcare services include lack of healthcare coverage; one in four adolescents lack healthcare coverage. Other barriers include transportation, lack of confidentiality, and state laws regarding parental consent. Poverty, cultural traditions, and sexual violence are factors that diminish the individual's ability to protect against sexually transmitted infections. Nurses can play a key role in assessing and educating the teenager regarding the transmission of these diseases. In addition, screening for sexually transmitted infections plays an important role in sexually transmitted infection prevention. The screening process provides an opportunity for the healthcare provider to dispel myths about sexually transmitted infection transmission, to promote products to prevent transmission, and to teach skills for refusing unwanted sex or negotiating safer sex (Fortenberry, 2005).

ANSWER: Ashley is at risk for obtaining a sexually transmitted infection. The nurse should share with Ashley that the most effective protection from a sexually transmitted infection is abstinence. Ashley must decide if she truly does not want to have intercourse with Eric again or if she doesn't want to admit to herself she is sexually active. Either way, she needs to communicate with Eric. The most effective form of protection for sexually active adolescents is using a condom. In the Netherlands, adolescents are encouraged to use two methods of protection against sexually transmitted infections and unintended pregnancy—the pill and the condom—which has been dubbed the *double-dutch* approach. The results have been very effective and this approach would be appropriate for Ashley.

See [thePoint](#) for a summary of Key Concepts.

UNIT II

Maintaining Health Across the Continuum of Care

C H A P T E R

8

Health Assessment and Well-Child Care

Case History

Recall Lindsay Jenkins from Chapter 2? Her aunt and uncle are adopting a baby from Korea and the baby is arriving soon. Sally and Mark Jenkins have been trying to have children for the past 12 years and have decided to adopt. They are working with an adoption agency that specializes in Korean adoptions. They fly to Los Angeles to meet their new daughter and promptly return home. The flight home is a blur. Stephanie, their daughter, has black-button eyes and spiky black hair with a tendency to stand straight up at the crown of her head. She stares at her parents as if to say, “Who are you strange pale people?”

Sally is so excited to have a baby at last. She wants to do everything right. The agency requires the baby to be seen by their pediatrician within 48 hours. The first visit is not for immunizations or uncomfortable interventions, but rather an opportunity for a doctor to conduct the first physical examination and to

answer the parents’ questions. The day after they return home with Stephanie, both Mark and Sally take Stephanie to visit Dr. Lehnus and Ms. King, the nurse practitioner.

The day of her appointment, Stephanie is 4 months 10 days old. She weighs 14 lb 3 oz, is 24 in long, and her head circumference is 16 in. Her medical record from Korea shows that she was delivered vaginally and without difficulty. She received the diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP) at 2 months and at 4 months. She also received the liquid oral polio vaccine (OPV) at 2 months and at 4 months. Her record indicates that her mother was hepatitis B surface antigen (HBsAg) negative; there is no record of Stephanie receiving a hepatitis B (HepB) vaccine. The adoption agency recommends that all infants from Korea begin the HepB vaccination series on arrival in the United States.

CHAPTER OBJECTIVES

1. Describe the levels of prevention that are used as primary approaches to pediatric health teaching.
2. List the childhood immunizations and their schedule of administration for those routine vaccines and identify the side effects associated with each of the vaccines.
3. Discuss key components in the health assessment of children from infancy through adolescence and what is covered in each component (e.g., past medical history, social history, anticipatory guidance).
4. Elicit a pediatric health history pertinent to either the health supervision needs or illness-related problems of children from birth through adolescence.
5. Discuss key approaches to interviewing the child and the family based on developmental considerations, psychosocial/emotional considerations, and level of acuity of illness.
6. Perform a basic physical examination on a child that reflects knowledge of the developmental differences in the various body systems from birth through adolescence.
7. Identify how the physical examination process may need to be altered based on developmental considerations.
8. Differentiate normal from abnormal findings obtained while either taking historical information or performing the physical examination.
9. Discuss the healthcare areas that are covered during health surveillance visits of children of each age group.
10. Select age-appropriate teaching techniques to relay anticipatory guidance and disease prevention information.

See **thePoint** for a list of Key Terms.

Data obtained from a comprehensive health history, together with clinical findings based on a complete physical examination, form the framework for assessing the healthcare needs of the child and family. Developing skills in both history taking and physical examination requires that the nurse have a solid knowledge base regarding physical growth and normal developmental milestones. In addition, the nurse must be an astute listener, an inquisitive interviewer, and an observant clinician with the ability to differentiate normal from abnormal findings.

This chapter focuses on the steps needed to perform a complete health assessment of children from the neonatal period through adolescence. The various components of health supervision are identified, including childhood immunizations and anticipatory guidance issues. An in-depth discussion of the pediatric health history is presented, as is an overview of the comprehensive pediatric physical examination. Tips on examination techniques and communication with parents, children, and teenagers are also provided. Subsequent chapters of the text contain more specific information about each body system and expand on the information found in this chapter.

LEVELS OF PREVENTION

QUESTION: What are a form of primary prevention and a form of secondary prevention appropriate for Stephanie this month?

Health is more than the absence of disease. Being healthy is being whole in mind, body, and spirit. Many of the conditions that affect health—food, shelter, education, income, sustainable resources, peace, social justice, and equity—are not readily amenable to intervention through the healthcare system. Nonetheless, children and their families are entitled to broad-based health education services that promote healthy lifestyles and prevent illness.

WORLDVIEW: In developing countries, overpopulation, poor sanitation, contaminated water, malnutrition, and inadequate housing present major threats to health. In developed countries, major health problems are more likely to be lifestyle-related and the result of accidents, alcohol and substance abuse, tobacco use, violence, or environmental pollution. Poverty is a linking factor and threatens health in all societies.

Child health has improved remarkably in the United States since the beginning of the 20th century. This progress has resulted from a combination of social and economic changes, advances in therapeutic medicine and surgery, and implementation of public health measures such as immunization programs aimed at the prevention of specific childhood diseases. Today, healthcare is more prevention focused than ever. The objectives set forth in the Healthy People 2010 report (U.S. Department of Health and Human Services, 2000) establish a healthcare agenda in which preventive strategies for social and medical problems are identified in addition to treatment. Preventive healthcare is viewed as part of a continuum of intervention that includes primary, secondary, and tertiary levels.

Primary Prevention

Primary prevention is directed at recognizing susceptibility to disease and using strategies to prevent it from occurring. Primary prevention efforts often target those individuals at increased risk. The use of immunizations is an excellent example of primary prevention. Other examples of primary prevention include chlorination and fluoridation of water and anticipatory guidance given to parents of toddlers about the need to keep chemicals out of their child's reach.

Secondary Prevention

Secondary prevention is directed at early identification of risk factors for specific diseases and the initiation of early intervention to prevent the development of such diseases. Because of the increased awareness of specific factors known to be antecedents of childhood illnesses and disabilities, the care of children is becoming more focused on prevention. Many secondary prevention efforts are the result of government or social agency

initiatives. Examples of secondary prevention strategies include state-mandated neonatal screening for specific congenital and inherited metabolic disorders such as phenylketonuria and congenital hypothyroidism, hearing and vision screening in schools, and special screening programs for genetic diseases in at-risk populations.

Tertiary Prevention

Tertiary prevention is the avoidance of complications and additional disability for those children with known diseases, disabilities, or medical conditions (special needs children). Tertiary prevention focuses on eliminating or halting the progression of a disability associated with existing disease states. An example of tertiary prevention is the provision of chest physiotherapy to a child with cystic fibrosis.

Prevention efforts can be targeted at the individual child, the family, or the community. Preventive strategies can decrease the probability that low- or medium-risk children will develop particular diseases or conditions and subsequently enter high-risk categories of disease states or impaired health status. Therefore, this group of children benefits the most from participation in prevention programs.

Nurse's Role

Nurses play important roles in protecting children's health at all three levels of prevention. As healthcare continues to move from acute care settings to the home, short-stay centers, child care centers, schools, and school-linked services, nurses have opportunities to provide direct clinical prevention services (e.g., immunizations), coordinate services as case managers, provide leadership in the development and implementation of community-based prevention strategies, and continue to advocate at local and national levels for greater awareness of children's health issues and service needs. Because children are a vulnerable population, nurses must support the development and implementation of policies and legislation that will best serve our nation's children.

ANSWER: Immunization is a form of primary prevention. Stephanie's immunization schedule will need to be compared with the recommended schedule, and any doses that are missing will be given. A form of secondary prevention includes performing a newborn metabolic screening. Stephanie will receive a purified protein derivative test to determine whether she has been exposed to tuberculosis.

IMMUNIZATION

The widespread use of immunization remains one of the most significant advances in pediatrics, altering the morbidity and mortality associated with once common and feared childhood diseases. The use of vaccines has repeatedly proved to be the most cost-effective way of eliminating preventable diseases.

Unfortunately, success has been accompanied by unacceptably low rates of immunization as a result of complacency and fears of harmful consequences. The estimated rate of coverage with at least four doses of DTaP; three of inactivated polio vaccine (IPV); one of mumps, measles, and rubella (MMR); three of *Haemophilus influenzae* type B (Hib); and three of HepB in children age 19 to 35 months for 2006 was 80.6%. If varicella is added to the requirement, the coverage rate drops to 77% (Centers for Disease Control and Prevention, 2007a). For select diseases, high rates of coverage are needed to provide protection to the general population—a concept known as *herd immunity* (see [thePoint](#) for Supplemental Information: Key Terms Pertaining to Immunity). The doubling of pertussis cases during 2003 to 2004 (Centers for Disease Control and Prevention, 2007b), the highest number in 40 years, is worrisome evidence of the need to remain vigilant.

Reasons for low immunization rates include failure of healthcare providers to use every encounter as a chance to vaccinate, failure to administer vaccines to vulnerable children on time, unnecessary delays in vaccine administration based on misinformation about contraindications, and the erroneous beliefs held by parents that the diseases are no longer a threat.

Vaccine failures and waning immunity also contribute to the inability to eradicate some diseases. The resurgence of measles in college-aged students in the 1980s led to further study of the vaccine's immunogenic properties and identification of the need for a booster vaccination when the levels of protection begin to fall around the age of 12 years. Tetanus is another example of a vaccine given in infancy that needs to be boosted around age 12, every 10 years thereafter, and at times of injury. Breakthrough cases of varicella occurred after only one vaccine, and a second booster dose is now recommended for all children.

Recommended Childhood Immunization Schedule

QUESTION: What would be an appropriate immunization schedule for Stephanie for the next 6 months?

Routine childhood immunization is an integral part of health maintenance for children. In the United States, the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC), the American Academy of Pediatrics (AAP) Committee on Infectious Disease, and the American Academy of Family Physicians (AAFP) share the responsibility for establishing recommendations for the administration of vaccines in the public and private sectors. Delay in providing recommended immunizations at recommended times can put the child at risk for acquiring serious disease. To ensure that all children are adequately protected, healthcare providers are encouraged to follow the recommended routine and catch-up immunization schedules and administration guidelines from the ACIP, AAP, and AAFP (see Appendix E). The World Health Organization provides guidelines for immunization practices for the rest of

the world because many developing countries do not have the infrastructure to generate national guidelines.

The pediatric nurse needs to be familiar with issues regarding childhood immunizations (Nursing Interventions Classification [NIC] 8–1). Vaccine research is ongoing, and recommendations for their use often change. New combination vaccines are being tested, and if proved to be safe and effective as well as affordable, will help to reduce the number of injections needed. Chart 8–1 presents resources for current information regarding immunization practices in the United States.

The recommended age for beginning primary immunization of infants is at birth (see Appendix E). Children

who began primary immunization at the recommended age but did not complete the immunization series according to the recommended schedule should receive only the missed doses, rather than beginning the series again. The link to the recommended immunization schedule for infants, children, and teens who start late or are behind schedule is found in Appendix E. These tables contain information about the minimum age for a first dose of a vaccine, the minimum interval between doses, and whether a particular vaccine is needed at all (e.g., pneumococcal conjugate vaccine [PCV] and Hib are not given to children 7 years or older because these diseases do not pose the health risk that they do in young infants and children).

NIC 8–1 Nursing Interventions Classification: Immunization/Vaccination Management

Definition: Monitoring immunization status, facilitating access to immunizations, and providing immunizations to prevent communicable disease

Activities:

Teach parent(s) recommended immunizations necessary for children, their route of medication administration, reasons and benefits of use, adverse reactions, and side effects schedule (e.g., hepatitis B, diphtheria, tetanus, pertussis, H. influenza, polio, measles, mumps, rubella, and varicella)*

Inform individuals of immunization protective against illness but not presently required by law (e.g., influenza, pneumococcal, and hepatitis B vaccinations)

Teach individual/families about vaccinations available in the event of special incidence and/or exposure (e.g., cholera, influenza, plague, rabies, Rocky Mountain spotted fever, smallpox, typhoid fever, typhus, yellow fever, and tuberculosis)

Provide vaccine information statements prepared by CDC
Provide and update diary† for recording date and type of immunizations

Identify proper administration techniques, including simultaneous administration

Identify latest recommendations regarding use of immunizations

Follow the five rights of medication administration

Note patient's medical history and history of allergies

Administer injections to infant in the anterolateral thigh, as appropriate

Document vaccination information per agency protocol (e.g., manufacturer, lot number, expiration date, etc.)

Inform families which immunizations are required by law for entering preschool, kindergarten, junior high, high school, and college

Audit school immunization records for completeness on a yearly basis

Notify individual/family when immunizations are not up-to-date

Follow the American Academy of Pediatrics, American Academy of Family Physicians, and U.S. Public Health Service guidelines for immunization administration

Inform travelers of vaccinations appropriate for travel to foreign countries

Identify true contraindications for administering immunizations (anaphylactic reaction to previous vaccine and moderate or severe illness with or without fever)

Recognize that a delay in series administration does not indicate restarting the schedule

Secure informed consent to administer vaccine

Help family with financial planning to pay for immunizations (e.g., insurance coverage and health department clinics)

Identify providers who participate in federal "Vaccine for Children" program to provide free vaccines

Inform parent(s) of comfort measures helpful after medication administration to child

Observe patient for a specified period of time after medication administration

Schedule immunizations at appropriate time intervals

Determine immunization status at every healthcare visit (including emergency room and hospital admission) and provide immunizations as needed

Advocate for programs and policies that provide free or affordable immunizations to all populations

Support national registry to track immunization status

*Also recommended: hepatitis A, Rota Teq, meningococcal polysaccharide, and human papillomavirus vaccines.

†Immunization card.

- Centers for Disease Control and Prevention National Immunization Program (NIP) (www.cdc.gov/vaccines)
- Immunization Action Coalition (IAC) (www.vaccineinformation.org)
- IAC—*Administering vaccines: Dose, route, site, and needle size* (www.immunize.org/catg.d/p3085.pdf)
- Morbidity and Mortality Weekly Report (MMWR)*, a newsletter issued weekly by the CDC
- National Network for Immunization Information (www.immunizationinfo.org)
- Package inserts accompanying the vaccines
- Recommendations of the ACIP of the CDC
- The Red Book: Report of the Committee on Infectious Disease, published regularly by the AAP

WORLDVIEW: Children adopted from abroad may not be properly immunized before their arrival in the United States. Immunizations should begin immediately, according to the recommendations listed in Appendix E. Immunization status of refugee or immigrant children should also be reviewed on arrival in the United States, and deficiencies should be addressed.

Educating and reminding parents about the importance of keeping their child up to date with vaccines is an important role of the pediatric nurse. A discussion of each of the immunizations recommended from infancy through adolescence follows, including information about schedule, common side effects, and other considerations.

ANSWER: The recommended schedule of immunizations for Stephanie for the next 6 months is shown in Table 8-1.

Diphtheria–Tetanus–Acellular Pertussis

Diphtheria and tetanus are rare diseases in the United States. Those infected are usually elderly people who have not received tetanus and diphtheria toxoids vaccine (Td) boosters in the previous 10 years. Serologic tests indicate that naturally **acquired immunity** to tetanus and diphtheria toxin does not occur in the United States. Universal vaccination with appropriately spaced boosters (Td) at 10-year intervals is necessary to provide continued protection. Pertussis is commonly known as *whooping cough* because of the high-pitched inspiratory whooping sound heard in children with this disease. It is an acute, highly communicable infectious disease with significant mortality in infants younger than 1 month of age. Diph-

TABLE 8-1
Sample Recommended Schedule of Immunizations for Stephanie Jenkins

As Soon as Possible	6 Months*	8 Months	10 Months
	eIPV		
	DTaP		
Hib	Hib	Hib	
Hep B	Hep B		Hep B
PCV	PCV	PCV	

*If in flu season, an influenza vaccine is recommended.

theria is an acute infection of the upper respiratory tract, the trachea, or both and is associated with membranous obstruction of the upper airway.

The diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP) is a combination of diphtheria and tetanus toxoid and acellular pertussis given as a series of five injections. During the first year of life, three doses each of DTaP are recommended at ages 2, 4, and 6 months, with a fourth dose given between 15 and 18 months of age. The fifth dose of DTaP is recommended again between ages 4 and 6 years and serves as a booster at primary school entry. Multiple doses of DTaP vaccine are necessary to provide adequate and lasting immunity. Antibody titers decrease over time; therefore, immunity is boosted with recommended administration of a single dose of tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccines (Tdap) (the adolescent preparation that has a much lower dose of acellular pertussis and diphtheria) at ages 11 to 12 years with subsequent regular Td (tetanus and a much lower dose of diphtheria toxoid) every 10 years thereafter.

The vaccine is injected intramuscularly in either the vastus lateralis or the deltoid muscle, depending on the child’s muscle mass. In 1% to 3% of children, there may be tenderness, redness, or swelling at the site of the injection, and fever that usually presents within the first 48 hours (Burns et al., 2008) (Nursing Interventions 8-1). Rarely, a child may spike a temperature of 104.8°F (40.4°C) or higher after DTaP immunization, as well as experience convulsions within 3 days; collapse or shock-like state; or persistent, inconsolable screaming (longer than 3 hours) within 48 hours of vaccination.

The only true contraindications to immunization are a history of severe anaphylactic reaction to a vaccine or vaccine component, or encephalopathy within 7 days after a dose of DTaP. The current DTaP has a significantly lower probability of vaccine-associated reactions than the previous version. Systemic reactions (anaphylaxis, anaphylactic shock, encephalopathy, or encephalitis) may occur up to 7 days after administration of DTaP (most reactions occur within 72 hours).

There are no documented cases of central nervous system injury or death associated with DTaP administration. Generally, immunizations should not be given to a child

NURSING INTERVENTIONS 8–1

Potential Reactions Associated With Immunization

Potential Reaction	Interventions
Pain with injection	Apply topical anesthetics (e.g., EMLA, LMX4, vapocoolant) at the injection sites, giving enough time for the anesthetic to have the desired effect (see Chapter 10). Administer oral sucrose for infants up to 3 months of age. Encourage parents to hold a young child during injection. Use distractions such as bubbles, blowing on pinwheels, and reading stories to reduce attention to pain and potentially relax the muscle. Encourage teens to use headsets to listen to music.
Localized redness or tenderness is a potential side effect of any immunization given intramuscularly or subcutaneously	Ice packs for the first 24 hours, followed by warm compresses if the inflammation persists, can help with symptomatic relief. Acetaminophen at the appropriate dose per weight can be given prophylactically before the vaccine is administered and continued every 4 hours for 24 hours.
Fever	Acetaminophen as above
Myalgia	Acetaminophen as above

with serious illness. Exercising this precaution avoids adding the risk of complicating an existing illness or confusing symptoms of the illness with a side effect of the vaccine. Most DTaP reactions occur with the fourth or fifth dose.

caREminder

Signs and symptoms that may warrant careful consideration about administration of subsequent vaccination with DTaP include convulsions with or without fever occurring within 3 days after vaccination and the following events occurring within 48 hours of vaccination: fever 105°F (40.6°C) or higher that is not attributed to another cause; collapse or shocklike state; and persistent, inconsolable crying lasting 3 hours or more.

A routine booster dose of Tdap is recommended at age 11 to 12 years for children who completed the recommended childhood DTaP series and have not had a Td booster. A Tdap booster dose is also recommended for 13- to 18-year-old children who have not received Td (catch-up immunization). Booster doses of Td are then recommended to be given every 10 years thereafter.

Haemophilus Influenzae Type B

H. influenzae type B (Hib) is the most virulent of the six strains of *H. influenzae*. In past years, it was the leading cause of invasive diseases, including bacterial meningitis. The Hib vaccine has proved to be a major safeguard for the health of young infants and children. During the first year of life, three doses of Hib vaccine are recommended at ages 2, 4, and 6 months.

Three types of Hib conjugate vaccine are available for use in infants. Infants given PRP-OMP (PedvaxHIB or

ComVax) at ages 2 and 4 months do not require a third dose at age 6 months. A final dose is, however, recommended between 12 and 15 months of age. DTaP/Hib combination products should not be used for primary immunizations in infants until the age of 6 months, but can be used for a booster dose after any Hib vaccine. Hib vaccine is administered intramuscularly in either the vastus lateralis or the deltoid muscle, depending on the muscle mass. The vaccines against Hib are major weapons in the prevention of childhood bacterial meningitis, and their use brought about a dramatic decline in the incidence of all types of invasive infections resulting from Hib.

Four conjugate vaccines and combination Hib/hepatitis B vaccines are licensed for use in the United States. PRP-D is recommended only for infants age 12 months and older; HbOC, PRP-OMP, and PRP-T are recommended for infants beginning at age 2 months. The vaccines are interchangeable for primary and booster dosages. However, PRP-OMP requires only two doses in the primary series as opposed to three doses with the other vaccines. The number of doses that the child receives depends on the age at which the vaccine was first given. Aside from a slight fever and soreness at the injection site, no other side effects are commonly associated with this vaccine (see Nursing Interventions 8–1).

Hepatitis B

Hepatitis B virus (HBV) is a potentially fatal viral infection, frequently culminating in cirrhosis or liver cancer during adulthood. HBV infection can occur perinatally or any other time during childhood. HepB vaccine is given in a series of three intramuscular doses. The AAP and the CDC recommend administration of HepB vaccine to all infants at birth. The three-dose schedule of

HepB vaccination for infants born to HBsAg-negative mothers is dose 1 at birth; dose 2, 1 month after dose 1; and dose 3, 6 to 18 months. Routine testing of infants to determine the presence of anti-HBsAg is not recommended except in infants whose mothers tested positive during pregnancy. If medically stable, a child born prematurely should receive the full dose of each vaccine at the appropriate chronologic age.

Approximately 95% of infants and 90% of adults who receive three injections develop immunity to the virus. Universal vaccination of all infants is recommended, and adolescents who have not previously received three doses of HBV vaccine should initiate or complete the series by 11 to 12 years of age. No follow-up antibody testing is needed for infants born to HBsAg-negative mothers (see Chapter 24).

Infants born to HBsAg-positive mothers should receive HepB immunoglobulin within 12 hours of birth in addition to completing the series of three vaccines. Otherwise, these infants face a 90% risk of developing chronic HepB and subsequently developing liver cancer or cirrhosis in their mid 30s to early 40s. Within 6 months of the last dose of vaccine, these infants should be tested to determine whether they are immune. If they are not immune and are anti-HBs antigen and HBsAg negative, additional vaccinations are given along with repeated testing for the presence of protective antibodies. Five percent of these children do not seroconvert.

Two recombinant DNA HepB vaccines are available in the United States. The most common side effect observed after vaccination has been soreness at the injection site (see Nursing Interventions 8–1). Rarely, anaphylaxis or anaphylactic shock may occur within 7 days.

Measles–Mumps–Rubella

Before the advent of the current vaccine, measles and rubella were common childhood diseases associated with a characteristic exanthem. Measles was associated with significant morbidity and death. Rubella, on the other hand, was a mild disease for children, but resulted in devastating sequelae for the fetus of a pregnant woman, especially during her first trimester. Mumps is characterized by swelling of the parotid glands and has associated secondary complications, although they are less severe and less frequently seen than with measles.

Measles–mumps–rubella (MMR) vaccines contain minute amounts of neomycin, and measles and mumps vaccines are derived from chick embryo tissue cultures, which may contain allergenic substances. Egg-sensitive individuals should be referred to an allergist before vaccination. Children with contact dermatitis to neomycin and egg protein allergies without anaphylaxis may be immunized; observe them for 60 minutes after vaccination (Piquier-Gibert et al., 2007; Robertson & Shilkofski, 2005).

MMR vaccine should be administered between ages 12 and 15 months, with a second dose at either age 4 to 6 years or 11 to 12 years to provide lasting immunity to measles. A minimal interval of 4 weeks between doses is recommended. The mumps virus vaccine is combined with measles and rubella; it should not be administered to infants younger than age 12 months, because persisting maternal

antibodies can interfere with the immune response. Because rubella presents a high risk to a developing fetus, the goal of rubella immunization is protection of unborn children rather than the recipient of the immunization. Vaccination of pregnant women with MMR is contraindicated.

MMR is administered by subcutaneous injection. Because of the risk of a diminished immune response or tissue damage, intramuscular injection is not recommended. Occasional soreness, redness, or swelling at the site of the injection can result after vaccination (see Nursing Interventions 8–1). In occasional cases, 5 to 20 days after the first dose there may be a rash, fever, generalized lymphadenopathy, or a seizure related to a high fever. One to 3 weeks after the first dose there may be joint pain, stiffness, or swelling lasting up to 3 days. Rarely, systemic reactions (anaphylaxis, anaphylactic shock, encephalopathy, or encephalitis) may occur 7 to 15 days after MMR administration.

Inactivated Poliovirus

QUESTION: Stephanie received the oral polio vaccine in Korea; the vaccine is no longer given in the United States. Does this present a problem for Stephanie? What questions can you anticipate that Sally may have regarding this immunization?

Poliovirus is an enterovirus with three serotypes that caused a range of diseases from asymptomatic illness to lower motor neuron paralysis. In 2000, the enhanced injectable inactivated polio vaccine (or eIPV) for subcutaneous administration became the vaccine of choice to provide protection against polio, replacing the trivalent polio vaccine (OPV) because of its associated risk of vaccine-acquired polio. The OPV is no longer distributed in the United States. The inactivated vaccine is highly immunogenic and, after three doses, induces immunity equal to or greater than that of the OPV. There have been no documented cases of vaccine-associated polio paralysis with the use of the inactive vaccine. The vaccine is given intramuscularly in the vastus lateralis with a primary series of three doses at 2, 4, and 6 to 18 months of age; and a booster at 4 to 6 years. Local inflammation is the most common side effect. Rarely, anaphylaxis or anaphylactic shock may occur within 7 days.

ANSWER: The oral polio vaccine that Stephanie received in Korea has an extremely slight risk of sequelae. Stephanie has had no reaction to the OPV and will now receive the IPV in the United States; therefore, she is at no additional risk at this point. Sally may have questions regarding the risks associated with the vaccine, and you can reassure her that there have been no cases of paralysis associated with the IPV.

Varicella-Zoster

Chickenpox, the primary infection caused by the varicella-zoster virus, is an extremely contagious type of

herpesvirus. It is generally considered a benign, self-limited infection in the usually healthy child. However, chickenpox has a high financial impact and inflicts harm in certain populations, particularly neonates and immunocompromised children.

Varicella vaccine (Varivax, Merck & Co., Inc.; a live, attenuated varicella-zoster virus vaccine) is recommended for administration in children at 12 to 18 months with a second dose at 4 to 6 years or in any child age 18 months or older who has not been immunized and has no history of chickenpox. The second dose is given at least 3 months after the first in children younger than age 13 years; for those older than 13 years, doses should be administered at least 4 weeks apart. The vaccine is given subcutaneously in the upper arm or anterolateral thigh.

The Varivax vaccine is well tolerated, with a small percentage of children experiencing mild fever and/or rash development in the month after immunization. Lesions, often located on the face, chest, and back, usually resemble mosquito bites and can last a few days. Other adverse reactions include pain at the site of injection and fever, as with other vaccines. If the child develops lesions, teach parents to avoid close association with immunocompromised individuals, pregnant women without history of or immunity to varicella, and newborn infants of such mothers.

Alert! Varivax is contraindicated in individuals with a history of hypersensitivity to any component of the vaccine, including gelatin; individuals with a history of anaphylactoid reaction to neomycin; individuals who are pregnant; and individuals who are immunosuppressed, have cellular deficiencies, or received blood products within the past 5 months.

Hepatitis A

Hepatitis A causes a viral primary infection in the liver that is most often nonsymptomatic in infants and young children. Children between 12 and 23 months of age should receive the vaccine. Havrix and Vaqta are approved for intramuscular administration in the deltoid in a series of two doses. The second dose of Havrix is given 6 to 12 months after the first dose. The second dose of Vaqta is administered 6 months after the first dose. Muscle soreness and slight redness are the most common side effects (see Nursing Interventions 8–1).

Pneumococcal 7-Valent Conjugate Vaccine and Polysaccharide Pneumococcal Vaccine

Streptococcus pneumoniae continues to be the leading cause of bacteremia, bacterial pneumonia, and otitis media, and is the second leading cause of meningitis in children. Children younger than 2 years of age are particularly vulnerable because of their decreased ability to produce antibodies against polysaccharide antigens and the frequency of colonization in this age group. Therefore, immunization of infants with the 7-valent PCV, Prevnar, can prevent *S. pneumoniae* disease and its complications. The

PCV contains seven serotypes that represented more than 80% of invasive pneumococcal infections in young children prior to vaccine licensure. A four-dose series (at 2, 4, 6, and 12 to 15 months of age) is recommended. Dosing needs for infants and children who start later vary with age of the child (see Appendix E). Doses are administered intramuscularly in the vastus lateralis. The PCV is a safe and effective vaccine. Fever is rare, and when it occurs, it is seen more after the second dose. Redness and tenderness at the injection site occur in a small percentage of children (see Nursing Interventions 8–1).

For children 2 years or older with chronic illnesses associated with an increased risk of pneumococcal disease, vaccination with a 23-valent pneumococcal polysaccharide vaccine (or PPV) is recommended. High-risk conditions include functional or anatomic asplenia, cochlear implants, chronic disorders of the pulmonary system, cardiovascular diseases, nephrotic syndrome or renal failure, diabetes mellitus, chronic liver diseases, immunosuppressive conditions, chemotherapy with alkylating agents, antimetabolites, or long-term systemic corticosteroids. The vaccine is given either intramuscularly or subcutaneously. Revaccination is recommended in children with a high risk for severe pneumococcal infection, including those likely to have a rapid decline in their serum antibody concentration 3 years after initial vaccination, and for those who will be less than 10 years old at revaccination. For children older than 10, the interval for revaccination is 5 years or more. Local reactions are the most common adverse event.

Influenza

Human influenza is very contagious, and the highest illness attack rate is in children. There are two licensed influenza vaccines: trivalent inactivated (TIV) and live attenuated (LAIV). These vaccines should ideally be given in the months of September, October, and November, before the influenza season begins, so the individual has sufficient time to build up immunity. Both vaccines are grown in eggs; therefore, individuals with a history of hypersensitivity, especially anaphylactic reactions, to eggs or to a previous dose of influenza vaccine must be cleared by an allergist and then closely monitored if the vaccine is administered.

The TIV is given intramuscularly and is recommended as an annual vaccination for children 6 to 23 months of age. It is also recommended yearly for children with chronic cardiopulmonary disease (hemodynamically significant heart disease), rheumatoid arthritis, Kawasaki syndrome, metabolic diseases, renal failure, hemoglobinopathies, immunosuppression, or long-term aspirin therapy. Children younger than 8 years of age should receive two doses at least 1 month apart if they are first-time vaccine recipients. Soreness at the injection site can occur with the TIV. Young children who have not had a prior influenza vaccine can experience fever, malaise, and myalgia (see Nursing Interventions 8–1).

The LAIV is recommended for healthy people age 2 to 49 years and is administered intranasally. The LAIV has better efficacy than the TIV in young children (Belshe

et al., 2007). Because those who receive the LAIV can shed virus for up to 7 days after receiving the vaccine, the TIV is the preferred vaccine if a child is in contact with a severely immunocompromised person. It is contraindicated in children and adolescents receiving aspirin-containing therapy, because of the association of Reye syndrome with aspirin and wild-type influenza infection. Reactions to the LAIV can include nasal congestion or rhinorrhea, headache, fever, vomiting, abdominal pain, and myalgia; these reactions are more commonly seen after the first dose. Acetaminophen, rest, and adequate hydration may be helpful. The LAIV should not be given if a child has congestion that would impede spraying. This intranasal vaccine comes in a prefilled nasal sprayer (0.5 mL), with 0.25 mL sprayed into each nostril immediately after thawing.

Meningococcal Vaccine

Neisseria meningitidis is a common cause of bacterial meningitis in children and young adults. First-year college students living in dormitories are a vulnerable at-risk group. Meningococcal (groups A, C, Y, and W-135) polysaccharide diphtheria toxoid conjugate vaccine (MCV4 [Menactra]) should be given at the 11- to 12-year-old child's visit, with catch-up for teens entering high school. First-year college students who have had no prior immunizations for *N. meningitidis* should preferably receive MCV4, but can be given the older meningococcal polysaccharide vaccine (MPSV4). Children (≥ 2 years) and adolescents with terminal complement deficiencies or anatomic or functional asplenia, and certain other high-risk groups should receive MPSV4 if the child is 2 to 10 years old, or MCV4 if the child is older. It is administered as a single 0.5-mL intramuscular injection, preferably in the deltoid muscle. There are no recommendations for a booster dose. Local pain, headache, and fatigue are the most commonly reported side effects, occurring in a small percentage of children.

Rotavirus

Rotavirus is the primary cause of severe diarrhea in young children worldwide (Nakagomi & Cunliffe, 2007). Rotavirus (RV) vaccines are live-attenuated oral agents. Dosage guidelines vary by manufacturer product and age at first administration. Generally doses are administered at 2, 4, and possibly 6 months of age. Adverse events associated with vaccine administration include diarrhea, vomiting, nasopharyngitis, otitis media, and bronchospasm.

Human Papillomavirus

Human papillomavirus (HPV) is a highly prevalent cause of sexually transmitted infection that can cause cervical cancer. Gardasil (Merck & Co., Inc.), recommended for adolescent females, is a three-dose recombinant vaccine, effective against HPV types 6, 11, 16, and 18, given intramuscularly over a 6-month period. The HPV series should be started at 11 to 12 years; the minimum age is 9 years. The goal is to vaccinate girls before initiation of any sexual activity, not only vaginal intercourse. Oral

HPV infection is strongly associated with oropharyngeal cancer (D'Souza et al., 2007). Local pain, swelling, and erythema are the most commonly reported side effects; fever and nausea are reported less frequently.

Considerations, Contraindications, and Precautions for Immunization

Strict attention to proper vaccine storage as well as administration protocol (e.g., exposure to light, or limitations in length of time vaccine can be out or mixed before administered) are essential to ensure vaccine effectiveness. In medical offices, use a thermometer to maintain a daily temperature log.

Simultaneous administration of routine vaccines at different anatomic sites is safe (Tradition or Science 8–1). Interchangeability of brands of a specific vaccine, however, is a question that may arise. All three brands of Hib vaccine are interchangeable. When immunizing against pertussis, the use of a vaccine from a single manufacturer is preferred. The rule of immunizations is simple if related to situations in which the manufacturer of the previous dose is unknown or the manufacturer's product is not available. The rule is: Use any product; do not miss the opportunity to immunize the child.

Fears and lack of knowledge regarding contraindications to immunization can needlessly interfere with a child's protection against life-threatening, but preventable, disease. Awareness of the reasons for withholding immunizations, both for the child's safety in minimizing adverse reactions and in achieving maximum benefit, is important for the pediatric nurse (Tradition or Science 8–2).

Low-grade fever and minor respiratory infections are *not* contraindications for vaccination. The only true contraindications to immunization are a history of severe anaphylactic reaction to a vaccine or vaccine component, or encephalopathy within 7 days after a dose of DTaP. Any adverse vaccine event must be reported in the

TRADITION OR SCIENCE 8-1

Is simultaneous administration of routine vaccines safe?

EVIDENCE-BASED PRACTICE

Multiple studies have demonstrated the safety, reactogenicity, and immunogenicity of routine childhood vaccines when administered simultaneously as separate or combined injections (Gabutti et al., 2004; Heinger et al., 2007; Pichichero et al., 2007; Shinefield et al., 2006; Tichmann-Schumann et al., 2005; Zepp et al., 2007). Separate injections administered simultaneously improve vaccination rates and are cost-effective by eliminating multiple office visits; combined vaccines achieve these goals plus minimize distress to infants and are more acceptable to parents.

TRADITION OR SCIENCE 8–2

Is there a link between the MMR vaccine and autistic spectrum disorder (ASD)?

EVIDENCE-BASED PRACTICE

Some parents refuse to vaccinate based on this unsubstantiated correlation; the topic has been amplified by inaccurate postings on the Internet. A link between the MMR vaccine and ASD was initially proposed by Wakefield et al. (1998) from a sample of 12 children. This stance was later retracted by 10 of the authors, noting that no causal link was established between the MMR vaccine and ASD (Murch et al., 2004).

A steady increase in children with ASD has been noted, but with no change in the rate of increase when the MMR vaccine was introduced in the study population (Kaye et al., 2001; Mäkelä et al., 2002; Taylor et al., 2002). The seeming increase in cases of ASD may be attributed to a broader concept of ASD and increased detection. Many studies have demonstrated a lack of correlation between MMR vaccination and ASD (Demicheli et al., 2005; Fombonne et al., 2006; Madsen et al., 2002; Smeeth et al., 2004; Wilson et al., 2003). In fact, incidence of ASD continued to increase when MMR was withdrawn (Honda et al., 2005) and when thimerosal was removed from vaccines (Schechter & Grether, 2008).

The evidence is convincing that there is no correlation between the MMR vaccine and ASD.

Vaccine Adverse Event Reporting System. The Vaccine Injury Compensation Program provides a system of no-fault compensation associated with the administration of specified vaccinations. A guide discussing contraindications to childhood vaccinations is available at no charge from the CDC.

caREminder

High fevers and severe illness are reasons to delay immunization, but only until the child has recovered from the acute stage of the illness to avoid adding the risk of adverse side effects from the vaccine to a child who is already ill, or confusing symptoms of the illness with a side effect of the vaccine. Minor illnesses such as a cold, otitis media, or mild diarrhea without fever are not contraindications to immunization.

Vaccines derived from live viruses are generally not administered to any child with an altered immune system, because severe vaccine-induced illness may result. MMR and varicella vaccination are contraindicated in children with immunodeficiency or therapeutic immunosuppression. This includes children on high-dose, long-term steroid therapy (>14 days) for at least 1 month until after discontinuing steroids. There are similar warnings about the need to delay immunizations for a specified period of

time for children receiving immunoglobulin and blood products. However, MMR is recommended for all asymptomatic HIV-infected persons and should be considered for all symptomatic HIV-infected persons because of the severity of the illness if an HIV-positive individual were to contract measles. Immunization with MMR or varicella is generally deferred during pregnancy.

Alert! As with any medication, rare severe systemic reactions such as anaphylaxis or generalized urticaria are possible. Because of the potential for anaphylaxis with the administration of a vaccine, observe any patient receiving a vaccine for several minutes after the vaccine is given for signs of immediate allergic/anaphylactic reaction.

Strategies for Improving Immunization Status

Education remains the most important tool in increasing immunization rates in this country and the world. Do not assume that the general public understands and accepts the premises for routine childhood immunizations. It is important to assess the parent's or caregiver's level of knowledge about immunizations and the diseases they prevent. Remember that changes in the recommended schedules of immunization can also be confusing to parents. They may not understand that certain vaccine-preventable diseases, such as measles and varicella, are highly contagious and that their unimmunized child is at risk if exposed to such diseases should an outbreak occur. New parents may not know the recommended times for the various vaccinations or the number of doses needed to be considered fully protected. Provide opportunities for parents to ask questions and inform them that combination vaccines are safe and reduce the number of injections that the child will receive, which is an important consideration.

Without a doubt, the risk from disease is always greater than the risk from vaccine for all individuals for whom vaccines are not contraindicated. Obtain informed consent before vaccinations are given. Many providers use immunization sheets (e.g., those available through the CDC) to provide information about the vaccines and their known side effects.

Explain the risks and benefits of immunization; it is the caregiver's responsibility to decide whether the child should be immunized (Clinical Judgment 8–1). Laws in most states require a minimum number of immunizations before school entry. Parents may decline immunizations on religious or, in some states, ideologic grounds. However, in the event of an epidemic, the health of the greater community takes precedence over the rights of the unimmunized individual. For instance, if a case of polio were to occur in a school setting, unimmunized children could be excluded from school for a specified period of time. If available, use state or regional immunization registries to help track and improve the delivery of vaccines.

The general public in the United States has no first-hand experience with most vaccine-preventable illnesses, because many have been virtually eliminated as a result of

CLINICAL JUDGMENT 8–1

An Unimmunized Toddler

Jason is a 15-month-old who was brought into the clinic by his mother because he has a cold, has been very fussy, and has been pulling at his ears. He has not been to your clinic before.

Questions

1. What other information should the nurse obtain?
2. What are the major issues that must be addressed at this visit?
3. Is Jason too sick to receive immunizations today?
4. Which immunizations should Jason receive today?
5. What should Jason's mother be taught about potential reactions to the vaccines?

Answers

1. The history of present illness:

How long has Jason been sick? (3 days)

Has he had a fever? (he has felt pretty warm but not hot)

What, if anything, has been done to treat him? Has it helped? (no treatment)

Is anyone else sick at home? (brothers have colds)

Review of systems

Past medical history

Birth history

Previous illnesses (colds; diarrhea; no injuries, serious or chronic illnesses)

Current medications (none)

Allergies (none known)

Immunization status (received the HBV in hospital at birth, none since)

Growth and development

Family and social history

Physical examination: normal except bilateral mucoid discharge from nares and bulging, erythematous tympanic membranes; rectal temperature of 100°F

2. Upper respiratory tract infection and bilateral otitis media; deficient immunization status
3. No. He does not have a high fever or serious illness.
4. HBV (second dose), DTaP, IPV, MMR, Hib, varicella, pneumococcal, hepatitis A
5. Acetaminophen should be given prophylactically before the injection and every 4 hours for 24 hours.

Application of ice at injection site, if needed, for 24 hours, and then warm compresses

Immunization-specific reactions (e.g., soreness at site, rash)

Notification of healthcare provider of fever more than 105°F (40.6°C), seizure, persistent and inconsolable crying lasting 3 hours or more, or collapse or shocklike state

Importance of continuing immunization series

routine childhood immunization practices. The phenomenon of “out of sight, out of mind” is operational; the longer it has been since a disease was prevalent, the harder it is to convince people that there is still a threat. Pediatric nurses must educate parents and caregivers about the need to vaccinate to ensure a healthy start and a healthy tomorrow for children.

HEALTH ASSESSMENT FROM INFANCY THROUGH ADOLESCENCE

Health assessment includes obtaining a health history and performing a physical examination. This history is a critical component that assists the health professional in determining which areas of the physical examination merit additional attention.

Communication Skills

Astute communication skills are particularly important when working with children. Young children are

nonverbal, and older children may not have the cognitive ability to put into words or to understand the importance of directly communicating their concerns. Adolescents may also be limited by their cognitive abilities; they may think the examiner will know or ask about issues that are pressing for them. Developing good communication skills is essential for both obtaining a health history and for performing a physical examination, and requires a conscientious and concerted effort. The nurse must be able to receive and send information while concentrating on both verbal and nonverbal messages that are being exchanged. Psychosocial factors that relate to one's ability to communicate successfully include the ability to be empathetic, to be an active listener (i.e., listening to what is said, or not mentioned, and how it is said), and to convey respect.

caREminder

When asking about sensitive issues, explain why the information is needed. The respondent may be more willing to respond and give an honest answer.

NURSING INTERVENTIONS 8–2

Communication Techniques for Conducting a Health History

- Introduce yourself, give your title, and state the purpose of the interview.
- Ask the parent/caregiver and child how they wish to be addressed.
- Use open-ended questions as much as possible, but follow with closed or direct questions when specific information is needed.
- Ask one question at a time and use language that the adult and child understand.
- Ask for clarification, if confused by the person's choice of words or explanation.
- Summarize to ensure that you correctly understand what was said.
- Close the interview by giving the parent/caregiver and child an opportunity to reflect to determine whether any additional information should be shared.

An awareness of cultural issues such as cultural communication patterns, health beliefs and practices, and specific cultural values is another important factor, as is attending to the parent's or child's nonverbal cues.

External considerations that affect communication include privacy, interruptions, comfort in the physical environment, and note taking. The need to ensure privacy involves arranging a setting so that conversations are not overheard by others or, if interviewing must be done at the bedside, pulling bedside curtains to partition the area and asking visitors (nonparents) to step out of the room. Interruptions break the flow of communication and are distracting; therefore, discourage unnecessary interruptions and ask not to be disturbed except for an emergency. Ensure a comfortable room temperature, adequate lighting, a quiet setting, and a place for the child or parent and examiner to sit and see each other. If the nurse stands during the interview, the message conveyed is that of the need for haste. When interviewing children and adolescents about their symptoms or healthcare issues, consider the child's or teen's developmental stage and his or her cognitive ability. Keep note taking to a minimum, so attention can be focused on who is speaking and what is being said. Clarify what has been said and summarize the information given by the child or parent.

The nurse must be aware of the previously mentioned communication skills and techniques when conducting an interval or episodic history interview related to a specific health problem (Nursing Interventions 8–2). Familiarity with a child and family can sometimes result in failure to actively listen or communicate as effectively by taking issues for granted.

Health History

QUESTION: How do you anticipate Sally Jenkins will respond to the routine questions of a health history? What tactics can the nurse use to make Sally less anxious?

The complete health history is divided into component parts that are addressed in a systematic fashion (Chart 8–2). Information required from a complete health history can be obtained through either a direct interview alone or through a combination of direct interview and a health questionnaire. If a questionnaire is used, verify that the informant can both read and write, and that the questionnaire is at an appropriate level of understanding.

CHART 8–2 COMPONENTS OF A COMPLETE PEDIATRIC HISTORY

- Identifying or biographic data
- Reason for seeking care (chief complaint)
- History of the present illness
- Past medical history
 - Obstetric and perinatal history
 - Hospitalizations, accidents, surgical procedures, ingestions, and injuries; emergency department visits
 - Previous illnesses (serious or chronic)
 - Current medications: prescription, over the counter, and complementary
 - Allergies
 - Immunizations
 - Nutrition and feeding practices
 - Growth and developmental milestones
 - Habits and behaviors
- Family health history
- Social and environmental history
- Review of systems

TABLE 8 – 2
Components of a Cultural Assessment

Attribute	Assessment Questions
Ethnic or racial identity	<ul style="list-style-type: none"> • Does your child identify as belonging to a specific ethnic or racial group? If yes, which? • Do both parents identify with the same group?
Acculturation	<ul style="list-style-type: none"> • Where was your child born? Where were both parents born? If outside the country, how long have you been in the country and where have you lived previously? • How much is your family immersed in the dominant culture versus your ethnic culture? • Does your family’s home have adornments (art, religious objects) primarily from your family’s ethnic background?
Language	<ul style="list-style-type: none"> • What language is spoken in the home and by whom? • What language is preferred when speaking with those outside the family? • Are you able to understand and speak the dominant language (e.g., English)? • Is an interpreter needed? • Do you have concerns about reading or understanding the instructions on medicine containers?
Religion	<ul style="list-style-type: none"> • Do you have a religion to which you ascribe? • How much does your family participate in religious-based activities? • Are there any religious needs that you want to continue if in the hospital?
Ethnic group affiliation	<ul style="list-style-type: none"> • Is shopping done within the family’s neighborhood with access to ethnic food choices? • What are the characteristics of the family’s social networks? • Are most activities (school, shopping, recreation) performed within the ethnic group?
Community affiliation	<ul style="list-style-type: none"> • What are the characteristics of your family’s neighborhood? Is it ethnically diverse? • Does your family feel accepted or discriminated against in the community? • Is the healthcare team doing anything that makes your family or child uncomfortable?
Family interactions	<ul style="list-style-type: none"> • How are decisions made in your family? Who makes important decisions? • How is affection demonstrated in your family? • When do children require disciplining and how is this done?
Traditions	<ul style="list-style-type: none"> • What do we need to know about your family’s traditions to provide healthcare? • What are your family’s dietary habits? • Are there foods or fluids that you think will help you stay healthy or get better (e.g., hot or cold beverages or foods)? • Are there any foods or fluids that you should not have or that might make you sick? • Are there special clothing or dressing preferences that you have based on your ethnic customs?
Healthcare practices	<ul style="list-style-type: none"> • Are there practices that help your child stay healthy such as herbs, vitamins, specific foods, jewelry/medals, lotions? • How long has the problem been present? (Try to get specific times, not just “long time” or “short,” because time orientation may vary among cultural groups.) • What has been done to help the child get better? Have any herbs, medicines, or other treatments been given? Have you used any folk practices? Has the child been treated by a religious or community leader? What is that person called? • Are there any medicines or treatments that you think might help? • Are there restrictions on the gender of the healthcare provider?

Adapted from Friedman, M. (1990). Transcultural family nursing. Application to Latino and black families. *Journal of Pediatric Nursing*, 5, 214–222.

WORLDVIEW: Seek the services of an interpreter who is fluent in the language of the informant and preferably trained to perform interpreter duties whenever the historian and interviewer are not fluent in the same language. Asking a sibling to interpret for the parent may be perceived by the parent as a sign of disrespect. Parents also may be reluctant to disclose information about a genetic problem or sexual issue if their child is interpreting for them. An individual who is familiar with both a specific language and culture is referred to as a *cultural broker*. The use of a cultural broker is preferred in instances when there is a language or cultural barrier.

Cultural and spiritual dynamics are essential to accurate data collection (see Tables 8–2 and 8–3). For school-aged children, the parent may provide information, but also direct questions to the child as appropriate. Give the young adolescent (age 12–14 years) the choice of whether the parent is present during the interview and examination, but always allow time to talk alone with the adolescent. Interview the older adolescent alone. Address issues of confidentiality with both the adolescent and the parent; tell them that what each one says in confidence will not be

TABLE 8–3
Components of a Spiritual Assessment

Attribute	Assessment Questions
Values, relatedness	<ul style="list-style-type: none"> • What do you value most in life? With whom do you enjoy spending time? • What brings you strength, comfort, joy, and hope?
Sources of support	<ul style="list-style-type: none"> • Do you use specific practices that help you cope? • Is there someone or something that you find especially helpful to you? • Who provides support for you in times of stress?
Meaning	<ul style="list-style-type: none"> • What is the meaning or purpose of life? • What is the meaning and purpose of suffering? • Do you feel that your current situation has a specific meaning or purpose? • In what ways will this illness affect your life's goals?
Beliefs	<ul style="list-style-type: none"> • What are your spiritual beliefs about a higher being, birth, death, bad things that happen, health, and illness? • What events in your life have affected your spiritual beliefs? • Do other family members share your spiritual beliefs and practices? • How can we incorporate your spiritual beliefs into your child's healthcare?
Affiliation	<ul style="list-style-type: none"> • Do you identify with a specific religion? • To what extent does your family participate in worship or related activities? • Does your child attend religious school?
Practices	<ul style="list-style-type: none"> • Describe the spiritual activities (e.g., prayer, scripture reading, meditation, communing with nature) that play an important part in your family life. • Do you have spiritual beliefs that relate to your daily habits and activities? • What are the spiritual practices that your child ascribes to? • Would blood product use or organ donation be proper given your religious beliefs? • Would limiting or withdrawing medical care be proper given your beliefs? • Are there specific practices relating to end of life to which you ascribe?
Dietary/dress practices	<ul style="list-style-type: none"> • Do your beliefs influence or prescribe your dietary or dress practices? What are they?

discussed with the other unless the information is something that the individual agrees to share. Issues of confidentiality generally center on sexual activity, birth control, and feelings about oneself or the parent–child relationship. Tell the adolescent at the start of the interview that thoughts about harming oneself or others cannot be kept confidential. Encourage and promote positive communication between parent and adolescent.

Many adolescents are afraid to ask questions and are grateful when the topic is approached by the nurse. Phrasing questions in a nonthreatening way is a useful technique. For example, instead of asking a direct question about a sensitive area, a nonthreatening approach would be to say, “Some teens your age tell me that they have tried smoking. Is this something you might have tried?” Remembering the acronym HEEADDSS provides an easy reminder about key topics to discuss with all adolescents (Chart 8–3). To start, ask the teen what they are good at. Help them to identify their strengths. A teen who gets a positive message about what is right with them is often more open to working on behaviors they could improve on.

ANSWER: Questions about each topic are asked that Sally has no information with which to respond.

The fact that she knows very little may make her feel anxious

and inadequate. One tactic would be to say, “Share everything you know about Stephanie.” This approach would allow Sally to discover she does have newfound knowledge about Stephanie.

Identifying or Biographic Data

To begin the health history, obtain the child's name, nickname, birth date, sex, and the identity of the person providing the information. If an interpreter is present, include the name of this individual as well. If appropriate, record a statement about the reliability of the information in the written notes about the health history. For instance, if the informant provides only vague details or inconsistent information, this should be noted. The informant may not be able to provide a complete health history for various reasons, including foster care, adoption, or death of parents. In such situations, note as “information not known by informant.”

caREminder

Even if the informant is a parent, he or she may not be knowledgeable regarding the child or the child's current condition.

CHART 8-3 ADOLESCENT HISTORY

H—home/family life and involvement, exposure to violence (in the home or community as a victim or witness), presence of a support system (profile of parents, friends, and others)

E—educational performance, employment, vocational development, future plans

E—exercise and eating behaviors and practices; amount and type of exercise; type and amount of intake, paying close attention to nutritional risk factors for eating disorders; overweight and underweight

A—activities, including sports, after-school involvement, risk-taking behaviors (safety concerns, such as driving under the influence, drag-racing cars, hitchhiking, high-risk sex)

D—drugs (alcohol, tobacco, and other street drugs) tried and used, onset, duration, frequency, type

D—depression

S—suicidal thoughts and suicide attempts

S—sexual history

Females

- *Menarche/menses*: age at onset; duration, quantity of flow, and frequency of menses; last menstrual period; any problems with dysmenorrhea
- *Sexual activity*: sexual behaviors and practices (include questions ranging from self-masturbation, kissing, necking, petting, oral copulation, to intercourse); if applicable, frequency of sexual coitus and age at start; sexual orientation (males, females, bisexual); number of sexual partners; issues of date rape, prior sexual molestation, assault, or prostitution
- *Contraceptive history*: understanding of various types of contraceptives for females and males; current and past use of contraceptives
- *Obstetric and gynecologic history*: number of pregnancies, past gynecologic procedures or illnesses (pelvic inflammatory disease)
- *History of sexually transmitted diseases*: type, dates, and treatment; sexually transmitted disease history in partner; any current signs or symptoms
- *Body image*: perceptions about her body and sexual identity
- *Anticipatory guidance*: preparation for her emerging sexual development
- *Partner*: involvement and commitment to family planning
- *Other*: personal concerns or issues

Males

- *Spermarche*: age of first ejaculation
- *Sexual activity*: sexual behaviors and practices (include questions ranging from self-masturbation, kissing, necking, petting, oral copulation, to intercourse); if applicable, frequency of sexual coitus and age at

start; sexual orientation (females, males, bisexual); number of sexual partners; prior sexual molestation, assault, or prostitution

- *Contraceptive history*: knowledge about condoms to prevent pregnancy and sexually transmitted diseases, consistency of condom use or other methods of birth control, whether he and his female partner discuss using a method of birth control, male responsibility if he fathers a child
- *History of sexually transmitted diseases*: type, dates, and treatment; sexually transmitted disease history in partner; any current signs or symptoms
- *Body image*: perceptions of his body and sexual identity
- *Anticipatory guidance*: preparation for his emerging sexual development
- *Partner*: involvement and commitment to family planning
- *Other*: personal concerns or issues

Reason for Seeking Care (Chief Complaint)

After obtaining the child's biographic data, determine the reason for the child's visit. This section typically is designated as either the *reason for seeking care* or *chief complaint*. These terms are used in situations when symptoms or signs of illness are the focus of the encounter. Parents and children may find the phrase "reason for seeking healthcare" easier to understand, especially if they do not view a symptom or clinical finding as a "complaint." In either case, record the description of the complaint in the parent's, caregiver's, or child's own words. Put this statement in quotation marks; it represents the person's spontaneous response to a simple, open-ended question such as "What brings you here today?" "What seems to be the matter?" or "What concerns you about your child?"

If a symptom or problem is identified, include the duration of this concern in the statement (e.g., "My baby's been throwing up for 2 days.") Be sure to include the child, as appropriate, during history taking. The child's perception of the reason for the visit may differ from the caregiver's and may add information to the chief complaint.

History of the Current Illness

Obtaining a history of the child's current illness directs the physical examination and guides the nurse's overall assessment of the child's health. When gathering data, be sure to determine the onset, duration, and nature of each symptom; any precipitating or related factors; and any relief measures or remedies taken. At the end, the nurse should possess data that describes the chronology of the problem and any other associated manifestations plus the exclusion of other possible pertinent symptoms (i.e., negative findings). Investigate eight factors for each symptom identified (Table 8-4).

Past Medical History

Determining a child's past medical history is another important component of the overall assessment. This section

TABLE 8 – 4

Symptom Assessment

Factor	Assessment Questions
Location	For symptoms such as pain, rash, lesions, or paresthesia, inquire regarding the specific body location or locations, whether the symptom is localized or generalized, and, for pain, whether it is deep or superficial or radiates.
Quality or character	Assess the character or quality of the symptom by asking the historian to describe the symptom. For example, is the pain dull, sharp, aching, burning, stinging, or throbbing? Is the rash a bright red or pink, bumpy, blistery, or flat? Does the child's cough sound like a bark or a whooping noise? Is the symptom getting better, worsening, or staying about the same?
Quantity and severity	Ask questions about the amount and severity or intensity of the symptom: <ul style="list-style-type: none"> • When the infant vomits, estimate how much formula or breast milk is vomited—a tablespoonful or 2 to 3 oz? • With heavy menstrual bleeding, does the teen completely saturate a pad? • How often must the pad or tampon be changed? Rate the intensity of the pain using a developmentally appropriate tool (e.g., face scale or numeric rating scale), or the intensity of itching using a 0- to 5-point scale with 0 point being no pain and 5 points the worst itching you have ever had. Questioning about the effect that the symptom or illness has on the child's activity level (e.g., playing and school attendance, sleeping, and eating) is a useful method to determine the severity of the problem.
Timing	Timing or temporal relationship of a symptom relates to its onset, duration, when it occurs, and frequency as well as precipitating factors. Try to determine the exact date or time that the symptom appeared and how long it lasted. Were there any periods when the symptom abated (i.e., was it intermittent or steady)? Timing can also be related to the quality or intensity of the symptom. Ask if there are any precipitating factors or any variations in the intensity or quality of the symptoms related to time of day, night, or month.
Setting	The setting in which the symptom appeared is often relevant. For example, is the child's stomachache present only during math class at school?
Aggravating or relieving factors	Ask about factors that may seem to make the symptom better or worse. Does the pain subside if the child does not put weight on the leg? What medication or alternate therapies has the adolescent tried for menstrual cramps and have they helped relieve the cramping?
Perceptions of the child and parent	How the parent/caregiver and child perceive the symptom alerts the nurse to areas of potential anxiety. For instance, parents of a child who has frequent epistaxis may be concerned about leukemia.
Associated factors or symptoms	Query the child about associated factors or symptoms that might be present and not mentioned by the historian. A review of systems related to the symptom is done at this point in the health history. Many healthcare professionals do the total review of systems here rather than after the family health or disease history.

of the history is a profile of the child's past illnesses, healthcare, health promotion activities, growth and development, injuries, and hospitalizations. The information obtained provides additional clues regarding past events that may have influenced the current problem or situation.

Obstetric and Perinatal History

Determine the duration of gestation and aspects of the pregnancy, labor, and delivery. When did the mother

obtain prenatal care? Did she experience any prenatal vaginal bleeding, premature contractions, or other problems? Was it a vaginal delivery, or, if it was a cesarean section delivery, for what reason? Did the mother consume alcohol, use drugs, or smoke during her pregnancy? Ask about the infant's birth weight, length, and Apgar score, if known. Also ask whether the child was born prematurely and whether the infant went home with the mother after birth or if any complications, such as ABO incompatibility or hyperbilirubinemia,

occurred. Ask questions about length of hospital stay for premature infants, the need for assisted ventilation, and whether any diagnostic tests were done such as lumbar punctures, blood cultures, or imaging studies.

Hospitalizations, Emergency Department Visits, Accidents, Surgical Procedures, Ingestions, and Injuries

Ask the parent about any hospitalizations, emergency department visits, surgical procedures, radiographic or diagnostic imaging studies, or poison ingestion. Include the date of the event or approximate age of the child at the time of the event.

Previous Illnesses (Serious or Chronic)

Ask about serious or chronic health conditions or prior life-threatening illness. Seek information about the age of presentation and age of diagnosis as well as treatments given.

Current Medications

Determine all current medications, including prescription, over-the-counter, and complementary medications, that the child is or has recently taken. Include the name and dosage as well as the method and duration of administration, and the presence of any side effects. It is also important to ask about the use of complementary therapies or folk remedies. Determine when the last dose of a medication was given and the parent's understanding of the indications and dosing requirements for all medications.

Allergies

Note any known allergies. If the child has a history of asthma, allergic rhinitis or conjunctivitis, or atopic skin disease, note age of onset. Ask the parent to describe the type (e.g., if present, characteristics of rash, urticaria, or angioedema) and severity of symptoms and how the child was treated.

Immunizations

Review the child's immunization record. Ask the parent whether any untoward reactions occurred related to an immunization. If so, have them describe what happened. List the date of the last tuberculin skin test as well.

Nutrition and Feeding Practices

To calculate an infant's caloric intake, ask the parent about the frequency of breast-feeding or the type and amount of formula given during the past 24 hours. As solids are introduced, determine what is being offered, how much, and how frequently. Also, determine whether the younger child is still feeding from a bottle or has switched to a cup. For the older child, ask about whole or reduced-fat milk intake during a 24-hour period and the number, portion size, and type of foods eaten each day (i.e., description of typical breakfast, lunch, dinner, and

snacks). Using food groups or the food pyramid as a questioning guideline is another approach. A 3-day or 1-week food diary is useful if a nutritional disorder is suspected. See Chapters 4 to 7 for additional discussion about nutritional assessment for different age groups. Other feeding issues to address include problem areas for the breast- and formula-fed baby (e.g., propping of bottle, taking a bottle to bed at night, breast-feeding difficulties). For toddlers and older children, nutritional problems may be a result of snacking on food with empty calories, excessive soft drink consumption, self-feeding, food jags, and skipping meals.

Growth and Developmental Milestones

QUESTION: What are the fine motor and gross motor skills appropriate for a 4-month-old child?

Seek evidence of the attainment of developmental milestones by performing an appraisal of key developmental areas: fine and gross motor, language, personal, social, psychosocial, and cognitive (see Chapter 3). For infants and young children, ask about age at which the milestone was achieved. Growth parameters are best assessed by measuring height, weight, and head circumference, and calculating the body mass index (BMI) (see the section on Physical Examination in this chapter).

For the school-aged child and adolescent, inquire into school performance (grades) and the child's socialization with peers (e.g., "What do you do after school?" "What hobbies or recreational activities interest you?"). The nurse can ask how the child is doing in each subject and whether the child is in an age-appropriate grade or in any special programs in school. Assess the ability to form friendships with peers and inquire about problem areas such as being bullied or having "bad" grades. For the adolescent, issues related to sexual development and identity emerge as major areas. Obtain a comprehensive sexual history including sexual identity and activity.

The nurse may want to use a quick checklist for this assessment that details developmental milestones for the various age groups; refer to Chapters 4 to 7 for summary tables and to *Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents* (Hagan, Shaw, & Duncan, 2008).

ANSWER: Stephanie's fine motor skills should include reaching for items and grasping. Her gross motor skills should show good head control and perhaps rolling over. She should smile spontaneously, squeal, laugh, and turn toward a voice.

Habits and Behaviors

A child's habits and behaviors should also be discussed during the health history. Does the child have any unusual rituals or behaviors? Address sleep patterns and discipline

practices. For young children, gather information about toileting and temperament. Ask the older child or teenager privately about gang involvement, tobacco and drug use, alcohol consumption (Chapter 29 further discusses substance abuse), and sexual activities or practices. Be sure to ask adolescents about feelings of sadness or depression.

Family Health History

To get a more detailed picture of a child's health history, it is important to ask about the child's family health history. Obtain information about the age and health or cause of death of the child's closest family members. The use of a genogram to diagram relationships and to identify family health problems readily provides data in a visual fashion (Fig. 8–1). Inquire about any family history of heart disease (age of onset), sudden death, high blood pressure, kidney disease, diabetes, allergies, or asthma; any genetically inherited diseases, mental retardation, congenital anomalies, or illnesses; seizures; learning disabilities; and alcoholism. In addition, it is also important to ask about whether there is anyone else in the family with symptoms similar to the child's presenting problems.

Social and Environmental History

The family unit and support system are important factors in health promotion and disease prevention. Determine family cohesiveness and interpersonal relationships by seeking information about who lives with the child, who is the primary caregiver, and whether the family has a support system to help with child care or in times of need. If the biologic parents are separated or divorced,

inquire about involvement of the out-of-home parent. Family living arrangements, home environment, and economic status have implications for healthcare planning and management. Address questions in a sensitive manner and with an explanation given to the family about the importance of the nurse knowing these issues to facilitate the care of their child.

Seek information about the safety of the home setting and community (e.g., If the home has iron bars on the windows, can the bars be released in case of fire? If the child has access to a swimming pool, do the parents know cardiopulmonary resuscitation?). Health promotion practices or behaviors (e.g., use of car seat restraints and bicycle helmets, use of sun protection, poison control measures, smoke and carbon monoxide detection devices, and removal of firearms from the home) can be identified (see Chapters 4–7). Obtain and update information about safety strategies specific to each developmental stage or age for all children.

Review of Systems

The review of systems evaluates the past and present health states of each body system, is a double-check to determine whether significant data were omitted, and also allows the nurse to determine health promotion needs. Ask about specific signs and symptoms for each body system and also query about health promotion activities related to a particular body system.

Each health challenge chapter in this text (Chapters 14–30) discusses alterations in a body system and includes a section called Focused Health History. This section discusses pertinent information to obtain for a review of that particular body system.

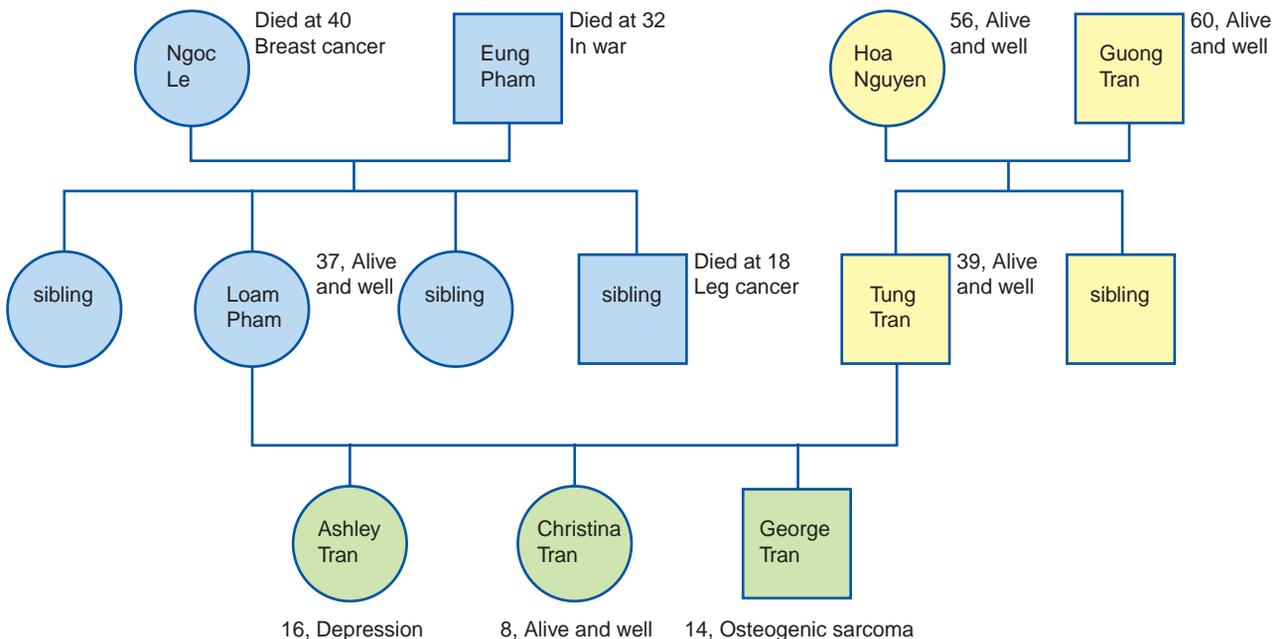

FIGURE 8–1. A genogram provides a pictorial overview of family health challenges and can assist in detecting disease trends or risks. Shown here is a genogram of the Tran family mentioned in Chapter 1. Note the inherited pattern of tumor-type cancers. The possibility of the genetic predisposition to cancer (the p53 mutation) may become evident with a genogram. The Tran family shows the incidence of multigenerational tumors and death at a young age. Circles represent females; squares represent males.

Physical Examination

QUESTION: Today's examination is to be basically noninvasive to determine the status of Stephanie's health, and to allow Stephanie and her parents to get to know the physician, nurse practitioner, and office nurses. This is Stephanie's first physical examination in the United States. What are three components of a physical examination usually done at birth to rule out congenital malformations?

After obtaining a child's health history, it is important to perform a complete physical assessment. The usual approach to the physical examination of infants and young children is to start with the chest and work downward, and then finish with the head and neck. The traditional sequence in preschool and older children starts with inspection of the head and works downward (head to toe). The usual sequence may need to be altered based on such factors as the child's developmental age and presenting symptoms, but the important point is to eventually cover all aspects of the examination.

caREminder

Wait until the end of the examination to perform the more intrusive procedures that are likely to distress the young child, such as inspection of the mouth and otoscopic examination of the ears.

When examining infants be sure that the infant is always able to view the parent. Approach toddlers and preschoolers gradually, and keep them close to the parent. Modesty is an issue that surfaces with some preschool children but takes on heightened importance to school-aged children. Make every effort to provide appropriate covering and to expose only the area to be examined. Perform hand hygiene before beginning the examination and don gloves to examine the genital and rectal areas. Warm hands before palpation. Warm a cold stethoscope by rubbing it in the hands. Follow safety measures and have all needed equipment readily available. Allow time for the child or adolescent to ask questions and to clarify what, if any, physical findings are found. Developmental Considerations 8–1 identifies age-appropriate approaches to the physical examination.

ANSWER: It is known that Stephanie tolerates her diet well and is voiding and producing stool without difficulty. However, it is still important to examine her mouth to check the hard and soft palates for notches, clefts, and unusual arches. The incidence of cleft palate disorders is highest in Asian populations. Listening to heart sounds to determine that there is not a murmur, and examining her hips for any hip joint instability are also important components of today's physical examination to rule out any congenital problems.

Vital Signs

QUESTION: How would a nurse obtain accurate vital signs on a 4-month-old infant?

Begin the physical examination by measuring the child's vital signs: respiration, pulse, blood pressure, and temperature (see [thePoint](#) for Procedures and Supplemental Information: Assessing Vital Signs and Supplemental Information Assessing Vital Signs). Compare findings with normal ranges for the child's age (see Appendix D). Pain is often considered the fifth vital sign (see Chapter 10 for assessment of pain).

KidKare ■ Choose your words carefully when explaining actions to a young child. Avoid saying, for example, "I'm going to take your pulse now." The child may think that you are going to actually remove something from his or her body. A better phrase would be, "I'm going to count how fast your heart beats."

Respiration

Measure the child's respiratory rate first, before you conduct other procedures that may affect the rate. Count the number of breaths the child takes.

Pulse

Assess the apical pulse rate for 1 full minute to detect possible alterations in rhythm, preferably when the child is quiet; if the child is crying or fussy, note this. Document the child's activity during pulse assessment. Variations in heart rate generally are much more dramatic in children than in adults. Assess for factors known to affect heart rate and quality, including medication, activity, hyperthermia or hypothermia, hypoxia, apprehension, pain, increased intracranial pressure, hypovolemia, and hemorrhage.

Blood Pressure

Measuring blood pressure is a routine part of physical assessment in children older than age 3 years and in younger children who have symptoms that warrant investigation (e.g., pulse strength difference between upper and lower extremities). Various devices can be used to measure blood pressure, including mercury-gravity or aneroid sphygmomanometers and electronic devices that use oscillometric or Doppler techniques. Use a properly sized cuff for accurate readings.

Temperature

Normal body temperature is roughly 98.6°F (37°C) measured orally. Body temperature can be influenced by many nonillness-related factors. Exercise, crying, and environmental heat can increase temperature. In contrast, exposure to cold air can lower body temperature, as can vasodilating and anesthetic agents. Diurnal variations in body temperature also occur. Body temperature is generally lowest between 1 and 4 AM, and is highest between 4 and 6 PM.

DEVELOPMENTAL CONSIDERATIONS 8–1

Physical Examination From Infancy Through Adolescence

Infancy

Examine an infant in a parent's lap or on the examination table if the infant is quiet. Leave the diaper on and wrap the young infant in a blanket to maintain warmth and security. Use comforting measures such as a pacifier or bottle if the infant becomes fussy. Talk softly and establish eye contact. Avoid sudden, startling movements. Parents can help with the ear examination by having the older infant rest his or her head against their shoulder. Use the pediatric head of the stethoscope when auscultating in small infants.

Early Childhood

It is best to examine the young child while he or she is sitting in a parent's lap. Examiner and parent sit opposite each other with knees touching to use knees as an examination surface. Use play techniques to gain attention and distract child with stories. Let child handle equipment but be mindful of safety issues. If the child is uncooperative, quickly perform what has to be done. Call the child by name and praise him or her frequently.

Middle child

Give the preschooler the choice of either sitting on a parent's lap or sitting on the examination table. Tell the parent to stay close to and within eye contact of the child. Explain procedures and what is being done in simple terms that the child understands. Interact with the child, allow the child to handle equipment, and encourage the child to talk about him- or herself. Modesty concerns start to emerge.

Middle child

Allow the older school-aged child the choice of whether to have a parent present. Be cognizant of need for privacy and modesty concerns. Explain procedures and equipment (e.g., allow child to listen to own heart). Teach about body function while examining. Focus on dialoguing and interacting with the child. Common issues are ticklishness when palpating and hesitancy to allow genitalia to be checked. To reduce ticklishness when palpating the abdomen, place the child's hand under your hand, have the child bend at the knees, or use a stethoscope to apply pressure to palpate. These are also useful techniques to use if the child is complaining of abdominal pain and is fearful of having his or her abdomen palpated. Provide for covering of genitalia and be matter of fact with the child about examining the genitalia (i.e., explain that you look at all children's private parts to be sure that everything is fine). This is also an opportunity to teach about approaching sexual development.

Adolescence

Allow the adolescent to undress in private before the physical examination. Explain what is being done and why in terms easy for the adolescent to understand. Actively talk with the adolescent during the examination and frequently emphasize normal findings (e.g., "Your ears are fine," "Your eyes are great"). Ask the adolescent questions about sexual changes and let him or her know that these changes are normal and expected. When examining the genitalia of an adolescent of the opposite sex or if a male examines the breasts of a female, it is common and standard practice to always have someone present who is of the same sex as the adolescent being examined.

ANSWER: While Stephanie is calm and held by Sally, count her respirations for a full minute without touching her. The quality of her breath sounds will be evaluated later. Just touching her with a stethoscope will increase her respiratory rate. With a warmed stethoscope, listen to the apical pulse for a full minute. Obtain an axillary temperature while Stephanie remains on her mom's lap. A blood pressure in all four extremities can be obtained at a later visit.

Anthropometric Measurements

QUESTION: Plot Stephanie's height, weight, and head circumference on the growth chart for girls, birth to 36 months, and then calculate her percentiles. What would you expect to see?

Obtaining accurate anthropometric measurements provides valuable information about how a child is growing (see Tradition or Science 28–1 and **thePoint** for Procedures: Growth Parameter Assessment). When plotted on a growth chart, this information allows comparison with other children of the same age and sex, and reveals the child's own pattern of growth (see Appendix A for CDC growth charts). Standard growth charts are age (birth–36 months and 2–20 years) and gender specific. When the CDC growth charts were revised, data on low-birth weight infants was included but not data on very low-birth weight infants (<1,500 g). Alternate charts are available to assess the growth of very low-birth weight infants. Currently, the most appropriate charts to use are the Infant Health and Development Program charts (Guo et al., 1997).

Growth charts for children with specific conditions have been compiled (e.g., Down syndrome, Turner's syndrome, cerebral palsy, achondroplasia). These charts are useful for comparing a child with other children with similar diagnoses; however, because the charts are based on small numbers of children, they should not be used alone. Plot the child's measurements on both the CDC growth charts and the specialty charts.

ANSWER: Stephanie's weight is in the 75th percentile and her height and head circumference are in the 50th percentile. Stephanie's appearance confirms that she is chubby, with dimpled wrists and knees. This provides a starting point to track Stephanie's own growth curve.

Height

For infants and toddlers up to age 24 months, height measurement is best done by placing the vertex of the infant's head at the top of a flat measuring board and the soles of the feet firmly against the footboard (Fig. 8–2). Be sure to extend the hips and knees fully for accurate measurement.

For children older than age 2 years, a wall-mounted stadiometer provides the most accurate standing height measurement. Place the movable measuring rod on the

FIGURE 8–2. To obtain an accurate height measurement, the examiner ensures that the infant's head is against the end point and his or her hips and legs are fully extended on the measuring board. The measurement scale is calibrated from the head end point (e.g., in this example, the scale starts at 1 in).

topmost part of the child's head while he or she is standing without shoes and with the heels, buttocks, and shoulders just touching the wall. Instruct the child to look straight ahead without tilting the head. In some older children unable to stand independently (e.g., wheelchair bound), upper body height is measured using adaptive equipment.

Weight

Verify that the scale is calibrated correctly before measuring a child's weight. Weigh an infant, who should be nude, on an infant scale, placing your hands close to the body to prevent the child from falling off the scale (Fig. 8–3). Change the protective paper on the scale with each use; disinfect the scale per facility policy. Use the same scale, when possible, to weigh an infant returning for assessment of weight gain or loss.

If a child is old enough to stand alone, typically after age 2 years, weigh the child on a stand-up scale; the child can wear underpants or an examination gown. If a very young child is scared to stand on the scale alone, weigh both the parent and the child and then subtract the parent's weight.

BMI measurement is useful in determining whether a child is overweight or underweight. Calculate BMI for children beginning at age 2 years as follows:

$$\text{BMI} = \left(\frac{\text{Weight in kilograms}}{(\text{Height in centimeters}) \times (\text{Height in centimeters})} \right) \times 10,000$$

or

$$\text{BMI} = \left(\frac{\text{Weight in pounds}}{(\text{Height in inches}) \times (\text{Height in inches})} \right) \times 703$$

After calculating, plot the child's BMI measurement for age on the appropriate gender-based grid (see

FIGURE 8-3. Older infants are usually more cooperative with being weighed when allowed to sit on the scale. Note the close proximity of the nurse's hands for safety.

Appendix A). A child with a BMI measurement between the 85th and the 95th percentile is at risk for being overweight, with a measurement higher than the 95th percentile being overweight. A child with a BMI measurement lower than the 5th percentile is considered underweight.

Head Circumference

At every well-child visit up to age 2, measure head circumference (occipitofrontal circumference) by wrapping a paper tape measure around the maximum occipitofrontal circumference (Fig. 8-4). Take two separate readings, the measures should agree within 0.2 cm ($\frac{1}{4}$ in). If there is a difference of more than 0.2 cm, remeasure and record the average of the two measures in closest agreement to avoid error in obtaining this critical measurement (MCHB, n.d.).

General Appearance

The child's general appearance is an important indicator of wellness or the severity of an illness. In a complete physical examination, record the child's general appearance

FIGURE 8-4. Head circumference is measured by wrapping the paper tape over the eyebrows and around the occipital prominence.

prior to the physical assessment of the individual body systems. These observations represent the examiner's subjective impression of the child's overall state of health based on the physical examination and the time spent interviewing the child, parent, or both. Note whether the child appears sick or well, functions at a developmentally appropriate level for age, and appears well nourished and hydrated.

In addition, other relevant indicators include the child's state of hygiene in terms of body odor, general grooming, and cleanliness, as well as the condition of the child's clothing. The child's behavior, interactions with others, overall personality, and activity level are important to observe. For infants and young children who are ill, the type of cry or voice (e.g., hoarse, husky, weak, or high pitched) is an important clinical assessment. Likewise, altered state of consciousness, coma, apathy, restlessness, delirium, and irritability are descriptors that, if present, should be reported as part of the initial impression. Note any unusual postures, positions, or body movements as well as facial expressions (e.g., frozen watchfulness [hypervigilant and fearful], grimaces of pain, or avoidance of eye-to-eye contact), because these often are important assessment clues.

Integumentary System

Physical assessment of the integumentary system (the skin, hair, and nails) involves careful observation and, at times, palpation. A well-illuminated room or natural daylight is essential for accurate assessment. Room temperature is an important consideration, because cold-induced cyanosis or flushing with heat can alter physical findings, especially in the newborn and young infant. Removal of nail coloring and cosmetics may be needed. Observe the entire body surface; otherwise, lesions or rashes under clothing can be missed. Maintaining modesty is always an important consideration.

Skin

Assess the skin for color and pigmentation, texture, temperature, moisture, and turgor. Unusual and distinctive odors can be caused by metabolic disease, poor hygiene, or infection.

WORLDVIEW: A child's skin color and pigmentation are influenced by racial characteristics. For example, Asian children often have a natural yellow tone to the skin that is not a result of increased bilirubin. African American children may have a bluish tinge to their gums, buccal cavity, borders of the tongue, and nail beds. Cyanosis in African American children may be difficult to detect because of their darker skin pigmentation.

Color

Changes in skin coloring that are important to note are pallor, cyanosis, erythema, plethora, ecchymoses, petechiae, and jaundice. Pallor (paleness) or an ash-gray color can be caused by anemia, syncope, shock, or lack of

exposure to sunlight and is best observed in the face, mouth, conjunctivae, or nail beds.

Cyanosis occurs when reduced (deoxygenated) hemoglobin present in the blood results in a bluish skin tone. Peripheral cyanosis often results from cold or anxiety and is the result of temporary vasoconstriction; central cyanosis involves the lips, mouth, and trunk, and indicates reduced oxygen-carrying capacity of the blood. Central cyanosis indicates cardiovascular, respiratory, and hematologic diseases.

Erythema, or redness of the skin, can result from many factors, including local inflammation, infection, hypothermia or hyperthermia, alcohol, blushing, allergy, or other dermatoses.

Plethora is another term used to describe redness of the skin, especially the cheeks and lips, but is caused by an increased number of red blood cells. The increased production of red blood cells is a compensatory mechanism from chronic hypoxia.

Ecchymoses are large, diffuse areas of black and blue color caused by bleeding into the skin and commonly result from injury. Location and pattern of bruising may reveal cases of potential child abuse. In contrast, petechiae are small (<3 mm), distinct pinpoint hemorrhages into the skin or mucous membranes often seen with blood disorders or systemic infection.

Jaundice is a yellowish pigmentation resulting from depositions of bile pigment in the skin, sclerae, and mucous membranes. Jaundice is indicative of hepatic disease and severe infections in infants. In contrast, carotenemia is a yellowish discoloration of the skin from deposits of carotene caused by excess ingestion of yellow and orange vegetables. Carotenemia is typically seen in the palms, soles, and face; the sclerae and mucous membranes are not involved.

Pressing the skin or nail bed causes a whitening appearance that provides contrast to assess color changes. Pressing the skin with a glass slide to produce a blanching effect helps in the assessment of jaundice (yellow remains), pallor (the color change in the skin is slight), and petechiae (lesions remain).

Texture and Moisture

Assess skin texture and moisture using inspection and palpation. Children's skin is normally smooth, soft, and slightly dry to the touch. Note any variations such as scars, keloids, excessive dryness, or dermatitis.

Temperature

Assess temperature by palpating the skin with the back of the hand, comparing both symmetric parts and the lower and upper extremities of the body for degree of warmth or coolness.

Turgor

Assess skin turgor, or elasticity, by grasping a fold of skin on the upper arm or abdomen between the fingers and quickly releasing the tissue (Fig. 8–5). Skin that immediately returns to place without residual marks has good

FIGURE 8–5. To assess skin turgor, the examiner grasps a fold of skin on the child's abdomen and quickly releases it.

turgor or adequate hydration. Skin that only slowly returns to place (tents) or retains marks indicates decreased turgor and poor hydration. The presence of edema is determined by pressing the thumb into any area that looks swollen or puffy; if the imprint of the thumb remains, edema is present.

Skin Lesions or Rashes

Carefully inspect all skin lesions or rashes; wear gloves to palpate. Note the location, size, distribution of the lesions over the body, and distinguishing features of the primary or secondary lesion, including color, shape, raised, crater-like or flat hard or soft if a mass, and exudate (common primary and secondary skin lesions in children and adolescents are described in Chapter 25). Viral, bacterial, and fungal skin infections often have characteristic skin patterns and physical findings that aid in their diagnosis. Using a body diagram to sketch lesions or indicate their distribution is helpful in recording physical findings. Note any warmth or scratch marks. The dermatoglyphics, or skin patterns, of the hands and feet may indicate a genetic condition (e.g., presence of simian crease with trisomy 21).

Hair and Nails

Inspect the scalp for lesions, crusting, or scaling and the hair for distribution, color, texture, amount, and quality. In children, scalp hair is normally shiny, silky, and strong. However, unusual hairiness anywhere in the body, hairlines that extend to mid forehead, or tufts of hair on the skin over the spine or sacrum represent deviations from normal. Similarly, white locks of hair; loss of hair (alopecia); and dry, brittle hair (suggestive of nutritional deficiency or thyroid disorder) are important clinical findings. In newborns, lanugo (the soft, downy hair that covers the infant) is normal, as is the presence of pubic and axillary hair in the adolescent. White ova (nits) attached to the hair shafts indicate pediculosis.

Assessment of the nails involves inspection for color, shape, and texture. The nails are normally pink, convex, smooth, and hard but flexible. Two significant deviations in nail shape to note are clubbing, in which the base of the nail becomes enlarged and swollen, and spoon nails

(koilonychia), in which the nail assumes a concave curve. Clubbing is associated with chronic hypoxia; spoon nails are sometimes noted in a patient with iron-deficiency anemia. Also look for nail biting or picking, pits, grooves, lines, brittleness, or signs of infection or injury. Assessment of hair and nails is also discussed in Chapter 25.

Head and Neck

Observe the head for size, shape, and symmetry from different angles, and palpate for signs of fractures or swelling. The shape of a newborn or infant's head can be influenced by unusual positioning in utero, oligohydramnios (deficiency of amniotic fluid), length of pushing during labor, positioning after birth, genetic disorders, or congenital anomalies. Palpate the suture lines and fontanel of the infant to check for overriding sutures and flat, depressed, or bulging fontanel. The anterior fontanel measures 1 to 5 cm in length and width until it normally closes at around age 7 to 19 months; the posterior fontanel may be closed at birth and, at the latest, should close around age 2 months. If still open, it should measure less than 1 cm. Slight pulsations may be noted when palpating the anterior fontanel. In palpation of the newborn's skull, it may indent and then spring back; this is a normal finding called *craniotabes*.

Note head posture and control in the infant, which is a sign of developmental maturation. By the age of 2 months, slight head lag is present; by 3 to 4 months, head lag should be minimal. Head measurements from the most prominent point of the occiput around the head just above the eyebrows and pinna are measured serially until age 24 months, and later if there is a concern.

Ask the older child to look up, down, and sideways to assess range of motion, limitations of movement, or pain. Inspect the face for symmetric appearance, proportions, and movement of facial structures. Palpate the sinuses of children and, if warranted, percuss, depending on the stage of sinus development.

The major structures of the neck are the trachea, which is normally midline, and the thyroid, located at the base of the neck. Inspect the neck for any swelling, webbing (seen in females with Turner's syndrome), or venous distention. Palpate the trachea with the thumb and index finger on opposite sides to detect any deviations. The thyroid gland is not normally palpable in children. To palpate for an enlarged thyroid, the examiner should stand behind the child and place the fingers over the gland at the base of the neck and then ask the child to swallow. Infants and young children have short necks, making thyroid palpation difficult. Laying the infant or young child supine across the parent's lap may facilitate palpation for an enlarged thyroid.

Eyes

Assessing the eyes requires examining the external and internal structures and testing for visual acuity.

External Structures

Assessment of the external eye involves inspection for position, placement, size, symmetry, color, and movement.

The distance between the inner canthi of the eyes determines whether the eyes are wide set (hypertelorism) or close set (hypotelorism), with 2.5 cm being the average distance between canthi (Engel, 2006); wide- or close-set spacing of the eyes can be a normal variant or associated with a genetic condition. (See Chapter 28 for illustrations of eye structures, eye placement, and epicanthal folds.)

Inspect the eyelids when assessing the external structures of the eyes. When the eyelids are open, their placement should be somewhere between the upper border of the iris and the upper border of the pupil. Ptosis refers to lids that droop and cover the pupil, whereas sunset eyes refers to a condition in which the sclera (the white, opaque covering of the eye) is apparent between the upper lid and the iris; both ptosis and sunset eyes are abnormal findings. Incorrect positioning of the eyelids includes entropion, lids that roll abnormally inward, and ectropion, lids that roll abnormally outward and expose conjunctiva. Note the palpebral fissures (the opening between the upper and lower eyelids). They should be symmetric, equal in width, and straight across. Slanted palpebral fissures are seen both in children of Asian descent and in children with chromosomal syndromes (e.g., trisomy 21). Inspect the inner canthus of the eye and note any redness or edema.

Note discoloration of the eyelids, change in size such as seen with edema, lesions (e.g., blocked sebaceous glands or salmon patch as seen in newborns and young infants), and movement problems. Note excessive tearing or discharge. In young infants, inspect for any swelling of the nasolacrimal sac area and, if present, palpate the area for tenderness. The eyebrows are normally symmetric in both shape and movement and do not meet in the midline. Look for any unusual loss of hair. Inspect the eyelashes for outward curve and any debris, nits, or loss of lashes.

Inspect the edges and lining of the eyelids, also known as the *palpebral conjunctiva*, for signs of inflammation (blepharitis) or lesions (stye or chalazion). The palpebral conjunctivae are normally pink and glossy and can be inspected easily by gently pulling the lower lid downward while the child looks up. To inspect the lining of the upper lid, either hold the lashes and pull downward and forward while the child looks down or roll the upper eyelid over a cotton-tipped applicator. The bulbar conjunctiva is transparent; however, dilatation of its blood vessels results in redness (conjunctivitis). An overgrowth of conjunctival tissue (pterygium) can occur, spreading over the cornea.

Inspect the sclera for any changes in coloring, including a yellow tint resulting from jaundice, a bluish tint that may be associated with osteogenesis imperfecta, or black marks that are frequently a normal finding in dark-skinned people or may be associated with an imbedded foreign body. The newborn's sclera is usually blue at birth, resulting from the thin choroid, and typically changes to white between 3 and 6 months of age. The pupils should be round, clear, and equal. Inspect them for size, equality, and movement. To test their response to light, darken the room for easier observation and separately shine light directly into the pupil of each eye. The

pupils should respond with brisk constriction. The opposite eye should also show a consensual reflex movement (constriction) to the light. To test for accommodation, the child should look at a penlight that is held at a distance and then is quickly brought toward the midline of the child's nose. The normal responses are pupillary constriction and convergence of the axes of the eyes. The pupils should constrict as the object comes near. Normal pupillary findings can be noted as PERRLA: pupils equal, round, react to light, and accommodation.

Note the color, shape, and size of the iris. Lack of eye coloring and a pinkish glow are seen in albinism. Black-and-white spots on the iris are termed *Brushfield spots* and are noted both in children with trisomy 21 and in normal children. Shapes that deviate from the characteristic roundness of the iris are important findings. A cleft or notch of the outer edge of the iris is termed a *coloboma*. Note any signs of inflammation. The cornea covers the iris and the pupil, and it should be clear and transparent.

Extraocular Muscles

Assessment of extraocular muscle function involves testing for normal range of eye muscle movement and discerning any abnormal movements, such as strabismus and nystagmus. Two key means to assess extraocular function and binocular vision (using both eyes for vision) include the corneal light reflex test, also known as the *Hirschberg test*, and the cover test. To test the corneal light reflex, shine a penlight into the eye from a distance of about 16 in. The light should shine symmetrically in the middle of both pupils (see Chapter 28).

Investigate any malalignment (unequal or uncentered sites of reflection) for muscle imbalance. A tendency to have strabismus or intermittent crossing of eyes either inward or outward is normal during the first 6 months of life. The cover test can detect either a phoria (tendency to deviate from alignment) or tropia (overt malalignment); perform it at both near and far gazes. While the child is gazing at a near object (13 in) and then again at a far object (20 ft), one eye is covered and then uncovered. Movement of the uncovered eye indicates malalignment. The examiner should uncover the occluded eye and observe whether the occluded eye moves; normally, the eyes remain fixated. In the alternating cover-uncover test, the occluder is moved from one eye to another while the child is fixating on an object. Movement noted in the eyes during the covering or uncovering is an attempt to reestablish fixation and indicates muscle malalignment (Burns et al., 2008). Elicit nystagmus, or rapid, oscillating, jerky eye movements, by instructing the child to follow an object held about 12 in away, through the six cardinal fields of gaze (i.e., movements in the left and right lateral, left and right inferior, and left and right lateral superior). A few beats of nystagmus are normal only if present in the far lateral gaze.

Ophthalmoscopic Examination

The ophthalmoscopic examination is a specialized skill that involves practice and a cooperative child. It allows

visualization of the interior structures of the eye through the use of light and lenses.

To see the various eye structures, it is best to perform this examination in a darkened room. Examine the child's right eye using the examiner's right eye and right hand and the child's left eye with the examiner using the left eye and left hand. Set the diopter reading at +8 to +2. First examine the eye from a distance of 10 to 12 in, moving inward at an angle until the child's face is reached and changing the dial of the ophthalmoscope as needed to focus. The pupil reveals a red glow if the lens and cornea are transparent and the retina is normal. In newborns and young infants, the red reflex appears lighter; in darker skinned individuals, the red reflex often appears darker. While slowly moving inward, adjust the diopter setting to see the fundus clearly. If the examiner and the child have normal vision, a reading of 0 diopter results in a sharp focus of the fundus. Moving the diopters compensates for nearsighted or farsighted eyes. If the examiner with normal vision must use red diopter lenses to focus the fundus, the child is nearsighted. If the examiner needs black diopter lenses to focus the fundus, the child is farsighted.

The optic disk appears creamy white, yellow-orange, to pinkish; is round or oval; and normally has clear margins. In newborns, the disk has a pale appearance. Arteries are smaller and brighter than veins and have a thin stripe of light down the middle. The macula is similar in size to the optic disk and is located to the temporal side of the disk. The macula is somewhat darker than the rest of the fundus. The fovea centralis, the area of almost perfect vision, appears as a tiny, white, glistening dot in the center of the macula and is sensitive to light.

Visual Acuity

Testing for visual acuity in young infants is generally done by testing certain reflexes and attending behaviors. Normal visual milestones are presented in Chapter 3. Test light perception by observing whether the infant blinks and has pupillary constriction in response to a bright light. An examiner should be able to elicit certain attending behaviors in a newborn or infant when an object is placed in the line of vision. These responses are age dependent. At age 3 months, an infant should be able to fixate and attempt to follow an object such as a toy, penlight, or face; by 5 months, the infant should follow these targets through all fields of gaze. Commonly used letter or symbol vision tests include the Allen picture cards, for children age 2 to 3 years; the Blackbird Preschool Vision Screening System; the Snellen E chart, for children age 3 to 6 years; and the standard Snellen chart, used as soon as the child knows the alphabet. Color deficiency (or colorblindness) is tested using the Ishihara and Hardy-Rand-Ritter tests. Used respectively for school-aged children and preschoolers, these tests ask the child to look at pseudoisochromatic cards and identify the numbers or the symbols hidden by certain confusion colors. Failure to recognize the number or symbol against the color field is diagnostic.

Ears

Assessing the ears requires examining the external and internal structures and testing for hearing acuity.

External Structures

Inspect the external ear first for placement and position. The top of the pinna (cartilaginous portion of the ear) should meet or cross an imaginary horizontal line drawn from the inner eye to the occiput, and the pinna should angle no more than 10 degrees from a line drawn perpendicular from the imaginary horizontal line. Low-set or obliquely set ears are associated with chromosomal disorders and genitourinary abnormalities. Ears are typically extended slightly from the head; however, the newborn's ears are flat against the head. Inspect the mastoid area and palpate behind the ear; redness and swelling of this area and a protruding pinna are associated with mastoiditis.

Inspect the structures of the external ear including the helix, tragus, concha, and lobule for abnormalities in shape or structure; tenderness on movement is abnormal. Note any skin tags, nodules, sinus tracts, or pits in the skin found around the pinna. Note any discharge from the aural canal. Discharge from the external canal can be cerumen (soft, yellow-brown) or a result of external otitis (yellow or greenish discharge).

Internal Structures

The otoscope is used to visualize the canal and internal structures of the middle ear and is held in the inverted position like a pencil so that the examiner's little finger rests on the child's head and the otoscope moves with the child. Use the largest speculum that can fit into the ear canal to maximize the visual area. The position in which the child is examined varies with the child's age and ability to stay still. The infant's head often needs to be stabilized (e.g., the mother holding the infant next to her body with the child's head turned to one side and mother's hand stabilizing the head). To straighten the ear canal in children younger than 3 years, pull the pinna down and back or out (Fig. 8–6A). For children older than 3 years, who have undergone anatomic changes, the pinna is pulled up and back to the 10-o'clock position (Fig. 8–6B). Individual variations may require manipulating the earlobe in a slightly different direction than what is the usual practice. Insert the speculum into the auditory meatus slowly and carefully, and inspect the canal. Normally, the canal is pink with small hairs. Note any lesions, discharge, or foreign bodies in the canal.

Inspect the tympanic membrane for color and landmarks. The color is normally translucent, light pearly pink, or gray. Erythema can be a normal finding if the infant or child is crying or has a fever; however, marked erythema is associated with infection (otitis media). Serous otitis media can present as dull yellow or gray. Likewise, bubbles (circles or rings) behind the tympanic membrane indicate the presence of fluid. Perforations leave scarring and an ash-gray color. When assessing landmarks, think of the tympanic membrane as a clock.

FIGURE 8–6. Ear examination. (A) In children younger than age 3 years, the pinna is pulled down and back to straighten the ear canal and visualize the tympanic membrane. (B) In children older than age 3 years, the pinna is pulled up and back.

The cone of light or light reflex is seen around the 5- to 7-o'clock position. The umbo (tip of the malleus) is normally found at the center of the clock and is seen as a small, round, opaque spot. The manubrium (long process of the malleus) is the white line extending from the umbo upward to a knoblike protuberance (the short process of the malleus) around the 1-o'clock position.

caREminder

Fluid behind the tympanic membrane causes bulging that distorts or obliterates the appearance of the landmarks. Negative pressure in the middle ear causes retraction of the tympanic membrane with abnormally prominent landmarks.

Compliance or mobility of the tympanic membrane can be evaluated by tympanometry testing or pneumatic otoscopy, which can be used to detect otitis media. During this procedure, the examiner exerts pressure against the tympanic membrane by creating a seal with the speculum and using a bulb attachment to puff air into the canal (Fig. 8–7). It is normal for the tympanic membrane to move when this is done.

FIGURE 8–7. A pneumatic otoscope is used to evaluate mobility of the tympanic membrane. Note the mother helping to restrain and position the infant.

Hearing Acuity

An assessment of hearing acuity can be performed by play audiometry in specialized settings or by audiometry using earphones in children age 4 years and older. Other, more sophisticated tests, such as evoked otoacoustic emissions and brain stem auditory-evoked response, may be performed for an infant or a child at risk for hearing loss (see Chapter 28 for further information about auditory testing).

Face and Nose

Observe the face for symmetry, spacing, size of structures, and facial expression. The nose should be symmetric and midline to an imaginary line drawn from between the eyes to the center of the notch in the upper lip. Genetic differences can be observed in the shape of the bridge of the nose with a characteristic flattened appearance in Asian and some African American children. Inspect the external nares for patency, discharge, flaring, horizontal nasal creases, and any lesions. To check for patency in newborns, block one nostril and at the same time close the infant's mouth; observe whether the infant continues to breathe smoothly. Use a penlight or an otoscope to visualize the internal nasal cavity by pushing the tip of the child's nose upward while the neck is tilted backward.

For a closer inspection of the mucous lining of the inferior and middle turbinates, insert a nasal speculum gently into each nostril. Note the color, consistency, and integrity of the nasal membranes and septum as well as the septal alignment. The mucosa is normally pink, and the septum should be midline. Mucosal membranes that are pale, grayish, boggy (spongy texture; as seen with allergic rhinitis), bright red (which may be seen with upper respiratory infection, or nasal medications and substance abuse), or excoriated (digital injury as in nose-picking and snorted substance abuse) are noteworthy.

Note the amount, color, and texture of any nasal discharge. Watery discharge associated with crying is

normal. In contrast, a thin, clear discharge is seen with allergies and sinusitis (either clear or mucopurulent rhinorrhea). Purulent discharge indicates either a viral or a bacterial infectious process. The finding of unilateral nasal discharge is significant as is the presence of polyps (soft overgrowths of gray mucosa).

Mouth and Throat

Assessment of the mouth and throat begins at the lips. They should be pink, firm, symmetric, and moist, with no lesions or excoriations. A thin upper lip with a long philtrum is associated with fetal alcohol syndrome (see Fig. 14–11). The buccal mucosa, gingivae, tongue, and palate are normally pink, firm, smooth, glistening, and moist. However, the normal appearance of the gums, tongue margins, and buccal cavity may be a bluish color in African American children. Note the presence of texture changes, increased size (hyperplasia), furrows in or limited movement of the tongue, or any unusual odor (halitosis). Palpate for notches, clefts, or unusual arches in the hard palate. Any lesions, swelling, excoriations, or bleeding in these structures is abnormal. If the tip of the tongue cannot touch the roof of the mouth, the child has a tight frenulum, which is rare. While observing the teeth, one can assess for number, hygiene, and the presence of malocclusion, caries, or staining. The uvula should be midline and move upward when a gag reflex is elicited.

The tonsils normally undergo hypertrophy during early childhood, followed by gradual shrinkage beginning around age 10 years. The tonsils are normally the same color as the surrounding buccal mucosa and often have crypts on their surface (see Chapter 16). Increased redness or tonsillar exudate indicates infection. Table 8–5 provides a guide for assessing tonsil size.

The use of a tongue blade to view the oral cavity is helpful if a clear view of the buccal mucosa is not obtained. The tongue blade can be slipped between the inner cheeks and the gumline. If the child is frightened by the tongue blade, an examiner can obtain a clear view of the back of the mouth in other ways. For the infant or toddler, inspect the mouth when the child cries. Tilting the young child's head backward and asking the child to say "ahhh," often enables a clear view of the tonsils, uvula, and oropharynx.

TABLE 8–5
Guide to Tonsillar Size

Scale	Tonsillar Position
1+	Just visible
2+	Halfway between the tonsillar pillars and the uvula
3+	Touching the uvula
4+	Touching each other

Alert! Never insert a tongue blade in the mouth of a child who exhibits signs or symptoms of epiglottitis, because this may cause respiratory arrest.

Thorax and Lungs

Begin assessment of the thorax and lungs with inspection of chest configuration, movement, and symmetry. Record any abnormalities such as unusual roundness (barrel shape), protuberant or depressed sternum, unusual knobbing of the rib cage, or asymmetric movement including retractions and their locations above the clavicles, suprasternal, substernal, and/or intercostal areas (Fig. 8–8). The abdomen and chest should move together in a synchronous fashion, but chest movement associated with breathing varies with age. Abdominal or diaphragmatic breathing is characteristic of young children. In children older than 7, particularly females, thoracic respirations are predominant.

Note the rate, depth, quality, and regularity of respiration as well as the ratio of the inspiratory to expiratory phase of breathing. Respiratory rate is influenced by age and disease status.

Listen for audible signs of impaired respiratory efforts, such as stridor, barking or staccato cough, audible wheeze,

snoring, or grunting. Palpating the chest for tactile fremitus (a vibratory sensation) and percussion to determine dullness, resonance, or tympany can sometimes provide additional information. However, auscultation of the lungs is always necessary for evaluating the child's respiratory status. Use the diaphragm of the stethoscope to auscultate the lung fields (front, back, and axillary areas) by systematically and symmetrically (comparing one side with another), listening for breath sounds as the child takes a deep breath in and blows out. Pretending to blow out the light of an otoscope or penlight is a useful game that encourages deep breathing in younger children.

Breath sounds are classified as vesicular, bronchovesicular, or bronchotubular depending on the sound's loudness and duration during inspiration versus expiration. These breath sounds are normally heard in a distinct area of the chest but become abnormal findings when absent or heard in noncharacteristic locations. See Table 8–6 for characteristics of normal breath sounds. Atypical sounds include crackles or rales (discontinuous, soft popping or interrupted explosive sounds), which can be coarse, medium, or fine; rhonchi (continuous snoring or low-pitched sound); friction rubs; or wheezing (continuous, musical, high-pitched sound) (see Focused Physical Assessment 16–2). Absent or diminished breath sounds in any area are also pathologic and indicate obstruction.

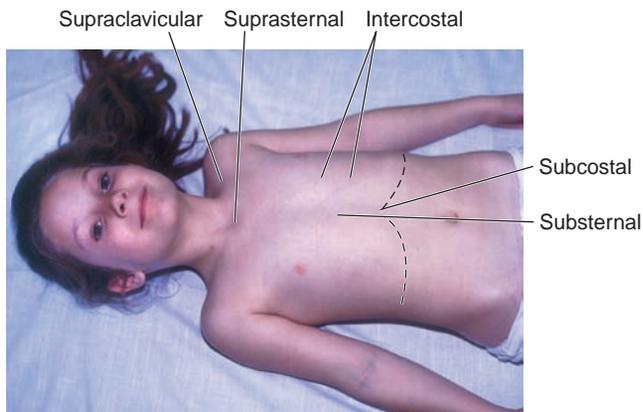

FIGURE 8–8. Possible sites of retractions.

caREminder

In infants and young children, lack of subcutaneous fat and smaller distances between structures may make breath sounds readily transmitted across lung fields. Keep this in mind when assessing the presence, location, and nature of breath sounds in infants and young children. To detect transmitted sounds from the upper airways, place the diaphragm next to the child's mouth or nose to determine whether what is heard in the lung fields is just like the sound as heard near the mouth or nose. Referred sounds are loudest near their origin.

TABLE 8–6

Characteristics of Normal Breath Sounds

Sound	Quality	Relationship of Inspiration (I) to Expiration (E)	Normal Location
Vesicular	Soft, swishing	I is longer, louder, and higher pitched than E (I > E)	Throughout lung field
Bronchovesicular	Louder and higher pitch than vesicular; mixed	I and E are equal (I = E)	Over manubrium and upper intrascapular region where trachea and bronchi bifurcate
Bronchotubular	Tubular, harsh, hollow	I is short; E is long (I < E)	Over trachea

Cardiovascular System

Observe the child for signs of cyanosis, edema (peripheral, sacral, or periorbital), mottled skin, clubbing of the nail bed, distended neck veins, or squatting posture, because these can all be signs of cardiovascular malfunction. Inspection of the chest in infants and young children with thin chest walls often reveals a cardiac pulsation, the apical impulse (AI), which is generally the point of maximal impulse (PMI), which is a normal finding. In contrast, any visible pulsation of the chest caused by a heave or lift of the ventricle, a sustained forceful thrusting of the ventricles during systole, is an abnormal finding. Use the fingers to determine the AI, the apex beat, or the PMI (area of most intense pulsation, which may or may not be the AI).

caREminder

The location of the apical pulse or PMI varies with age. In children younger than age 7 years, the PMI is found in the fourth intercostal space. For children younger than 4 years, the PMI is to the left of the midclavicular line (MCL) and is midclavicular between 4 and 6 years. In children older than 7 years, it is located to the right of the MCL and is found in the fifth intercostal space (Fig. 8–9).

Use the ball of the hand to palpate for the presence of a thrill, a vibratory sensation that feels like the belly of a purring cat. Thrills are pathologic findings. Use the fingertips to detect pulsations on the chest. Percussion of the heart has limited usefulness in the examination of children because of their small chest wall size and aversion to the chest being percussed.

Heart Sounds

Auscultation of heart sounds is an essential assessment skill when examining the cardiovascular system. Heart sounds are produced by the opening and closing of the valves, and by vibrations of blood against the walls of the heart and its vessels. Table 8–7 lists the sites of cardiac auscultation and provides descriptions of various heart

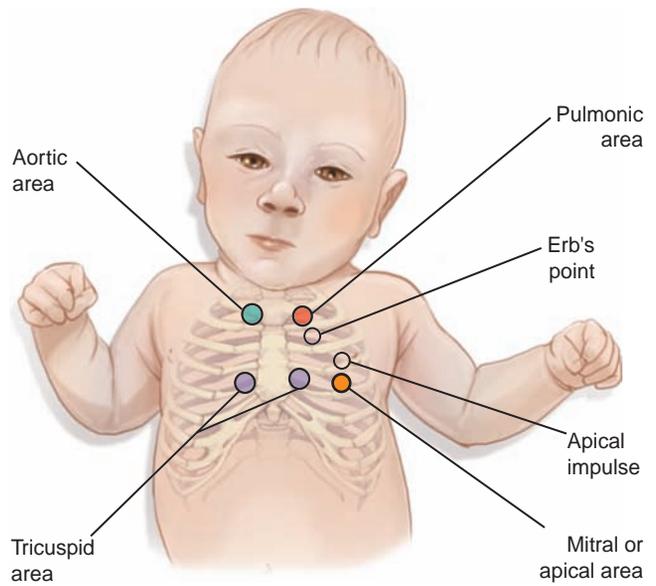

FIGURE 8–9. Location of the apical impulse in a child younger than age 7 years and normal locations of heart sounds.

sounds. Use the stethoscope’s bell to detect low-pitched heart sounds; use the diaphragm to detect high-pitched heart sounds.

Begin auscultation at the second right intercostal area, where the closure of the aortic valve is best heard. Move to the second left intercostal space to best hear the sound of the pulmonic valve closing. Because the second heart sound (S2) represents closure of both the aortic and pulmonic valves together, the aortic and pulmonic areas are the sites where the S2 is heard loudest. The sound made by the closing of these two valves can sometimes be heard as a split sound during inspiration. A normal physiologic split sound of S2 can often be heard in the pulmonic area. The aortic valve closes slightly before the pulmonic valve; the sound made by the closure of the aortic valve is normally louder than the pulmonic sound. Inspiration affects the timing of these two valve closures. Therefore, a normal physiologic split is accentuated with inspiration and

TABLE 8 – 7

Differentiation of Heart Sounds by Site, Location, and Characteristics

Cardiac Auscultatory Site	Location	Characteristics
Aortic area	Second right intercostal space	S2 heard louder than S1; S2 is “dubb” sound
Pulmonic area	Second left intercostal space	S2 split heard best
Erb’s point	Second and third intercostal space	S1 and S2 equal loudness; common site of innocent murmurs
Tricuspid area	Fifth right and left intercostal space	S1 heard as louder sound than S2; S1 is “lubb” sound
Mitral or apical area	Third to fourth intercostal space and lateral to the left midclavicular line (MCL) (in infants); fifth intercostal space, left MCL (around 7 years)	S1 heard loudest; S1 is synchronous with carotid pulse

fades out with expiration. A fixed split S2 that does not vary with respiration is abnormal.

Next, while carefully listening, inch down the left sternum to Erb's point at the second and third left intercostal spaces close to the sternum. Here, S1 and S2 are of equal intensity. S1 is heard loudest at the tricuspid and mitral or apical areas. The tricuspid area is at the fifth right and left intercostal spaces close to the sternum and represents the area where closure of the tricuspid valve is best heard. The mitral area is located at the third to fourth intercostal space and lateral to the left MCL in infants and at the fifth intercostal space, left MCL in children around age 7 years. Mitral valve closure is heard best here.

Two additional heart sounds, S3 and S4, warrant consideration. S3 is a normal sound, produced by vibrations during ventricular filling. It is often a difficult sound for unskilled examiners to detect. S4, although an abnormal sound in older adults, can be a normal finding in some children and young adults. S3 and S4 are best auscultated with the infant or child laying on his or her left side.

When listening to the heart, evaluate the rate, rhythm, quality, and the intensity of the heart sounds. S1 and S2 should be clear and distinct sounds. In addition, their intensity should be consistent with expectations at a particular auscultatory site. The rate should be synchronous with the radial pulse and consistent with the norms for cardiac rate by age of the infant or child. Fever, exercise, and anemia increase cardiac rate and the S1 intensity.

caREminder

Many young children have periods of sinus arrhythmia, in which the heart rate increases with inspiration and decreases with expiration. This common finding is considered a variant of normal if the arrhythmia disappears during breath holding.

Murmurs

Murmurs are blowing or swooshing sounds caused by turbulent blood flow in the chambers of the heart or its vessel. Infants and children often have innocent or functional murmurs that must be differentiated from serious organic murmurs. Innocent murmurs are frequently heard in young children and are nonpathologic. A child's thin chest wall is believed to transmit these sounds easily. Functional murmurs are caused by conditions such as fever and anemia that lead to increased blood turbulence. When these conditions are corrected, the murmur disappears. Organic murmurs are associated with pathology of the chambers, valves, or vessels.

When a murmur is detected, note the following information:

- **Location:** where it is heard the best and whether it is heard in other auscultatory areas (i.e., Does it radiate? To where?)
- **Timing:** when the murmur occurs—during S1, which represents ventricular systole; during S2, which represents diastole; or throughout the entire cardiac cycle

TABLE 8 – 8

Grading Scale for Classification of Heart Murmurs by Intensity

Grade	Characteristics
Grade I	Soft and difficult to hear
Grade II	Soft but easily heard
Grade III	Loud, but no associated thrill
Grade IV	Loud with an associated thrill
Grade V	Loud and audible with edge of the stethoscope; thrill present
Grade VI	Very loud and heard with stethoscope off the chest; thrill present

- **Intensity:** soft, loud, very loud (Table 8–8)
- **Pitch:** low, medium, or high
- **Variation with position:** heard when sitting, standing, supine, or squatting
- **Quality:** describe the sound using terms such as *musical*, *blowing*, *harsh*, or *rumbling*

Innocent murmurs of childhood differ from pathologic murmurs (Chart 8–4, Table 8–9). Auscultate with the child in at least two positions—supine, sitting, or laying on the left side—and use both the bell and diaphragm of the stethoscope. Innocent murmurs often disappear with a change of position.

Vasculature

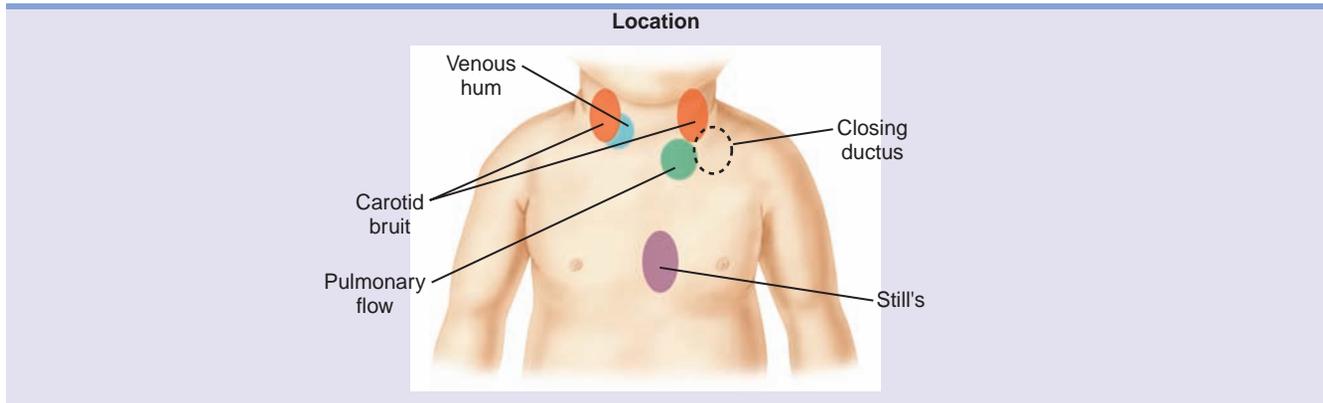

Assessment of the vascular system involves palpation of the peripheral arteries for equality, rate, and rhythm. Palpate the radial, femoral, popliteal, and dorsalis pedis pulses to determine blood flow for vascular integrity. To assess these pulses in infants, move from lighter to deeper palpation as necessary; use one or two fingers for the femoral pulses midway between the iliac crest and the symphysis pubis. Flexing the knee is helpful in palpating

CHART 8–4 CHARACTERISTICS OF INNOCENT HEART MURMURS

- Soft sounding
- Short duration
- Occurring during systole
- Vibratory and of medium pitch
- Heard best at the left lower sternal or midsternal border
- No radiating
- Not associated with physical findings of cardiac pathology

TABLE 8 – 9

Location and Characteristics of Benign Heart Murmurs in Children

Typical Age	Name	Characteristics	Description and Location
Newborn	Closing ductus		Transient, soft, ejection Upper left sternal border
Newborn to 1 year	Peripheral pulmonary flow murmur		Soft, slightly ejective, systolic To left of upper left sternal border and in lung fields and axillae
Preschool or early school age	Still's murmur		Grades I through II/VI, musical, vibratory Multiple overtones Early and midsystolic Mid/lower left sternal border Frequently also a carotid bruit
Preschool or early school age	Venous hum		Soft, hollow, continuous Louder in diastole Under clavicle Can be eliminated by maneuvers
Preschool and later	Carotid bruit		Early and midsystolic Usually louder on left Eliminated by carotid compression
Adolescence and later	Pulmonary flow murmur		Grades I through II/VI soft, nonharsh Ejection in timing Upper left sternal border Normal P2*

From Bickley, L. S. (2002). *Bates' guide to physical examination and history taking* (8th ed.). Philadelphia: Lippincott Williams & Wilkins. Reprinted with permission.

*P2 = pulmonic second sound

the popliteal pulse. Palpate for the dorsalis pedis along the upper medial aspect of the foot (Fig. 8–10).

Breasts

As part of the assessment of the thorax, after assessing the lungs and cardiovascular systems, assess the breasts.

Observe the position of the nipples and note the presence and location of any supernumerary nipples. Identify and record the Tanner stage of female breast development as a measure of the acquisition of secondary sexual characteristics. Transitory breast enlargement in neonates is common and is caused by a maternal hormone effect. Gynecomastia in young children and male teenagers

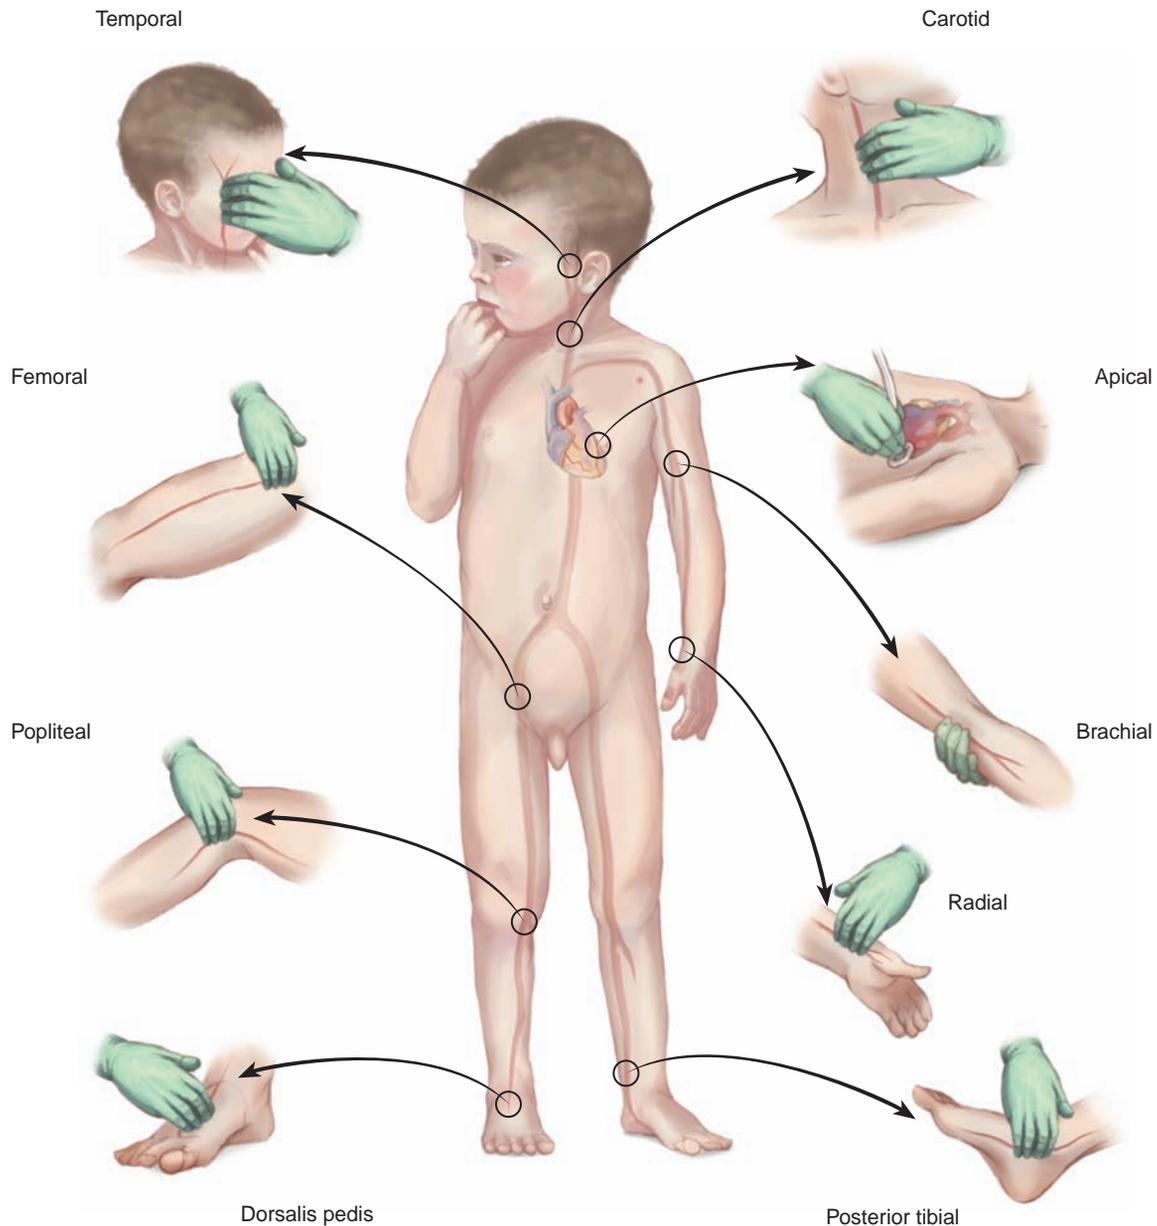

FIGURE 8-10. Locations of peripheral pulses.

needs evaluation. Palpate the breasts for masses. If masses are felt, note their location, size, shape, consistency, and mobility along with whether they are discrete masses or tender to the touch.

Teach adolescent females how to properly conduct monthly breast self-examination (BSE). The American Cancer Society recommends that women begin monthly BSE at age 20. The American Cancer Society has educational materials on BSE available for distribution by calling their local 1-800 phone number.

Abdomen

Begin the abdominal assessment by inspecting the contour and the skin covering the abdomen, generally while the child is in the supine position or resting flat in the

parent's lap. Look for any unusual shapes, asymmetry, or tenseness that could denote organomegaly, ascites, inguinal or femoral bulging, malnutrition, or tumor. A pot-bellied or prominent abdomen is a normal characteristic of infants and children until puberty. Note skin markings such as distended veins, striae, or bruises. Detection of unusual movements (e.g., peristaltic waves or abdominal respirations in children younger than age 7 years, or pulsations) can indicate gastrointestinal or pulmonary problems. In newborns and young children, inspect the umbilicus for discharge, fistulas, or signs of inflammation, and palpate for herniation. Note any midline protrusion from the xiphoid process to the umbilicus as an indication of diastasis recti abdominis.

Next, perform auscultation of the abdomen for bowel sounds or bruits (murmurs) in a systematic fashion by

firmly pressing the stethoscope and listening to all four (right and left, upper and lower) quadrants of the abdomen. Normally, bowel sounds are heard every 10 to 30 seconds and indicate peristaltic movement. Various pitches and frequencies of bowel sounds can indicate problems such as diarrhea or obstruction (heard as high-pitched, tinkling sounds); absent bowel sounds may indicate that peristalsis is not occurring.

caREminder

Always listen for bowel sounds before palpation to determine what the baseline sounds are, because palpation can stimulate peristalsis. Gently stroking the abdomen with one's fingers can help elicit bowel sounds. Listen for at least 5 minutes before determining that bowel sounds are absent or not heard.

Because of the small size of a young child's abdomen, percussion to determine areas of dullness, flatness, or tympany has limited clinical usefulness, but it can assist the examiner in assessing for liver enlargement.

Finally, palpate the abdomen, ensuring that hands and fingers are warm. Both superficial and deep palpations are useful in assessing pain and abnormal enlargement (organomegaly) or determining the presence of a mass. With a crying infant, put one hand behind the infant's legs and bend them at the knees while at the same time gently palpating the abdomen with the index finger of the other hand when the infant exhales with each cry. Check for tenting of the abdominal skin by pinching the skin together to see if it forms a fold; tenting indicates severe dehydration.

If an inflamed appendix is suspected, identify pain resulting from peritoneal irritation in the appendix region by performing the following tests with the child in a supine position: the iliopsoas, obturator, and Rovsing's sign (rebound tenderness). The iliopsoas test is performed by pushing down on the child's lower thigh as the child raises his or her leg. Look for the obturator sign by picking up the child's ankle in one hand and holding the knee with the opposite hand while flexing the hip and knee 90 degrees and rotating the leg internally and externally. If either elicits pain, it suggests irritation of the respective muscle, psoas, or obturator by the inflamed appendix. To test for Rovsing's sign, press deeply and evenly in the left lower quadrant and quickly withdraw pressure. If pain is elicited in the right lower quadrant during left-sided pressure or with quick release of pressure, the test is positive. In addition to these three tests, ask the older child to jump up and down to elicit whether there is peritoneal irritation; a child with appendicitis typically jumps only once and stops because of pain.

KidKare ■ To help with young children who are ticklish, ask them to bend their knees to relax the abdominal muscles and distract them by having them tell a story.

If a child complains of abdominal pain, always palpate the area of identified pain last. Perform deep palpation by either placing one hand on top of the other or by placing one hand to support the child's corresponding back structures and using the other hand to palpate the anterior structures.

To palpate the liver, start in the lower right quadrant by using two to three fingers and work up. In infants and young children, the liver edge is often palpable 1 to 2 cm below the right costal margin and feels firm and smooth. The tip of the spleen is sometimes palpable during inspiration in infants and young children as a soft, thumb-shaped mass about 1 to 2 cm below the left costal margin. Any enlargement greater than 2 cm is abnormal and needs referral. Kidneys are normally difficult to palpate beyond the neonatal period unless enlarged. Sometimes the tip of the right kidney can be a normal finding in the neonate. Palpate for a femoral hernia by placing the index finger on the femoral pulse, and the middle and ring fingers just medially on the skin over the area where a femoral hernia occurs. To check for an inguinal hernia in a young male child, the examiner's smallest finger should be gently slid into the external inguinal canal at the base of each testicle while asking the child to cough or laugh to determine whether bowel is present.

Lymphatic System

Assessment of the lymphatic system involves palpation with the fingertips in a gentle but firm circular motion to detect lymph node enlargement (Fig. 8–11). If enlarged lymph nodes are felt, note their size, color of the overlying skin, location, temperature, consistency, mobility, and whether tenderness is present. Assess for nodes in the areas anterior and posterior to the sternocleidomastoid muscle by having the child's head bent slightly forward and turned toward the side being examined while sliding one's fingers against this muscle. Palpate the preauricular, mastoid, submandibular, and supraclavicular areas. To assess for the presence of axillary nodes, hold the child's arm in a slightly abducted position at the sides while palpating this area. For the inguinal area, the child should be in a supine position. Refer back to the abdominal section for assessment of the spleen.

External Genitalia

Assess the external genitalia using a matter-of-fact manner, with respect for issues of privacy and modesty. This is particularly important when examining an adolescent.

KidKare ■ Tell the child that you need to look at his or her genital area as part of the examination. Starting around age 2 to 3 years, give a brief explanation to the child that indicates the purpose of the examination (e.g., making sure the whole body is healthy, or that everything is fine with his or her "private parts"). Before beginning the examination, ask the parent to

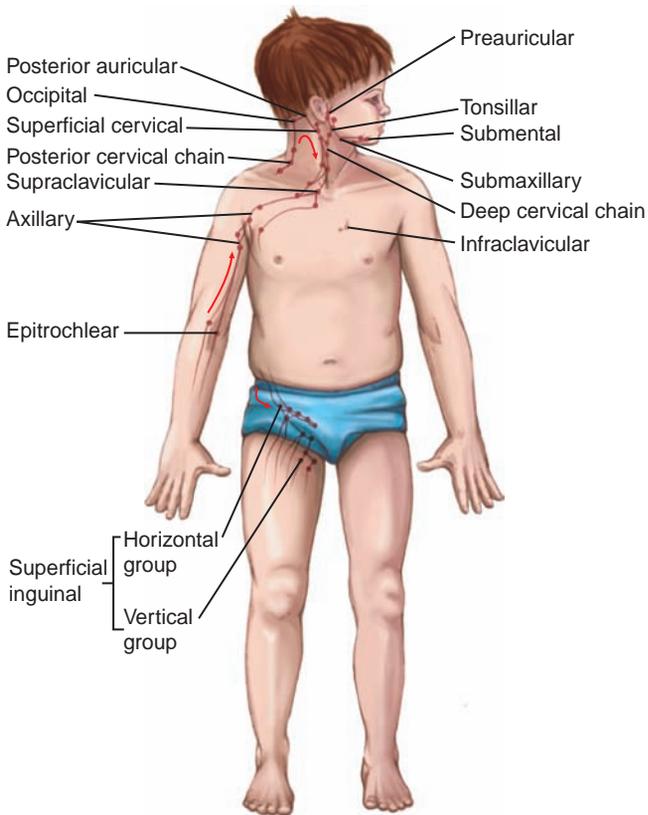

FIGURE 8-11. Superficial lymph nodes and lymph drainage.

tell his or her child that “it is OK for nurses to touch the child’s private parts to know that all is fine or to see if there is a problem” (if that is the case). The wording of this explanation will vary depending on the presenting problem and age of the child.

Note assessment of sexual maturation using Tanner staging of sexual development for males and females as outlined in Chapter 3.

Male Genitalia

To assess the male genitalia, inspect the penis for size, color, masses, and the presence of any skin lesions or discharge. Note whether the child is circumcised and, if not, whether the foreskin retracts easily.

Alert! Never forcefully retract the foreskin.

The foreskin is normally adherent in infants and young males until approximately age 3 years. Inspect the meatus for shape (slitlike), placement, and whether ulceration or discharge is present. If pubic hair is present, describe its distribution, quantity, and quality using Tanner staging. Pubic lice or nits are a significant find-

FIGURE 8-12. To palpate the testes in a young male, the examiner blocks the inguinal canal to prevent the testes from retracting into it.

ing. The strength and steadiness of the urinary stream are important to assess if there are questions about obstruction of flow. Also, ballooning of the foreskin in an uncircumcised male with voiding is associated with significant phimosis and should be referred to a urologist.

Inspect the scrotal sac for color, size, and symmetry; and presence of rugae, masses, and lesions. The left scrotum commonly hangs lower than the right. To palpate the testes in an infant or young male, hold the thumb and index finger of one hand over the inguinal canal area to prevent the testes from retracting (the cremasteric reflex) while at the same time palpating with the other hand (Fig. 8-12). If the testes cannot be felt, have the child sit cross-legged or stand and palpate again. If they still cannot be felt, feel the inguinal canal and, if the testes are present there, try to milk them down the canal and into the sac. Cold, excitement, touch, and stimulation can stimulate the cremasteric reflex, causing the testes to ascend temporarily. Normally, the testes are smooth, equal in size, and oval; the size of the testes depends on the stage of sexual development. Note any masses, swelling, tenderness, or asymmetry and, if present, refer to a physician or nurse practitioner. Teach adolescent males how to perform testicular self-examination.

Female Genitalia

Inspection of the external female genitalia requires that the examiner be able to view the external genitalia and the vestibule (the area between the labia minora). Wear gloves and place the child’s legs in a frog-leg (soles of the feet touching) position. The adolescent female is more comfortable if her legs are placed in stirrups. The appearance of the external genitalia depends on the child’s stage of sexual maturation. Observe the labia majora, labia minora, and the clitoris area for size, color, skin lesions, and masses. Note the presence of pubic hair and the appropriate Tanner stage. Refer a child with pubic hair before age 8 years for an endocrinologic evaluation.

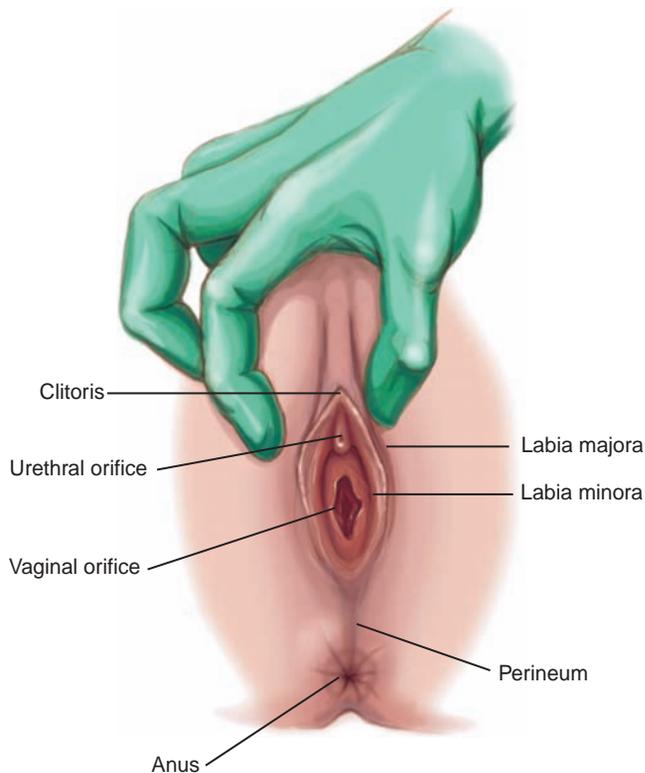

FIGURE 8–13. Normal female genitalia.

Gentle upward and lateral traction of the labia majora allows a thorough inspection of the vestibule area, including the urethral meatus, vaginal opening, and hymen, as well as the fossa and posterior fourchette (Fig. 8–13). Note any unusual redness, discharge, edema, scarring, tears, or lesions. The female genitalia is responsive to estrogen. Maternal estrogen is responsible for the redundant hymen and prominent labia seen in the young infant. Likewise, the effect of endogenous estrogen during puberty again changes the appearance of the labia and the hymenal tissue (which becomes flowery and pale pink).

Ambiguous genitalia and fused labia in infants are abnormal findings and indicate significant pathology. Minor labial adhesions are a common problem seen in young children and are treated only if there is interference with urinary or vaginal drainage. Treatment consists of application of estrogen-containing cream and good hygiene until separation occurs, followed by long-term use of petrolatum to the area. The speculum examination requires special training and is not discussed in this textbook.

Anus

Although the anus is a part of the gastrointestinal system, it is inspected while examining the external genitalia. Inspection of the anus can be performed in the supine position with the child's legs up and knees bent or in the knee chest, prone, or side-lying recumbent position depending on the age of the child. Observe the anus for tone by scratching the anal area and noticing the “wink” response (anal reflex). Note any unusual laxity that is not associated with the presence of stool in the ampulla. Gentle traction allows

for a closer view of the anal folds or rugae, which should have a wrinkled appearance. Record the location of anal tags, scars, fissures, hemorrhoids, or lesions. Also note perianal rashes, hyperpigmentation, or rectal prolapse.

Musculoskeletal System

The musculoskeletal system is subject to tremendous changes from infancy through adolescence. For example, joint range of motion changes with age. In infancy, the normal arc of motion is greatest and declines as the child matures. Therefore, the examiner must be familiar with normal physiologic findings seen in the musculoskeletal system as the child matures.

Assessment involves observing the infant for general body configuration, and spontaneous and symmetric movements of the extremities. Position will vary (supine, prone, standing with support), depending on which section of the musculoskeletal system is being examined. Inspect the back and the neck for full range of motion. Look for obvious deformities or any unusual findings such as a sacral dimple, extra digit, metatarsus adductus, or congenital torticollis. Palpate the clavicles, limbs, back, and neck for signs of tenderness, swelling, masses, or deformities; and assess range of motion in all joints. Assess muscle strength by picking up the infant with hands under the infant's axillae. Normal infants wedge their body against the examiner's hands. Evaluate the hips for developmental dysplasia of the hip by determining the presence of key positive signs. The two techniques that are used to identify hip joint instability in newborns and young infants are the Ortolani and Barlow maneuvers (see Nursing Interventions 8–3 and Fig. 8–14).

Alert! Never repeatedly manipulate a hip that is reducible or able to be dislocated. Doing so may cause vascular compromise.

As the infant matures and acquires greater musculoskeletal skills and control, additional features are included in the examination. It is important to ensure that clothing is not obstructing the examiner's view and the child is not wearing shoes, which can interfere with gait analysis and assessment for limb length discrepancy. The child should wear only underwear at this point in the examination.

To begin, observe the standing child from the front, back, and side to assess body configuration, symmetry, and proportions, and to detect any physical deformities. Have the child walk slowly without shoes, away from and then toward the nurse, and then walk on his or her heels and toes. Assess for gait asymmetry, irregularity, or weakness such as occurs in lower limb discrepancy or cerebral palsy. The gait of a toddler is normally wide spaced but is symmetric. In contrast, a painful (antalgic) gait has a shortened stance phase, and a child with in-toeing walks with one foot or both turned inward.

After observing the child walk, assess the pelvis and back. Place your hands on the iliac crests of the standing child to observe whether they are level or whether there is leg length discrepancy. Have the child bend one knee

NURSING INTERVENTIONS 8–3

Assessment for Developmental Dysplasia of the Hip

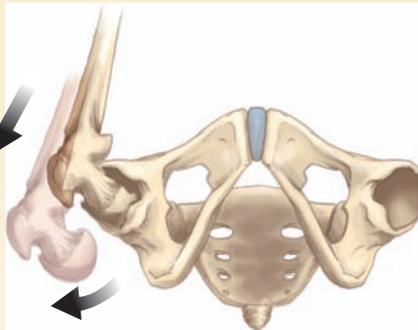

The technique of manual examination of an infant hip should only be performed by a trained examiner. The child should be lying supine and as relaxed as possible. Allowing the infant to suck on a pacifier or bottle may help to keep the child calm. Stand at the foot of the infant. First, place your thumbs on the inside of the infant's thighs. Place the middle finger down the outside of the infant's thigh, feeling for the head of the femur with the fingers. The hip and knee should be flexed. Both hips are grasped simultaneously to provide stability for the examination, but each should be examined independently. When in doubt about what is felt, stabilize the infant's pelvis with the thumb of one hand over the pelvis and the fingers under the sacrum. To examine an infant's left hip, use the left hand to stabilize the pelvis; use the other hand to manipulate the hip.

Technique	Positive Findings in the Neonatal Period
-----------	--

Ortolani maneuver	To perform this maneuver, which attempts to reduce a hip that has been dislocated, abduct the hip and lift the head of the femur anteriorly into the acetabulum. If the hip is reducible, it may be felt or heard moving into the acetabulum. The examiner feels a palpable "clunk."
-------------------	--

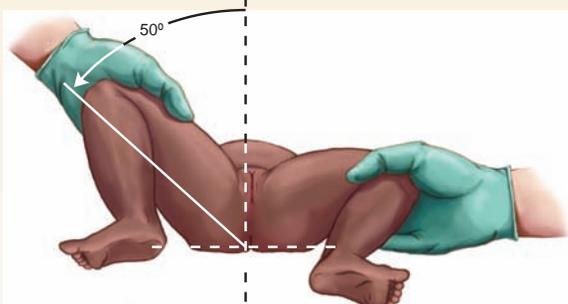

Barlow maneuver	To perform this maneuver, which attempts to dislocate an unstable hip, adduct the hip (bring 10–20 degrees past midline) and apply a gentle posterior force with the palm to the knee. If the hip is able to be dislocated, it can usually be felt slipping out of the acetabulum.
-----------------	--

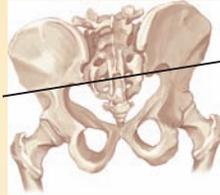

Technique	Positive Findings in Older Infants and Children
-----------	---

Abduction	Limited abduction of the hips
-----------	-------------------------------

Technique	Positive Findings in the Neonatal Period
Allis sign	Compare leg lengths by placing the infant in the supine position, flex them at the knees, and compare their heights.
Trendelenburg gait	When the child bears weight on the dislocated side, the unaffected side of the pelvis drops.

and raise that leg. Observe whether the pelvis remains level. If not and the opposite side tilts downward, this suggests dislocation of the contralateral hip.

Assess range of motion in the neck and the joints of the upper and lower limbs; assess the joints for heat, tenderness, and swelling. Muscle strength and tone are determined by having the child push his or her head or limb against the examiner's resisting hand.

Screen children for idiopathic scoliosis (puberty onset) beginning at age 8 to 9 years (see Chapter 20 for more information). Observe the child from the front and back; there should be no differences in shoulder height, scapular prominence, flank crease, and pelvis symmetry. Tell the child to slowly bend forward holding the hands with palms together or arms hanging

freely while the examiner sits level with and facing the child. The child should bend at the waist to 90 degrees of straight back flexion with legs straight, ankles together, and hands not touching the floor. Each level of the spine is observed. A "rib hump" is an abnormal finding suggestive of scoliosis.

Inspect the lumbosacral area for signs of overlying skin, hairy patches, hyperpigmented areas, or dimpling. These can be signs of spina bifida occulta. With the child sitting or standing, assess the neck for flexion, hyperextension, and rotation from side to side.

Next, inspect the lower extremities. There is a normal range of findings of the lower extremities based on developmental considerations. A "bowlegged" (genu varum) appearance, for example, is caused by lateral bowing of

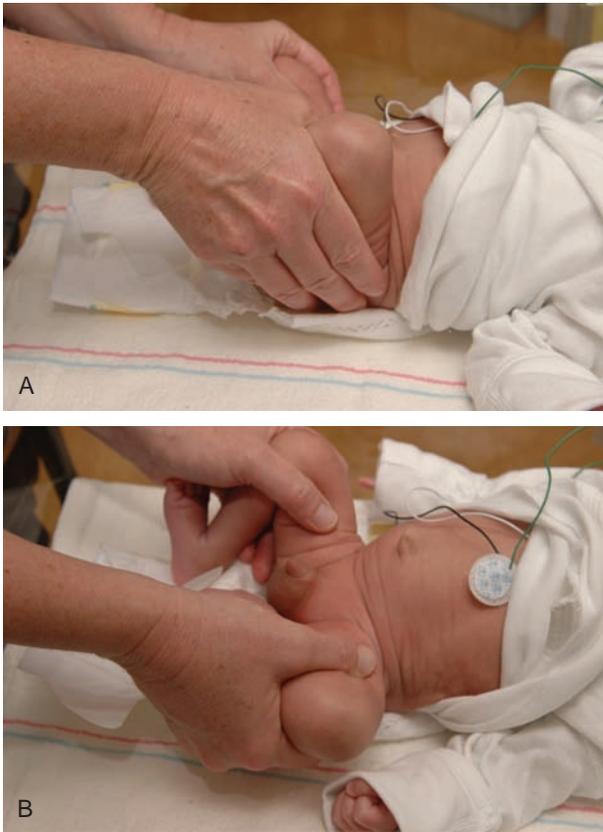

FIGURE 8-14. To perform the Ortolani maneuver, flex the hip and knee of the child (A), then abduct the hip (B), feeling for movement of the head of the femur into the acetabulum.

the tibia and is normal in the toddler years until 1 year after the child starts walking. A “knock-kneed” (genu valgum) appearance is a common finding between 3 and 4 years, and may persist until 7 years of age or slightly longer. To help determine whether the child’s stance is physiologic or pathologic (outside the range of normal), measure the space between the knees or the medial malleoli. In genu varum, the space between the knees when the medial malleoli are together is more than 5 cm (2 in). Genu valgum is indicated when the knees are together and the space between the medial malleoli is greater than 7.5 cm (3 in). Spacings greater than these measures are abnormal and are indications for referral.

Inspect the foot next. Until about age 3 years, children look flatfooted because the fat pad conceals the longitudinal arch, and greater joint laxity is common in infants and toddlers. Ask children who look flatfooted after 6 years of age to stand on their toes; this position should reveal the longitudinal arch. Observe the gait for pigeon toe or toeing-in, which can result from rotational problems originating at the foot–ankle, leg–knee, femur–hip, acetabulum, or a combination of these sites (Kliegman et al., 2007). To determine hip involvement, have the child lie in the prone position with the knees flexed at 90 degrees. The degree of medial and lateral rotation can then be determined. There are specific guides to determine normal angles for specific ages that can be found in advanced practice nursing or medical texts (see Burns et al. [2008]

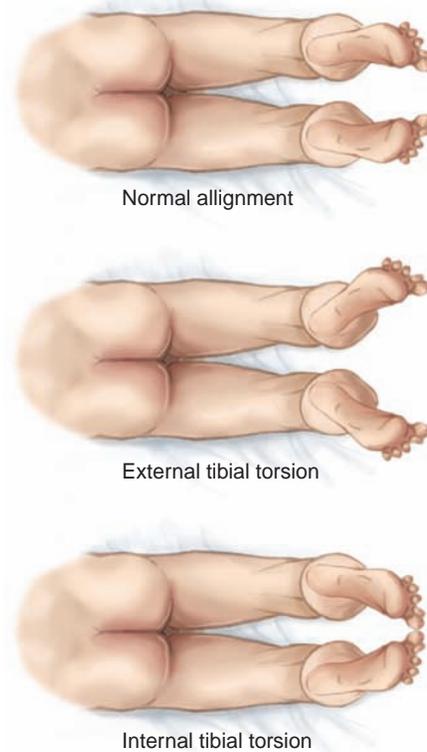

FIGURE 8-15. Thigh–foot angle. Position the child laying on his or her stomach, with the knees close together and flexed; compare the long axis of the foot (picture an imaginary line drawn down the center of the foot from the heel to between the second and third toes) with the long axis of the thigh (femur). (A) Normal alignment: slight external rotation. (B) External tibial torsion: excessive outward rotation. (C) Internal tibial torsion: inward rotation of the foot with a negative angle.

and Kliegman et al. [2007], respectively). The thigh–foot angle can also be measured to help in the assessment (Fig. 8-15). Assess metatarsus adductus by drawing an imaginary line bisecting the hindfoot to the toes. The line should pass through the second toe or between the second and third toes (Burns et al., 2008).

Neurologic System

Neurologic assessment focuses on several factors: mental status or behavior, achievement of developmental milestones (cognitive–perceptual, fine and gross motor, personal–social, and language acquisition), motor and sensory functions, deep tendon and infant reflexes, and cranial nerve function. Although the findings related to the nervous system are reported under the name of the neurologic system, the actual neurologic assessment is integrated throughout the physical examination.

Behavioral and Developmental Assessment

QUESTION: Sally is anxious to know what Stephanie should be doing and what she will do next. Which developmental screening tool would be appropriate to assess Stephanie?

Behavioral assessment of the child is important and should occur during both the health history and the physical assessment. While taking a history and performing the physical examination, assess the child's state of consciousness and look for clues of neurologic problems, such as hyperirritability, restlessness, hyporeactivity, tics, or unusual repetitive behaviors, as well as indicators of alterations in level of consciousness. The Glasgow Coma Scale adapted for pediatrics (see Tables 21-1 and 21-2) is an objective measurement of consciousness and is a useful tool if a problem is suspected. Also assess the older child's mood and intensity as part of your neurologic assessment. A sad affect may indicate depression. It is important to obtain the parents' perspective about their child's behavior and any changes in behavior that have been noted.

To assess developmental milestones in infants and children, determine whether the child has mastered certain tasks (see Chapters 4-7). Standardized tests such as the Brazelton Neonatal Behavioral Assessment Scale, the Denver II, the Early Language Milestone, the Ages and Stages Questionnaire or the Child Development Inventory, and the Clinical Linguistic and Auditory Milestone Scale (by Capute) are useful screening tests. The child may be referred for other, more sophisticated testing if problems are found at the screening level.

ANSWER: The Ages and Stages Questionnaire would be a useful screening assessment tool and a fun way for Sally to see Stephanie's skills.

Motor and Sensory Function

QUESTION: Describe the reflexes that Stephanie should display. Which one should she not display?

Motor functioning is included as part of the musculoskeletal examination. The development of motor skills is age related, with a cephalocaudal progression of development (e.g., the child must have head control to sit and sits before he or she walks). In infancy, look for the presence or absence of specific infant reflexes (Table 8-10). Handedness, the preferential use of one hand over the other, typically does not occur until 3 to 4 years of age. Hand preference that occurs prior to 18 months of age may indicate weakness on the other side or a neurologic problem. In the older child, observe the child's level of activity and movement. Test muscle strength and symmetry by having the child squeeze your fingers, press the soles of his or her feet against your hands, and push his or her arms and legs against your hands. Assess the range of motion of all joints.

Several tests of cerebellar functioning can be performed with an older child. Have the child hop, skip, jump, and walk heel-to-toe. Ask the child to extend an arm and then touch a finger to the nose with eyes open and then shut. Inability to successfully perform these

functions may indicate a cerebellar tumor. Similarly, have the child stand and rub the heel of one foot down the shin of the other leg with eyes open and closed. While the child is standing with heels together, have the child close his or her eyes, ask the child to stand still with arms at the side, and note whether the child leans or falls to one side; this is an abnormal finding known as *Romberg's sign*.

Additional tests may elicit "soft" neurologic signs of abnormality on select motor or sensory tests. Minimal choreoathetoid (involuntary purposeless and uncontrollable) movements in the fingers of an extended arm in a child younger than age 4 years is one example of a soft neurologic sign. Another example is mirror movement of the fingers of the child's opposite hand when he or she is asked to perform a finger-to-thumb movement with one hand. These findings are called *soft*, because they may or may not indicate an abnormality. Furthermore, their significance as an indication of a neurologic disorder should be interpreted cautiously, because their significance is a matter of controversy and because these signs may disappear as the child ages. In contrast, hard neurologic signs such as spasticity or hypotonia strongly indicate underlying neurologic pathology.

Sensory functioning includes vision, hearing, and peripheral sensation. Vision and hearing are assessed as part of the evaluation of cranial nerves, and also through separate auditory and visual testing (see Chapter 28 for more information). Assess peripheral discrimination in children old enough to cooperate by having the child close his or her eyes, then touch different parts of the body with either a pin or cotton ball, or a warm or cold object. Ask the child to identify which object is being used. Again with the child's eyes closed, touch different parts of the body at the same time and ask the child to tell what body part is being touched.

Assessment of cranial nerve function is outlined in Table 8-11. Some of the techniques used to assess individual cranial nerves are age dependent (e.g., an infant will not follow commands). If a neurologic problem or symptom is present, a complete neurologic examination is needed. Otherwise, a screening examination is usually done, including assessment of the head. (See Figure 21-8 for locations of cranial sutures.)

Reflexes

The neurologic system undergoes dramatic growth and maturation during the infancy period. The presence and disappearance of primitive infant reflexes occur in a specific sequence (see Table 8-10). Therefore, the absence or persistence of these reflexes is cause for alarm; these reflexes are important considerations in the assessment of a child during the first year of development. The Moro, grasp, tonic neck, and parachute are the most important primitive reflexes. Their presence or absence during specific periods of development or an abnormal reflex response can signal a central nervous system disorder.

Testing deep tendon reflexes is a routine part of the neurologic examination. Reflex testing can be done with

TABLE 8-10

Assessment of Infant Reflexes

Reflex	How to Test	Usual Response	Abnormal Findings
Newborn Reflexes			
Babinski sign 	Stroke sole of foot along lateral edge from heel upward.	Toes fan, dorsiflexion of big toe	Persistence beyond age 24 months
Crawling	Place infant on abdomen.	Crawling movements with arms and legs	Asymmetric movements
Dance or stepping 	Hold infant with feet lightly touching firm surface.	Feet move up and down	Persistence beyond age 4 to 8 weeks
Extrusion	Touch tip of infant's tongue.	Tongue extends out	Persistence beyond age 4 months
Galant 	Stroke lateral side of spine from shoulder to buttocks.	Back moves to side being stroked	Persistence beyond age 4 to 8 weeks
Moro	Place infant in semiupright position; let head fall backward with immediate resupport with the examiner's hands.	Symmetric abduction and extension of arms, flexion of thumb, followed by flexion and adduction of upper limbs	Persistence beyond age 4 months; asymmetric or absent response
Palmar grasp 	Place finger or object in infant's open palm.	Infant's fingers curve around finger or object and resist its removal	Absence or persistence beyond age 10 months
Rooting 	Stroke corner of infant's mouth.	Infant opens mouth and turns head to side being stroked	Absence or depressed; disappears by age 3 to 4 months when awake

TABLE 8 – 10
Assessment of Infant Reflexes (Continued)

Reflex	How to Test	Usual Response	Abnormal Findings
Startle 	Clap hands loudly.	Infant extends and flexes arms quickly	Absence or persistence beyond age 4 months
Sucking 	Place nipple 3 to 4 cm into the infant's mouth.	Infant begins sucking	Absence or depressed; disappears at age 3 to 4 months when awake
Later Reflexes			
Parachute 	Suspend the infant by the trunk and suddenly flex body forward.	Infant spontaneously extends arms, hands, and fingers	Normally appears by age 6 to 8 months, remains throughout life
Tonic neck 	Turn infant's head quickly to one side when supine.	Extension of arm and leg on side that head turned with flexion in opposite limbs	If locked in the "fencer's position"; normal from age 2 to 6 months

a reflex hammer or the side of the hand. The usual deep tendon reflexes that are tested include the biceps, triceps, brachioradialis, quadriceps (patellar), and the Achilles tendon (Table 8–12). Tap the area over the tendon and look for either extension or flexion. Often, children must be distracted to elicit the appropriate reflexes, because prior tensing of muscles, such as occurs with anxiety or fear, can alter results (Fig. 8–16). To test for the plantar response, lightly stroke the lateral side of the sole of the foot and across the ball of the foot with an upward motion. The normal response is plantar flexion of the toes and sometimes the whole foot (note in Table 8–10 that a normal response in an infant is dorsiflexion of the great toe and fanning of the toes). If meningeal irritation is suspected, test for the presence of the Kernig or Brud-

zinski sign. The Kernig sign (inability to extend the legs fully when lying supine) and the Brudzinski sign (flexion of the hips, resistance, pain, crying when the neck is flexed from a supine position) are associated with meningeal irritation.

Commonly tested superficial reflexes are the abdominal, cremasteric, and anal reflexes. Test the abdominal reflex by stroking the abdominal skin with the handle of a reflex hammer or with a wooden applicator tip, moving from the side toward the midline in all four quadrants. The umbilicus moves toward the stroking. This reflex may not be present in infants younger than age 6 months. Elicit the cremasteric reflex by gently stroking the inner aspect of the thigh of the male in a downward direction. Elevation of the testis on that side is the normal response. Test the anal

TABLE 8 – 11

Assessment of Cranial Nerve Function

Cranial Nerve	Assessment of Function
I Olfactory	Not routinely tested. Have child close eyes, occlude one nostril at a time, and ask him or her to identify various common aromatic scents (e.g., vanilla, orange, peanut butter, peppermint).
II Optic	Test for visual fields and visual acuity; fundoscopic examination.
III Oculomotor	Check pupil size and reactivity. Have child follow the light in the six cardinal positions of gaze and raise eyebrows. Observe position and symmetry of eyelids when open.
IV Trochlear	Have child move eyes downward and inward.
V Trigeminal	Palpate jaw and temple muscles for symmetry and strength as child bites down (motor function). Test for corneal reflex by lightly touching the cornea with a wisp of cotton. Have the child close both eyes and determine whether the child can tell when the forehead, cheeks, and chin are touched with a cotton wisp (sensory function).
VI Abducens	Check for ability of the eyes to move laterally.
VII Facial	Have the child smile, lift eyebrows, or show his or her teeth (motor function). For an infant, observe for facial symmetry when crying. Ask child to identify various tastes of substances (e.g., sugar, salt, or lemon juice) placed on the anterior two thirds of the tongue with an applicator. This evaluates sensory function and is a test not routinely done.
VIII Acoustic	Test hearing. Clap hands from behind (not next to ear so air movement is felt) to see if infant responds; whisper to child from behind so he or she does not see your lips moving. (See Chapter 28 for more information on audiometry and other selected hearing tests.)
IX Glossopharyngeal	Test the child's ability to identify the taste of various substances (see cranial nerve VII) placed on the posterior of the tongue. This test is not routinely done. Phonation and swallowing are tests of motor function.
X Vagus	Elicit gag reflex by placing a tongue blade to the posterior palate; check ability to swallow, and note hoarseness. Check that uvula is midline and the soft palate rises when the child says "ahhh."
XI Accessory	Have child shrug shoulders while pressure is applied by the examiner's hands to determine strength. Similarly, tell the child to try to turn his or her head to the side while the examiner places a hand against the face to resist this movement.
XII Hypoglossal	Ask child to stick out his or her tongue and move it in all directions. Place a tongue blade against the side of the child's tongue and ask the child to move it away.

reflex by stroking the perianal skin and observing a brisk contracture of the anal sphincter (the "anal wink").

ANSWER: One assessment of a young infant's neurologic well-being is the presence and absence of specific primitive reflexes. Stephanie, at 4 months, should still demonstrate a positive Babinski sign and a palmar grasp, and the tonic neck reflex should be extinguishing. She should no longer demonstrate the stepping reflex, Galant sign, Moro's response, or a rooting reflex. Share with the parents these outward signs that indicate the formidable inward neurologic development that takes place during these early months.

Database and Interpretation

Knowledge and skills of pediatric health assessment develop over time and with practice. The history plays a critical role in understanding issues influencing the

child's health and well-being, and in directing the physical examination. Techniques of physical examination are often easier to develop than the assessments important to accurate history taking.

Having conducted a health history and performed a physical examination, the nurse has a database from which to derive a plan of action. As additional data are received, modifications in the assessment and plan can be made.

HEALTH SURVEILLANCE VISITS

QUESTION: Stephanie is adjusting to a new family, a new community, and a new environment. How would you adjust a schedule of visits to meet this family's needs?

In providing health supervision for today's children, the healthcare professional must recognize that physical well-being, mental health, cognitive development, new

TABLE 8 – 12
Assessment of Deep Tendon Reflexes

Deep Tendon Reflex	Method of Testing	Normal Finding
Biceps	Flex the forearm, place your thumb over antecubital space, and tap with reflex hammer.	Slight flexion of forearm
Triceps	Abduct arm and support forearm with your hand, child’s forearm hangs free; or, hold child’s wrist over his or her chest to flex arm at elbow. Tap directly above elbow.	Partial extension of forearm
Brachioradialis	Place child’s arm and hand in relaxed position with arm flexed and palm down. Tap the radius about 1 in (2.5 cm) above wrist.	Flexion of forearm and palm turns upward
Quadriceps	Have child’s legs flexed at the knees and dangling. Tap midline just below the patella. Distract an older child by asking him or her to lock the fingers of the hands tightly together and try to pull them apart. Tap while the child is busy doing this task.	Partial extension of the lower leg
Achilles	Use same position as for quadriceps testing or, in supine position, flex knee and support that leg on the other leg. Lightly support foot in your hand in dorsiflexion and tap Achilles tendon.	Foot plantar flexes (downward)

A 4-point scale is typically used to grade the level of response: 4+, hyperactive, very brisk; 3+, brisker than average; 2+, average; 1+, diminished; and 0, no response. If the child tenses the muscle and tendon group to be tested, the deep tendon reflex is difficult to elicit.

psychosocial morbidities, and social efficacy are influenced by socioeconomic variables, behavior factors, family and cultural considerations, environment, education, access to healthcare, and the availability and quality of community resources. Guidelines developed for health

surveillance of infants, children, and adolescents are based on the beliefs that health supervision is as follows:

- A longitudinal process that promotes a partnership and shared agenda between the healthcare professional, the child, and the family
- Personalized to fit the individual
- Contextual (i.e., views the child in the context of the family and the community)
- Supportive of the child’s self-esteem, sense of competence, and mastery
- Focused on the strengths as well as the problems and issues of the family and community
- Part of a seamless system that includes community-based health, education, and human services
- Complementary to health promotion and disease prevention efforts in the family, the school, the community, and the media (Hagan et al., 2008)

Effective health promotion and prevention has greater implications for infants, children, adolescents, and their parents or caregivers than with any other population group. Pediatric health supervision involves promoting health, preventing mortality and morbidity, and enhancing development and maturation. Prevention requires both an orderly and routine schedule of activities based on knowledge of predictable physical and psychosocial development (attainment of developmental milestones), as well as recognition and prevention of disease as a constant, ongoing process rather than an episodic one. Guidelines for health supervision visits have been developed by the AAP and Bright Futures (see Appendix G). Each health promotion visit with a healthcare provider

FIGURE 8–16. To facilitate evaluation of deep tendon reflexes in a child’s lower extremities, the child may be distracted by having him or her lock the fingers together and then try to pull his or her hands apart.

should include screening procedures, and health promotion and disease prevention strategies, primarily the use of immunization and the physical examination. Focus the history and assessment parameters, and provide anticipatory guidance based on the child's physical and developmental stage (e.g., at each visit measure length/height and weight, and assess development; measure head circumference at every visit until the child is 2 years old; screen for autism at 18 and 24 months of age). Should a scheduled well-child care visit be used to address an identified health problem, then the well-child care visit should be rescheduled.

ANSWER: Stephanie needs to receive several immunizations to catch up to the recommended schedule. Sally will benefit from frequent visits to reassure her and educate her about the health of her new daughter. One recommendation would be monthly visits between now and Stephanie's 8-month appointment, progressing to every other month until she is 1 year old.

ANTICIPATORY GUIDANCE

QUESTION: What is an example of anticipatory guidance appropriate for a 4-month-old child?

The components of anticipatory guidance for children of all ages and their parents or caregivers include discussions about healthy habits, social competence including family relationships and parent-child interactions, and community interactions. Focus these discussions on age-appropriate topics in each of these areas (e.g., weaning, toilet training, school readiness); see Chapters 4 through 7 for specific information. Issues about healthy habits center on lifestyle choices, injury and violence prevention, nutrition and healthy eating choices, physical activity, oral health, mental health (issues of self-esteem, depression, anger, and suicide), and sexuality education.

Social competence discussions emphasize the need for teaching family and societal rules about resolving conflict; age-appropriate discipline; developmentally appropriate behaviors; praise and encouraging expression of feelings; the ability to show respect for and communicate in a positive manner with siblings, peers, parents, and individuals in authority positions; showing affection; positive role modeling by parents; inquiring about school-related progress and career choices for teenagers; and allowing opportunities for socialization and achieving developmental milestones. Community interaction discussions acquaint parents and caregivers with available community resources that are family and child focused, such as parent and community support groups, early intervention programs for at-risk children, community and after-school activities for children and teenagers, and child care resources and guidelines. The need for financial assistance, Medicaid, food, housing,

and transportation are also items to address during social competence discussions.

The nurse needs to assume a proactive role in discussing anticipatory guidance issues with children and their families. Emphasizing and teaching about the value of a healthy lifestyle and behaviors is the responsibility of all members of the healthcare team. Every healthcare encounter is an opportunity for health teaching that should not be overlooked. A pediatric or adolescent health assessment is never complete if anticipatory guidance issues are not identified and addressed whether through discussion, providing written literature, or stressing the need for a follow-up health surveillance visit.

Well-child care encompasses health assessment and management of symptoms commonly seen in minor illnesses. It also involves effective health teaching of children and their families.

The nurse's role in managing common pediatric illnesses involves planning and delivering treatments and medications, evaluating the effectiveness of therapies, teaching patients and their families, assessing the urgency of a situation (see Chapter 31), and giving feedback to physicians and other healthcare professionals. Specific disease management is covered throughout this text (Table 8-13).

TABLE 8-13

Common Childhood Symptoms of Illness

Symptom	Chapter
Runny nose, cough, sore throat, wheezing	16: The Child With Altered Respiratory Status
Earache	28: The Child With Sensory Alterations
Rash/itching	25: The Child With Altered Skin Integrity 24: The Child With an Infection
Abdominal pain, nausea, vomiting, diarrhea	18: The Child With Altered Gastrointestinal Status 17: The Child With Altered Fluid and Electrolyte Status
Headache, seizure	21: The Child With Altered Neurologic Status
Limp, fractures	20: The Child With Altered Musculoskeletal Status
Fever	31: Pediatric Emergencies
Anemia	23: The Child With Altered Hematologic Status
Dysuria, frequency	19: The Child With Altered Genitourinary Status

CHART 8-5 FACTORS THAT INFLUENCE TEACHING ON HOME MANAGEMENT

- *The family's financial resources:* if they have money or insurance coverage for expensive medications or treatments (e.g., prepacked oatmeal bath for a rash is fairly expensive; for families with limited resources, cornstarch may be suggested as an alternative)
- *Literacy level:* ability to read, write, and follow written instructions
- *Home environment:* safety factors, sanitation, physical surroundings
- *Lifestyles:* work commitments of parents and schooling considerations
- *Previous skill levels and available equipment:* for example, do they have a thermometer? Do they know how to use it?
- *Social network:* to assist with other children or provide needed relief for parents
- *Willingness to perform the required treatment:* in other words, emotional readiness and stability
- *Access to home healthcare resources:* for example, a visiting nurse or respiratory therapist

When instructing family members on home management, be cognizant of factors that affect teaching effectiveness (Chart 8-5). Help the family by solving problems that address factors that might influence successful home management. Take time to practice procedures or administration of medications with the parent or child, and plan for return demonstrations to assess competency level (see Chapter 9). The parent or child, depending on his or her age, needs specific information about signs and symptoms that indicate a worsening or an improvement in the child's condition. Finally, access to a telephone and an emergency plan of action if the child's condition suddenly worsens are important considerations for planning home management care.

The nurse plays a key role in promoting health maintenance behaviors in children and their families. Careful listening and observation during the history and physical examination, and effective teaching techniques optimize the nurse's effectiveness in fulfilling this role.

ANSWER: If Stephanie is not rolling over now, she will be soon. Parents often have become accustomed to placing the baby down for a few minutes without anticipating the baby rolling off. This new skill enables the infant to roll from changing tables, beds, or couches in a few seconds, and makes them vulnerable to trauma from falls. Sally, as a new caregiver, should establish the habit of never taking her hand off Stephanie on a surface from which she could fall.

See [thePoint](#) for a summary of Key Concepts.

Pharmacologic Management

Case History

Jose Diaz is 4¹/₂ years old. He has been very congested with a cold for the past several days. Now he is irritable, whiney, and pulling on his left ear. His mother, Claudia, is concerned because Jose has asthma, and often a viral or bacterial infection will trigger a flare-up. Sure enough, Jose wakes up in the night coughing incessantly and wheezing. After a nebulizer treatment of albuterol, Jose's coughing subsides enough to sleep, but he is still wheezing. The next morning, Claudia takes him to the pediatrician. The pediatrician gives Claudia a written prescription for Prelone, a liquid glucocorticoid. Clau-

dia has had experience with this medicine before and then resist taking the medication. Claudia is uncomfortable confronting the physician and she asks the nurse what other type of medicine she could give Jose.

Jose's regular medications include a morning and evening nebulizer treatment with albuterol and cromolyn sodium. His asthma is also responsive to allergic triggers, so in the spring and fall he takes a liquid antihistamine at night. He weighs 40 lb.

CHAPTER OBJECTIVES

1. Discuss age-based variations in pharmacokinetics and pharmacodynamics.
2. Describe safety measures to reduce the risk of error in administering medications to children.
3. Explain developmentally appropriate techniques to administer medications via different routes to children.

See [thePoint](#) for a list of Key Terms.

Medication administration is one of the most challenging and critical aspects of pediatric nursing. Unlike the adult “one-dose-fits-all” principle, dosing for children must be individualized. Medication administration to children must focus on age-related developmental considerations because the pharmacokinetic and pharmacodynamic drug effects are less predictable in children, especially in young infants. This is because of their much smaller size and immature organ systems. Likewise, safe administration of the right dose to the right patient at the right time through the right route is a critical issue, because children are at highest risk for medication errors resulting from increased potential of mathematical errors in calculating dosages or drawing up medications, and are a group more vulnerable to potential side effects and overdose. Ensuring safe administration of medication is a multidisciplinary responsibility that involves the nurse, physician, and pharmacist, who all serve as a check and balance to each other.

DEVELOPMENTAL CONSIDERATIONS IN PHARMACOKINETICS AND PHARMACODYNAMICS

QUESTION: The correct dosage for prednisolone is 1 to 2 mg/kg/day. Given Jose’s weight and a twice-daily order, how many milligrams per dose should Jose receive?

Pharmacokinetics

Pharmacokinetics is the process that involves the absorption, distribution, metabolism, and elimination of drugs; it is the action of the body on the drug. A child’s size and age are key factors that affect the ability of his or her key organ systems to handle the absorption, distribution, metabolism, and elimination of drugs. The capacity of the neonate’s enzyme network to metabolize drugs ranges from 10% to 40% of that of the adult. Renal elimination of drugs in the neonate is also less efficient and takes several years to reach adult capacity. Liver function reaches adult capacity and exceeds it within the first several months of age. Because a child’s age is one of the most influential variables in understanding the pharmacokinetic functions of absorption, distribution, metabolism, and

elimination and excretion of drugs, different dosages are required for neonates (preterm and term), infants, and young children (Chart 9–1). All four pharmacokinetic functions are important considerations in the choice of medications and the selection of safe dosages for a child.

caREminder

Some children metabolize drugs rapidly. Periods of rapid growth may lead to subtherapeutic drug levels, and some drugs may have paradoxical effects in children. Also, preverbal children cannot describe symptoms associated with side effects. Therefore, closely monitor children for desired effects, toxic effects, and side effects of drugs.

Body weight or body surface is a key factor that must be considered in calculating dosages for a child. **Body surface area (BSA)** is the measured or calculated surface of a human body, the area covered by skin. As the child increases in weight and organ system maturity, and his or her metabolic rate changes, larger and sometimes smaller amounts of drugs (depending on the balance between growth and distribution in body tissues and drug metabolism) are needed to maintain therapeutic drug levels (e.g., the nurse may administer 25 mg of a drug to a 1-year-old child vs. 100 mg of the same drug to a 10-year-old child). In pediatrics, there are no standard amounts of a drug given per age; rather, dosage is based on weight using an established amount of the drug per body weight (e.g., 10 mg/kg/day for children older than 1 month of age). Dosages must be calculated using either BSA or weight per kilogram until the child reaches an adult weight (see the later section titled Prescribing the Correct Dose), because the child’s size is a critical factor in the absorption, distribution, metabolism, and elimination of drugs. This must be taken into consideration so as not to overwhelm the body’s organ systems that are responsible for these functions.

The mother who is breast-feeding and taking medications also has developmental considerations. Certain medications are contraindicated with breast-feeding because of their adverse effect on the developing infant (e.g., methotrexate). The American Academy of Pediatrics’ website has information about such contraindicated drugs (see [thePoint](#) for Organizations). Other medications may be taken by the mother with instructions about how soon before or after breast-feeding the mother can take the drug, instructions to take the drug before the infant’s longest sleep period, and, if necessary, instructions on the need to temporarily withhold breast-feeding. Hale’s *Medications and Mothers’ Milk* (2006) is an excellent resource on this topic.

It is also important to consider herbal supplements. They may have one or two main ingredients, but contain many other chemicals that may not be identified on the label. Mothers, therefore, may assume that herbs are natural and thus safe when breast-feeding. However, certain herbs can be very harmful to infants (e.g., buckthorn berry, coltsfoot leaf). The Organization of Teratology Information Services has information on medications and herbal agents in its databases (see [thePoint](#) for Organizations). Be aware of these issues when caring for an

CHART 9-1 DEVELOPMENTAL PHARMACOKINETICS**Factors That Affect Absorption of Drugs**

- 1. Gastrointestinal**
Gastric pH is high in neonates, with adult values by 2 years of age. Acidic drugs are more bioavailable; basic drugs have decreased bioavailability.
Gastric and intestinal motility (transit time) is decreased in neonates and infants but increased in older infants and children.
The bile acid pool and biliary function are diminished in the newborn and reach full capacity during the first several months of life.
- 2. Rectal**
Only select drugs are suitable for rectal administration. In addition, length of exposure to the rectal mucosa affects absorption.
- 3. Intramuscular**
Variable in the pediatric age group secondary to (1) blood flow and vasomotor instabilities, (2) insufficient muscle tone and contraction, and (3) decreased muscle oxygenation.
- 4. Topical/transdermal**
Decreased with increased thickness of the stratum corneum and directly related to skin hydration.
Neonates and infants have increased skin permeability, allowing greater penetration of medication and a greater surface area-to-body weight ratio with potential for toxicity.
- 5. Intraocular**
The membranes of infants and neonates are particularly thin; ophthalmic eye medications can cause systemic effects in infants and young children.

Factors That Affect Distribution

1. Neonates have a higher proportion of total body water that rapidly reduces during the first year of life. Adult values are gradually reached by 12 years of age. This factor is an important consideration related to the water solubility of a drug.
2. Children have a lower proportion of body fat than do adults, so lower doses of lipophilic drugs (e.g., digoxin) are required.
3. Protein binding of drugs is age dependent. Total protein concentration at birth is only 80% of adult values, which leads to more free or active drug circulation and potential for toxicity.
4. Fetal albumin in the newborn period has limited drug-binding ability.
5. An immature blood-brain barrier during the newborn period can lead to higher concentrations of drugs in the brain than at other ages.

Factors That Affect Metabolism

1. The newborn's enzymatic microsomal system is less effective.
2. Liver maturation varies among individuals; each liver enzyme becomes functional at a different rate.

Factors That Affect Elimination

1. Glomerular filtration and tubular secretion are reduced at birth.
2. There is gradual increase in renal function, with adult values reached the first 1 to 2 years of life.

infant who is breast-feeding, and educate mothers about use of medications and herbal teas or supplements.

ANSWER: First convert Jose's weight from pounds to kilograms. Forty pounds divided by 2.2 is equivalent to 18 kg. Jose's dose would be 18 to 36 mg per day divided in two doses. The physician's order is for 15 mg twice a day. This fits within the desired 9 to 18 mg per dose.

Pharmacodynamics

Pharmacodynamics refers to the actions of the drug or how a drug produces physiologic and biochemical changes

at the cellular, tissue, and organ levels. For example, ceftazidime works by binding to penicillin-binding proteins on the cell walls of susceptible microbes to inhibit bacterial cell wall synthesis. Furosemide is a sulfonamide "loop" diuretic and acts on the loop of Henle and proximal and distal renal tubules. Thus, the action of a drug, or its pharmacodynamics, is an important consideration in selecting the drug of choice to use in pharmacotherapy.

Liver enzymes are not mature in infants, so when drugs are metabolized via hepatic enzyme systems, clearance may be delayed with a prolonged drug half-life. Therefore, infants are more sensitive than older children and adults to the same concentration of certain medications, such as opioid analgesics and benzodiazepines.

Because of differences in pharmacodynamics, acetaminophen is less toxic to children because of their higher store of glutathione than adults.

THE SIX RIGHTS

Administering medications to children can be challenging and even hazardous. Children's immature systems for metabolizing drugs, and their smaller size put them at risk for adverse consequences of medication administration. Their cognitive processing may limit their understanding that medications are needed to help them recover or maintain their health. Meticulous attention to the six rights of medication administration will help ensure accurate medication administration in the least traumatic manner.

The six rights are guidelines to facilitate safe administration of the correct medication. The six rights include

1. The right medication
2. The right dose
3. The right patient
4. The right route
5. The right time
6. The right approach

Documentation of assessments (with medications, this includes assessment for side effects) and interventions is always important; some consider documentation the seventh "right."

The Right Medication

QUESTION: Jose has been prescribed Prelone. Look up Prelone. Are prednisone, prednisolone, and methylprednisolone the same medication?

Selection of a medication is based on the child's need for pharmacologic therapy and the ability of the child's body to handle the drug (i.e., to absorb, distribute, metabolize, and eliminate the drug). Many medications prescribed for children do not have U.S. Food and Drug Administration (FDA) approval for use in children; this practice is known as *off-label use*. Prescribers use pediatric pharmacologic reference sources to prescribe these off-label medications and ask pediatric nurses to administer these medications. With the enactment of the FDA's Pediatric Studies rule in 1998, new drugs that seek FDA approval and are likely to be used in children must include labeling information for pediatric use.

The nurse's responsibility in administering the right medication should be viewed as a multistep process. To administer the right medication, the nurse must

1. Know the medication to be administered—its indication for use, action, contraindications, and side effects
2. Understand the connection between the patient's condition, illness, or disease and the use of a particular medication. If such a link is not present, clarify the medication order

3. Select the correct medication from the patient's medication drawer or from medications sent to the unit from the pharmacy
4. Verify the medication label with the patient's medication administration record; a triple verification of labels with the medication administration record can help to prevent medication identification errors. Check the label when first obtaining the drug, when preparing the dose, and when returning the container to the patient's medication box or discarding it

This process is absolutely necessary to ensure that every child receives the correct medication. The nurse must know the indications for the medication prescribed and its potential side effects, and must be knowledgeable about the child's medical illness, disease, or condition so that if an unusual, unlikely, or contraindicated medication is prescribed for a pediatric patient, the nurse can clarify the order. For example, an order to give trimethoprim-sulfamethoxazole (Bactrim) to a child with a known sulfa allergy should alert the nurse to address this issue with the practitioner who prescribed the medication. It is also important to ensure that all allergies to medication are clearly visible on the patient chart, all order forms, and on the medication administration record.

The nurse must also properly identify the medication sent from the pharmacy or the medication taken from the patient's personal supply, as ordered, with the patient's medication administration record. Check the expiration date. Do not use expired medications; return them to the pharmacy and order a replacement medication.

ANSWER: All three medications are glucocorticoids; however, the dosage for an equivalent effect is very different.

The Right Dose

QUESTION: If a medication is so foul tasting that the child gags and spits the medicine back up, how do you determine the dose you have given?

There are two considerations in dosing: prescribing the correct dose for the child and dispensing the correct dose for the child.

Key points to remember when determining the right dose include the following:

- Pediatric dosages are calculated based on weight in kilograms or BSA.
- Adult dose reference ranges, rather than kilogram dosing, may be used in children who weigh more than 50 kg (with some providers using 40 kg as the cutoff point).
- Always double-check math calculations, particularly when preparing a medication that is not supplied as an exact dose. Double-checking mathematical calculations helps to prevent mathematical errors and makes it more likely that the correct amount of medication (a portion of the amount supplied) is given to the patient.

- Compare calculations with the actual order to verify that it is within the recommended range.

Prescribing the Correct Dose

In pediatrics, dosages are calculated using body weight or BSA. To verify the right dose using body weight, look up the established standard dose from a pediatric reference and multiply this number by the child's weight in kilograms to determine whether the dose ordered is correct. For example, if the reference dose is 10 to 20 mg/kg/24 hours divided every 6 hours, and the child's weight is 10 kg, the child should receive 100 to 200 mg per 24 hours, or 25 to 50 mg every 6 hours.

A reverse calculation can also be done starting with the original order. For example, the order says to give 25 mg every 6 hours for a child weighing 10 kg. Multiply 25 mg times 4 (every 6 hours is 4 times a day) to find the total daily dose, which in this case is 100 mg/24 hours. Divide the 100 mg/24 hours by the patient's weight to obtain the milligrams per kilogram per 24 hours. Thus, 100 mg/10 kg comes out to 10 mg/kg/24 hours. Look up the reference range for the drug and compare the two. In this

case, the reference range is 10 to 20 mg/kg/24 hours; hence, the dose that was ordered (100 mg/24 hours) is within the established reference range.

BSA is the most accurate measure for dosing medications for children; it is primarily used when calculating doses of cancer chemotherapeutic drugs. Infants have more BSA than would be expected from their weight because the ratio of BSA to weight varies inversely with length. To verify the right dose using BSA, the child's height and weight are needed. First, determine the correct dose from a pediatric reference and then use a **nomogram** (Fig. 9-1)—a graphic calculating tool, usually containing three parallel lines scaled for related variables so that when a straight line connects values of any two, the value may be read directly from the third at the point intersected by the line—which computes the relationship between height and weight, to obtain the child's BSA.

Alert! The nomogram includes both pounds and kilograms; make sure the correct scale is used. If the weight is measured in kilograms, but graphed in pounds, the resulting BSA will be incorrect.

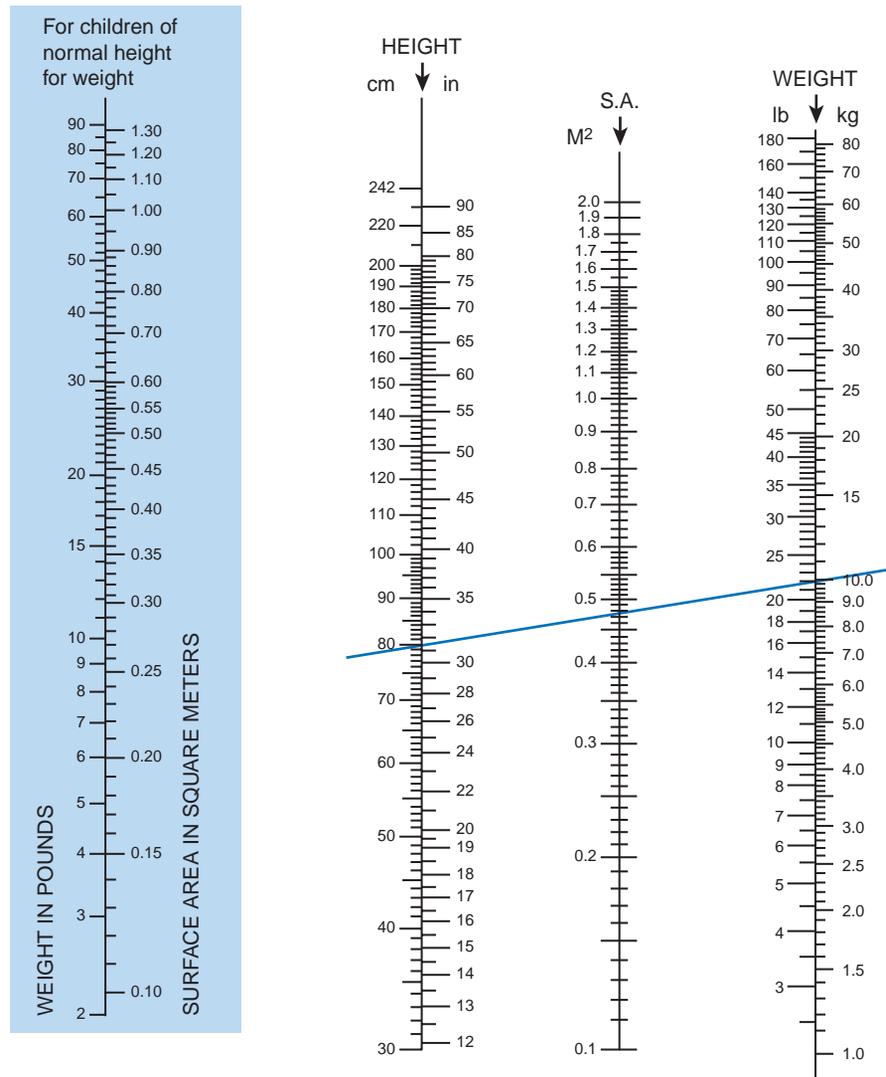

FIGURE 9-1. Nomogram for estimation of BSA. If the child is of average size, use the shaded box on the left to find the weight (on left) and then the corresponding surface area (on right). In the nomogram on the right, the child's surface area is indicated where a straight line that intersects the height and weight levels intersects the surface area (S.A.) column. In this example, the intersecting line indicates a child who is 80 cm tall and weighs 10 kg; the BSA is 0.47 m².

An alternative to using the nomogram to calculate BSA is Mosteller's formula: BSA equals the square root of weight (measured in kilograms) times height (measured in centimeters) divided by 3,600.

$$SA (m^2) = \sqrt{\frac{\text{Weight (kg)} \times \text{height (cm)}}{3600}}$$

After you have verified the correct dose from a pediatric reference and you know the child's BSA, you can determine whether the correct dose has been ordered. To do this, multiply the dose given in the pediatric reference by the child's BSA. For example, if the reference recommends 100 mg/m²/24 hours divided every 12 hours and the child's BSA is 0.5 m², the child should receive 50 mg/24 hours, or 25 mg every 12 hours. If the actual order reads 25 mg every 12 hours (50 mg/24 hours), the dose ordered is within the established reference range.

When looking up reference ranges for dosing, verify the maximum amount of the medication that should be given either per dose or per 24 hours. Maximum dosage is important, especially in the overweight child. For example, if the body weight of a child weighing 100 kg were used to determine a drug dose, the amount of drug ordered would likely exceed the liver's capacity to metabolize the drug or the renal system's ability to safely eliminate the drug. Often, adult range of dosing is used as the drug reference for children who weigh more than 50 kg.

Although most drugs are dosed by weight, there are certain factors that may also influence dosing in children. For example, age-related metabolic changes and organ dysfunction may be factors in addition to weight that are considered when determining an appropriate dose of a medication for an individual child. Therefore, monitor drug levels and physiologic parameters of children in kidney, liver, or heart failure. Likewise, closely monitor preterm and young infants for untoward (or adverse) drug effects.

Alert! The nurse is responsible for knowing whether the prescribed dose of medication is within a safe dosage range. If the prescribed dose is incorrect, notify the prescribing practitioner immediately.

Dispensing the Correct Dose

Before administering a medication to a child, nurses are often called on to draw up an individualized dose from either a multidose container or a single-dose container that contains more medication than needed. It is important, therefore, to set up equations in a consistent fashion when drawing up an individualized medication. For example, if a multidose container is labeled as cephalexin (Keflex), 250 mg/5 mL, and the ordered amount is 200 mg of oral suspension, set up the equation as follows: 250 mg/5 mL = 200 mg/ x mL. To calculate the value of x , cross-multiply so that $250x = 1,000$; then divide 1,000 by 250 so that $x = 4$. This tells you that 4 mL must be drawn up to obtain the necessary 200 mg cephalexin. Similarly, an oral syringe containing 15 mg/mL ranitidine syrup may be sent from the pharmacy. If the order calls for 10 mg ranitidine syrup orally, set up the equation as 15 mg/1 mL = 10 mg/ x mL to calculate that the nurse would draw up 0.67 mL.

Administering intravenous (IV) medications is often challenging in pediatrics, especially if the nurse must prepare a drug that comes as a powdered medication. The final volume is not always equal to the initial fluid volume used; the powder may also add volume. The nurse must first dilute the powdered medication with sterile normal saline or water, then determine the final concentration of the medication, and then calculate how much fluid is needed to obtain the ordered amount of medication. For example, a child is to receive 225 mg ampicillin IV, and a 250-mg vial is sent from the pharmacy. The vial says to use 1.8 mL sterile diluent with a resulting final volume of 2 mL. The resulting solution is 250 mg/2 mL. The nurse sets up a math proportion and calculates that 1.8 mL of the final volume is needed to obtain 225 mg ampicillin ($225 \text{ mg}/x \text{ mL} = 250 \text{ mg}/2 \text{ mL}$).

Infusion times are also important considerations for maintaining blood levels of the drug or to prevent adverse reactions. Use only recommended infusion times to deliver IV medications. Infusion times (e.g., 5, 20, 30, 60 minutes) and required fluid volume dilutions for medications are based on established concentration levels necessary to deliver IV medications; consult a reference source for dilutions and infusion times.

ANSWER: Usually the decision to readminister the dose is dependent on the toxicity of the drug (e.g., digoxin has a narrow therapeutic range), absorption rate of the drug, and amount of time between administration and vomiting. Generally, if it is less than about 5 minutes, readminister the medication; if it is more than that, do not readminister unless it is certain that the child did not get the dose. Readminister only once per dose. If it is known that a child will vomit or fight a particular medication, then a change in medication may be the solution.

The Right Patient

All children who have been admitted to a healthcare facility should be identified by an identification band attached to their body and not according to the bed they are in. Accurate identification serves two purposes:

1. To reliably identify the individual as the person for whom the service or treatment is intended
2. To match the service or treatment to that individual

For administration of medication and other services or treatments, the Joint Commission adopted a two-identifier requirement to ensure reliable identification of patients as a safety goal. Acceptable identifiers can include two of the following on a wristband: the individual's name, date of birth, assigned identification number, telephone number, or other person-specific identifier. Bar coding with two or more person-specific identifiers is also being used. Take the patient's medication administration record to the bedside to perform your double-identifier check. Verify the medication about to be delivered by checking the medication label with the child's identification band.

If the child does not have an identification band in place, the nurse must first identify the child before administering any medication. A parent should identify a baby or a younger child. Ask an older child his or her name and date of birth or other identifier.

Alert! Use extra caution when there are children with the same last names on the unit or when the parent of the child does not speak English. Charts may be confused and orders may be written for the wrong patient. Check allergy wristbands to verify that the child does not have an identified allergic reaction to the medication about to be administered.

The Right Route

QUESTION: Prednisolone is available in an IV and an oral form. If Jose worsens and is admitted to the hospital, could his medication be administered at the same dose intravenously?

The route of administration affects the absorption, effectiveness, and the speed of action of medications. For example, based on efficacy studies, certain childhood immunizations are administered intramuscularly (IM), whereas others are given subcutaneously (Sub-Q). The nurse, therefore, must be familiar with the various routes of administrations for all childhood vaccines. Medications given IV, IM, or Sub-Q will have differing peaks and durations of action. Morphine sulfate administered IV rather than Sub-Q as ordered could severely compromise a child's respiratory status because the IV route results in faster absorption of the medication. Similarly, medications given through a jejunostomy tube rather than a gastrostomy tube will have different absorption rates because of the different motility rates in various sections of the gastrointestinal tract.

Incorrect administration techniques can also be problematic. Faulty administration of Sub-Q insulin can result in lipodystrophy. Application of a thick layer of topical cortisone medication can result in increased steroid absorption, and too-rapid IV infusion of vancomycin can result in red man syndrome (an anaphylactoidlike reaction causing an erythematous, maculopapular rash, and intense flushing of the skin; patients may also experience dizziness, headache, chills, chest pain, and respiratory difficulties). Therefore, careful attention to proper administration technique and vigilance in monitoring for adverse reactions are critical nursing responsibilities.

To reduce the chance that the medication is administered via the wrong route, colored syringes (e.g., amber colored) may be used as an added safeguard to help differentiate oral medications from IV medications that are dispensed in clear syringes from the pharmacy. For IV drugs, routinely label all infusion lines to be sure that the right drug is inserted into the right infusion line. Use extra caution for patients with multiple IV infusion lines and gastric infusion devices so that gastric medications are not incorrectly injected into IV and arterial lines.

ANSWER: Jose's medication probably could not be administered at the same dose intravenously. Prednisolone is available in an IV form; however, the most commonly used IV steroid agents are hydrocortisone and methylprednisolone. IV hydrocortisone is administered at 2 mg/kg every 6 hours and methylprednisolone is administered at 0.5 to 1.0 mg/kg every 6 hours.

The Right Time

Medications given at the wrong intervals can affect therapeutic blood levels. The use of military time helps to reduce the problem of medications being given at incorrect times. Each institution may have its own policy about scheduled times (e.g., once, twice, three, four times per day) for medication. The general rule of practice is to administer a medication within the time frame of a half hour before or after the scheduled time period. Adhering to scheduled medication times is particularly important for medications that must be given every 4, 6, or 8 hours around the clock to maintain therapeutic drug levels for optimum drug effectiveness.

There are certain situations in which the pediatric nurse must be particularly alert to timing issues. If drug blood levels are ordered at specific times to coincide with administration of certain medications at specific times, the nurse is responsible for administering the medication at the required time and notifying the laboratory of the time that the blood sample must be collected. Determining peaks and troughs of drugs is an important part of the management plan for certain medications.

Some medications should be given with meals, just before meals, on an empty stomach, or at a specified time (e.g., 2 hours after meals or at 8 am, 3 pm, and 9 pm). Therefore, timing of these drugs is an important issue. For example, drug absorption can be altered if a certain drug is given with food, or a drug may need to be given before meals to promote effective gastrointestinal functioning. A daily dose of steroids, for example, is often given in the early morning to mimic the normal physiologic response of the body. Thus, the nurse must be knowledgeable about the medications being administered and their mechanism of action.

caREminder

Timing is often important when administering oral medications to infants. Because many young infants are on demand feedings, the nurse may need to adapt the medication schedule for certain drugs based on the infant's feeding pattern.

The Right Approach

QUESTION: Describe the "right approach" for a child in early childhood. How is it different from that for an infant or a child in middle childhood?

Often, individuals are less attuned to the sixth right of administering medications to children. The right approach—how one addresses the child and the task at hand, and considers the emotional status and developmental level of the child—is especially important when administering medication to children because of their varying cognitive levels, inability to recognize cause and effect (“I get the medicine now and it makes me feel better in a little while”), and lack of abstract thought. One’s approach to the child, age-appropriate explanations, and administration techniques often affect the success of administering the medication to the child in the least traumatic manner possible (see Developmental Considerations 9–1).

ANSWER: Infants cannot anticipate a bad taste. Position the infant upright, and present a pleasant- or neutral-tasting substance to ensure that the child is awake and swallowing. Give the medication slowly enough to allow the child to swallow and prevent any risk of aspirating, and give a pleasant-tasting “chaser.” Four-year-old children are very different. They remember bad tastes and smells. The smell and memory of the taste may be enough to induce retching without even tasting the medication. An aversion to the artificial fruit-flavored syrup may make the oral suspensions even more noxious. Four-year-olds can put up amazing resistance and can also understand the necessity of taking a medicine (e.g., “You need to take this medicine to make it easier to breathe”). Successful administration requires eliciting some degree of cooperation on the part of the child. Practicing atraumatic nursing care also means not overpowering the child, but instead gaining their cooperation. Give them other options. Do not rule out the tablet. A prednisone tablet is very small. The child may accept a crushed pill in pudding or even swallow half a small pill on a slice of banana.

AVOIDING COMMON ERRORS IN MEDICATION ADMINISTRATION

Medication administration involves a series of steps: calculating and prescribing a drug, transcribing the medication order, dispensing the drug, and delivering the drug to the patient. Errors in administration can involve mistakes at any one or more of these steps. Likewise, an error can involve a mistake by a single healthcare care provider or multiple providers. Knowledge of common problems associated with each of these steps is important to avoid a drug error.

Prescribing and Transcription Errors

QUESTION: Given the plethora of corticosteroids, what are some possible errors in transcribing these medications?

Medication errors related to prescribing and transcription are generally grouped into four categories: poor handwriting, decimal errors, misused abbreviations, and

incorrect calculations. Many healthcare agencies have adopted computerized medication records, which eliminate the problem of incorrect interpretation of handwriting. However, to avoid a transcription error in situations when typed medication orders are not common practice, the nurse and pharmacist must carefully interpret handwritten medication orders and clarify all medication orders that are not clearly written.

Decimal errors, the most common error in pediatric medication calculation, can be avoided by never placing a decimal and a zero after a whole number (called the *trailing zero*) because the decimal point might not be read correctly (e.g., 4.0 mL might be read as 40 mL; write 4 mL). Place a zero (called the *leading zero*) before fractions that are less than one (e.g., write 0.6 mL, not .6 mL, which might be confused with 6 mL if the decimal is inadvertently missed).

Use abbreviations sparingly. For instance, do not use the abbreviations q.d., q.o.d., IU, or u. Instead, write out “every day,” “every other day,” “international unit,” or “unit.” It is recommended that the Latin abbreviations for the eyes and ears not be used; instead, write out right or left and ear or eye. Avoid other dangerous abbreviations including μg (write mcg instead), H.S. (write out half strength or at bedtime), S.C. or S.Q. (write Sub-Q or subQ), and c.c. (write mL). In addition, because they are easily confused with one another, always write out morphine sulfate and magnesium sulfate. Urge prescribers to write out instructions rather than using abbreviations.

Ask for clarification of medication doses that are not within the pediatric reference range. The individual who ordered the medication may have made a mathematical error or used an incorrect weight when calculating the amount of medication that was needed. Use caution when interpreting large doses more than 1,000. Commas should be used for dosing units at or above 1,000, or words such as 100 thousand or 1 million should be used to avoid errors.

Important points for the nurse to remember to decrease prescribing and transcription errors include the following:

- Clarify medication orders that are poorly handwritten.
- Pay strict attention to the rules about when a leading zero is necessary and not using a trailing zero.
- Use abbreviations sparingly and only use approved abbreviations.
- Double-check all math calculations.
- Verify with the pharmacist or prescriber unusually large volumes or dosage units for a single-patient dose.

ANSWER: The variety of corticosteroid compounds and dosages, including very similar sounding names, increases the risk of a prescription or transcription error. The nurse should verify that the prescribed dose is appropriate for the prescribed medication.

Dispensing and Administration Errors

The pharmacist or the nurse may be involved in dispensing errors. Math errors may be made in calculating

DEVELOPMENTAL CONSIDERATIONS 9–1

Medication Administration

Age Group/Developmental Group	Tips/Guidelines
All ages	<ul style="list-style-type: none"> • Solicit the parent's involvement in medication administration as appropriate. • Some oral medications are extremely difficult for a child to take because of palatability issues. In such instances, the medication may need to be mixed with food or a liquid to disguise its taste. Some pills may be crushed and mixed in small amounts of applesauce, chocolate syrup, ice cream, or pudding to disguise their taste. Do not crush enteric-coated pills. • Preschoolers and older children may wish to suck on an ice pop or ice prior to oral medications to numb the tongue and reduce unpleasant tastes. • Offer choice of fluid after oral medication administration, as appropriate, to reduce taste of medication. • Whenever possible, take the child to the treatment room for painful procedures such as IV insertion and injections. Do not perform painful procedures at the child's bedside or in the playroom to maintain these as safe havens for the child. • If possible, give medications IV rather than IM or Sub-Q to avoid pain and intrusion. • Never lie to a child that an injection will not hurt. Use a topical anesthetic whenever possible before injections to decrease pain.
Infancy	<ul style="list-style-type: none"> • Unless contraindicated, hold the infant in an upright position while delivering oral medication. • An infant who has just been fed and is sleeping deeply may not want to suck. Try to administer medications either before a feeding or when the infant is not sleeping deeply after a feeding. • Place oral medication in a <i>small</i> amount of pleasant-tasting, nonessential food (e.g., not formula, cereal), if an infant can eat from a spoon. Check compatibility of the medication with the substance mixed in (e.g., Viracept has a very bitter taste when mixed with acidic juices and should be mixed with milk). Remember that the more liquid the medication is mixed with, the greater the volume the child must take. • If the infant cannot eat from a spoon, place oral medication in a nipple that is not attached to a bottle. • If the infant refuses to take oral medication, place it in a syringe and squirt it inside the mouth, toward the back of jaw. Then rub the submandibular area bilaterally to elicit swallowing. • Very strong-tasting medications may cause an infant to gasp and increase the risk of aspiration. Prepare the infant that something to swallow is coming in his or her mouth; introduce a nipple, then give a small amount of juice (or other diluent), then juice with the medication. • For difficult-to-feed infants or those with respiratory difficulties, administer oral medication slowly. The infant may need to rest between short spurts of medication administration. • Praise an older infant for compliance. Comfort after administration.

(Continued)

DEVELOPMENTAL CONSIDERATIONS 9–1

Medication Administration (*Continued*)

Age Group/Developmental Group	Tips/Guidelines
Early childhood	<ul style="list-style-type: none"> • Explain in simple terms the reason for the medications, such as “This will help you get well” or “This will make your tummy ache go away.” • Use administration approaches used with infant, with the exclusion of the nipple. In the stage of initiative, older children in this age group may think it is fun to use an oral syringe. Assist or supervise children as they push the syringe plunger to get the medication into their mouth. • Offer realistic choices that will allow the older child in this age group some control over the situation (e.g., “Would you like to take your medicine with water or juice?” “Do you want your IV in your right hand or your left hand?”). • An older child may want to suck on ice pop to numb the tongue before taking unpleasant tasting medications. • Provide distraction. • Permit expression of anger. • Provide preparation through play. • If the child is not able to cooperate in taking oral medications, situate the child on your lap with his or her legs in between your legs. Place one of the child’s arms behind your back and hold the other arm in your nondominant hand while administering the medication with your free hand. This is often a two-person procedure, especially if the child spits out the medication. • In a two-person procedure, have one person hold the child in his or her lap as described previously while the other person places the fingers of one hand around the child’s cheek and slowly instills the oral medication from a syringe into the side of the child’s mouth with the other hand. After a small amount is instilled, press the child’s cheeks together until he or she swallows the medication; repeat this maneuver until medication administration is complete. • After the medication has been administered, praise the child for his or her efforts. • Have another person available to help the child hold still to ensure safety during injections. Place a Band-Aid on an injection site, because older children of this age fear their blood will “run out of the hole.” Allow the child to assist in placement. Comfort after injection.
Middle childhood	<ul style="list-style-type: none"> • Give concrete explanations of the purpose of the medication using drawings and diagrams of targeted body parts. • Some children may hide their medication and pretend they have taken it; be alert for this. • Give as much choice as possible regarding administration. • The child may want to suck on an ice pop to numb the tongue before taking unpleasant tasting medications. • Allow independence from the parent in the process of medication administration.
Adolescence	<ul style="list-style-type: none"> • Use approaches suggested for the school-aged child. • Depending on the maturity of the adolescent, use more abstract rationales for medication.

portions of medication to draw up to obtain an exact dose. If the nurse makes a math error, the amount of medication that is to be drawn up is incorrectly identified. In some situations, the amount to be drawn up is correctly calculated; however, the amount drawn up is not the amount calculated.

Two registered nurses should check high-alert medications (drugs that have a high risk of causing harm when an error occurs) such as insulin, digoxin, opioids, drugs used for sedation, heparin infusions, and chemotherapeutic agents before they are administered. Review the original order for these medications and verify that the dose of the drug that was ordered is the amount that has been drawn up to administer to the child. For digoxin and chemotherapeutic agents, verify from the original order that, based on a reference range for the dosing and the patient's weight or BSA, the correct dose was ordered.

Smart pumps can help reduce medication administration errors. Such enhanced IV pumps contain dynamic software that is programmed to ensure that the first five rights of medication administration are maintained (the sixth right, approach, cannot be ensured by technology). There are currently two types of smart pumps. The technology in type 1 pumps allows the nurse to identify the drug, its concentration, and solution, which provides a safety guardrail. Type 2 pumps contain the same technology found in type 1 pumps, with the addition of built-in bar code readers to identify bar-coded drug labels as well as to confirm unique patient identification information and record the bar-coded ID badge of the nurse. Remember, however, that technology is not a replacement for sound nursing judgment. Sometimes the nurse will start to administer a medication and the parent or child may question why the medication is being given. They may even refuse to take the medication because of concerns about, or prior adverse reactions to, a drug. Always listen to their concerns, because the prescribing provider may have made a mistake or may be unaware of prior adverse reactions or that the child has a contraindication to the medication.

Important points for the nurse to remember to decrease dispensing and administration errors include the following:

- Double-check math calculations and amounts that are drawn up for dispensing.
- Use a two-nurse system to verify doses and amounts drawn up for high-alert medications.
- When a parent or patient questions whether a medication should be administered, answer questions and, if appropriate, double-check the medication order and/or call the prescriber to discuss the concern expressed by the patient or parent.

Reporting Adverse Drug Reactions and Medication Errors

It is important to complete appropriate agency forms if an adverse drug reaction or medication error occurs. In the situation of an adverse drug reaction, identify the patient's symptoms and notify the prescriber and

pharmacist. Discontinue use of the medication until instructed to do otherwise. Likewise, if a medication error is made, notify the prescriber and pharmacist immediately. Monitor the child for adverse reactions.

ADMINISTERING MEDICATION TO CHILDREN

Successful medication administration must focus on safety and age-appropriate behavioral and developmental considerations. All health professionals are responsible for administering safe dosages and monitoring for toxic effects and side effects of drugs. Although not prescribing medications, the nurse must know how to calculate therapeutic dosages to determine whether they are safe to administer and what toxic effects and side effects are associated with the drugs being administered. Follow general safety measures to reduce the occurrence of adverse events (Nursing Interventions 9–1).

Medication administration reflects one of the finer points of the art of pediatric nursing. The resistance of the infant, toddler, or preschooler to swallowing foul-tasting or smelly medications can be dramatic in its display and time-consuming for the nurse. Assess the child's cognitive level. Explain to the child (or parent, when applicable) the reason that a medication is being given and any procedure that is necessary for the administration of the medication, using explanations that are simple and appropriate to the child's cognitive level. A child may cooperate more with a procedure if the proper explanation has been made. Soliciting the aid of the parents can be especially useful, because they may have already developed a method of medication administration that is acceptable to the child. Do not deceive the child about the fact that you are administering medication (e.g., by pretending that you are giving the child something good to eat). Similarly, do not use the medication as a reward or punishment. Guidelines for administering medication by age group are presented in Developmental Considerations Table 9–1.

Routes of Administration

Some of the more common routes of medication administration are discussed in the following paragraphs. Administration of inhaled medication is discussed in Chapter 16 and intrathecal medication is discussed in Chapter 22. See [thePoint](#) for Procedures on Medication Administration: Enteral; Medication Administration: Nasal; and Medication Administration: Subcutaneous.

Administering Oral Medication

QUESTION: Describe different techniques and measuring devices to give liquid medications. Which would be most appropriate for a 4-year-old?

NURSING INTERVENTIONS 9–1

Safety Tips for Medication Administration

- Never leave medications at the child's bedside unless permitted by institution policy.
- When checking medication labels, pay close attention to the spelling of the medication because many drugs have similar names.
- Perform hand hygiene before preparing medications.
- Prepare medications in a quiet, well-lit area.
- Check drugs for discoloration or unusual precipitates.
- Use a calculator to check drug doses and calculate doses twice.
- Do not give a drug that another nurse has prepared.
- If medications are prepared in a syringe beforehand, label the syringe with the name of the drug, its concentration, date and time drawn, and your initials.
- Remember to remove syringes (and needle if used) from the child's bedside and place in an appropriate sharps box.
- For liquid oral medications, use an oral syringe or medication cup to ensure accurate dosage measurement. Teach parents that use of a household teaspoon or tablespoon may result in dosage error because they are inaccurate.
- Remember to remove caps from oral syringes before administering medications and discard in a proper receptacle. Caps left at a child's bedside or when left in place (which then pop off while administering the medication orally) may be aspirated.
- Be aware of drug incompatibilities with other medications or fluids. This is especially important when administering multiple IV medications or when the patient is receiving parenteral nutrition or lipids.
- There should be a healthcare prescriber's order if the nurse is to administer medication brought in from home. The pharmacist should identify the medication.
- Check the time interval between medication administrations for all PRN (as needed) drugs to ensure that enough time has elapsed.
- Label external medications "for external use only" and store separately from other medications.
- Record IV fluid amounts used to deliver IV medications in the patient's intake and output record.
- Be especially careful when administering high-alert medications such as antineoplastic drugs, digoxin, insulin, or opioids. Medications delivered by the parenteral route also demand vigilance both in preparation and while infusing.
- Use vials of sterile water or normal saline for injection as a one-time injection solution and not as multiple-dose vials.
- Be aware of potential drug–drug and drug–food interactions.
- Monitor results of drug levels, when ordered.
- Obtain a careful drug allergy history and be sure that an Allergy Alert is posted on the patient's chart and that the patient wears an Allergy Alert bracelet.
- Check with the pharmacist or current drug manual before crushing tablets to ensure that it is not contraindicated.
- Administer enteral medications through oral or catheter-tipped syringes only. Use the largest syringe size practical; larger syringes generate fewer pounds per square inch than smaller syringes, thus reducing the potential of tube rupture. Do not use Luer Lok–tipped syringes to avoid inadvertent IV or IM administration of medication, because needles cannot be attached to oral or catheter-tipped syringes. It is desirable to flush with water or saline after medication administration to infuse the medication. When determining the amount of flush solution, consider the child's fluid status (e.g., potential for fluid overload), gastric or intestinal tube size, institutional policy, and manufacturer recommendation. If air is used to flush the tube, it is especially important to verify compatibility of medications when multiple medications are administered at one time (to avoid clogging the tube).

The oral route should be used to administer medications whenever possible (see [thePoint](#) for Procedures on Medication Administration, Oral). The gastrointestinal tract provides a vast absorptive area for medications, and administration by this route is less invasive, thus less traumatic, than IM or IV injection.

Children, however, have a natural aversion to foul-tasting and smelly substances. They may cry and refuse to take medication administered orally or may try to spit out

the dose if it tastes or smells bad. When administering oral medication, never mix it with the infant's formula or necessary food source (e.g., cereal) or with the child's favorite food. Doing so may lead to the dislike of that food, as well as to a distrust of the caregiver. Similarly, distrust may result if the child is told that the medication tastes good or desirable. The overall objective of administering oral medications is to administer the entire dose to the child while creating the least aversion to the medication as possible

KidKare ■ When possible, offer the child a choice of drink after distasteful medications (unless contraindicated). Older children can suck the medication from a syringe, pinch their nose, or drink through a straw to decrease the input of odor, which adds to the unpleasantness of some oral medications.

A complication associated with administering oral medications is aspiration. Positioning and strategies noted in Developmental Considerations 9–1 will reduce this risk (see also Fig. 9–2).

ANSWER: A cooperative 4-year-old could take an oral medication in a small medication cup. With an uncooperative child, spills are less likely with the syringe. A standard syringe may be used to draw up a liquid medication; however, errors involving the route of administration have led to manufacturers producing syringes specifically for oral medication. The hub is off-center so that they look different from a standard syringe. Spoons with measured increments in the handle are commonly given to parents by pharmacies but are infrequently used in hospitals. Small plastic measuring cups are accurate for larger volumes (e.g., more than 15 mL).

Administering Intravenous Medication

QUESTION: If Jose’s respiratory condition warranted hospital admission, Jose could receive his systemic glucocorticoid intravenously. What is a concern of administering IV glucocorticoids to young children?

The IV route provides direct access into the vascular system. For this reason, it is an ideal route to use when drugs must be delivered rapidly, when high serum concentra-

tions of a drug must be maintained, or when reliable absorption is necessary. For the child with established IV access, administration of medications via this route can be performed in a manner that is relatively nonthreatening to the child. See Chapter 17 for a discussion of venous access and IV therapy, and **thePoint** for Procedures on Medication Administration: Intravenous; Heparin Lock/Flush; Intravascular Therapy: Peripheral Catheters; Intravascular Therapy: Peripherally Inserted Central Catheters; Intravascular Therapy: Totally Implantable Devices; and Intravascular Therapy: Tunneled Catheters.

To minimize adverse effects associated with high serum drug levels (e.g., nephrotoxicity, ototoxicity) and to avoid venous irritation from concentrated solutions, IV medications are usually diluted. Young children may develop fluid overload from the extra 50 mL of fluid commonly given to administer medication “piggybacks” to adults. Most institutions have specific policies on diluting drugs and administering diluted drugs. IV medications can be delivered in various ways, depending on the drug (e.g., pain medications or diuretics may be given IV push, whereas antibiotics are often given over 30 to 60 minutes) and the child’s fluid status (e.g., infants cannot handle large fluid volumes; children with renal, cardiac, or other problems may require fluid restriction).

caREminder

Some medications are very irritating to the veins (e.g., nafcillin sodium and phenytoin). Giving them over a longer period or in more fluid can help minimize this irritation.

IV medications can be given directly into the IV tubing (IV push), or via volume control chamber or syringe pump. Medications given IV push immediately enter the vascular system with almost instantaneous effects (Fig. 9–3). IV push medications are usually administered over a few minutes and necessitate small amounts of extra fluid

FIGURE 9–2. (A) Administering oral medication to an infant. Note how the right-hand-dominant nurse can control the infant’s movements by holding the infant’s left arm (the infant’s right arm is tucked under the nurse’s left arm) and tucking the infant’s head in the crook of her arm. The nurse can then use her right hand to administer the medication. (B) Administering oral medication to a toddler. With the child sitting on the parent’s lap, place the syringe on the side of the tongue and slowly drip the medication into the child’s mouth.

FIGURE 9-3. Medications administered IV push enter the vascular system immediately.

intake. Syringe pumps are used to deliver medication with minimal amounts of excess fluid required (Fig. 9-4). Low-volume tubing can be used to minimize the amount of drug wasted in the tubing. The pump is set to administer the drug over the predetermined period. For children who can tolerate extra fluid volume, IV medications can be administered via a volume control chamber (e.g., Buretrol). The drug is diluted in a specific amount of fluid in the volume control chamber, taking into account how much fluid the drug must be diluted in, the child's IV flow rate, and the fluid volume in the tubing. After the volume control chamber is empty, the drug remains in the IV tubing. Therefore, it is necessary to know how much fluid the tubing holds (commonly 15–20 mL) so at least that amount can be given to flush the medication through the tubing into the vein. Tag the volume control chamber with tape or a designated sticker, so that everyone is aware that a medication or flush is infusing (Fig. 9-5).

FIGURE 9-4. Syringe pump used to administer IV medication.

Alert! Include the extra fluid given to administer IV medications and flush the tubing in the calculation of the child's total fluid intake, particularly in young children who may not be able to handle the extra fluid or those with unstable fluid balance.

IV medication can also be given via continuous drip. Standardizing IV infusion concentrations can reduce the number of medication errors (Bullock et al., 2006).

Adverse effects of IV medication administration include extravasation of the drug into surrounding tissue, resulting in temporary or permanent damage, and reaction to the drug, including side effects and anaphylaxis. The nurse must intervene to minimize these hazards (Clinical Judgment 9-1). Before administering an IV

FIGURE 9-5. Proper labeling assists in identifying when medications have been placed in the IV volume control chamber.

CLINICAL JUDGMENT 9–1

IV Medication Administration

Ari is a 12-year-old boy who has been hospitalized for the past 4 days with staphylococcal pneumonia. His current weight is 38 kg. As part of his treatment he is receiving IV fluid at 125 mL/hour and nafcillin 1,200 mg every 4 hours via peripheral IV. The reference source says that nafcillin must be diluted 10 to 20 mg/mL and given over 30 to 60 minutes. Ari has had his IV restarted four times since admission and complains bitterly that the IV site burns during nafcillin administration. You review his chart and find that the nafcillin has been given in 65 mL of fluid followed by 15 mL to flush the IV tubing, then 45 mL to maintain his 125 mL/hour IV rate.

Questions

1. The recommended dose of nafcillin is 100 to 200 mg/kg/24 hours given every 4 to 6 hours. Is Ari's dose within the suggested range?
2. What factors concerning Ari's IV may indicate a problem?
3. Is the nafcillin being diluted in the best way to manage this situation?
4. How will you dilute the nafcillin based on Ari's current IV rate?
5. What will indicate that the more prolonged administration of a less concentrated solution has addressed the problem? If nafcillin administration remains problematic, what are alternatives for you to consider or address with the rest of the healthcare team?

Answers

1. Yes:

$$\begin{aligned} 38 \text{ kg} \times 100 \text{ mg} &= 3,800 \text{ mg/24 hours} \\ &= 633.3 \text{ mg every 4 hours} \\ 38 \text{ kg} \times 200 \text{ mg} &= 7,600 \text{ mg/24 hours} \\ &= 1,266.7 \text{ mg every 4 hours} \end{aligned}$$

Ari is receiving 1,200 mg every 4 hours, almost 190 mg/kg/24 hours.

2. Ari's IV has been restarted on an average of once every 24 hours, which is too frequent. In this situa-

tion it may indicate that the nafcillin is injuring the veins. Nafcillin is very irritating to the veins, but when well managed, the patient should not be very uncomfortable during administration.

3. No, it is diluted in the maximum concentration recommended ($1,200 \text{ mg} \div 65 \text{ mL} = 18.5 \text{ mg/mL}$, which is close to the maximum dilution concentration), and the nafcillin is administered over 40 minutes ($65 \text{ mL} + 15 \text{ mL flush} = 80 \text{ mL}$ given at a rate of $125 \text{ mL/hour} = 2 \text{ mL/minute} = 40 \text{ minutes for } 80 \text{ mL}$), a period of time slightly longer than the shortest recommended administration time of 30 minutes.
4. Infuse the nafcillin over a longer period of time (60 minutes), diluted in more fluid. Subtract the 15 mL of fluid needed to flush the medication through the tubing to find out the amount of fluid left for that hour in which to dilute the nafcillin: $125 - 15 = 110 \text{ mL}$ to dilute the 1,200 mg nafcillin. $1,200 \text{ mg} - 110 \text{ mL} = 10.9 \text{ mg nafcillin/mL}$. This concentration is closer to the recommended minimal dilution of 10 mg/mL and should be less irritating to the vein than the previously administered 18.5 mg/mL.
5. Effective management may be indicated by maintenance of one peripheral IV site for 72 hours and the nafcillin not burning upon administration. If the problem continues, dilute the nafcillin in even more fluid, either manipulating the IV rate to end up with the same fluid balance (e.g., giving 150 mL the hour the nafcillin is administered and then 100 mL the next hour) or, if Ari can tolerate the extra fluid, increasing the fluid amount for the hour the nafcillin is administered. Consult with the clinical pharmacist. The length of time over which the nafcillin is administered should not be increased beyond 60 minutes, because this may affect serum drug levels and administration of other medications he is receiving. It may be appropriate to insert a PICC line (peripherally inserted central catheter).

medication, check the site to ascertain that the IV fluid has not infiltrated the tissue. Medications given intravenously enter the vascular system quickly. Anaphylaxis or toxic side effects (e.g., respiratory or cardiac depression) may manifest immediately or after a period of time. Know the medication's potential side effects and adverse reactions, monitor the child for these, and teach the child and family to notify the health professional if these or any other unusual signs or symptoms appear. Check your

institution's policy on which drugs must be administered by a physician and which must be verified for accuracy by another nurse.

Many medications are incompatible with other drugs, diluents, and IV solutions. Check a reference source for compatibilities, flush well between administration of incompatible drugs, or give via different IV access. Do not mix medications or give medications in the same line when administering blood products.

ANSWER: Glucocorticoids are not irritating to the vein, and for that reason they would not need to be diluted or given especially slowly. Jose is big enough and does not have any cardiovascular complications that would create fluid restrictions. IV administration of a medication allows for a rapid increase in serum levels of a medication. A side effect of high-dose glucocorticoid administration is mania and psychosis. For Jose, his parents, and the nurses, administering the medication while preventing dramatic increases in serum level is a concern.

Administering Intramuscular Medication

When using the principles of atraumatic care, administration of medications via the IM route should be rare. Children fear invasive procedures, needles, and shots. Using an IM injection to deliver pain medication in itself causes pain and, frequently, psychological distress in the child. Most drugs, including pain medications and antibiotics, can be given orally or intravenously. The rectal route may be psychologically traumatic but should not be physically painful.

If a medication is ordered IM, advocate for the child. Consider whether the medication can be given via another less traumatic route, such as orally or rectally. If the child has an IV line, can that route be used to administer the drug? If the drug is to be given routinely, it is probably less traumatic to insert an IV line than to give repeated injections. Check with the pharmacist and/or prescriber to change the route of administration. If a medication must be administered IM, use a topical anesthetic (e.g., EMLA, LMX4, vapocoolant) prior to giving the injection.

Prior to administering an IM injection, evaluate the child's size, muscle development, motor capabilities, and diagnosis (see [thePoint](#) for Procedures on Medication Administration: Intramuscular). These factors help determine the most appropriate site for injection (Fig. 9–6). For example, a child must have been walking for at least a year before the dorsogluteal site is used. Even then, the muscle is small, poorly developed, and close to the sciatic nerve, which is relatively large in young children. Therefore, the ventrogluteal or vastus lateralis site is a safer choice in an infant. If multiple injections are necessary, rotate injection sites.

KidKare: ■■■ Tell the child it is all right to make noise or cry out during the injection. His or her job is to try not to move the extremity.

Volume of fluid to be injected and needle size must also be considered when administering IM injections. The maximum volume that the muscle will accommodate depends on muscle size; thus, it varies with age of the child and the site used. Needle gauge and length also vary depending on the muscle mass. Generally, a 25-gauge

needle is used for neonates, a 23-gauge for infants, and 20- to 22-gauge needles for older children.

Complications associated with giving IM injections in children include intra-arterial or IV injection, nerve injury, muscle fibrosis or contracture, and infection at the injection site. If it is necessary to use this route, give meticulous attention to proper technique, and note location to avoid complications. IM injections may also not be deposited in the muscle. A study of obese adults demonstrated that injection at the dorso- and ventrogluteal sites would be deposited in subcutaneous tissue (Zaybak et al., 2007).

Administering Rectal Medication

The rectal route is not the preferred route because of potential emotional trauma to the child and unpredictable absorption in the colon. Absorption can be further affected by the presence of stool in the colon and rectum. However, the rectal route may be the best choice for a child who cannot tolerate oral medication and in whom a parenteral route is not available (see [thePoint](#) for Procedures on Medication Administration: Rectal).

Avoid cutting rectal suppositories if possible. If the suppository must be cut to obtain the ordered dose, then it must be cut lengthwise. Cutting a suppository lengthwise helps absorption at the required rate. The drug may not be dispersed evenly within the suppository.

Position the child in a left lateral position with the right leg flexed or in the knee–chest position to expose the anus and help relax the external sphincter for ease of insertion. Remove the suppository packaging and lubricate the suppository with a water-soluble lubricating jelly. Gently insert the apex of the suppository (pointed end) past the internal anal sphincter to prevent expulsion (Bradshaw & Price, 2006). In an infant or toddler, insert the suppository with the little finger. The index finger can be used for older children.

KidKare: ■■■ Instruct the child to pant like a puppy because this provides distraction and relaxes the anal sphincter.

Hold the child's buttocks together until the child relaxes or loses the urge to push. If the child has a stool within 30 minutes, examine the stool for the presence of the suppository.

Administering Otic Medication

Do not administer otic medication if it is cold. Cold medication may cause discomfort and produce vomiting or vertigo in the child. If kept in the refrigerator, allow the medication to come to room temperature before administration. Warm the solution by gently rotating the bottle in your hands before administration (see [thePoint](#) for Procedures on Medication Administration: Otic).

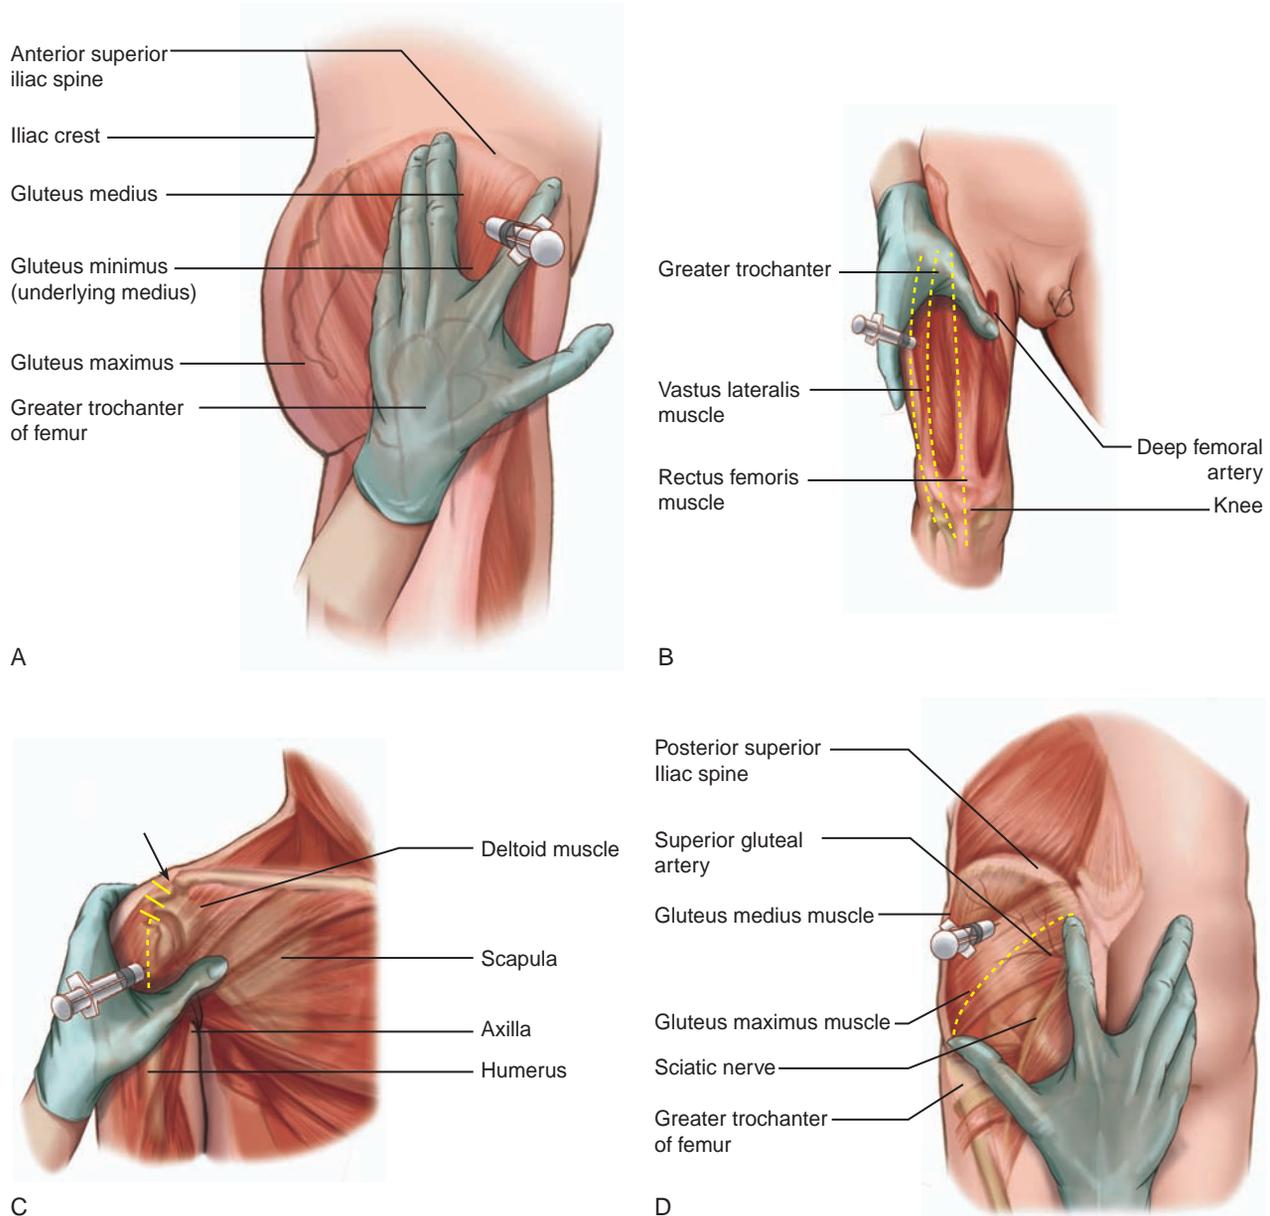

FIGURE 9-6. Intramuscular injection sites in children. (A) Ventrogluteal: Use the hand opposite the side for injection to locate landmarks (e.g., to give in child’s left hip, use your right hand to locate landmarks). Locate by placing your palm on the greater trochanter, index finger on the anterior superior iliac spine, and middle finger on the posterior edge of the iliac spine. Inject into center of V formed by index and middle fingers. (B) Vastus lateralis: Palpate greater trochanter and knee. Divide into thirds; site is in middle third. Draw two imaginary lines from greater trochanter to knee: one mid anteriorly and one mid laterally. Injection site is located between these lines in midlateral anterior thigh. (C) Deltoid: Identify lower edge of acromion process and point on arm in line with axilla. Site is one to three finger breadths (depending on size of child) below acromion process and just above axilla. Inject into middeltoid region. (D) Dorsogluteal: Locate posterior superior iliac spine and the greater trochanter; imagine a line between the two. Inject in the upper outer region above this line into the gluteus medius muscle.

Have the child lie in a supine position with his or her head turned to the appropriate side. Pull the earlobe down and back for children younger than 3 years of age (Fig. 9-7A). For older children, pull the pinna up and back (Fig. 9-7B). Administer the ordered amount of drops into the ear canal, holding the dropper a half inch above the ear canal, being careful not to touch the drop-

per to the ear to prevent contamination of the dropper with microorganisms. Gently massage the tragus (area anterior to the ear canal) unless contraindicated because of pain. Have the child remain in the supine position with the head turned for 2 to 3 minutes. Insert a small cotton ball into the entrance of the ear canal to prevent the medication from leaking out into the external ear.

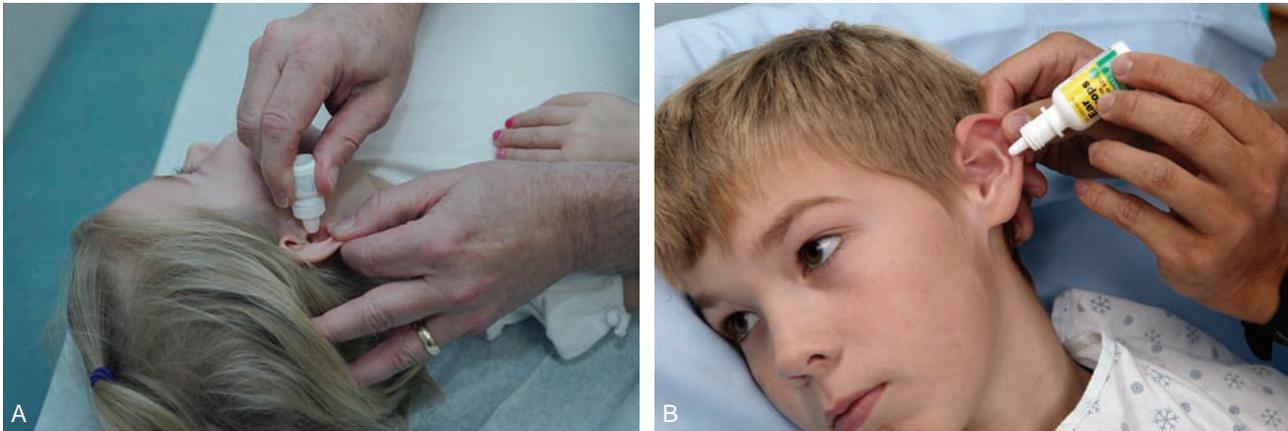

FIGURE 9-7. Positioning for administering ear drops. (A) In the child younger than 3 years of age, the pinna is pulled down and back. (B) In the child older than 3 years of age, the pinna is pulled up and back.

Administering Ophthalmic Medication

Bring medication to room temperature before administration to avoid unnecessary discomfort during administration (see [thePoint](#) for Procedures on Medication Administration: Ophthalmic). If it is not room temperature, warm eyedrops by holding the vial between the hands until warm. Assess the eyes for debris and cleanse them with a cotton ball soaked with normal saline if necessary. Move from the inner canthus of the eyelid to the outer canthus. Use only one sweep of the eye with each cotton ball to prevent contamination.

Position the child supine in bed, or another flat surface, looking up. Restrain the uncooperative child for administration. Rest your dominant hand against the child's forehead. With the other hand, pull down the lower eyelid to expose the conjunctival sac. This positioning prevents poking the child in the eye with the dropper or medication tube and allows for correct placement of the medication.

With the eyedropper, instill the correct amount of drops into the conjunctival sac, being careful not to touch the dropper to the eye to prevent contamination of the dropper or bottle. An alternate method of administration is to have the child close his or her eyes and tip the head backward. Place the medication drops on the inner canthus of the eye and instruct the child to open the eyes.

If administering ointment, place a thin ribbon of ointment along the entire conjunctival sac from the inner canthus to the outer canthus. Twist the ointment tube at the end to dislodge the ointment from the tube. Have the child keep his or her eyes closed for up to 1 minute after administration.

Ophthalmic medication should not be shared. Teach families that each family member must have his or her own medication to prevent cross-contamination.

Administering Topical Medication

Medications are given topically through the skin (transdermally) and are absorbed because of the skin's relatively

rich blood supply (see [thePoint](#) for Procedures on Medication Administration: Topical). Because skin thickness and blood flow to the skin vary with age, the potential for toxic effects of the drug must be considered. Children have a larger BSA and a thinner layer of cutaneous and subcutaneous tissue, so there is an increased risk for systemic absorption and effects through topical application.

Assess the child's skin integrity before administration of topical medication. Observe for cleanliness, and clean off dirt and excess lotions as needed. Do not apply topical medication to skin with open lesions unless ordered.

Cleanse the skin, as ordered or per reference manual recommendations, before application of the medication. Use a basin of warm water and a washcloth only. If an open wound is present, use gauze instead of a washcloth. Dry skin well after washing. Some medications require cleansing all old medication off the skin before applying new medication. Other medications require applying new sterile medication over the old medication without cleansing the area.

Apply topical medication to the site. Use the correct amount as ordered and the administration technique for the type of topical medication (see also Chapter 25).

caREminder

An excessive amount of medication may result in irritation of the skin and adverse systemic effects. Unintentional absorption through mucous membranes can result in systemic toxicity.

Administer gels, ointments, pastes, lotions, and creams using cotton swabs, tongue blades, or gloved hands. Gloves help to reduce transmission of microorganisms and protect the caregiver from absorbing the medication through his or her hands. If a powder is ordered, sprinkle it over the site; ensure that the child's head is turned away so that none is inhaled. If a spray is ordered, check with a reference source or the manufacturer's recommendations;

most sprays must be shaken before administration. Spray over the site and ensure that the child's head is turned away to reduce potential of inhalation. Powders and sprays are easily inhaled, which may cause lung tissue damage or may increase absorption through the respiratory system. Apply a dressing over the site if indicated to prevent the medication from being rubbed off, and to protect clothing and the site. However, occlusive dressings may increase absorption of the medication and should not be used with topical steroids.

Apply transdermal and topical systemic medication patches to a flat area of the skin; they are self-adhesive. Flat areas help the medication remain in contact with the skin, promoting even absorption. Rotate application sites to reduce skin irritation. Do not cut medication patches to fit area or reduce dose, because cutting alters the dose administered. Therefore, the medication may not be distributed evenly on the patch, and one cannot predict the amount of medication left on the patch.

Education About Pharmacologic Agents

Before children are discharged from a healthcare setting, parents and older children should have a basic understanding about all medications that are to be taken at home, including over-the-counter medications. Education should include the information presented in TIP 9-1.

Assess the ability to pay for prescription and over-the-counter medications, if this could be an issue, and provide information about resources available to obtain needed medications. Assess if the child will take the form of medication prescribed (e.g., the child only tolerates liquid medications and the pill form was prescribed). Assess if the family has proper storage for medications (e.g., if receiving drugs that need to be refrigerated, do they have a refrigerator?).

Also assess the ability of a parent to administer a medication, or for the child to self-administer a medication, before discharge from the healthcare setting. Return demonstrations are an important evaluation tool to assess safe administration of medication. Situations that would require return demonstrations include

- Administering oral medications to infants and young children
- Measuring small amounts or exact doses using a syringe. Although consumers were more likely to obtain a correct dose with a syringe over a dosing cup, one third measured inaccurately with a syringe (Sobhani et al., 2007)
- Giving injections or delivering medications through special tubing (e.g., nasogastric, gastrostomy, or jejunostomy tubes)
- Administering ophthalmologic or nasal medications
- Using metered-dose inhalers, spacers, or inhalation equipment
- Teaching parents or patients with limited cognitive abilities or when multiple medications must be administered so that the correct dose and the correct medication are given as directed

Administering Medication in School, Camp, or Childcare Settings

QUESTION: What are some issues that might arise related to administering medications to Jose after he starts kindergarten?

Nurses who administer medications to children in non-medical settings, such as schools, camps, or childcare settings, should have a written protocol that outlines the agency's regulations on administering medications. See Chart 9-2 for key elements that should be addressed in such a protocol.

School districts often allow nonnursing staff to administer medications to children under the training and supervision of a nurse. In such instances, the nurse is responsible for the training of those who will be administering medications and the ongoing supervision of these individuals. Documentation of such training and supervision is important.

A parent or healthcare provider may request that over-the-counter medications be administered to children in nonmedical settings. Once again, the agency should have a protocol in place to handle these requests. Often, statements from both the parent and physician are required. In such instances, each child's over-the-counter medication should be labeled with the child's first and last name as well as the name and phone number of the physician who recommended the medication. Note the current date and date of expiration. Identify instructions regarding dosing and frequency as well as indications for when to notify the parent or physician that the child is not responding as anticipated.

ANSWER: Jose will need to have a copy of his prescription, an inhaler and spacer, and directions on their use at the school for any possible acute asthmatic episodes.

Verbal Orders

All healthcare agencies should have a policy and protocol about nurses taking verbal orders for administration of medication. This should be a practice that is done only in emergency or unusual circumstances. The nurse who takes such orders should listen to what the prescriber says, write the order down, and then read the order back to the prescriber.

Resources for Safe Medication Practices

The Institute for Safe Medication Practices is an excellent resource that provides education about adverse drug events and their prevention. All healthcare providers should be familiar with the national safety goals identified by the Joint Commission that pertain to medication preparation and administration to pediatric patients. A useful

TIP 9 –1 A Teaching Intervention Plan for Medication Management at Home

Nursing Diagnosis and Outcome

Deficient knowledge: correct techniques for medication management

Outcome: Child and family will appropriately store, administer, and monitor for side effects of medications.

Interventions

Teach the child and family the following about medications:

Medication-Specific Issues

- The reason the drug is being given, how much should be taken, and the frequency of administration. Make sure that the parent and older child know the name of the medication.
- Specific instructions about taking an “as-necessary” drug or a drug that is to be taken under specific circumstances (e.g., a drug used for fever control or medications to be taken as part of a rescue plan for a child whose asthma symptoms are worsening). Cover when, how often, and how long to take “as-necessary” drugs.
- Signs and symptoms that indicate that the drug is effective or not effective (e.g., fever subsides or child remains febrile)
- Signs and symptoms of medication adverse reactions, side effects, or toxicities
- Possible drug interactions with other medications or foods
- Storage issues, if applicable (such as the need for refrigeration or to keep at room temperature, avoid direct sunlight)
- Monitoring issues (such as peak flow or blood glucose levels), if applicable
- Pregnancy risk factors of a drug for specific drugs prescribed for female teenagers
- Tips about administering “difficult-to-take” drugs (e.g., offering an ice pop or ice to numb the tongue prior to unpalatable medications)
- Written individualized medication information (essential). If the parent cannot read, provide pictures (e.g., a picture of a medication measuring spoon with the numbers written in and an arrow pointing to the amount to be administered; if the medication is to be taken twice a day a picture of the child sitting up in bed smiling and stretching with the sun up and one of the child lying in bed with eyes closed and the moon in the sky).

Herbs

- Signs and symptoms of herbal adverse reactions, side effects, or toxicities

- Caution about the use of alternate or complementary therapies and the need to discuss these with a healthcare provider before their use, because they may contain dangerous elements such as iodine and heavy metals.

Storage

- Store all medications out of children’s reach, in a locked cupboard, if possible.
- Never remove medication labels.
- When medication is no longer needed, safely dispose of it at your pharmacy, community household hazardous waste center (check if they accept medications), or place unused drugs in sealed bag/container (crush solid drugs, mix with water) with undesirable substance (kitty litter, coffee grounds) and dispose in trash.
- Check all medications once a year and discard all leftover, outdated, or unlabeled medications.
- Follow storage instructions as directed (e.g., refrigerate medication if label indicates; do not freeze).

Administration

- Follow label instructions or administer as indicated by your healthcare practitioner or pharmacist.
- Give most medications on an empty stomach for better absorption; for exceptions (e.g., erythromycin), read and follow label instructions.
- Use oral syringes or medication measuring spoons to measure doses; household teaspoons are not accurate for medication measurement.
- Do not tell a child that medication is “candy.”
- If needed, mix in small amounts of nonessential foods (e.g., applesauce, jelly), not in favorite or staple foods.
- If child immediately vomits the entire dose, readminister recommended dose unless instructed not to do so (e.g., digoxin).
- If child vomits more than 1 hour after a dose was administered, wait and give the next scheduled dose.
- Give the entire course of antibiotics, even if the child’s condition improves, unless otherwise instructed.
- Never give medications prescribed for someone else, even if the illnesses seem similar.

Contact the Healthcare Provider If

- Child vomits more than one dose of the medication
- Symptoms of illness that the medication is to treat do not improve
- Child’s condition appears worse or changes occur, such as a rash or trouble breathing

CHART 9-2 KEY ELEMENTS FOR PROTOCOL ON ADMINISTRATION OF MEDICINES IN A NONMEDICAL SETTING

- The child's first and last names are on the container.
- Medication is prescribed by a licensed health professional; and the name, address, and phone number of the health professional who ordered the medication appear on the container.
- Medication is in the original package or container.
- The date the prescription was filled and the date it expires appear on the container.
- Medication is in a childproof container.
- A statement from the healthcare provider indicates the name of the drug, the diagnosis or reason the medication is needed, and whether any serious reactions might occur, or an alert for the nurse about the possibility of a serious drug reaction.
- A policy about self-administration of medication (e.g., the use of inhalers or an EpiPen) should be identified for children who are capable of self-administration, exhibit responsible behaviors, and are in need of speedy access to their medication.
- Information about security and proper storage of medications should be identified in the agency's protocol.
- Nonmedical agencies generally require a written request from the child's parent or guardian asking them to administer the medication per the healthcare provider's specific instruction.

source of information about complementary and alternative agents is the National Center for Complementary and Alternative Medicines. Pediatric nurses should be familiar with current reference handbooks that focus on pediatric and neonatal patients, and should have them readily available. Many hospitals subscribe to Micromedex, an online program that contains current information about pharmacologic agents.

Pain Management

Case History

The Tran family was introduced in Chapter 1, with Ashley, the older sister; the parents, Loan Pham and Tung Tran; and George, the younger brother. In this case study, George is struggling with metastatic cancer that originated from osteogenic sarcoma in his right leg. George is currently at home. His affected leg was amputated several months ago, he had chemotherapy both before and after the surgery, but the cancer continues to spread. It had metastasized to his lungs prior to diagnosis. He has some respiratory distress with mild exertion and he tires very easily. The healthcare team and his family are managing his pain and their goal is to keep George pain free.

George is taking both a long-acting opioid, MS Contin every 12 hours, morning and evening, and a nonsteroidal anti-inflammatory drug (NSAID), ibuprofen two tablets four times a day, with meals and at bedtime. He also has an order for immediate-release morphine sulfate if the pain breaks through his long-acting and NSAID regimen. This sometimes occurs when he has an active day. George is on adult doses of his pain medication. He weighed more than 50 kg at the time of diagnosis, but weighs less than that at this time.

George demonstrated in the hospital and at home that he is reluctant to admit when he is in pain. He told the nurses that “it made him feel like a baby” to complain about pain, because in Vietnamese culture, pain is considered part of living. His home care nurse came up with the idea of establishing a database in George’s computer for him to enter his pain rating and any descriptions of pain and other

symptoms at regular intervals throughout the day. The database follows the comprehensive pain assessment guidelines of the National Comprehensive Cancer Network Clinical Practice Guidelines. It includes the intensity of the pain, which George evaluates on a 10-point scale. It also includes whether the pain occurs at rest or with activity, the locations of the pain, and the quality of the pain. George and the home health nurse review this database weekly, and then send it to the nurse practitioner who works with George’s oncologist. This system of pain evaluation works well for all those involved. George prefers documenting his symptoms privately on the computer and the healthcare team has richer data from which to develop George’s pharmacologic pain management interventions.

George has also developed a number of strategies to help him cope with pain; most effective for him is distraction. When he had pain before his diagnosis, he found video games distracted him. Video games still are engrossing for George, and the more his life in the video game is at stake, the greater the distraction. When his friends come over and play group combat video games, he can block out his pain and his altered body image. He also enjoys reading and working online coursework offered by the “virtual high school.” His parents continue to be proud of his academic achievements. When he is very tired, he will put on headphones and listen to music favorites. As you read the following objectives, apply them to George Tran and the management of his pain.

CHAPTER OBJECTIVES

1. Explain the physiologic mechanisms that lead to the sensation of pain.
2. Identify factors that may intensify or modulate the pain experience.
3. Discuss the assessment techniques and tools used to evaluate pain in children.
4. Describe pharmacologic interventions used to manage pain in children.
5. Describe biobehavioral nursing interventions to control pain and anxiety in children.
6. Contrast manifestations of chronic pain with acute pain and how management strategies for children in special pain situations may differ.
7. Discuss the role of the nurse on the interdisciplinary pain team.

See [thePoint](#) for a list of Key Terms.

Pain is a warning that alerts us to injury and illness. When a child experiences pain, we are obligated as healthcare providers to intervene and prevent further pain. The bedside nurse can relieve a child's pain or be the final barrier that leaves the child to suffer.

Until fairly recently, the notion that children do not experience pain, or feel it less intensely than adults do, was unfortunately widespread in the medical community. The literature before 1970 is virtually devoid of information about children's pain. Advances in science and consumer demands have encouraged changes in how children's pain is recognized and treated. The explosion of knowledge in this field has expanded our knowledge of the phenomenon of pain, and the implications for assessing and treating children. Application of this knowledge, however, remains deficient in clinical practice, with the result that pain in children continues to be undertreated (AAP, Committee on Fetus and Newborn and Section on Surgery, Canadian Paediatric Society, and Fetus and Newborn Committee, 2006; MacLean, Obispo, & Young, 2007).

Pain has deleterious effects. It must be recognized and treated. A significant number, up to 96%, of children report experiencing pain (van Dijk, McGrath, Pickett, et al. 2006), and neonates are subjected to many painful and stressful procedures, the majority without analgesia (Carrbajal et al., 2008). More than 2.4 million children younger than the age of 15 years were discharged from hospitals in the United States in 2005. Of these, almost all underwent procedures, operationalized as surgeries, invasive procedures, and therapeutic treatments (e.g., injection of chemotherapy) (DeFrances, Cullen, & Kozak, 2007). Pain and discomfort are most frequently mentioned as the worst aspects of hospitalization and the most in need of improvement (Lindeke, Nakai, & Johnson, 2006). An estimated 15% to 20% of children have chronic pain (APS, 2004). To improve the treatment of children's pain, the healthcare team must make a consist-

ent effort to ensure that comfort is a priority for all patients.

Each child's experience of pain depends on existing pathology and individual characteristics such as physiology, developmental level, temperament, coping styles, and previous experiences. Knowledge of pain physiology and of developmentally appropriate assessment and management techniques are necessary for the nurse to care and advocate for this vulnerable population. The pain assessment and management plan must be individualized to optimize each child's pain relief.

NEUROPHYSIOLOGY OF PAIN

Pain is a highly complex, dynamic, and subjective process. Acute pain elicits a reflexive withdrawal, with physiologic, metabolic, and behavioral responses. In contrast, an individual tends to adapt to persistent or chronic pain. Thus, the response to pain may be attenuated, but chronic pain is just as valid and debilitating to the child as acute pain.

Historically, pain impulse transmission was viewed as a predictable response pattern, from one point to another. However, research indicates that the portion of the nervous system that responds to pain is "plastic"—changeable and variable between and within individuals, even to the same stimuli at different times (Fitzgerald & Howard, 2003). Many factors influence how the stimulus is transmitted, what path it takes, how it changes (or is modulated) along the way, and how the person perceives it. The basic mechanisms of pain impulse transmission in children are similar to those in adults.

Nociceptive and Neuropathic Pain

The four levels of **nociception** (the activity produced in the nervous system by noxious, potentially tissue-damaging, stimuli)—transduction, transmission, perception, and modulation—are briefly summarized in Chart 10–1. Numerous reviews offer a more in-depth study of the pathophysiology of pain (Fitzgerald & Howard, 2003; Godfrey, 2005; Renn & Dorsey, 2005; Woolf, 2004).

Neuropathic pain refers to conditions associated with injury or dysfunction of the peripheral, central, or autonomic nervous system, or abnormal processing of sensory input (Berde, Lebel, & Olsson, 2003). Defining clinical characteristics of neuropathic pain are **dysesthesia** (impaired sensitivity to touch, such as paresthesia and cutaneous hypesthesia), **hyperalgesia** (excessive sensation from pain), **allodynia** (nonpainful stimuli, such as light touch, is perceived as painful), motor abnormalities, and autonomic disturbances. Chronic nociceptive pain may also alter the excitability of the peripheral and central nervous systems, resulting in sustained or recurrent pain with neuropathic qualities.

Developmental Patterns

Neuroanatomic and neuroendocrine components of the pain pathway are sufficiently developed in the neonate to

CHART 10–1 LEVELS OF NOCICEPTION

Transduction

Tissue injury from trauma, surgery, or disease releases chemical mediators such as prostaglandins, bradykinin, serotonin, norepinephrine, substance P, and histamine, which cause pain at the periphery and facilitate movement of pain impulses along peripheral nerves. Primary afferent fibers, most commonly A delta and C fibers, when excited by mechanical, thermal, or chemical stimuli, depolarize and transmit information about noxious stimuli from the periphery to the dorsal horn of the spinal cord (Fig. 10–1).

Pain can be controlled at this level of nociception with NSAIDs, local anesthetics, and some anticonvulsants. NSAIDs relieve pain by interfering with the production of prostaglandins. Local anesthetics and some anticonvulsants block sodium channels, thereby preventing conduction of the action potential of primary afferent fibers.

Transmission

All incoming information related to pain crosses the dorsal horn of the spinal cord on its entry into the central nervous system (CNS). Neurotransmitters (adenosine triphosphate, glutamate, substance P) continue the pain impulse from the peripheral nociceptors to the dorsal horn neurons. The signals are transmitted through the CNS to the brain stem, thalamus, and the cerebral cortex.

Exogenous and endogenous opioids block the release of some neurotransmitters, including substance P, by binding to opioid receptors at the spinal level. Chronic pain, such as neuropathic pain, is treated by preventing glutamate and aspartate from binding with N-methyl-D-aspartate (NMDA) receptors at the spinal level. Dextromethorphan, ketamine, and methadone are believed to relieve pain by acting as NMDA antagonists.

Perception

At this level of nociception, the person becomes conscious of the pain. Several central structures are involved in pain perception; no single “pain center” exists. The reticular system is believed to warn the individual to recognize pain and initiate an autonomic response. The somatosensory cortex provides recognition of the location and quality of the pain. The limbic system initiates the emotional and behavioral response to pain. Cognitive and behavioral techniques, such as distraction and guided imagery, modify pain perception by directing the cortical structures to attend to competing information.

Modulation

The CNS rapidly sends descending messages back through the dorsal horn, thus inhibiting the transmission of noxious stimuli. Neurotransmitters such as endorphins, enkephalins, serotonin, norepinephrine, γ -aminobutyric acid, and neurotensin modulate pain. Baclofen and antidepressants (e.g., the tricyclics and some selective serotonin reuptake inhibitors) are used to modulate chronic pain at this level of nociception.

allow the transmission and perception of pain (Simons & Tibboel, 2006) (Developmental Considerations 10–1).

Although infants may not remember painful experiences as distinct, actual events, the functional structures for long-term memory—specifically, the integrity of the limbic system and diencephalons—are well developed in newborns (Ponder, 2002). These early painful experiences may be stored as procedural memory, not accessible to conscious recall. This possibility would explain why the infant who experiences a heel stick withdraws from subsequent swabbing of the heel with an alcohol wipe, seemingly in response to the memory of a previous painful procedure.

Ample evidence indicates that both term and preterm neonates have the capacity to experience and remember pain much like older children and adults do (Fig. 10–1). In fact, one important difference in the nociceptive pathways of newborns *increases* their vulnerability to pain. Mechanisms that inhibit pain impulse transmission, neurotransmitters, and receptors are not mature in the neonate (Fitzgerald & Howard, 2003). Therefore, neonates likely feel even more pain, with the same stimulus, than an older child or adult would experience. Tissue injury in infants has long-term effects, altering response in later life (Schmelzle-Lubiecki et al., 2007).

caREminder

The nervous system of a young child is still developing and malleable. Early pain experiences may permanently alter how the child processes and reacts to future painful stimuli. Limit painful procedures, such as suctioning, needle sticks, and tape removal to those that are absolutely necessary. Ensure that pharmacologic and biobehavioral interventions are consistently used to prevent or optimally reduce the pain of every necessary procedure.

FACTORS THAT INFLUENCE THE PAIN EXPERIENCE

Perception of pain results from the integration of physiologic and psychosocial factors inherent in the pain experience. The multiple factors that influence children’s pain experiences do not operate in isolation. They are listed separately for ease of discussion, but all contribute in varying degrees to the overall pain experience. Considering them when providing care and remembering that children react individually, given their unique characteristics and situation, is important.

Type of Pain Experience

QUESTION: Based on his history, what are George’s experiences with acute and chronic pain?

Children may experience pain acutely, possibly as the result of a therapeutic procedure or brief illness or condition, or chronically.

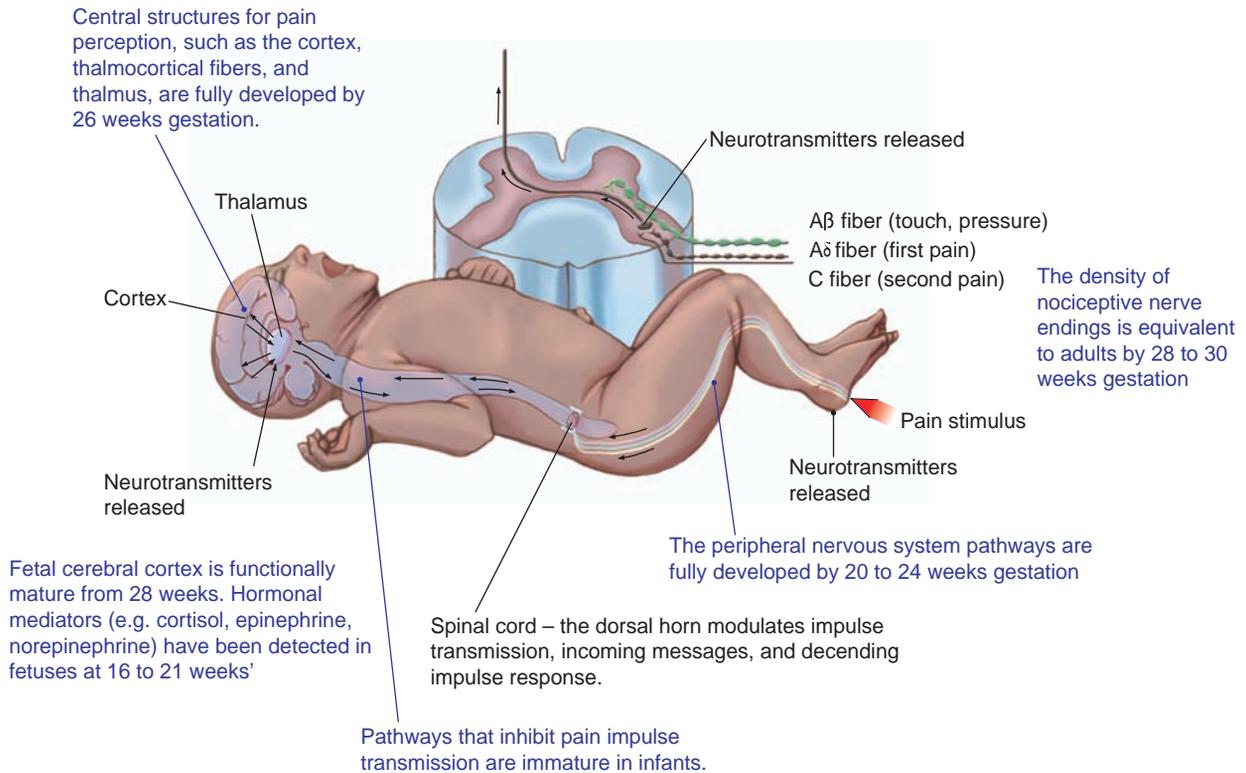

FIGURE 10–1. Transmission of pain impulse in an infant.

Acute Pain

Acute pain is a common adverse stimulus that occurs as the result of injury, surgery, or illness. The severity of the physical damage and physiologic response may play a role

in the child’s overall perception of pain. The acute pain experience generally resolves as the body heals.

Although pain can be beneficial as a warning to avoid further injury, the effects of pain are generally deleterious. Pain, in children of any age, evokes a negative physi-

DEVELOPMENTAL CONSIDERATIONS 10–1

Pain Conduction and Perception in the Young Child

Pain Mechanisms	Young Child
Conduction	Myelination in process: A delta nerves with varying degrees of myelin with possibly slower conduction velocity offset by shorter distances the impulse has to travel; C fibers also conducting impulses Nerves in skin with increased density at birth, increasing sensitivity to stimuli
Perception of pain	Newborns possibly deficient in neurotransmitters that inhibit pain impulse transmission Age dependent; possible inability to verbalize pain in terms that adults understand Possible increased intensity of pain experience as a result of lack of control or unfamiliar situations Limited repertoire of coping methods View of pain as punishment Inability to understand cause and effect (medicine makes pain go away)

ologic, metabolic, and behavioral stress response. Unrelieved acute pain can lead to impaired mobility; anorexia, causing poor nutritional intake; delayed wound healing; anxiety and irritability; somatic symptoms; sleep disturbances; avoidance; developmental regression; and increased parental distress. Untreated pain affects length of convalescence and hospitalization. Pain can have a considerable effect on morbidity and mortality. For example, premature infants undergoing cardiac surgery who received relatively light anesthesia had more postoperative complications and mortality than those given deeper anesthesia (Wong, McIntosh, Menon, et al., 2003).

Procedural pain is a specific type of acute pain related to care. Children's healthcare experiences often involve painful procedures, specifically the pain of needles for shots and blood sampling.

caREminder

Procedures that may seem minor to an adult may be remembered by a child as a terrible experience, which may influence the child's reaction to subsequent procedures and healthcare experiences.

Pain is a major source of iatrogenic stress in prematurely born infants. Stabilizing premature infants and delivering lifesaving care to them frequently subjects them to stressful, invasive, and painful procedures. On average, these fragile newborns endure 14 procedures per day. Fewer than 35% of these neonates received analgesics prior to these procedures, and almost 40% of these infants did not receive any analgesics while in the neonatal intensive care unit (Simons et al., 2003).

Unstable vital signs, particularly blood pressure, as a result of pain may result in additional complications such as intraventricular hemorrhage in the premature infant (Wong et al., 2003). The physiologic effects of pain result in a catabolic state that has the potential to be especially damaging to infants and young children, who have higher metabolic rates and less nutritional reserves than adults. Medical and developmental outcomes can be improved by attending to early signs of stress while delivering care and attempting to minimize stressful episodes (AAP, Committee on Fetus and Newborn and Section on Surgery, Canadian Paediatric Society, and Fetus and Newborn Committee, 2006).

Chronic Pain

Acute pain may develop into chronic pain if the pain experience extends beyond the normal trajectory of healing for the amount of tissue damage sustained. Although neurochemical, neuroanatomic, and neurophysiologic changes accompany some chronic pain syndromes, lack of objective indicators for pain despite subjective or behavioral expressions of pain characterizes chronic pain pathology.

Chronic pain may be persistent, recurrent, or both and can be experienced as fluctuations in pain severity, quality, regularity, and predictability (APS, 2004). Examples of recurrent pain are colic, abdominal pain, growing pains, and headaches. Chronic pain is categorized by the International Association for the Study of Pain (1979) by duration (less than 1 month, 1–6 months, or longer than 6 months). Biologic, psychological, developmental, and sociocultural factors affect the severity of children's chronic pain experiences and any associated functional disabilities.

ANSWER: George experienced severe acute pain, and both mild procedural pain and severe pain for short intervals when he was hospitalized for his right leg amputation. He experienced the usual procedures: intravenous (IV), lab blood draws, and also the amputation surgery. George also experienced chronic pain in a more mild form before the diagnosis of the osteogenic sarcoma and now he experiences the chronic pain of metastatic cancer.

Child Characteristics

Characteristics of the child such as age, cognitive level, previous pain experience, temperament, coping style, gender, and ethnic and cultural background influence the interpretation of and response to acute, chronic, and procedural pain. These characteristics cannot be changed, but their influences must be understood by the nurse to better care for the child experiencing pain.

QUESTION: What are some aspects of George's character, family, and past experiences that influence his response to pain?

Age and Cognitive Level

Age and cognitive ability influence how a child defines and understands pain (Developmental Considerations 10–2). As age and the child's level of cognitive development increases, the child's understanding of pain, coping strategies, and the effect of pain also increases.

Children's ability to communicate their pain and describe the experience reflects their maturity. Children younger than 8 years of age display more behavioral distress than older children when subjected to painful procedures (Dahlquist, Power, Cox, et al. 1994; Humphrey, Boon, van Linden van den Heuvel, et al. 1992). School-aged children and adolescents rank the word *pain* to indicate greater pain intensity than the words *hurt* and *ache*, respectively (LaFleur & Raway, 1999). A child's language of pain also reflects previous pain experiences, ethnic and cultural background, and specifically the words and expressions used by family members and peers.

DEVELOPMENTAL CONSIDERATIONS 10–2

Cognitive Level Effect on the Pain Experience

Remember that developmental gains build on each other and that children often regress when stressed. The behaviors that were achieved most recently are the first lost.

Infancy

Lacks words for pain
Has memory for painful events
Responds to parent's anxiety

Early Childhood

Toddler

Responds differently according to temperament (difficult, easy, and so forth)
Uses words for pain (e.g., owie, boo-boo, hurt)
Is egocentric; needs autonomy, sense of control

Preschooler

Has language to express pain
Mixes fact and fiction; has magical thinking
Lacks cause-and-effect thinking
Has beginning concept of time (medicine will start working when the television show is over)
Fears bodily injury or mutilation
Thinks the more blood there is, the worse the injury must be

Uses delays to put off treatments
Does better if allowed to handle equipment and see how it works
Needs some control over situation

Middle Childhood

Fears body mutilation
Has logical reasoning but needs to relate abstractions to concrete things
Beginning to understand cause and effect
Can delay gratification
Understands time
Relies less on parent and more on self-initiated coping resources

Adolescence

Understands abstractions
Needs to maintain self-esteem, control
Benefits from practice of biobehavioral techniques beforehand to maintain control
Feels invincible so may not adhere to treatment or medication regimens
Thinks that the nurse knows when pain medication is needed, so may not request analgesics

KidKare ■ Find out what words the child uses to describe pain and use these terms during interactions with the child.

Children are believed to judge pain severity and unpleasantness by comparing the pain with previous sensations (McGrath & Hillier, 2003). Younger school-aged children tend to select the extremes of Likert-type pain rating scales, regardless of the number of rating choices (Chambers & Johnston, 2002), whereas reports from adolescents reflect a greater variation. Older children generally develop a wider frame of reference as they encounter more diverse pain experiences. Therefore, a child who has experienced pain before may be better able to describe it than a child who has not.

Research comparing children's expectations of pain with their actual pain experiences indicates that younger children are less accurate than older children in predicting their procedural pain intensity. Also, children who expect more pain tend to report more postopera-

tive pain than others do (Cheng, Foster, & Hester, 2003).

Previous Pain Experience

Past experience with pain also affects pain perception. Infants who have experienced painful procedures display a more intense behavioral response to subsequent procedures (Holsti, Grunau, Oberlander, et al. 2005; Von Baeyer, Marche, Rocha, et al. 2004). Repeated painful events in infants born at or less than 28 weeks gestational age was associated with lower cortisol response to stress and lower facial reactivity to pain (Grunau et al., 2005). Older children who were exposed to painful procedures as neonates demonstrate lower pain thresholds, which suggests that this behavioral response persists (Buskila et al., 2003; Hermann et al., 2006).

In addition to past exposure to pain, the nature of a child's pain experience affects the child's subsequent response. Fear and anxiety may intensify the perception of pain (Kain, Mayes, Caldwell-Andrews, et al. 2006; Kleiber et al., 2007), especially if previous experiences have been

negative (McGrath & Hillier, 2003). Children with a history of negative pain experiences are likely to experience distress during subsequent painful events (Dahlquist et al., 1986; Kleiber, Craft-Rosenberg, & Harper, 2001). It is the quality, not the quantity, of previous procedures that is related to the distress.

caREminder

Optimizing pharmacologic and biobehavioral strategies to prevent pain, anxiety, and distress during the first procedure will help to relieve pain during subsequent pain experiences.

ANSWER: George has had many and varied pain experiences. His most intense pain experiences, both physical and emotional, were during his hospitalization when he lost his leg. He copes well with chronic pain at home, but as is explored in Chapter 13 with regard to palliative care, he becomes very anxious and distressed at the idea of hospitalization.

Temperament and Coping Styles

Temperament has been described as innate personality that predisposes the child to react with a certain behavioral response style (Thomas & Chess, 1977). It is a relatively stable trait and correlates with the child's response to pain. "Difficult" (poorly adaptable) children are more prone to display distress behaviors than "easy" (adaptable to new situations) children (Rocha et al., 2003). More intense children also tended to receive more postoperative pain medications (Helgadóttir & Wilson, 2004). Temperament has not been shown to influence the actual intensity of the pain experience, but it does seem to influence children's expression of pain behaviors.

Anxiety amplifies the pain experience. Many of the cognitive-behavioral techniques for pain reduction (relaxation, deep breathing, distraction, hypnosis) work because they reduce anxiety and fear, and increase the child's sense of control or mastery over the situation (Kuttner & Solomon, 2003). Children who feel a sense of control and are actively involved in their situations respond with more adaptive behaviors. For example, the child who helps remove bandages often tolerates a painful dressing change better than one who is restrained and must endure the procedure passively.

Coping style, the strategies a child uses to cope with stressors, is another individual characteristic influencing pain. Examples of different coping styles are information seeking, approaching, attending to the pain versus avoiding, distracting, or focusing attention away from the painful stimuli (Fig. 10–2). In an experimental pain situation, matching coping style with intervention (e.g., distraction or focusing on the pain in a nondistressing manner) results in better pain outcomes for older children; for younger children, distraction was more effective (Piira, Hayes, Goodenough, et al. 2006). This suggests

FIGURE 10–2. Some children prefer to look away from painful stimuli, such as this child who is having his implanted port accessed.

that children may need different coping strategies based on age and coping style.

ANSWER: George has always been a child with an easy temperament and, despite a rich history of pain experiences, he seldom exhibits pain behaviors. This makes it challenging for his home health nurse and his worried mother to reassure themselves that his pain is well managed. He also has developed several strategies of distraction that are effective for him—particularly active and violent video games.

Gender

Studies have demonstrated that gender may influence a child's response to pain. Boys may be more stoic, underestimate their pain, and report a greater perceived ability to control and reduce pain whereas girls were more likely to exhibit behavioral distress, overestimate, and use more affect laden words to describe their pain experiences (McGrath & Hillier, 2003; Myers et al., 2006; Sallfors, Hallberg, & Fasth, 2003). Perception of pain has been found to decrease for boys from grades 3 to 9, but prevalence of complaints, especially headaches, increases for girls (Sunblad, Saartok, & Engström, 2007). A substantial increase in chronic pain prevalence is observed in girls during early adolescence (Fendrich et al., 2007; Perquin et al., 2000) and females are more likely to report continuing pain (Martin, McGrath, Brown, et al. 2006).

Gender differences in coping strategies have been found, but there was no difference in coping efficacy (Lynch, Kashikar-Zuck, Goldschneider, et al. 2007). Girls used more social support seeking and positive statements than boys, whereas boys used more behavioral distraction techniques (Keogh & Eccleston, 2006; Lynch et al., 2007).

Gender variation may result from societal norms and expectations reinforced much earlier in children's lives. For example, parents of toddlers report that their boys are less sensitive than girls to common bumps, bruises, and pains. Daycare workers are more likely to provide physical comfort to girls hurt on the playground than to

boys. Gender-related differences thus may be influenced by ethnic, cultural, and societal expectations and customs (McGrath & Hillier, 2003). Healthcare providers are not immune to these societal biases of pain expression and must take care that they do not affect treatment.

ANSWER: Contributing to George's reluctance to admit pain is his desire to be seen as an adult and a man.

Ethnicity and Cultural Background

Research in adults indicates that ethnic differences in pain sensitivity and tolerance exist and may contribute to ethnic disparity in the experience and treatment of clinical pain (Green et al., 2003; Im et al., 2007). Biologic, psychological, sociocultural factors, cultural or ethnic background, and social setting all influence pain perception, communication, tolerance, response, coping strategies, treatments, and effectiveness of these treatments. Culture shapes an individual's subjective experience of pain and teaches behavioral responses to pain through modeling, direct explanations, instruction, and observation. Culture acquisition begins in infancy and continues into adulthood. Yet, individuals within an ethnic or cultural group must not be stereotyped as having a particular set of pain beliefs and behaviors. Intracultural variation results from individual experiences, education, and current circumstances.

Few studies have examined cultural effects of children's perceptions and communication about pain. Research regarding validity and reliability of pain scales indicate that behavioral pain scales are less reliable than self-report pain scales for children of different cultural backgrounds. This finding suggests that differences in children's behavior during painful procedures may reflect cultural influences. No differences in the sensation of pain have been reported, but there are differences in pain-related behavior. Hispanic children control their pain-related behavior at a younger age than Anglo children (Beyer and Knott, 1998).

Genetic and cultural factors influence variability in individual response to pain treatments (Lea, 2005). Genetic factors may alter the absorption, distribution, metabolism, excretion, or action of medications.

Worldview: Codeine, for example, is poorly metabolized by up to 10% of white and African American patients (Roden et al., 2006) and 1% of Asians, who lack the enzyme to convert the analgesic to its active form (Burroughs et al., 2002). Diet and herbal remedies can alter drug metabolism, but children and parents may not divulge the use of alternative therapies to relieve pain to a traditional healthcare provider.

Parental Influence

Because children are legal minors, their healthcare rights are assumed by their parents. Parents and legal guardians access and secure treatment for children in pain. Therefore,

the parents' perceptions, expectations, beliefs, and treatment concerns influence children's pain experiences. Explore the parents' cultural beliefs about pain. Supplying information about pain management and discussing parents' concerns may be effective for updating parents' knowledge and ensuring the parental participation necessary to provide optimal pain relief for children (Kain et al., 2007).

The meaning given to a child's pain may be a parental barrier to providing effective pain relief. Parents of children who died of cancer reported that their children died in pain (Jalmsell et al., 2006). Yet, families and children with cancer expected the child would suffer with symptoms, like pain (Ameringer et al., 2006; Woodgate & Degner, 2003). They believed it was necessary for the child to continue to fight these symptoms, because fighting the symptoms was more tangible and less frightening than fighting the cancer.

Results of research into the accuracy and value of parents' assessment of children's pain have been mixed. Parents' predictions of children's pain and distress correlate with children's actual behaviors (Kankkunen, Pietila, & Vehvilainen-Julkunen, 2004) and the child's self-report (Baxt et al., 2004; Zisk, Grey, Medoff-Cooper, et al., 2007). Although some studies indicate better correlation between parent and child pain ratings than between those of healthcare providers and children (Garcia-Munitis et al., 2006), other studies indicate that parents under- or overestimate their child's postsurgical pain (Kankkunen et al., 2004; Voepel-Lewis, Malviya, & Tait, 2005). Pain ratings of child and parent and of child and nurse demonstrate a moderate relationship. Therefore parents' and nurses' ratings of a child's pain should be considered estimates, not self-reports (Zhou, Roberts, & Horgan, 2008).

Parents report that their children experience more pain than they had expected after day surgery. Unsatisfactory discharge information, inability to comply with discharge instructions resulting from fatigue, lack of trust in children's self-reports of pain, and fear of addiction from pain medications were significant barriers to parents' ability to manage their children's pain after surgery (Kankkunen et al., 2004; Kankkunen, Vehvilainen-Julkunen, Pietila, et al., 2003).

Parental satisfaction with children's pain management reflects not the amount of pain children experience after surgery, but whether parents receive enough information and feel that their expectations have been met (Melnik, Small, & Carno, 2004; Polkki et al., 2002). Poor communications between healthcare providers and parents, as well as low expectations for pain relief, continue to be barriers to effective pain management (Kankkunen et al., 2003). Parents are hesitant to voice their concerns about their child's pain, because they do not want to be perceived as difficult or as challenging the nurses' expertise (Simons, Franck, & Roberson, 2001). Therefore, nurses must open the lines of communication and encourage dialogue about children's pain if relief is to be achieved.

ANSWER: George's medications are to be given on a routine basis. George works directly with his home health nurse, and he and his family know when his pills are to

be taken. One important strategy to keep George as pain free as possible is clear communication between the family and the healthcare providers. Having a home health nurse who can speak Vietnamese would help George's mother appreciate a routine pain medication schedule.

Influence of Healthcare Professionals and Systems

QUESTION: How has George's oncologist's decision to use hospice care in the home affected George's pain management?

Assessment and treatment decisions made by the healthcare team affect the adequacy of pain management. Children are often assessed inappropriately and are undermedicated and, consequently, pain management is suboptimal (MacLean et al., 2007). Barriers to effective pain management are numerous and result from complex interactions among patients, their families, healthcare professionals, and healthcare systems.

All healthcare providers, including nurses, contribute to ineffective pain management. Nurses do not consistently assess infants and children with developmentally appropriate, valid, and reliable pain intensity scales (Broome & Huth, 2003). Nurses also believe that children overreport their pain (Vincent, 2005). Patient, family, nurse, and physician communication regarding pain may be incomplete and ineffective (Van Niekerk & Martin, 2003). Physicians tend to order inadequate amounts and occasionally inaccurate doses of pain medications to be given on an as-needed basis (Hamers et al., 1998). Given these as-needed orders, nurses tend to undermedicate by administering dosages less often than prescribed (Vincent & Denyes, 2004). Nurses also tend to choose the lowest opioid dose or administer nonopioid analgesics instead of opioids. These errors may be based on inadequate or inappropriate knowledge, attitudes, and beliefs about pain assessment and pain management for children (Vincent & Denyes). The priority nurses place on pain influences clinical practice and how well patients' pain relief needs are met.

caREminder

Pain management is a major facet of nursing care. Its central role must be recognized as a priority, and adequate time must be allotted to assess and manage pain appropriately.

ANSWER: George is receiving home healthcare through an adult hospice organization that is accustomed to patients in severe and chronic pain, and therefore is less likely to be undermedicated.

ASSESSING PAIN IN CHILDREN

QUESTION: Evaluate George's assessment tool according to the following information. Is it standardized? Is it adequately assessing all aspects of his pain?

Standardizing the pain assessment techniques used within a healthcare organization to include only valid, reliable, and developmentally appropriate tools facilitates efforts to communicate and document pain experiences effectively. Inconsistent techniques make it difficult to assess effectiveness of pain management.

In 1968, Margo McCaffery, a nurse, defined pain as "whatever the experiencing person says it is, existing whenever he says it does (p. 95)." Based on this definition and our understanding of pain, patients' subjective reports are considered the gold standard for pain assessment. Unfortunately, many children are unable to state where they hurt, how much they hurt, or even if they hurt. The infant or child's signs of pain may be misinterpreted for other causes of stress or irritability. Keeping in mind that pain is defined by the International Association for the Study of Pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage" (1979, p. 249), we should be highly suspicious if children report pain, act as though they are in pain, or any reason exists to suspect that a child has tissue damage.

An initial pain assessment should determine pain location, onset, duration, pattern, quality, intensity, and aggravating and alleviating factors (Nursing Interventions 10–1). See also [thePoint](#) for Procedures. Children as young as 2 years of age can indicate where they hurt, although their verbal descriptors may be nonspecific. For example, if the child has a limited vocabulary, "My tummy hurts" may actually indicate chest pain. The onset of pain provides key information to determine its potential cause. The quality of pain helps distinguish nociceptive, somatic, and visceral pain from neuropathic pain. This distinction is important for developing an effective pain management plan. Information about aggravating and alleviating factors helps to define the functional limitations of the child's pain. Alleviating factors that have been successful in the past should be included in the child's individualized treatment plan.

Valid, reliable, and clinically sensitive pain assessment tools are available to estimate the intensity of pain for children, from birth through adolescence. Pain assessment techniques can be classified as subjective reports, behavioral observations, or physiologic monitoring. Assessments that use a combination of methods may provide the most accurate appraisal of the child's pain-related distress. Composite pain measures use more than one parameter to assess the pain experience (Table 10–1). Typically, behavioral and physiologic indicators are used to assess pain in infants. For older children, self-report and behavioral or physiologic indicators are used.

A proposed hierarchy of assessment techniques can guide nurses in determining the presence and intensity of

NURSING INTERVENTIONS 10–1

Pain History Questions for Verbal Children and Parents*

1. What words do you use for pain? (Use these terms when conducting the interview.)
 2. When did the pain start? (*onset*) Have you felt this pain before? If so, when, and what do you think caused it?
 3. How long have you been feeling this pain? (*duration*)
 4. How often does the pain occur? (*frequency*) Is it all the time (*continuous pattern*) or just happens now and then (*intermittent*)? Is there a certain time of day it occurs?
 5. Where is the pain? (*location*) Does it go to (*radiate to*) other places? Point to the areas with one finger or use body outline tools to identify the site. Do you hurt anywhere else?
 6. How severe is the pain? (*intensity*) Use this tool (e.g., 0- to 10-point rating scale, visual analog scale, poker chip tool, face scale) to quantify intensity.
 7. What does the pain feel like? (*quality*) Describe it—for instance, pinching, burning, stabbing, dull, aching, sharp, throbbing. “Like an elephant stomped on it.” (Be careful not to lead the child to provide a quality indicator that is inconsistent with their actual pain experience. Instead, encourage children to use their imagination to help you understand how the pain feels.)
 8. Does anything make the pain worse? Better? What pain relief methods have you tried? What works best? What would you do/not do again (medications and nonpharmacologic or behavioral interventions)?
 9. How does the pain affect you? Can you put the pain out of your mind and carry on normal activities of daily living? Or does the pain keep you from doing things you want to do?
- *Encourage parents to supplement the child’s self-report with their observations or provide key information to define these factors for infants and younger children.

TABLE 10 – 1

Multidimensional Tools for Pain Assessment

Tool	Parameters	Comments
Premature Infant Pain Profile (PIPP) (Stevens et al., 1996) Age: preterm and full-term neonates	Gestational age, behavioral state, heart rate, oxygen saturation, brow bulge, eye squeeze, nasolabial furrow	Assessment of procedural and postoperative pain and determination of the efficacy of nonpharmacologic interventions
CRIBS (Krechel & Bildner, 1995) Age: term newborns	C, Crying; R, Requires oxygen administration; I, Increased heart rate and blood pressure; E, Expression; S, Sleeplessness	Valid and reliable assessment of postoperative pain, easy to use
Neonatal Infant Pain Scale (Lawrence et al., 1993). Age: preterm to 6 weeks	Six behaviors: facial expression, cry, breathing patterns, arms, legs, state of arousal	Easy to use clinically for acute pain, needs further testing for more ongoing pain (e.g., postoperative)
Children’s Hospital of Eastern Ontario Pain Scale (CHEOPS) (McGrath et al., 1985) Age: 1 to 7 years	Six categories: crying, facial expression, verbalizations, torso activity, if/how child touches wound, leg position	Tested in acute postoperative pain, insensitive to pain of longer duration; easy to learn; time considerations in that many behaviors are evaluated across the six categories
COMFORT Scale (Ambuel et al., 1992; van Dijk et al., 2001). Age: 0 to 3 years	Eight dimensions: alertness, calmness, respiratory response or crying, movement, mean arterial pressure, heart rate, muscle tone, facial expression	Valid and reliable as a measure of distress (Ambuel et al., 1992; Wielenga et al., 2004) and pain (Bear & Ward-Smith, 2006; Caljouw et al., 2007; van Dijk et al., 2000); scale may be valid without the physiologic indicators (Carnevale & Razack, 2002; van Dijk, et al., 2005)

patients' pain (Manworren, Paulos, & Pop, 2004). Ranked in order by their importance and reliability for assessing pain are self-report, presence of pathology or a condition associated with pain, behavior, proxy ratings, and, last, physiologic indicators of pain. Also consider events that influence the pain experience, obtain a pain history, and discuss expectations for pain relief with both the child and parents.

After the initial assessment, reassessment of pain should include at least location of pain and pain intensity. Conduct reassessments at routine intervals and at appropriate intervals after interventions are implemented (e.g., 15 minutes after IV administration of medications, 60 minutes after oral medications are given, 30 minutes after changing position).

Ideally, when a child has surgery, the child and family should be told before the procedure how pain will be assessed. This practice provides an opportunity to introduce and practice assessment under less stressful conditions. It also provides information regarding the child's baseline pain level. If the child is unable to accurately demonstrate the assessment method, another standard pain assessment tool may be introduced. Once an acceptable method is chosen, use this one consistently.

ANSWER: George's nurse is using a standardized comprehensive tool that measures intensity by self-report, location and quality of the pain, and whether the pain occurred at rest or with activity. Yes, it meets the recommended criteria. For more information, see the National Comprehensive Cancer Network website (www.nccn.org/professionals).

Self-Report Strategies

Pain is a subjective experience. Thus, self-report of pain is a critical component of a thorough pain assessment. Children as young as 18 months of age may indicate "ow," "ouch," and "hurt" (Stanford, Chambers, & Craig, 2005). Subjective reports of pain intensity may be solicited through the use of verbalizations or other nonverbal self-report tools (Table 10-2 and Figs. 10-3 to 10-7).

Use of the same self-report tool improves communication. The child, family, and healthcare team will be confused if, for example, at different times a 6-point scale (0 being no pain, 5 the most pain you could have) is used and at other times an 11-point scale (0 being no pain, and 10 the most pain) or other method of pain assessment is used. In this example, a pain intensity rating of 5 points could indicate either moderate or severe pain, depending on the tool used.

Developmentally appropriate pain intensity scales can be used to obtain a self-report from children as young as 3 years of age (Zempsky & Schechter, 2003). Although even younger children may be able to indicate that they are in pain and say where it hurts, pain intensity rating requires the child to understand certain abstract concepts.

Communicating children's self-report of pain requires assessment tools that are appropriate for ethnicity as well as age (Tradition or Science 10-1). Avoid stereotyping, but be aware that cultural factors influence a child's behavioral response to pain.

Worldview: Chinese characters are read vertically downward and from right to left. Thus, horizontally oriented scales are probably less appropriate for this population. Vertically oriented visual analogue scales (VASs) give more reliable results (Aun, Lam, and Collett, 1986).

Behavioral Observations

In the absence of self-report of pain, behavioral observations may be used. Cry patterns, facial expressions, and body movements have been investigated as behavioral measures of infant pain (Developmental Considerations 10-3). Published pain assessment tools that have demonstrated acceptable reliability and validity include observation of multiple behaviors to assess pain (Table 10-3). Behavioral signs of pain are more consistent for short, sharp, procedural pain than for longer lasting pain, such as postoperative pain (Gaffney, McGrath, & Dick, 2003).

Crying is one of the most widely accepted indicators of pain in infants. Accordingly, cry is often included as one dimension of valid and reliable behavioral pain scales. Amount or duration of crying has been used as an indicator of pain intensity. The cry of an infant generally evokes a response from the care provider. A pain cry is high pitched, tense, and irregular (Beacham, 2004). Cry characteristics differentiate cries of pain from cries indicating hunger, frustration, or fright. Unfortunately, clinicians interpret these cry characteristics inconsistently. Therefore, nurses must also use contextual cues to determine the stimulus that elicits an infant's cry.

Facial expressions indicate response to painful stimuli. A fairly consistent facial response to pain in infants includes several specific facial muscle actions. The overall expression is a frown or grimace, with eyes squeezed tightly shut, brows lowered together and bulging, nasolabial furrow, open square mouth with tight mouth stretch, taut cupped tongue, and chin quiver (Grunau & Craig, 1987) (see Fig. 10-8). These characteristics are less pronounced and are therefore difficult to see in premature infants, because their facial musculature is poorly developed, and in ventilated infants who have tubes and tape obstructing part of their face. In these situations, the three facial actions—brow bulge, tightly closed eyes, and nasolabial furrow—are sufficient to identify pain.

By 4 years of age, children have learned to control their facial expressions and may mask facial indications of pain (Gaffney et al., 2003). Closed eyes (95%), frown (78%), and clenched jaw (41%) were facial indications of pain exhibited by children 8 to 17 years of age at least once during a 3-day postoperative pain study (Tesler, Holzemer, & Savedra, 1998). These facial expressions did not correlate with children's self-report of pain. Yet facial expressions are often included as one dimension of

TABLE 10-2

Self-Report Methods for Pain Assessment

Method	Description	Comments
Direct questioning: measures pain location, intensity, quality Age: children as young as 2 to 3 years	Ask the child, using his or her word for pain, if he or she has pain, how the pain feels, where it is, when it occurs, and what helps relieve it.	Verbalizations by the child are the best marker of the subjective experience of pain; in nonverbal children, parents should be questioned.
Finger Span Scale (Merkel, 2002): measures pain intensity Age: children as young as 2 to 3 years	Ask the child how much he or she hurts. The thumb and index finger are close together, almost touching, for a small amount of pain, but are spread wide to indicate a lot of pain.	This method is difficult to document, but is a reliable method of communicating pain intensity.
Numeric Rating Scale: measures pain intensity Age: most children older than 7 years	Ask the child to rate pain on a 0- to 5-point or 0- to 10-point scale (0 being no pain, 10 being the worst pain you could have).	The child must understand numeric value, seriation, and greater than and less than. Define each number to ensure that the child's understanding is consistent with yours. Advantages to using a numeric rating scale are that it requires no equipment and is quick to administer.
Visual Analogue Scale (VAS) (see Fig. 10-3): measures pain intensity Age: most children older than 7 years	A single horizontal or vertical line, typically 10 cm long, is anchored by descriptors of pain at each end, such as "absent" to "severe." The child marks the line at any point on the continuum to indicate pain intensity.	Sometimes this scale is constructed with marks at equal intervals (a true VAS contains no markings between the anchors), which adds a numeric dimension to the tool. It can be a vertical or horizontal scale. See Shields et al. (2003) for predictors of a child's ability to use a VAS.
Faces (see Fig. 10-4) (Bieri et al., 1990; Bosenberg et al., 2003; Hicks et al., 2001; Hunter et al., 2000; Wong & Baker, 1988): measures pain intensity Age: children as young as 3 years	This scale consists of cartoon drawings or pictures ranging from no pain to the worst possible pain. The child chooses the picture that is most like how he or she is feeling at that time.	This scale is quick to administer and does not require verbal responses. Several different valid and reliable versions exist. Scales with smiling "no pain" face at the beginning produce significantly higher ratings than scales with neutral "no pain" faces (Chambers et al., 2005).
Oucher (see Fig. 10-5) (original white version developed by Beyer, Denyes, & Villarruel [1992]; and Yeh [2005]): measures pain intensity Age: photographs as young as 3 years, generally school-aged and older children can use the numeric scale	Six photographs depict a young child's facial expression, from no hurt to the biggest hurt you could ever have. Children point to the picture that most closely approximates their own level of discomfort. This method also uses a numeric 0- to 100-point scale.	Four versions have been developed to accommodate cultural bias: white, African American, Hispanic, and Asian. To use the numeric scale, the child must be able to understand sequencing and numeric value (i.e., be able to count to 100 by ones).
Poker chip tool (see Fig. 10-6) (Hester, 1979): measures pain intensity Age: 4½ to 13 years	Four red poker chips represent "pieces of hurt." The child chooses chips from 0 (no hurt) up to 4 chips (most hurt you could have).	This tool is good for preschool children. It is concrete, simple to use, and resembles a toy, so it is nonthreatening. It is easy to carry and disinfect, and it provides a nonverbal response (useful for intubated patients or when language barrier exists).
Body outline tool (see Fig. 10-7) (Eland & Anderson, 1977; Savedra et al., 1989; Van Cleve & Savedra, 1993): shows location of pain and measures intensity (if colors are ranked) Age: ≥4 years	This is a line drawing of a child's body, unclothed, nongender specific, front and back. The child marks an X or colors the painful area. Colors can be ranked in order of increasing pain intensity before coloring.	Young children may reverse right and left sides, and front and back of body. Validate responses and color choices with the child.

(Continued)

TABLE 10-2

Self-Report Methods for Pain Assessment (Continued)

Method	Description	Comments
Adolescent Pediatric Pain Tool (APPT) (Savendra et al., 1993): shows location of pain and measures intensity and quality Age: 8 to 17 years	This tool consists of a front and back body outline, a 100-mm word-graphic rating scale, and a pain descriptor list.	This tool evaluates three components of pain, so the child should be able to provide a more precise description than a method that evaluates only one component.
Pain diary: evaluates various aspects of the pain experience; used to assess chronic and recurrent pain Age: children who can write and record events	The child records events preceding pain onset, precipitating factors, severity, activity level, and events out of the ordinary that occurred. The child may also record medications or psychological techniques used.	This tool is inexpensive to use. Information is recorded shortly after it happens, so it should not be subject to recollection distortion. The child is actively involved in managing pain, which contributes to a sense of control. Information obtained is not as structured as in other methods, so you may obtain superfluous data. This tool is subject to the child's biases.
Varni-Thompson Pediatric Pain Questionnaire (Varni et al., 1987): measures pain intensity, quality; identifies location, sensory, affective, and evaluative aspects of pain perception; used to assess chronic and recurrent pain Age: ≥8 years	This tool has forms for the child, adolescent, and parent that use a combination of (1) VAS, (2) color-coded scale and body outline, (3) pain descriptors to circle, and (4) questions about family history and socioenvironmental influences.	This tool provides a detailed history of pain.

All responses require careful validation with the child.
Recommended ages are for cognitive age of the individual (developmentally delayed, mentally retarded).

valid and reliable behavioral pain scales for older children as well as infants.

Gross body movements observed in children with pain include those consistent with fighting off the pain, such as kicking, squirming, arching, or behaviors consistent with protecting or limiting further pain, such as withdrawal from painful stimuli, guarding, or limiting movement.

Individual behavioral responses to pain are complex and unique to the individual child and painful stimulus. For example, young children may use physical activity or sleep as a coping strategy to avoid or manage pain. Sleep may indicate pain, comfort, or exhaustion. The child may

have been experiencing pain, obtained relief, and is finally able to sleep; alternately, sleep may be interrupted by pain. Children may also sleep because of exhaustion, despite continued pain.

caREminder

Do not assume that a sleeping child has obtained adequate pain relief.

Emotions such as anxiety may manifest as distress. Tools that assess distress may not evaluate behaviors that are pain specific, but distress can intensify the pain experience and should be addressed. Often, psychological interventions (e.g., preparation, distraction, imagery) are effective in reducing distress.

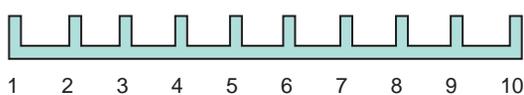

FIGURE 10-3. Visual analogue scale (VAS). It is only a true VAS if it has a 10-cm line (top) and a numeric pain scale (bottom).

Physiologic Parameters

Several physiologic parameters have been investigated as pain indices. They include heart rate, blood pressure, transcutaneous oxygen levels, palmar sweating, and hormone levels. Most are thought to reflect a global response to stress; they give an indication of physiologic status but are not necessarily specific to pain. Changes in

TRADITION OR SCIENCE 10–1

Does children's culture influence pain expression?

EVIDENCE-BASED PRACTICE

Children's cultural background may affect pain expression, but the same assessment tools are used in all populations. Initial studies of the reliability and validity of these tools included primarily white children. Although translations of assessment tools are available, few tools have been validated for cultural fitness (Van Cleve, Munoz, Bossert, & Savedra, 2001). Some diversity is emerging. African American, Hispanic, and Asian versions of the Oucher pain intensity scale have been developed, and their reliability and validity demonstrated (Beyer, Denyes, & Villarruel, 1992; Beyer & Knott, 1998; Yeh, 2005). Luffy and Grove (2003) found that the FACES and African American Oucher scales are valid and reliable tools for measuring pain in African-American children, and that the FACES scale was the most preferred. Gharaibeh and Abu-Saad (2002) found the Poker Chip, the Faces, and the Word Description scales to be valid and reliable for pain assessment with Jordanian children, but females preferred using the Poker Chip tool and males preferred the Faces scale. A translated version of the Adolescent Pediatric Pain Tool has been tested in Spanish speaking children of at least two different sociocultural backgrounds and has demonstrated initial validity and reliability (Van Cleve et al., 2001). More studies of pain assessment tools are needed to document preferences and the reliability and validity of tests in children of various ethnicities.

physiologic parameters may reflect anxiety, fear, or anger. Therefore, these indices may be more valid pain indicators in young infants (whose pain may not be influenced by fear, anger, or anxiety).

Autonomic Arousal

Pain is a stressor that activates the compensatory mechanisms of the autonomic nervous system (ANS). The ANS has two branches: the sympathetic nervous system (SNS) and the parasympathetic nervous system (PNS). SNS stimulation produces the "fight or flight" response, which results in tachycardia, peripheral vasoconstriction, diaphoresis, pupil dilation, and increased secretion of catecholamines as well as adrenocortical, thyroid, and pancreatic hormones.

Painful stimuli produce other signs of autonomic arousal. Research yields conflicting results, however, possibly because of differences in measurement, populations, and pain situations. Respiratory rate, systolic blood pressure, transcutaneous oxygen (TcPO₂) level, heart rate, and intracranial pressure have been found to increase with painful stimuli (Johnston, Stevens, Boyer, & Porter, 2003). Conversely, decreased heart rate, respiratory rate, oxygen saturation, and TcPO₂ levels have also been noted in response to pain (Foster, Yucha, Zuk,

et al., 2003; Logan et al., 2002). These variations underscore the possibility that vital sign changes may merely reflect physiologic stress. Therefore, when assessing vital signs, consider how they are related and how other factors, such as the child's situation, body position, fear and anxiety, behavior, and any medications given, may affect the parameters being evaluated.

Dilated pupils, another sign of autonomic arousal, may also be found in response to pain. Pupil size can be used as a component of pain assessment and to determine adequacy of treatment (e.g., small or decreased pupil size may indicate that the interventions were effective, and dilated pupils may signal untreated pain).

Hormonal and Metabolic Responses

Neuroendocrine hormone response is closely correlated with immune system response. Psychological and physical stress depresses immune responsiveness, an effect associated with an increased incidence of infections. Secretion of catecholamines, growth hormones, beta-endorphins, glucagon, cortisol, and other corticosteroids has been shown to increase in infants during minor procedures such as endotracheal suctioning and routine nursing care, and in those given inadequate anesthesia during surgery. These infants experienced significantly more postoperative mortality and morbidity than infants given appropriate pain management. Hormonal and metabolic responses are quite variable, however, and none has been shown to be a definitive measure of pain (Johnston et al., 2003a). In the current state of technological development, measuring hormonal response is invasive and expensive, and results are not immediately available, so assessment of this is not appropriate for clinical decisions regarding pain management.

Developmental Factors in Pain Assessment

Children manifest pain differently depending on their developmental stage. Nurses must know how to assess pain appropriately in children of all chronologic and developmental ages.

Solicit parental input to increase accuracy of the assessment. The parent knows the child's normal behaviors and can be invaluable in detecting and interpreting changes that may indicate pain. These assessments are susceptible to the parent's interpretations and biases, so a degree of subjectivity is inevitable. Parental appraisal of the child's pain may be influenced by the parent's own anxiety. Therefore, use parental judgment as an adjunct to, not instead of, the children's self-reports (Manworren et al., 2004; Zisk et al., 2007). The parent is also a good resource when assessing the child's usual coping style, which later affects decisions about interventions. Teaching parents about the cues children use to signal pain and the strategies they use to manage it can further add to the precision of the assessment process.

Preterm Infants

Nurses' judgment of pain in newborns is influenced by the vigor of the baby's response. Because the preterm infant

DEVELOPMENTAL CONSIDERATIONS 10–3

Pain Indicators in Preverbal Children*

Verbalizations

Preterm infant: Cry: less frequently heard in response to painful stimuli than in term infant; has more characteristics that arouse listener; higher pitched, often of shorter duration

Term infant: Cry: high pitched, tense, irregular, arouses the listener

Early childhood: Cry, pet terms for pain (e.g., “owie,” “boo-boo”)

Facial Expression

Preterm infant: Weaker grimace than in term infant

Term infant: Pain grimace (eyes tightly closed, brows lowered and drawn together, deepened furrow between nose and outer corner of lip [Fig. 10–8])

Early childhood: Grimace, clenched teeth, tightly shut lips or biting lips, wide open eyes, wrinkled forehead

Body Movement

Preterm infant: Less vigorous movements than term infant; often limp, flaccid, or listless

Term infant: Withdrawal of limb, rigid, guarded, flaccid

Early childhood: Self-limited movement, flexed or rigid extremities, guarding of painful area, restless (flailing, kicking, rolling head side to side, frequent position changes), touching or pointing to painful

area, aggressive actions (biting, hitting, pushing caregiver)

Physiologic Changes

In an unstable child, you may just see greater instability:

- Variability in heart rate, respiratory rate, shallow respirations
- Increased intracranial pressure
- Decreased oxygen saturation
- Increased or decreased blood pressure
- Dilated pupils
- Diaphoresis

Behavior

Infants: Change in sleep patterns, may sleep more or less than usual; irritable, cannot be comforted; avoids eye contact

Early childhood: Same behaviors as in infants, plus changes in activity level, anger, self-consolation (e.g., “rub my tummy,” rubbing own tummy)

Parental Input

How do the parents perceive their child’s level of comfort? Is this typical behavior? What are the changes? Does anything help alleviate the pain?

*The context in which the painful event is experienced affects the response. For example, an infant in a deep sleep often responds less vigorously to stimuli; severely ill children often move less vigorously and vary more (greater changes, wider ranges) in physiologic parameters.

and the extremely ill child’s response to pain is less robust than that of a term infant or healthier child, the healthcare team must recognize subtle pain cues (Fig. 10–9). Preterm infants often become limp, flaccid, or listless. Healthcare providers should take preventive measures to help support the infant during painful and stressful procedures (Fig. 10–10). The cry of a premature or medically compromised infant is higher pitched than that of a healthy term infant and has more characteristics that arouse a caregiver. This finding may be related to the inability of preterm infants to demonstrate the strong grimace and vigorous body movements that term infants display.

Distinguishing between agitation and pain is difficult, particularly in preterm infants, who may show more physiologic instability in response to these stressors (Ramelet, 1999). Behaviors of agitation and pain are

related and may resemble each other, but interventions are different, although some overlap. To distinguish between pain and agitation, assess the infant in terms of the nature of the painful stimuli, the environment, and behaviors (Table 10–4).

caREminder

The nurse is in a key position to assess for cues that indicate stress (e.g., gaze aversion, hiccups, yawning, flaccid posture) and physiologic instability (vital sign changes) resulting from pain. Implement interventions as appropriate for the situation—for example, allowing rest periods for the infant to regroup or stopping the procedure, giving pain medication, and providing physical boundaries and support.

FIGURE 10–8. Facial expression of pain in an infant, with forcefully closed eyes, lowered brows, deepened furrow between nose and outer corner of lip, and square mouth with cupped tongue.

Infancy

Crying is one way that an infant communicates to others. Although crying is a subjective measure, it is a valid

method of assessing an infant's distress and must be recognized and responded to. When assessing the infant's behavior, consider environmental factors (see Table 10–4) and determine how long the infant has been crying to arrive at appropriate interpretations and actions. Rely on behavioral observations and physiologic monitoring and maintain a high index of suspicion that pain is present.

Infant state influences the behavioral response to pain. Infants in deep sleep states are less likely to demonstrate as robust a response to pain as active, awake infants. Consider this difference when assessing infants for pain.

caREminder

If an infant is not responding vigorously, do not assume that the infant is not in pain. The infant may be in a sound sleep state or too weak to respond.

Early Childhood

Young children may not understand the word pain but can report “hurt,” “owie,” or “boo-boo.” Even older children and adolescents may use different words for pain that reflect different intensities; these words therefore may have to be further defined by the child in pain. The young child may be able to indicate where their pain is, but not be able to describe its intensity. If a child is having difficulty localizing the pain, it may be helpful to tell them to point to their pain (using the child's term for it)

TABLE 10–3

Behavioral Tools for Pain Assessment

Tool	Behaviors	Comments
FLACC (Malviya et al., 2006; Merkel et al., 1997; Voepel-Lewis et al., 2002; Willis et al., 2003) Age: 0 to 19 years	Five categories: face, legs, activity, cry, and consolability	Developed for use postanesthesia, but ease of use led to validity testing across all clinical acute care settings
Gauvain-Piquard Rating Scale (Gauvain-Piquard et al., 1987, 1991) Age: 2 to 6 years	15 behaviors in three categories: pain items, psychomotor atonia, anxiety items	Evaluates cancer pain intensity of longer duration, thus rates behaviors at times other than during procedures; depression closely associated with pain; variability in scores suggests scale discriminates between pain levels
Behavioural Observational Pain Scale (BOPS) (Hesselgard et al., 2007) Age: 1 to 7 years	Three indicators: facial expression, verbalization, and body position	Simpler to use than CHEOPS; validated in postoperative children
Parents' Postoperative Pain Measure (Chambers, Finley, McGrath, et al., 2003; Finley, Chambers, McGrath, et al., 2003) Age: 2 to 12 years	15-item behavioral checklist including items such as complain, cry, play, not do things normally does, act more worried, act more quiet, less energy, less eating	Reliable and valid; designed specifically for parents to use at home postoperatively

This is not an all-inclusive listing. Responses should be evaluated in a situational context (stimuli, pain event) and validated with self-report or physiologic parameters as appropriate.

FIGURE 10–9. Lack of physical boundaries adds to the disorganization (inability to stay in control and filter out extraneous stimuli) of this baby showing stress cues of crying, finger extension and splaying, and some leg extension.

with just one finger or have them show you where they would need a bandage placed.

Middle Childhood

School-aged children begin to communicate pain in terms that adults use. They are able to communicate effectively and generate excellent descriptors of pain such as squeezing, stabbing, and burning. Most can list things that aggravate and help alleviate their pain.

Self-report is considered the most reliable gauge of pain, so asking the child about the pain experience should provide the most accurate method of assessment. This approach avoids the problem that arises when the amount

FIGURE 10–10. Appropriate management of a baby undergoing a painful procedure includes pharmacologic interventions, physical support, and containment.

of pain the patient reports does not match the overt behavioral demonstration (Clinical Judgment 10–1). Recognize the potential for the child to regress with illness, pain, and hospitalization, and consider when selecting assessment methods. If the child is functioning at a less sophisticated developmental level, choose assessment methods that are appropriate for this lower level.

School-aged children and adolescents may show fewer overt behaviors in response to pain than younger children (Gaffney et al., 2003). School-aged children and adolescents may try to rest quietly when in pain. Observed body movements might be lying still, rigid, or curled in a fetal position; guarding or touching the painful area; and clenching fists. Children in these age groups may also be irritable, angry, sad, depressed, restless, withdrawn, and aggressive; sleep patterns may change.

Depending on individual coping style, school-aged children and adolescents may want to look at what is causing the pain (attend to the pain) or may look away and try to distract themselves from it.

Adolescence

QUESTION: Does George’s pain management plan acknowledge his desire to be in control?

The expanding cognitive abilities of adolescents should enable them to understand abstractions and describe pain in adult terms. Adolescents may not state that they are experiencing pain, however, because they think the nurse knows that they are in pain and will do something (e.g., giving medications) if and when it can be done. Adolescents may also be afraid to say they are in pain because their peers or parents will consider them to be “babies.” Remaining in control is particularly important to adolescents, and they may reflect this need by suppressing overt behaviors that indicate pain. This behavior does not mean that they are not experiencing pain. Fear of addiction is another factor that may prevent children, adolescents, and parents from expressing pain or accepting medications.

ANSWER: Yes, allowing George to privately document his pain experience, to take his medications at regular intervals, and select his NSAID give him control over his situation.

KidKare ■ Explain that opioid use for moderate to severe pain will not lead to addiction, which is actually a psychological craving for a drug. Physical dependence can be managed by tapering the dosage. Discuss the difference between “good drugs” and “bad drugs”; emphasize that “say no to drugs” does not apply to analgesics given for pain and monitored by the healthcare team.

TABLE 10-4

Is It Pain or Agitation?

Environmental Factors		
<i>May exacerbate perceived pain intensity or precipitate agitation</i>		
<ul style="list-style-type: none"> • <i>Recent occurrence or presence of any stimulus presumed to be painful:</i> Overt and covert, such as incision pain, fracture, otitis media, postextubation edema • <i>Routine care</i> is a stressor for sick and compromised infants, who have a greater degree of autonomic instability; plan care to allow undisturbed time and deliver care in a developmentally supportive manner; assessment should include considering basic infant care issues (e.g., time since last feeding, dry diaper). • <i>Noise and light levels:</i> Low levels contribute to an atmosphere of calm; high levels may have no effect on an infant in pain or may exacerbate the intensity of pain expression; high levels further disorganize an agitated infant and escalate the situation. • <i>Caretaker</i> who does not routinely care for the child will not be as sensitive to the infant's subtle cues, particularly of agitation, and may not as readily calm the child or know what is most effective in doing so. • <i>Lack of physical boundaries:</i> Well-defined boundaries (blankets, nests, buntings, something to push against to feel contained and keep extremities from flailing) assist an infant to stay organized; boundaries are particularly important for preterm infants, who do better with loose wrapping, whereas a term infant may need to be tightly swaddled. 		
Behavioral Cue	Pain	Agitation
Cry	Greater intensity, high pitched, tense, sudden, loud	Whining, tends to be more annoying than alerting to the caretaker
Facial expression	Pain facies, grimace, preterm show weaker response	Frowning, may look more "wild eyed," out of control
Activity	Tensed muscles, flexed extremities, may swipe at painful area; preterm may be limp, listless	Random movements of head and flailing extremities, hypertonic, arched posture
Sleep	Altered patterns	More regular patterns, agitated during awake state
Arousal	Greater intensity, wider fluctuations in vital signs, shallow breathing	Vital signs more stable, see decompensation as agitation is prolonged
These are generalizations; each infant is unique in response to situations and behaviors and must be evaluated individually.		

Pain, when combined with the other adolescent stressors of rapid physical and psychological change, may cause an adolescent to regress. Regression impairs coping abilities, and the adolescent may not function at the level at which she or he did previously. Recognize the potential for regression when selecting assessment methods. If an adolescent is functioning at a less sophisticated developmental level, choose assessment methods that are appropriate for this lower level.

Children With Communicative Impairment

Children may be unable to communicate their pain as a result of physical (e.g., cerebral palsy, coma) or cognitive impediments. The child who is handicapped still has the capability to experience both acute and chronic pain, although the child may lack the ability to communicate about pain effectively.

Parents provide valuable information in recognizing and assessing pain in children with cognitive impairments

(Carter, McArthur, & Cunliffe, 2002), although they may overestimate their child's pain during the early postoperative period (Voepel-Lewis et al., 2005). Parents report unique behaviors and behavior clusters used by their children to express pain (Hunt, Mastroyannopoulou, Goldman, et al., 2003).

If the child has cognitive deficits, use tools for pain assessment that are appropriate for that child's developmental level. Do not use chronologic age as a basis for pain assessment. When the child is unable cognitively to communicate pain, assessment methods used for infants may be used (e.g., crying, moaning, refusal to move, decreased appetite, irritability, sleep disturbance). Tools to provide a more objective measure of pain in this population have been developed (Table 10-5). Regardless of the tool, use the child's typical behaviors when pain free as a baseline to evaluate for pain and response to treatment. Use the method the child usually uses to communicate (e.g., letter board, shaking head, blinking eyes, specific words for pain).

CLINICAL JUDGMENT 10–1

A School-Aged Child in Pain

Carmen is a 7-year-old girl, weighing 25 kg, who was hit by a car while riding her bike yesterday. Her left femur is fractured and she is in traction; an IV catheter is in place. Her mother is staying with her. When she was admitted, both Carmen and mother were taught how to use the FACES scale to rate pain. Carmen has orders for acetaminophen with hydrocodone elixir (2.5 mg codeine/167.5 mg acetaminophen/5 mL), 5 mg every 4 hours orally as-needed for pain; ibuprofen, 200 mg every 4 hours orally for PRN pain; morphine sulfate, 2 mg every 2 hours IV for PRN severe pain. Carmen received acetaminophen with hydrocodone elixir 2 hours ago. When you go in to take her vital signs, she rates her leg pain as FACE 1 of the 0 to 5 FACES, her heart rate is 80 beats per minute, her respiratory rate is 22 breaths per minute, and her blood pressure is 106/64. She cries or moans frequently and is lying rigid.

Questions

1. Do you think Carmen is in pain?
2. What behaviors indicate that she is or is not in pain?
3. What would you do to treat Carmen's pain? When would you reevaluate Carmen's pain?
4. The next time Carmen's pain is reassessed, she picks FACE 4 of the 0 to 5 FACES. What would you do at this time?
5. When you evaluate Carmen 1 hour later, she picks FACE 2 of the 0 to 5 FACES, and she cries with movement, but is engrossed in the television show she is watching. What should you do?

Answers

1. Yes.
2. Nonverbal cues that indicate that she is having pain are crying and unwillingness to move.
3. Medicate with ibuprofen. Plan to give the PRN ibuprofen around the clock, because it is particularly effective for musculoskeletal pain. Carmen's subjective rating of her pain is FACE 1 of the 0 to 5 FACES, which indicates a small amount of pain. This subjective rating of pain is incongruent with objective findings; therefore, review how to use the FACES pain scale and verify Carmen's understanding of how to use the tool. Reassess in 1 hour.
4. Give morphine at 2 mg IV.
5. She seems more comfortable but is still rating mild to moderate pain. It has been 3 hours since she received the acetaminophen with hydrocodone elixir, so administer again and plan to alternate the elixir and ibuprofen every 2 hours, and give the morphine for breakthrough pain. Consider contacting the healthcare prescriber for an order for Valium or another muscle relaxant if Carmen has muscle spasms that contribute to her pain.

MANAGING PAIN IN CHILDREN

QUESTION: In Nursing Plan of Care 10–1, which diagnosis is most applicable to George? What would be a measurable outcome specifically for George to evaluate the expected outcome in Nursing Plan of Care 10–1?

The role of the healthcare team in pain management is to listen to the child and family, provide relevant education, maintain continuity of care, strive for the best pain assessment, and intervene appropriately. Inadequate pain management results in needless physical and psychological suffering.

Alert! Maintain a high index of suspicion regarding the presence of pain, and advocate actively for pain relief on behalf of the child. Children of all ages experience pain, and when the presence of pain is suspected, interventions must be implemented. Consider severe, unrelenting pain a medical emergency and immediately implement pharmacologic interventions as ordered.

To make appropriate management decisions, consider the individual child, the child's condition, and the type and intensity of the child's pain. The most successful pain management strategy is a dynamic, proactive approach (Nursing Interventions 10–2). This approach involves maintaining control of the pain with around-the-clock management. Interventions can be classified as pharmacologic or biobehavioral (nonpharmacologic). These methods should be used in conjunction to augment their individual effects.

Nursing diagnoses applicable to the child in pain are based on assessment findings. Identifying them may seem simple, but psychological aspects of pain must also be considered. Discuss the expectations of the child and family regarding pain relief. Do they expect that the child will achieve complete pain relief? Is their expectation realistic in the specific situation? Do they expect that pain will be relieved enough so that the child can participate in certain activities? Realistic goals should be mutually decided upon by the child, family, and healthcare team to avoid misunderstanding and mismanagement of the pain. Appropriate management techniques are determined based on the identified diagnoses (Nursing Plan of Care 10–1).

TABLE 10-5
Tools for Pain Assessment of Children With Impaired Communication

Tool/Indicator Sign Signal	Parameters* and Scoring	Comments
Noncommunicating Children's Pain Checklist-Revised (NCCPC-R) (Breau, McGrath, Camfield, and Finley, 2002b) Age: 3 to 18 years	Seven categories of 30 behaviors: vocal, eating/sleeping, social, facial expression of pain, activity, body/limbs, physiologic; 30 behaviors scored how often observed (0, not at all; 1, just a little; 2, fairly often; 3, very often); scores summed to create total scores (0-90 points)	Demonstrated reliability and validity; length of administration (approximately 10 minutes) may limit clinical utility; score of 57 points or more indicative of pain
Noncommunicating Children's Pain Checklist-Postoperative Version (NCCPC-PV) (Breau, Finley, McGrath, and Camfield, 2002a) Age: 3 to 19 years	Six categories of 27 behaviors: vocal, social, facial expression of pain, activity, body/limbs, physiologic; scored how often observed (0, not at all; 1, just a little; 2, fairly often; 3, very often); scores summed to create total scores (0-81 points)	Reliable and valid for assessment of postoperative pain of children with severe intellectual disabilities; length of administration (approximately 10 minutes) may limit clinical utility; score of 11 points or more indicates at least moderate pain
Checklist Pain Behavior (CPG) (Duivenvoorden et al., 2006; Terstegen et al., 2003) Age: 2 to 19 years	10 items: tense face, grimace, deeper nasolabial furrow, looking sad, almost in tears, eyes squeezed, panics/panic attack, cries softly, moaning/ groaning, penetrating sounds of restlessness, tears	Items discriminate between "absence of pain" and "presence of pain"
Pain Indicator for Communicatively Impaired Children (PICIC) (Stallard et al., 2002) Age: not indicated; in study, mean age of 10.1 years (standard deviation, 4.9 years)	Six behaviors: screaming, distressed face, tense body, difficulty in consoling, flinching	Presence of one or more of these cues correctly identified almost 75% of those considered to be in pain, whereas their absence identified 94% not in pain; a distressed-looking or "screwed-up" face is the strongest individual predictor of the presence of pain
Revised FLACC (Malviya et al., 2006; Voepel-Lewis et al., 2002) Age: 4 to 19 years	Face Legs Activity Cry Consolability; allows for individualization of the tool via open-ended descriptors in each category, which is scored from 0 to 2 points with a total of 0 to 10 points	Demonstrated reliability and validity; expanded original FLACC descriptors in Legs and Activity including verbal outbursts, tremors, increased spasticity, jerking movements, and respiratory pattern changes such as breath holding and grunting; scores suggest pain intensity of mild (0-3 points), moderate (4-6 points), severe (7-10 points)
Paediatric Pain Profile (PPP) (Hunt et al., 2004, 2007) Age: 1 to 18 years	20 items: cheerful, sociable, withdrawn, cried/moaned, hard to comfort, bit self/banged head, feeding, sleep disturbance, frowned, looked frightened, ground teeth, restless, spasmed, drew legs up, touched particular areas, resisted being moved, pulled away, twisted and turned/writhed or arched back, involuntary movements; items scored 0 to 3 points	Demonstrated reliability and validity; short, takes 2 to 3 minutes to complete; a score of 14 points or more suggests significant pain

*Items are given as representations of the concept and may not represent exact wording from tool. Although scores on some tools may suggest increasing pain intensity, if pain is present it must be treated, regardless of the intensity. Use cutoff scores in conjunction with other assessments to guide nursing interventions.

NURSING PLAN OF CARE 10–1: THE CHILD IN PAIN

Nursing Diagnosis: Acute pain related to effects of condition, treatment, injury

Interventions/Rationale

- Assess pain initially, every 2 to 4 hours, and as necessary (see Nursing Interventions 10–1); observe nonverbal cues such as posture, breathing patterns, movement, facial expression; ask about the parents' perception of child's comfort level. Use information from parents regarding child's usual behavior when in pain to assess level of pain.

Provides baseline assessment and collects information to develop pain management plan. Changes noted on subsequent assessments provide information about whether pain management is adequate. Parents know their child's behaviors best and are excellent resources regarding their child's behavior. A child's pain response is influenced by developmental age, condition causing pain, previous experience with pain, culture, and parents' responses to pain.

- Allow child to express feelings of pain; offer comfort and supportive measures.

Conveys the uniqueness of the child and the experience; may reassure the child and family and reduce anxiety.

- Teach child and family about condition, prognosis, medications, and treatment plan.

Provides a knowledge base on which the child and family can make informed decisions.

- Encourage parents to participate in care to the extent they feel comfortable doing so. Provide parents with concrete information about what they can do to help the child (e.g., read a story, help the child with coping strategies such as deep breathing).

Teaching parents empowers them and helps them feel that they have skills to support their child. Children seek parental comfort and may be more receptive to comfort measures provided by the parent.

- Administer medications (nonopioids, opioids, and coanalgesics) as ordered before pain escalates; evaluate effectiveness at appropriate interval, at least within 1 hour. When IV opioids are given, administer slowly over 5 minutes and observe for changes in respiratory patterns; reassure child and parent that addiction is not a concern (Nursing Interventions 10–3).

Pharmacologic strategies are the mainstay of pain management. Reassessment gives information about effectiveness of interventions and the need to alter them. Pain is easier to manage when it is less severe.

- Assess the effect of discomfort on the child's sleep. Help child and family to make a realistic and integrated schedule of activities, rest and sleep, exercise, and stress management. Organize care (e.g.,

medicate before activities, provide uninterrupted opportunities to rest and sleep).

Active involvement increases child's and family's sense of control, which may decrease stress and anxiety (which lower pain threshold). A proactive, preventative approach to pain management prevents pain from escalating; escalated pain is harder to control and alleviate. Decreasing pain enhances sleep.

- Control environmental factors such as room temperature, noise, light.

Noxious environmental factors may reduce pain tolerance.

- Provide a pleasant, relaxed atmosphere for eating and activities.

Unpleasant sights and odors can stimulate the vomiting center or pain center in the brain.

- Provide psychological support (Nursing Interventions 10–4). Explain all procedures to child in a developmentally appropriate manner (Nursing Interventions 10–5).

May decrease stress, fear, and anxiety, which lower pain threshold, and can alter pain perception and interfere with the child's ability to express pain.

- Identify, teach, and model coping behaviors that are effective for the child; encourage the child and family to practice these strategies (Nursing Interventions 10–6 and 10–7).

Coping strategies that the child can use are most effective in altering or reducing pain perception; many require practice to increase effectiveness.

- Implement biobehavioral strategies such as positioning, distraction, imagery, music, back rubs, relaxation techniques.

Biobehavioral measures can decrease pain and discomfort, and augment the therapeutic effects of medications by modifying physiologic reactions to pain; they increase a sense of control and help the child cope.

- Evaluate adequacy of pain management (Nursing Interventions 10–10).

Provides information about effectiveness of management and enables prompt revision of management plan if it is not achieving desired outcomes.

Expected Outcome:

- Child will remain free of pain. If pain cannot be alleviated, it will be reduced to an acceptable level as defined by the child, parent, and healthcare provider.

Nursing Diagnosis: Chronic pain related to effects of condition; altered pain processing

Interventions/Rationale

- See previous interventions as for acute pain and Nursing Interventions 10–9.

NURSING PLAN OF CARE 10–1: THE CHILD IN PAIN (CONTINUED)

- Evaluate current management regimen. Explore the need for opioids, nonopioids, and coanalgesics, and biobehavioral measures. Ensure around-the-clock dosing.

Using nonopioids, even if they are not effective alone, can reduce the dosage of an opioid required to effectively manage pain. Combining classes of analgesics enhances the effectiveness of each and may achieve pain relief with lower dosages of each single drug. Around-the-clock dosing helps prevent the pain from escalating and becoming more difficult to manage.

- Encourage the child to participate in developmentally appropriate activities and adhere to behavioral expectations and discipline based on family norms, home responsibilities such as chores, and school attendance.

These activities are normalizing for children; they help children to regain or achieve appropriate developmental tasks, decrease attention to pain behaviors (while making sure that pain control is as good as possible), and emphasize a productive role.

Expected Outcome:

- Child will perform activities of daily living and developmentally appropriate activities with minimal interference from pain and medication side effects.

Nursing Diagnosis: Anxiety related to effects of pain, lack of control over pain

Interventions/Rationale

- Assess child and parent for behaviors that reflect anxiety.
Children and parents frequently experience anxiety when faced with pain. Increased anxiety levels can increase pain perception and interfere with use of coping strategies.

- Encourage child and parent to learn about child's condition and treatment plan. Explain all procedures to child in developmentally appropriate terms.

Provides knowledge base upon which to make informed decisions and may decrease anxiety.

- Organize care to provide a pace that the child and family can cope with, and develop plan in conjunction with child and family. Provide predictability for the child (e.g., perform procedures at a consistent time and place each day, wear a specific object that signifies procedure time, maintain "safe" areas and times).

Predictability reduces anxiety. A pace that the child and family can accommodate provides them time to recover and maintain optimal coping strategies. Anxiety decreases coping abilities, thus increases pain perception.

- Plan experiences that the child can control, manipulate, and succeed in to decrease anxiety

arising from feelings of powerlessness (e.g., encourage child, as age appropriate, to participate in decisions regarding care and schedule, such as which dressings to remove first, how fast to remove them). Allow child to assist with dressing changes (e.g., removing old dressing, holding tape); encourage child to apply dressing to doll or stuffed animal.

Gives control and choice to the child, which may reduce pain perception.

- Assist child to assume a position of comfort; use biobehavioral approaches for comfort (e.g., back rubs, distraction with toys and games, imagery, soothing music, relaxation, controlled breathing).

Biobehavioral methods to relax may reduce pain perception.

- Project a calm, unhurried attitude while performing procedures.

Staff (and parental) attitudes and actions such as abruptness, rushing, and irritation increase a child's level of anxiety and decrease ability to cope.

- Listen and provide emotional support.

Children and families who feel that they have been heard and their concerns are being addressed may be less anxious.

- Prepare the child for procedures or consequences of pain in a developmentally appropriate manner (see Nursing Interventions 10–5). Emphasize that painful procedures are not punishment.

Child's cognitive abilities influence understanding of pain and use of coping strategies.

- Maintain sensitivity toward families who are battling with feelings of anxiety and may be angry with healthcare providers. Consider mental health referral when applicable.

Provides a therapeutic environment.

Expected Outcomes:

- Child will not demonstrate behaviors of, or verbalize, anxiety. Increased feelings of control will prepare child for painful situations and procedures. Child's pain will be controlled at acceptable levels.

Nursing Diagnosis: Deficient knowledge: Causes of pain and interventions

Interventions/Rationale

- Explain all procedures to child in age- and culturally appropriate terms. Emphasize that painful procedures are not punishment.

Ability to cope is influenced by knowledge, realistic expectations, and ability to control and manage pain.

- Answer questions in a nonthreatening manner. Provide concise and honest information at child's level of understanding.

Understanding the plan of care can help the child adhere to the plan.

- Give child and parents verbal and written instructions regarding list of medications, dosages, schedule, possible side effects, how to avoid or manage them, and when to report them to the physician or clinic. Also tell them where and how to obtain refills.

If a knowledge deficit exists, families cannot appropriately maintain the child's level of functioning or avoid complications.

- Have child and parents demonstrate biobehavioral strategies to manage pain.

Allows for validation that child and parents are performing technique appropriately and that technique is effective.

- Reinforce importance of regular communication and follow-up appointments with healthcare pro-

vider. Provide contact information of healthcare provider to consult for follow-up care.

Routine communication enables healthcare provider to detect adverse trends promptly and to implement interventions to address them. Drug therapy requires frequent assessments to monitor the drug's effectiveness and side effects.

Expected Outcomes:

- Child and family will receive developmentally and culturally appropriate explanations of pain and pain management.
- Child and family will understand pain mechanisms and know what they can do to relieve pain.

ANSWER: An appropriate diagnosis is: Chronic pain related to effects of condition. The expected outcome is that the child will perform activities of daily living and developmentally appropriate activities. For George, time spent on his online high school courses each day would be a measure of his ability to concentrate on an enjoyable and developmentally appropriate activity.

Pharmacologic Pain Management

Drug therapies are the essential interventions for treating pain and are thus an important component of managing both acute and chronic pain. Nurses play a key role in administering analgesics and monitoring for efficacy and side effects of these pain-relieving medications. A thorough understanding of nociception and pain pathways; accurate assessment of type and intensity of pain; knowledge of drug pharmacokinetics; and education of patients, families, and other health team members are essential to effective pain relief. When there is reason to suspect that

a child might be in pain, a trial of an analgesic is appropriate.

Categories of Medications

Medications used for pain management are classified into three categories, depending on their mechanism of action:

1. Nonopioid analgesics generally work at the site of injury to inhibit prostaglandin synthesis, thus decreasing pain.
2. Opioid analgesics, previously known as *narcotic analgesics*, relieve pain by binding to the opioid receptors in the central nervous system, blocking the release of substance P and preventing the pain impulse from crossing the neuronal synaptic cleft.
3. Coanalgesics have a primary indication other than pain relief, but they can also provide analgesia in certain painful conditions. This category tends to be a catch-all grouping of medications that includes anticonvulsants, antidepressants, and anesthetics (i.e., coanalgesics are any medications other than nonopioids or opioids that are used to treat pain).

These three categories of medications are typically used in combination to attack pain in a variety of ways at various points on the nociceptive pathway. By combining these analgesics, less of each individual medication is required to relieve pain, and the potential for side effects is thus less than it would be with single-agent therapy. This approach is called *balanced* or *multimodal analgesia*. Be familiar with concepts important to treatment with analgesics such as ceiling effect, titration, tolerance, equianalgesia, and physical and psychological dependence (see [thePoint](#) for Supplemental Information).

Nonopioid Analgesics

Nonopioid analgesics are indicated for mild to moderate pain or for use in conjunction with opioids for moderate to severe pain to augment and decrease opioid requirements. They work well for musculoskeletal pain. Nonopioids differ from opioids in that they are antipyretic, have

NURSING INTERVENTIONS 10–2

ABCDEs of Pain Management

Assessment is multidimensional and is more than just a pain intensity score.

Believe that the child has pain if the history supports it or the child reports it (either by behavior or words).

Communication is clear, concise, and patient focused.

Do something/intervene. Interventions should consider the child's developmental age, and the type and intensity of pain.

Evaluate the effectiveness of interventions; go back to assessment.

a ceiling effect, and do not produce tolerance or physical or psychological dependence. Nonopioid analgesics include acetaminophen and NSAIDs (see [thePoint](#) for Supplemental Information). They differ in chemical structure, so if one drug is not effective, another should be tried. The most commonly used nonopioids—over-the-counter acetaminophen and ibuprofen—are safe and effective for relieving children’s pain (Dlugosz, Chater, & Engle, 2006).

Alert! The overall incidence of side effects with acetaminophen is low in comparison with that for NSAIDs. However, unbridled use of acetaminophen can result in liver toxicity. Caution children and families about this potential threat, and caution them that a child may inadvertently receive too much acetaminophen, because it is included in many common over-the-counter remedies for treating symptoms of pain, flu, and the common cold.

Opioid Analgesics

Opioid analgesics are indicated for moderate to severe pain that is not relieved with nonopioids. Opioids differ from nonopioids in that they do not have an antipyretic effect or a ceiling of analgesia. Therefore, opioids will not mask fever, and opioid doses can be titrated upward until pain is relieved or intolerable side effects develop (Nursing Interventions 10–3). Several opioids are available in low-dose preparations, combined with nonopioids. Because of nonopioid ceiling of analgesia and potential for toxicity at higher doses, the nonopioid component limits titration of these combination drugs.

The different opioid drugs are classified, according to their receptor binding properties, as agonists, partial agonists, agonists–antagonists, or antagonists (see [thePoint](#) for Supplemental Information). Opioid analgesics include centrally and peripherally acting mu agonist opioids.

Morphine, codeine, hydrocodone, oxycodone, and hydromorphone belong to a class of chemicals called *phenanthrenes*. Methadone is a synthetic opioid, chemically classified as a benzomorphan derivative. Fentanyl and meperidine are considered phenyl piperidine derivatives. Although allergic reactions to opioids are rare, allergic reactions to one opioid in a class indicates allergy to all opioids in that class. Choosing an opioid from another class may limit the patient’s risk of a subsequent allergic reaction.

Physical dependence on opioids develops in as little as 7 days of continuous use (APS, 2005). Symptoms of opioid withdrawal, also known as *opioid abstinence syndrome*, include anxiety, irritability, chills, hot flashes, salivation, tearing, rhinorrhea, diaphoresis, piloerection, nausea, vomiting, diarrhea, abdominal cramps, and insomnia. Infants may also demonstrate increased crying; poor feeding (but ravenous sucking); and increased muscle tone, tremors, and jitteriness. To decrease the risk of opioid withdrawal, the dose should be gradually decreased (10% to 20% per day) or the time between doses gradually increased; do not simply eliminate doses (APS, 2003).

Alert! Use caution with children who may have developed physical dependence. Use of antagonists (naloxone) or mixed agonist–antagonists to reverse side effects may precipitate sudden withdrawal.

NURSING INTERVENTIONS 10–3

Opioid Side Effects

Common Opioid Side Effects	Interventions
Nausea and vomiting	Administer nonsedating antiemetic, phenothiazine antiemetic, or antihistamine as ordered.
Pruritus	Administer an antihistamine as ordered, apply cool compresses to the site.
Sedation	Assess level of consciousness; for chronic therapy, add stimulant as ordered (e.g., caffeine, dextroamphetamine, methylphenidate).
Respiratory depression (especially with IV, epidural, high doses)	Assess level of sedation, respiratory rate, and depth; have resuscitation equipment and naloxone available. Sedation always precedes respiratory depression, so monitor sedated children closely.
Constipation	Assess bowel sounds, administer a stimulating laxative and a stool softener, encourage ambulation, increase fluid and fiber intake.
Urinary retention	Monitor intake and output, apply a warm compress over the bladder, have the child ambulate if possible. May require catheterization.

Treatment of side effects also depends on the specific situation and whether they interfere with activities of daily living. For example, sedation may be desired during the immediate postoperative period but not desired for the patient with cancer.

If withdrawal symptoms are present, ensure a quiet, darkened environment; handle an infant as little as possible; ask older children what their needs are; and provide comfort measures (offer pacifier, swaddle infants, apply cool cloth to forehead for older children). Sedatives may be used to manage symptoms of withdrawal. Use a scoring method similar to one developed for neonatal abstinence syndrome (for infants born to opioid-addicted mothers; see Chapter 16) to help to keep monitoring and tracking of opioid weaning consistent.

Coanalgesics

Coanalgesics include medications such as tricyclic antidepressants, selective serotonin reuptake inhibitors, anti-convulsants, benzodiazepines, and local anesthetics. These drugs play a role in pain management by potentiating the effects of analgesics, treating the side effects of analgesics, or exerting an analgesic effect of their own (see [thePoint](#) for Supplemental Information). Most drugs in this category are not labeled for pediatric use.

caREminder

Painful procedures should not be performed without the addition of analgesic drugs.

Scheduling for Analgesic Administration

Pain is best managed by a proactive, preemptive approach. Anticipating and treating pain is much more effective and humane than trying to manage pain after it is present. Although PRN (*pro re nata*, which means *as needed, as necessary*) analgesic dosing may be appropriate for periodic pain such as an occasional headache, treating constant pain, such as pain from diseases, surgery, and trauma, demands a pain management strategy that provides pain relief for a longer duration than one dose of an analgesic can provide. PRN administration of pain medication tends to propagate a pain cycle with peaks (side effects like sedation) and troughs (pain) of drug action. If pain is present or anticipated for most of the day, medications must be scheduled and administered around the clock, with additional doses of analgesics available for prompt relief of breakthrough pain. Analgesic schedules should take into account the duration of action and half-life of the specific drug.

The effect of nonopioid medications is optimized by administering these non-sedating analgesics to opioid-naïve patients and by providing opioids for breakthrough pain. If, despite the use of scheduled nonopioids, a child continues to have pain, the management plan should progress to also provide opioids on a scheduled basis. When sustained-release or long-acting opioid analgesics are administered, additional quick-acting opioid preparations may be needed as a rescue dose during breakthrough pain episodes.

Route of Administration

QUESTION: If George's morphine dose were changed to IV, would the dose remain the same?

Route of analgesic administration will determine the rate of drug absorption and, therefore, the time and duration of analgesic effect. Dose is also route dependent. First-pass metabolism through the liver leaves only a small fraction of the drug available to relieve pain. If a route circumvents first-pass metabolism, the required dose of the analgesic is substantially lower than when the same drug is administered by a route that requires first-pass metabolism. For example, the IV route circumvents first-pass metabolism, so the recommended starting dose in a child for morphine by the IV route is 0.1 mg/kg, whereas the starting dose for morphine by the oral route to achieve equianalgesia is 0.3 mg/kg.

Oral Administration

If the child is able to take medications orally, and pain can be controlled, the oral route is preferred for analgesic administration. The oral route is convenient, and relatively steady blood levels of drug can be achieved to ensure steady and consistent pain control, with few peaks and valleys of pain and side effects. Oral analgesics are typically less expensive and come in a variety of formulations (e.g., liquids, suspensions, chewable tablets, pills, extended release capsules) to increase palatability.

Disadvantages of the oral route are delayed onset of action (typically 45 minutes) and delayed peak drug effect (typically 1–2 hours), which make this route less than optimal for severe pain of sudden onset. Children may be particularly vulnerable to undertreatment by this route, because they may refuse oral medications that have a noxious taste. Children also have difficulty understanding the need to take a medication regularly to prevent recurrence of pain, because they do not anticipate that the medication will wear off and that delay in taking it will delay its effects.

Intramuscular Administration

Injections are not recommended for administering analgesics and are specifically considered unacceptable for administering pain medications to children (APS, 2003). Children may not report or may deny pain in order to avoid an intramuscular injection. Painful administration makes this route inconsistent with the goal of analgesic therapy.

Other disadvantages of this route are the wide fluctuations in drug absorption, delayed peak effect (30–60 minutes), and rapid falloff of action. Injections also pose the potential risk of sterile abscess formation and fibrosis of the muscle and soft tissue. A rarely mentioned disadvantage is nurses' dissatisfaction with their role in administering medications by this route.

Intravenous Administration

IV administration circumvents first-pass metabolism and therefore provides a rapid onset of action. This route is most effective when treating unpredictable, severe pain of sudden onset. Initially, IV bolus doses of opioids are titrated to provide effective pain relief. This route is the preferred route of analgesic administration for patients who are unable to tolerate oral medications.

Continuous IV infusions of opioids provide a steady blood level and may be indicated for opioid-tolerant patients with persistent painful conditions. The APS (2003) warns, however, that administering continuous opioid infusions to opioid-naïve patients (either as a sole infusion or as a background infusion with patient-controlled analgesia) may increase the incidence and severity of adverse side effects without improving the quality of analgesia.

ANSWER: George's dose would need to decrease if it were given intravenously instead of orally, by as much as one third because of the first-pass effect.

Subcutaneous Administration

The subcutaneous route circumvents first-pass metabolism, but absorption is slow. Although subcutaneous administration of opioids is considered an alternative to the IV or oral route for providing steady-state analgesia, the need to use a needle to provide bolus doses or continuous infusions by this route makes it less acceptable for children.

Transdermal Administration

Local anesthetics and lipophilic opioids have been formulated to permit transdermal absorption. Although manufactured specialty local anesthetic creams provide onset of anesthetic action in 10 to 60 minutes after application, transdermal opioids have a delayed onset of action (12–16 hours) and are therefore not indicated for acute pain management. Only a few pain medications are available as transdermal formulations, and even fewer can be obtained at doses appropriate for children. However, this formulation provides a nonpainful route of analgesic administration.

Transmucosal (Sublingual, Buccal, Intranasal) Administration

The sublingual (under the tongue), buccal (between the teeth and cheek), and intranasal routes can be grouped as transmucosal medication administration techniques. These drugs are absorbed into the venous blood, bypassing first-pass metabolism to achieve rapid onset of effect. Children may be less receptive to the sublingual and buccal routes of administration because these analgesics have a noxious taste. Administration of analgesics by the intranasal route may cause a burning sensation on the nasal mucosa in addition to the unpleasant taste. Even with these disadvantages, children may prefer these routes over injections.

Rectal Administration

Although the rectal route is also considered an alternative to IV or oral administration, it is not well accepted by children older than 2 years of age. Drug absorption varies and is less predictable after rectal administration. Drug absorption by the rectal route depends on rectal content, irritation, drug retention, and amount of drug absorbed

directly into the systemic circulation versus the amount that is exposed to first-pass metabolism. Consider, for example, the difference in pediatric rectal and oral doses of acetaminophen. Although oral acetaminophen is dosed at 10 to 15 mg/kg to achieve an analgesic blood level, rectal doses of 40 to 60 mg/kg may be required. Pain scores have not been shown to be significantly different when these two routes of administration were compared (Owczarzak & Haddad, 2006; van der Marel et al., 2001), although the rectal route may provide longer analgesia for moderately painful procedures (Capici et al., 2008).

Regional Analgesia

This route encompasses a variety of techniques, including peripheral nerve blocks and intrathecal and epidural infusions. The use of these regional anesthetic techniques is becoming more common for pain management after pediatric urologic, orthopedic, and general surgical procedures, as well as for the relief of pain from sickle cell disease and cancer (Desparmet, Hardart, & Yaster, 2003). Regional analgesia is typically administered and managed by an anesthesiologist and can be quite effective in managing pain.

Peripheral Nerve Blocks

Peripheral nerve blocks can be used for procedures or injuries (femoral nerve block for fractured femur), for surgery with or without anesthesia (dorsal penile nerve or caudal block for circumcision), or to manage postoperative pain (ilioinguinal block for herniorrhaphy). Potential contraindications to these techniques include anatomic abnormalities, bleeding disorders, allergies to local anesthetics, and infection at the puncture site (Banks, 2007; McCamant, 2006). Disposable local anesthetic infusion pumps have been developed to extend peripheral nerve blockade for a limited time after hospital discharge.

Intraspinal Administration

The intraspinal routes provide profound analgesia with minimal systemic side effects (Saudan et al, 2007). Intraspinal most commonly refers to the *epidural* route, in which medication is infused into the epidural space (the space outside the dura); the *intrathecal* route (medication infused into the cerebrospinal fluid in the space surrounding the spinal cord) may be used to manage longer term pain syndromes. Analgesia is achieved at much smaller doses than required for systemic administration of opioids, because intraspinal opioids bind directly to the receptors on the dorsal horn of the spinal cord (APS, 2003). Opioids administered by the epidural route are also largely absorbed systemically by the epidural venous plexus. Therefore, intrathecal doses are considerably smaller than epidural doses, which in turn are substantially smaller than IV or oral doses. For example, 0.1 mg intrathecal morphine is equianalgesic to 1 mg epidural morphine, which is equianalgesic to 10 mg IV or 30 mg oral morphine (APS, 2003).

Epidural analgesia is the most commonly used regional anesthetic technique for intra- and postoperative pain

management for children requiring urologic, orthopedic, and general surgical procedures below the nipples (T4 dermatosomal level) (Desparmet et al., 2003). It works by blocking nociceptive impulses from entering the central nervous system. Use of this technology to relieve pain from sickle cell vaso-occlusive crisis and cancer is increasing.

The biggest advantage of epidural analgesia is profound pain relief. Analgesia is achieved through epidural infusions with or without patient-controlled epidural boluses of local anesthetics, opioids, and coanalgesics, such as clonidine. Epidural analgesia decreases morbidity and mortality associated with acute pain by decreasing pulmonary and cardiovascular complications, improving ventilatory function, and decreasing pain with movement.

Disadvantages of the epidural route are primarily drug related. Local anesthetics provide analgesia with minimal risk of causing sedation or respiratory depression. Local anesthetics administered by the epidural route can, however, cause hypotension and bradycardia by blocking the sympathetic nervous system and causing arterial and venous vasodilation. This hemodynamic response is age dependent and rarely occurs in children younger than 8 years of age. Epidural local anesthetics can also cause apnea in the fully conscious patient by blocking the motor efferents to the muscles involved in respiration. Another disadvantage of epidural local anesthetics is the potential for motor blockades that, although rarely life threatening, limit patient mobility.

Hydrophilic opioids, such as hydromorphone or morphine, administered by the epidural route remain in the cerebrospinal fluid for longer than lipophilic opioids do, thus providing longer duration of analgesia. Unfortunately, the hydrophilic opioids also have an increased risk for rostral spread, which increases the risk for sedation and respiratory depression.

Epidural catheters can be placed in children of all ages. Although the caudal, lumbar, and thoracic approaches are all used, the caudal approach is used most frequently because it is the easiest to access in infants and young children (Desparmet et al., 2003). To achieve analgesia at the thoracic level from the caudal approach, the catheter is threaded up the epidural space. Unlike adults, infants and children are usually heavily sedated or anesthetized for catheter placement.

Epidural placement is contraindicated in patients with acquired or congenital bleeding disorders because of the risk for epidural hemorrhage (Desparmet et al., 2003). Inability to place the catheter, infection at the site of catheter placement, and hemodynamic instability are other relative contraindications for epidural analgesia. Complications of epidural catheter placement include postdural puncture headache, neurologic sequelae (cauda equina syndrome), pain at the catheter site, and backache.

caREminder

Physiologic monitors can alert the nurse to respiratory events, but they must be used in addition to frequent, skilled patient assessments. In addition to monitoring for effective

analgesia, routinely assess for level of consciousness, respiratory effort, cardiac function, and level of sensation, especially if local anesthetics and hydrophilic opioids are given.

Patient-Controlled Analgesia

Patient-controlled analgesia (PCA) is a technique that enables patients to administer their own opioid bolus doses by a computer-controlled infusion pump. The pump is most commonly connected to an IV, but PCA is also used epidurally. The PCA pump is programmed, as ordered, to deliver a patient-controlled dose at an interval not more frequent than the ordered “lockout” period. Thus, the child can activate the pump and self-administer small, frequent bolus doses of opioid to optimize pain relief through a rapid response system. Medication can be administered as a patient-demanded bolus only or in addition to a continuous infusion. PCA use and prescriptions vary depending on the child’s diagnosis; type of pain; previous hospital experiences; history of opioid tolerance or naïveté; and the recommendations, standards, or practices of individual institutions or prescribers.

The advantage of using PCA as part of a pain management plan is that it adjusts for the patient’s individual variation in pharmacokinetics and pharmacodynamics. Also, the push-button device is easy to use and concrete; something the child can touch and hold. For some patients, particularly adolescents, PCA gives them a sense of control over their pain. PCA technology avoids the need for the child to ask, beg, or bargain for analgesic administration. After two decades of use in children, this technology is considered safe and effective.

One of the most important disadvantages is that anyone can push the PCA button—the nurse, the parent, the friend, or the 2-year-old sibling who is incapable of understanding the connection between pushing the button and opioid administration or the potential dangers. *PCA by proxy* is the term used when an unauthorized person activates the dosing mechanism. Teach family and visitors not to push the button for the child. Although the total amount of opioid that can be administered is preset, someone else pushing the button bypasses one of the built-in safety features of the system, which is that an oversedated patient cannot self-administer medication.

Authorized agent-controlled analgesia (AACA) is a mechanism for pain management when one individual is authorized and educated to activate the PCA mechanism in response to the patient’s pain when the patient is unable to do so (Wuhrman et al., 2007). This method is appropriate for children too young to self-administer medication, those unable cognitively to understand the concept (e.g., developmentally delayed children), and those physically unable to manipulate the button (e.g., children with cerebral palsy). The authorized agent may be the child’s nurse, parent, or significant other. Guidelines for AACA should clearly delineate the conditions under which the practice shall be implemented and should outline monitoring procedures to ensure safe use of AACA (Wuhrman et al., 2007). Teach the basic

concept of PCA, side effects associated with opioids, and simple methods of pain assessment, including indicators of pain and oversedation.

Another important disadvantage of PCA is that the child must continuously titrate and therefore attend to the pain to keep it under control. PCA is not a panacea; opioid side effects still occur and may discourage the child from achieving optimal pain relief.

A general recommendation is that children older than 5 years of age have the cognitive ability to use PCA (Wuhrman et al., 2007). Rather than following a strict age cutoff for PCA use, evaluate a child's appropriateness for PCA (Developmental Considerations 10–4).

Assess for appropriate and effective use of PCA by reviewing hourly PCA attempts and injections data. Although most PCA pumps provide immediate feedback (by a signal) to the child that the button has been depressed, it takes a few minutes for the child to experience pain relief, and the child may interpret the delay as a sign that the pump does not work. Determine whether the child has made more attempts than injections. Does he or she push the button repeatedly to get only one dose? Does the child demand PCA frequently? Is hourly lock-out reached or is the button pushed several times every hour? How hard does the child have to work to maintain comfort? Is the child able to rest and sleep? Does the child report that pain

is well controlled? What is the child's pain intensity score?

With this additional assessment, the nurse can determine whether the child understands the machine and whether PCA is appropriate for relieving the child's pain. This assessment also alerts the nurse to any need to provide additional education to the child and family to optimize PCA use. However, assessment may also indicate that other methods of pain control would provide more effective pain relief to this individual child.

Dose

QUESTION: Why does it matter whether George weighs more or less than 50 kg?

Analgesic doses required to relieve pain vary by child, route, drug, frequency, and administration techniques. Individual patient factors known to affect dose variability include type, cause, and severity of pain; ethnic and gender-related responses to analgesics; concomitant administration of other medications; past pain experiences; and previous opioid tolerance (APS, 2003).

Recommended doses of analgesics and coanalgesics that have a ceiling of effect generally reflect the dose required to achieve therapeutic analgesic blood levels, whereas recommended doses of opioids and coanalgesics that lack a ceiling of effect are considered initial dosages. These recommended doses are based on empiric evidence and clinical experience, and must be titrated to achieve optimal analgesia while minimizing analgesic-related side effects.

Initial analgesic dose recommendations vary by age and weight. In adults, research suggests that weight does not correlate with analgesic requirements for pain relief. Yet for children, initial analgesic doses are recommended in milligrams (or micrograms) per kilogram of the child's body weight. These recommendations are approximate and the prescriber should order doses based on clinical circumstances.

Therefore, give special consideration to children on both ends of the age and weight spectrum. Children who weigh more than 50 kg should be started at adult dose recommendations. Calculating doses by milligrams per kilogram in these children results in doses that exceed initial adult recommendations; therefore, this approach puts them at increased risk of overdose. Second, consider the smaller and younger child. The pharmacokinetics and clinical effects of opioid analgesics for infants and children older than 6 months of age are similar to those in adults (APS, 2003). Younger infants and neonates have slower drug clearance and longer elimination half-lives. Therefore, for preterm and term infants younger than 6 months of age, initial recommended pediatric opioid analgesic doses should be reduced to one quarter to one third the recommended starting dose for older children (APS, 2003).

Special dose considerations are required for children with disease processes that affect drug metabolism,

DEVELOPMENTAL CONSIDERATIONS 10–4

Criteria That Indicate a Child's Suitability for PCA

- Able to activate the device. A child with physical limitations may need advice that is adapted with the help of a biomedical engineer or occupational therapist.
- Able to quantify pain. The child needs to activate the pump when pain is starting or increasing, so that treatment is not delayed until pain is severe or intolerable.
- Unable to tolerate oral analgesics. Oral analgesics provide a longer duration of pain relief, so a child who can tolerate this formulation does not need to frequently request analgesia or activate a system to deliver it.
- Understands the relation between pushing the button and receiving medication.
- Understands the machine's safety mechanisms.
- Reports unsatisfactory pain relief with current regimen. The child and family must understand that the PCA is not a panacea, merely an alternate way to relieve pain. If the child's pain is not effectively relieved with PCA, other methods of controlling pain should be considered.

elimination, and the severity of analgesic side effects. Closely monitor children with liver, renal, pulmonary, cardiac, or neuromuscular diseases when opioids are administered and as doses are titrated to achieve pain relief. Infants and children with comorbid conditions may also require reduced analgesic doses and longer intervals between doses to adjust for their altered pharmacokinetics and their response to analgesics.

Opioid analgesics are frequently prescribed as *range orders*, such as hydrocodone/acetaminophen 1 to 2 tablets orally every 4 hours, or morphine 2 to 4 mg IV every 2 hours as needed for pain. The Joint Commission on Accreditation of Healthcare Organizations (2007) is concerned that range orders are unclear and subject to interpretation, therefore leading to inconsistent dosing and a potential threat to patient safety. To ensure that opioids are administered consistently by all nurses who care for a patient, the Joint Commission requires healthcare organizations to specify required elements of range orders. The American Society for Pain Management Nursing and the APS (2004) recognize that range orders provide for flexibility and safe dose adjustments, enabling nurses to respond promptly to a patient's unique and varied analgesic needs. To interpret range orders, complete a thorough pain assessment, assess the child's clinical current status, and consider the child's prior exposure and response to ordered or similar medications and concomitant administration of other drugs. Evaluate the child's response to each dose. Document and communicate assessments and interventions to facilitate safe and consistent treatment.

Children who report decreasing pain relief from previously effective doses of opioids may be experiencing tolerance to the analgesic effects of the opioid and may therefore require a different dosage or another drug.

caREminder

When converting the opioid-tolerant child to another opioid, equianalgesic tables provide an approximate point to dose from. Evaluate the child's clinical response to the new analgesic dose and titrate the dose to provide optimal pain relief.

ANSWER: Children who weigh less than 50 kg are traditionally given pediatric dosages according to weight. George, however, is still close to 50 kg and his pain is relieved by the adult dose.

Child and Family Education Regarding Pharmacologic Management

Explore child and family preferences for pharmacologic pain management and address any knowledge deficits that may be barriers to achieving optimal pain relief. A thorough pain history provides information about what has been successful and unsuccessful in the past. Previ-

ously successful interventions provide an excellent basis for a pain management plan. However, past medication use may not apply to the patient's current situation. Take such opportunities to educate the patient and the family about the pharmacologic options and the benefits of a balanced approach to pain relief.

Frequently cited patient and family barriers to using pharmacologic interventions are pain tolerance, pain expectations, and fears of opioid analgesics. Stoicism is highly valued by society (McCaffery & Pasero, 1999). Patients and family expect pain from surgery, trauma, cancer, and common healthcare procedures. They may not be aware of pain's deleterious effects and may fear analgesics; these fears might cause them to choose pain over pain relief. Fears that using opioid analgesics will lead to addiction, respiratory depression, and death may deter children and families from allowing these medications to be included in the pain management plan. The horrors of drug abuse and addiction are publicized in the media but are also familiar to families from personal experiences and community awareness efforts, especially school campaigns. Inform patients and families about pain relief strategies and the harmful effects of pain. Review ordered analgesics, specifically drug, route, dose, and frequency. Encourage the child and family to report onset of pain and unrelieved pain so that interventions can be provided promptly and the pain management plan can be adjusted to optimize analgesic interventions. Assure the child and family that reports of pain will be taken seriously and that pain relief is an important part of the child's treatment plan.

Openly discuss addiction and substance abuse with patients and families. Reassure them that opioid addiction is rare when these analgesics are prescribed for pain control. Remind them that addiction is defined by compulsive drug use, impaired control over drug use, and continued use of drugs despite harm (American Academy of Pain Medicine, APS, and American Society of Addiction Medicine, 2001). Educate patients and families about monitoring that is used to detect potential respiratory depression. Assure them that the goal of opioid treatment is to balance pain relief and analgesic side effects to achieve optimal pain management.

Biobehavioral Strategies (Nonpharmacologic) and Comfort Interventions

Nonpharmacologic therapies for pain management, or comfort measures, traditionally have been considered solely a nursing responsibility. These biobehavioral interventions are now common and often are termed *complementary* or *alternative*. These interventions are not alternatives to analgesics, however. Regardless of the term used to characterize these strategies, they should be provided in addition to, not instead of, pharmacologic therapies (APS, 2005) (Clinical Judgment 10–2).

Biobehavioral interventions provide coping strategies that may help to reduce pain perception and increase comfort. For example, cognitive-behavioral interventions may alter perception of the pain being experienced.

CLINICAL JUDGMENT 10–2

An Infant in Pain

Diep is a 3-kg, 1-week-old patient 20 hours after major abdominal surgery. Vital signs are heart rate, 166 beats per minute; respiratory rate, 50 breaths per minute and shallow; and oxygen saturation, 90%. She has slept for brief periods since surgery and has a high-pitched cry that is more intense after repositioning. She keeps her eyes closed most of the time and is not interested in her environment. She has had 0.1 mg morphine IV every 4 hours since surgery.

Questions

1. Is Diep's pain being relieved by the doses of IV morphine?
2. What behaviors indicate that Diep is in pain?
3. Is Diep receiving adequate analgesia for her level of pain?
4. What should you do to better manage Diep's pain?
5. When should you reevaluate Diep's pain level, and what will indicate that your interventions have been effective?

Answers

1. No.
2. Shallow respirations, intense high-pitched cry, sleep pattern disturbance, lack of socialization
3. Pain behaviors indicate that Diep is not receiving adequate analgesia with the morphine dose administered.
4. Add a nonopioid such as acetaminophen or NSAID, if not contraindicated by current clinical condition (poor urine output, potential for bleeding). Both dose and frequency of morphine could be increased, but slow titration is required in neonates because their livers are immature, increasing the potential for drug accumulation. Reevaluate pain status. Implement biobehavioral interventions such as positioning: place firm boundaries around her, blanket rolls or parent's (nurse's) hands, to help her feel more secure; swaddle; offer pacifier, sucrose. Monitor for respiratory depression. Diep is at high risk for respiratory depression, but opioids are not contraindicated.
5. Evaluate about 60 minutes after analgesics and nonpharmacologic interventions. Effective interventions will be demonstrated by decreased amount and intensity of crying. Possibly may see increased interest in environment but, given the stress of recent surgery and altered sleep patterns for the past 20 hours, would anticipate catch-up sleep, to occur with longer periods of deep sleep.

Depending on the individual child and situation, biobehavioral interventions, used alone or in various combinations, may prove effective in reducing the physiologic, behavioral, and subjective expression of anxiety, fear, and discomfort associated with pain. They also help the child maintain control. Unfortunately their effectiveness among children is highly variable, with limited research available to support effectiveness. Also, some techniques require time to be learned and implemented. Moreover, a role model or coach knowledgeable in the technique or its performance may be unavailable at the time pain relief is needed. Always consider the child's developmental level, individual needs, and pain experience when selecting these techniques.

Parental Involvement

Parents and children want to be together during painful procedures (Henderson and Knapp, 2006). Professional healthcare organizations have begun to recognize the importance and value of the parental presence during invasive procedures (AAP and APS, 2001; American Association of Critical Care Nurses, 2004; American Heart Association, 2005; Emergency Nurses Association,

2001). Parents who are knowledgeable about what is going to happen and about specific things they can do to facilitate pain management generally feel less helpless, are less anxious, and are better able to support their children. A parent's sensitive response to a child's reaction can promote the child's coping skills.

Treatment of children's pain by parents generally is suboptimal. The Parent's Postoperative Pain Measure, a validated pain assessment tool specifically designed to help parents quantify their children's pain at home after surgery, and explicit written instructions that supplement verbal discharge directions may guide parents to provide better pain management (Finley et al., 2003, Kankkunen et al., 2003). Parents may inadvertently encourage pain behaviors in children with chronic or recurrent pain conditions by rewarding the child with special privileges or relieving them of responsibilities, such as school attendance and chores, because of their pain (Bursch, Joseph, & Zeltzer, 2003). Strategies that reduce parental anxiety have been associated with decreases in children's reports of pain and their pain behaviors (AAP and APS, 2001). Therefore, carefully prepare parents for what will happen during a procedure and detail how they can coach the child to cope (TIP 10–1).

The child may display more distress behaviors when the parent is present. Providing the child with developmentally inappropriate amounts of control, lack of parental attention to the child, and providing praise and apologies to the child rather than focusing on distraction and coping skills may elicit these distress responses (Broome & Huth, 2003; Kleiber & McCarthy, 1999). Healthcare providers and parents should focus on the child and reinforce coping and distraction strategies to reduce distress during painful procedures.

Cognitive–Behavioral Interventions

The goal of cognitive–behavioral interventions is to teach patients to identify, evaluate, and change sensory and thought patterns to facilitate coping behaviors (Gerik, 2005). Cognitive behavioral interventions are effective for facilitating cooperation with medical procedures, modifying pain behaviors, decreasing psychological disability, reducing pain, lessening reliance on analgesics,

and enhancing self-efficacy and pain coping (APS, 2005). Cognitive–behavioral plans involve providing developmentally appropriate information, including sensory information, and encouraging active participation in mind–body strategies, also known as a *coping plan*, to avert attention from pain and to modify behaviors that may initiate or exacerbate the pain. General principles of psychological care should not be overlooked (see Nursing Interventions 10–4).

Specific cognitive–behavioral interventions include task analysis, distraction, relaxation, biofeedback, and hypnosis. These strategies have been used successfully with children who have pain from procedures, major surgery, sickle cell disease, cancer, headaches, fibromyalgia, and rheumatoid arthritis (APS, 2002; Gorski et al., 2004). Children older than 8 to 9 years of age benefit from cognitive strategies, such as relaxation techniques, that they can initiate and maintain themselves. Younger children benefit from being coached in distraction, imagery, and hypnosis (McGrath, Dick, & Unruth, 2003). The effectiveness of information

TIP 10 –1 A Teaching Intervention Plan for Parents of a Child Undergoing a Painful Procedure

Nursing Diagnosis and Family Outcomes

Interventions

Deficient knowledge: Supporting the child undergoing a procedure

Outcomes:

Family will support the child during procedure.

Parents and other family members will discuss interventions they can implement to support the child during a procedure.

Include the parents when teaching the child about the procedure. Speak with the parents after teaching, not in the child's presence:

- Clarify interpretations of what was taught.
 - Correct misconceptions.
 - Discuss how the child may respond before, during, and after the procedure.
- Discuss how parents can help the child cope. Give concrete, specific, and developmentally appropriate suggestions for how they can assist their child:
- Hold the child's hand.
 - Speak in a low, soothing tone; maintain eye contact with the child.
 - Touch other parts of the child's body, depending on the child's preference (using firm touch, pressure, stroking).
 - Keep the child informed of the procedure's progress, if doing so is consistent with the child's coping style (e.g., "It's half over now").
 - Coach the child during use of previously practiced relaxation techniques (e.g., deep breathing, counting).
 - Use distraction (e.g., blow bubbles, read stories).
 - Use positive reinforcement of desired behaviors (e.g., "You are breathing so deeply"; "You are holding your hand so still") rather than apologizing (e.g., do not say "I'm so sorry they are hurting you" or "I'm sorry you have to go through this").
 - Avoid threats, such as painful procedures (e.g., injections), in an attempt to get the child to behave.

NURSING INTERVENTIONS 10–4

Providing Psychological Support for the Child in Pain

- Encourage use of previously learned coping skills; remember that children regress when stressed.
- Perform painful procedures in designated areas, *not* in the child's room or playroom.
- Do not talk over the child; talk to the child or leave the vicinity.
- Reinforce that pain is not a punishment for misdeeds.
- Be honest; clarify communication.
- Ask the child “what do you think will help you in this situation?” and “what can I do to help?”
- Give the child control whenever possible (within reasonable limits) let the child remove a dressing, help set up for a finger stick, prepare a site by wiping with alcohol.
- Suggest actions the child *can* do (“hold your leg still”), rather than actions that the child cannot do (“do not move your leg”).
- Have the child and parents practice appropriate coping actions before they will be needed; give positive reinforcement for desired behaviors.
- Use the power of suggestion to help increase the efficacy of any strategy (e.g., “when you go on an imaginary trip the lumbar puncture seems to be over faster” or “this cold massage can make your leg feel better”).

and coping strategies varies by age among adolescents (LaMontagne et al., 2003).

Advantages of using cognitive–behavioral interventions are that they are generally independent nursing actions that are noninvasive, can be used in many situations, and provide the child and family with some control over the pain. These techniques may require time and practice and may not achieve the desired results when first used.

Providing of Information and Task Analysis

Ideally, preparation is done before the child is in pain. When a painful event happens under emergency conditions, preparation occurs almost concurrently.

Provide children and families with concrete, objective information about painful diseases, and before surgeries and other medical procedures (see Nursing Interventions 10–5). Be honest if pain is anticipated.

Break down complex procedures into specific steps and reinforce coping strategies for each distinct task. Model, or demonstrate, coping behaviors. Detail parents' coaching role and reinforce the need to emphasize the coping plan, rather than praising the child or apologizing for the pain.

Encourage the child to take an active role in managing situations. Feeling in control of a situation may reduce anxiety. The child might help remove a dressing, pick the site in which to insert an IV line, or arrange a schedule for the day (given that certain events must occur).

KidKare ■ Give sensory information such as “this may feel like it is pinching, stinging, poking, cold” or “you might not feel much of anything; tell me what it feels like for you.” Tell the child it may hurt, but that there are things that can be done to help make it not so bad.

Distraction

QUESTION: George is receiving an around-the-clock medication regimen; however, if he experiences breakthrough pain he is able to distract himself effectively with action life-and-death video games. Do you think other teenage boys would also find these a successful distraction from pain?

A goal of distraction interventions is to divert the child's attention away from the pain through controlled, purposeful behaviors (see Tradition or Science 10–2). A variety of distractors have been tested with children for painful procedures: party noisemakers and bubble blowers, kaleidoscopes, nonprocedural talking and listening to stories, humor and jokes, music, puppetry, counting, pop-up books, videos, and video games (Fig. 10–11). The distractor must be unique and powerful enough to hold the child's attention, leaving fewer attentional resources available to focus on distressing and painful stimuli (Carlson, Broome, and Vessey, 2000). This finding has inspired the use of virtual reality devices and the development of pain reduction programs tailored to specialized patient populations (Das et al., 2005; Gershon et al., 2004; Wint, Eshelman, Steele, et al., 2002).

Distraction techniques should be developmentally appropriate and tailored to the child's preferences. If distraction is successful, remember that the child will display fewer overt signs of distress even if pain is not reduced. Therefore, distraction techniques should be used with pharmacologic interventions if the situation warrants.

NURSING INTERVENTIONS 10–5

Helping the Child Cope With Planned Painful Events

Before the Procedure

- Be honest and specific about what will happen, if doing so is consistent with the child's coping method.
- Give information as appropriate to the child's developmental level and previous experiences. The older the child, the more details should be included with rationales for actions, and the further in advance of the event the child should be told:
 - Infant: As the procedure is carried out
 - Toddler: Immediately before the procedure (does not understand the rationale for a painful procedure)
 - Preschool/child younger than age 7 years: Up to a day in advance (unable to reason beyond the immediate event, because understanding of cause and effect does not emerge until early school age)
 - Older child: Several days in advance (gives the child time to think about what methods they can use to cope in the situation).
- Give procedural information:
 - What is to be done and why
 - Where the procedure will occur (treatment room, operating room)
 - How the child will get to where the procedure will be performed
 - What equipment will be used
 - Who will be in the room
 - Who will do the procedure
 - How long it will take
- Show the child the room and let him or her manipulate equipment when possible.
- Give sensory information:
 - What the room will look like
 - Sounds the child may hear (e.g., beeping from the pulse oximeter, buzzing alarms, machinery moving)
 - Smells to expect
 - How it will feel (e.g., hard table, cold antiseptic, pressure, pinch)
- Elicit and answer questions. Discuss what the child thinks will happen, how they usually respond to similar situations, and things they might do to cope with this one.
- Prepare room and equipment before bringing child to room; seeing things being set up or delays in performing procedure heighten anxiety.

During the Procedure

- Administer analgesics and anesthetics to prevent and relieve the pain of the procedure.
- Implement biobehavioral interventions:
 - Ensure that favorite objects (blanket, stuffed animal) are present.
 - Minimize extraneous noise; move noisy machines, mute alarms; speak quietly in a low tone.
 - Avoid sudden, jarring movements.
 - Position the child for comfort within restrictions for the procedure.
 - Tell the child what you are doing, if doing so is consistent with the child's coping method.

After the Procedure

- Give a clear signal when procedure is finished (pick up, sit up, "it's done now").
- Review the experience with child and family (play therapy).
- Clarify perceptions.
- Reinforce or reward positive coping behaviors.
- Discuss alternatives for future success.

ANSWER: The text states "the distractor must be unique and powerful enough to hold the child's attention, leaving fewer attentional resources available to focus on distressing and painful stimuli." Action video games have demonstrated a unique ability to engross teenagers' attention. Therefore, they are likely to be applicable to other teenagers.

Relaxation

Relaxation eases pain by decreasing stress, reducing muscle tension, inducing feelings of control, changing autonomic reactivity, and providing distraction (McGrath et al., 2003). Relaxation alone is effective in treating children's migraines and other headaches (Eccleston et al., 2003).

However, no data indicate that relaxation alone is effective in lessening chronic, cancer, surgical, or procedural pain, and therefore it should be combined with analgesics, distraction, imagery, or hypnosis (McGrath et al., 2003).

Relaxation training teaches children awareness of and control over physiologic and muscular reactions to anxiety. Children should learn and practice relaxation techniques with a coach before using them. Under stressful conditions, a support person may be needed to guide the child in relaxation techniques.

KidKare ■ When teaching relaxation techniques, keep the environment quiet. Enhance relaxation by telling children to feel their bodies sinking into the furniture.

TRADITION OR SCIENCE 10–2

Is distraction effective in reducing pain?

EVIDENCE-BASED PRACTICE

Research evaluating the efficacy of distraction for pain reduction suggests a variable but overall reduction in children's observed distress behaviors (Cohen, 2002; Kleiber & Harper, 1999; Landolt, Marti, Wildmer, & Meuli, 2002; Windich-Biermeier et al., 2007). A number of factors influence children's response to painful procedures and influence the effectiveness of distraction when parents serve as distraction coaches (McCarthy & Klieber, 2006).

Infants exposed to movie distraction displayed fewer distress behaviors than infants not exposed (Cohen et al., 2006). Virtual reality games have been effective in reducing children's self-reported pain during procedures (Das et al., 2005; Gershon et al., 2004; Wolitsky et al., 2005). A meta-analysis that included 28 randomized controlled trials with 1,951 children found that distraction, as well as hypnosis, was effective in reducing self-reported pain in children undergoing needle-related procedures. Combined cognitive-behavioral interventions reduced observer-reported and behavioral measures of child distress (Uman et al., 2006). Another meta-analysis of 19 studies with a total sample of 535 children concluded that distraction reduced distress behavior and self-reported pain (Kleiber & Harper, 1999). Research demonstrates that distraction is effective in reducing pain behaviors. Distraction should not be used as a replacement for pharmacologic management if the situation warrants such.

Instruct them to wipe their minds clean, like a blackboard, thinking of nothing but the words that you are telling them. Speak in a calm, low, measured tone.

Deep breathing and tension-relaxation (alternately tensing and relaxing specific muscle groups) are two common relaxation techniques used in clinical practice. One deep breathing method is to have the child slowly take

FIGURE 10–11. A child using distraction for pain management.

five deep breaths in through the nose and slowly exhale through pursed lips. Monitor for hyperventilation when implementing these breathing techniques. Consider instructing the child using a PCA pump to use this technique after pushing the PCA button. If the pain is not relieved after taking 100 deep breaths, the child should push the PCA button again.

Another breathing method is to have the child count from 1 to 10, saying the number with each exhalation, and gently inhaling through a slightly open mouth. This sequence can be repeated until the child experiences calm. “Blowing the pain away” can be particularly effective with younger children. At the first sign of pain, children are taught to take a breath and blow out as hard as they can. Doing so helps them to maintain control by acting upon the aversive stimulus, rather than letting it overwhelm them.

Muscle relaxation can be taught in a variety of ways. A descriptive way to help children learn what tenseness and relaxation feels like is to tell them, “Hold your arms [legs] out very straight, tense or squeeze your muscles until the count of 10 [count from 1–10], now let go.” Or “Breathe in and hold it. Feel the tightness in your chest. Breathe out all at once and feel the tension leaving your body completely.” Another method of muscle relaxation is to start with the feet and work gradually up the body. For example, “Feel your feet relaxing, sinking into the mattress. They are very heavy. Now feel your calves sinking further down, very relaxed,” and so on.

Biofeedback Training

Biofeedback is another technique for teaching relaxation. Computer programs provide a visual depiction of physiologic functions. This visual feedback enables children to recognize and alter physiologic functions, like muscle tension, skin temperature, and heart rate, by using their body's responses, like a video game controller. The child is instructed to use mental imagery to increase or decrease reactivity in the system being monitored. Reinforcement occurs when the child is able to effect change in the desired direction, thus strengthening self-control over the physiologic function. Use of biofeedback requires specialized training and equipment. This technique has been effective in reducing and relieving pain from migraines and recurrent headaches, chronic regional pain syndrome type I, and fibromyalgia (Andrasik & Schwartz, 2006; McGrath et al., 2003).

Imagery and Hypnosis

Imagery is a method of distraction and can also enhance relaxation. Children are actively involved in creating vivid, visual daydreams, picturing themselves engrossed in a pleasant situation or visualizing creative ways to decrease their body's pain, such as pain switches or magic gloves (Kuttner, 1986) (see Nursing Interventions 10–6). Imagery and hypnosis have been shown to reduce pain from procedures, cancer, surgery, migraine, and chronic abdominal pain (Butler et al., 2005; Huth, Broome, & Good, 2004, Kohen and Zajac, 2007; Miranda and Sood, 2006).

NURSING INTERVENTIONS 10–6

Imagery: The Pain Switch and Magic Glove

Coach the child in using imagery to help “block” the traveling of pain messages. The *pain switch* controls the area of pain (e.g., leg, arm, abdomen) and the child visualizes turning the pain switch off to that area, so that messages cannot travel, much as a light switch controls electricity. Color can also be incorporated into the imagery. Have the child picture a color—for example, red when pain can travel or is present, black when the switch is turned off.

A *magic glove* can be “put” on the hand, finger by finger, to diminish the pain associated with venipuncture or finger stick. A magic blanket might be used in areas where a glove would not work, such as the back or abdomen. The hands are extremely sensitive parts of the body. One can take the magic glove and hold it over other parts of the body (e.g., over the cheek before dental work) to induce numbness or decrease pain.

Imagery begins with achieving a relaxed state. Guide the child to choose a favorite place. Cue the child to experience this familiar surrounding by exploring the sights, sounds, smells, and their feelings when they are in the special place. For example, if the child likes the beach, have them imagine walking and feeling the sand between the toes, feeling the sun warming the body, the cool water on his or her feet or knees, and hearing the waves lapping at the shoreline. For an amusement park, suggest smelling the popcorn, hearing the people, seeing the lights, riding the roller coaster. Throughout the experience, let the child be the guide. Prompt the images of “what do you see, hear, smell, feel, or taste?” “what are you doing now?” or “where are you going?”

Be aware of fears the child has, such as of water, animals, or activities, so that they are not brought into the imagery, making it a negative experience. Do not lead the child; let the child become immersed in their personal image and take command of the experience.

Hypnosis is an altered state of consciousness, an intensified trance, in which concentration is focused and absorbed, and attention is intensified, yet the child is physically relaxed. Peripheral awareness is reduced, but social cues are heightened (Butler et al., 2005). The child dissociates from immediate physical surroundings and experiences, allowing perceptions and sensations to be modified or enhanced. Success, as measured by physiologic responses to hypnosis, indicates that results do not depend on the patient’s expectations (APS, 2005). Hypnosis is effective in reducing pain, but not in alleviating pain, so analgesics are also required. A hypnotic state must be induced under the supervision of an experienced practitioner.

Imagery and hypnosis are diversionary methods that require practice and training. These techniques are not appropriate for infants and toddlers, but they are highly effective with children, whose cognitive boundaries permit captivation in imagination.

Biophysical Interventions

Biophysical management techniques attempt to affect physiologic responses directly during painful experiences. Biophysical strategies used to reduce pain in older children and adolescents are generally contraindicated in high-risk neonates because of the physiologic response that is evoked, which may cause deleterious vital sign changes and make the infant more susceptible to intraventricular hemorrhage. Strategies appropriate for older children include cold, heat, traditional massage, acupuncture and acupressure, and transcutaneous nerve stimulation. Nursing Interventions 10–7 and Tradition or Science 10–3 provide developmentally appropriate biophysical interventions for preterm and high-risk infants.

Positioning

Swaddling and holding are comforting and help infants and small children achieve a more relaxed state. Facilitated tucking (in which the caregiver places a hand on the infant’s head and feet while providing flexion and containment) (Ward-Larson, Horn, & Gosnell, 2004), swaddling (Huang et al., 2004), and other positional interventions serve to limit excessive, uncontrolled movements that may exacerbate pain. They also provide physical boundaries that may assist infants in organizing themselves. Infants older than 3 to 6 months often fight against swaddling, which may intensify anxiety and pain. The amount of comfort derived from being held is a function of the individual child’s personality and situation.

Proper positioning and splinting provides support for and decreases muscle tension over painful areas (Fig. 10–12). The child’s situation dictates appropriate actions: Pressure on an incision may exacerbate pain but might be helpful when a child with an abdominal incision has to cough and breathe deeply, pressure may reduce abdominal pain caused by gas, or elevation of a swollen extremity may decrease swelling and thus pain.

During procedures, positioning for comfort (a secure, parental-hugging hold and close physical contact) has not been demonstrated to be more effective at reducing pain, fear, and distress scores than traditional procedure positioning (laying the child down and restraining them) (Cavender et al., 2004), although upright positioning during IV starts reduces distress scores (Sparks, Setlik, & Luhman, 2007).

Cutaneous Stimulation

Cutaneous stimulation is often applied over the painful area. This technique may not be possible in some situations, as with an extremely painful area, altered skin integrity, or with a cast or dressing in place. When direct cutaneous stimulation is not feasible, alternative sites may be used, including sites adjacent to the painful area,

NURSING INTERVENTIONS 10–7

Biobehavioral Pain Management and Comfort Strategies for Infants

Using several methods can enhance soothing. Monitor infants for cues indicating stress (e.g., gaze aversion, hiccups, finger splaying [rigid extension and separation of fingers], yawning, fussing, becoming limp, going into a sleep state or “shutting down,” bradycardia) and implement or withdraw interventions on the basis of the infant’s response. Ability to comfort is a function of the child’s unique response, the pain situation, the interventions implemented, and the caretaker’s sensitivity in reading the baby’s cues.

- Environmental stimuli: Dim lights, decrease noise.
- Supportive boundaries: Use blankets, bunting; adult hands surround infant, containing the child but not moving.
- Swaddling: Tightly wrap in blanket with extremities flexed and hands uncovered to facilitate hand-to-mouth behavior; tight wrapping provides too much stimuli for preterm infants, who should be loosely wrapped with boundaries to push against, which gives a feeling of containment and security.
- Positioning: Decrease muscle tension and pulling on painful area, limit movement—for example, support legs in a flexed position if there is an abdominal incision, elevate extremity.
- Hand-to-mouth behaviors: Encourage.
- Sucking: Offer pacifier, thumb, or fingers.
- Sweet solutions: Encourage breast-feeding or give oral sucrose solution or glucose, or coat a pacifier with the solution and let the infant suck on it 2 minutes prior to and during painful procedures (may decrease pain perception); remove the pacifier when the procedure is completed and infant is calm.
- Auditory stimuli: Use uterine sounds, instrumental music, humming, parent’s voice (more effective with older infant); make sure not to overstimulate the child.
- Holding: Support parent with proper armrests, footrests, pillows so the parent is comfortable.
- Rocking: Use rhythmic, continuous, horizontal motions (the person holding stands and gently turns trunk side to side, with feet stationary, so that the child moves in the horizontal plane).
- Touch: Use firm pressure or stroking; preterm infants do better with firm touch on their head or heels, not the trunk.
- Visual stimuli: This is more effective with an older infant. Use parent’s face, pictures, mobiles.
- Recovery periods: If infant is showing signs of stress, stop procedures when possible and allow infant to reorganize; implement other comfort measures to augment those already in use.

between the pain and the brain, or the contralateral site. Use caution when applying cutaneous strategies in preterm infants to avoid physiologic instability and damaging their more friable skin.

Massage improves circulation, loosens tight joints, decreases stress hormone levels, promotes relaxation and sleep, and can help in pain relief. In adults, foot and hand massage has been shown to further reduce surgical pain when used as an adjunct to analgesics (Wang & Keck, 2004). Massage may be done on the total body or localized to the back, extremities, or painful area (use alternative sites if massage directly applied to the painful site is not tolerated). Use a firm movement to massage, particularly with ticklish children. Gentle massage of the leg for 2 minutes prior to heel stick may decrease pain response in preterm infants (Jain, Kumar, & McMillan, 2006).

Healing or *therapeutic touch* is another cutaneous intervention that may relieve pain. Studies suggest it may be beneficial for pain; however, studies are minimal and results not conclusive (Bardia et al., 2006; Engebretson and Wardell, 2007).

Thermal cutaneous therapies involve application of heat or cold. Heat acts through conduction or convection to increase blood flow to skin and superficial organs, but decreases blood flow to underlying muscles, which pro-

motes muscle relaxation (APS, 2005). Thermoreceptors in the skin are activated by heat (McCarberg & O’Connor, 2004). These receptors generate nerve signals that block nociception in the spinal cord. Heating devices appropriate for thermal application include hot packs, hot water bottles, warm moist compresses, heating pads, chemical gel packs, and warm baths. Muscle temperature should reach at least 40°C (104°F) to achieve optimal biophysical effect (McCarberg & O’Connor, 2004). Heat is most effective in relieving pain from inflammation and spasm.

Cold causes vasoconstriction and local hypoesthesia, reducing swelling and muscle spasm (APS, 2005). Wrap ice, ice packs, and chemical gel packs to protect the skin from direct contact and apply for no more than 15 minutes at a time. Ice massage is effective for injection pain, headaches, toothaches, or brief, painful procedures. Ice massage may be done using an ice cube. Another convenient method is to fill a paper cup with water and freeze it; the water expands over the cup edges and the cup is held at the bottom to massage. Use circular or back-and-forth motions. Have the child lie on a plastic-backed pad to absorb melting water. Cold therapy is contraindicated in vaso-occlusive conditions such as sickle cell disease (APS, 2005).

TRADITION OR SCIENCE 10–3

Are nonnutritive sucking and sweetened solutions effective in reducing pain behaviors in infants?

EVIDENCE-BASED PRACTICE

Sucking during painful stimuli such as circumcision, in addition to other analgesia such as dorsal penile nerve blocks (South et al., 2005), heel stick (Akman et al., 2002; Blass & Watt, 1999), and eye examinations (Mitchell et al., 2004) attenuates pain distress behaviors and has a pacifying effect for preterm infants and newborns. Sucking a pacifier at a rate of at least 30 sucks per minute provides an analgesic effect (Blass & Watt, 1999). No short-term negative effects of nonnutritive sucking have been identified; data on long-term effects are not available (Pinelli, Symington, & Ciliska, 2002).

One of the most widely studied biobehavioral interventions for neonatal procedural analgesia is the use of sweet-tasting substances. Studies in rats demonstrated raised pain thresholds with the use of sucrose and reversal of these effects by an opioid antagonist (Blass, Fitzgerald, & Kehoe, 1987). Thus, it was hypothesized that sucrose, and perhaps other sweetened solutions, have analgesic properties that are mediated through opioid pathways.

Reduced cry times and pain scores have been demonstrated in preterm and term infants given varied concentrations and amounts of sucrose and glucose solutions (Akcam & Ormeci, 2004; Akman et al., 2002; Gradin et al., 2002; Greenberg, 2002; Mitchell & Waltman, 2003; Mitchell et al., 2004; Razmus, Dalton, & Wilson, 2004; Reis et al., 2003; Taddio, Shah, Shah, & Katz, 2003). Sucrose and glucose are effective for providing analgesia during procedures with as little as 0.05 to 2 mL 7.5% to 50% concentration (Okan et al., 2007; Wong et al., 2003). Repeated use of sucrose for procedural pain in preterm infants is effective and safe (Stevens et al., 2005). Sucrose and glucose are easy-to-use methods of pain relief for infants. The analgesic effect of these sweetened solutions fades as children age. Future research is needed to identify when and why these analgesic properties vanish.

Similar analgesic effects have been noted with breastfeeding in healthy newborns (Efe & Ozer, 2007; Gray et al., 2002; Shah, Aliwalas, & Shah, 2006). The sweet milk or the skin-to-skin contact may be the key to the success of this intervention. Kangaroo care, in which the preterm neonate is placed in skin-to-skin contact with a parent, has also been shown to decrease physiologic measures (Ludington-Hoe, Hosseini, & Torowicz, 2005) and objective pain scores after heel lancing (Johnston et al., 2003b). Maternal holding is more analgesic than nonmaternal holding (Phillips, Chantry, & Gallagher, 2005).

Researchers have tried to differentiate the benefits from nonnutritive sucking and sucrose, but have concluded that a combined approach is best for relieving the pain of heel sticks and other painful procedures (Akman et al., 2002; Greenberg, 2002; Mitchell et al., 2004).

FIGURE 10–12. Children will often assume a position of comfort to alleviate pain, such as see in this child who flexes his knees after abdominal surgery. Distraction with electronic games and parental presence may also help reduce pain perception.

Alert! Heat and cold applications are not recommended for use on infants, who are more prone to thermal injury because of their skin structure. These interventions should also be avoided in children with conditions that alter skin sensations, such as spina bifida, or nonverbal children who are unable to alert care providers of temperature extremes that may cause tissue injury. Stop thermal therapies if the child complains or if blanching or redness occurs; monitor skin integrity. Do not use on sleeping children.

Acupuncture and Acupressure

The premise underlying acupuncture and acupressure is that pain is relieved by strategically placing needles (acupuncture) or pressure (acupressure) to restore the flow of chi (qi) through the 12 meridians of the body. Few studies have investigated the effectiveness of acupuncture or acupressure for children (Kundu & Berman, 2007). Studies in adults indicate that acupuncture reduces the pain of dental restoration, sickle cell disease, low back pain, dysmenorrhea, and migraine headaches.

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) is a method by which a small electrical current is applied to the skin by conductive pads attached to a battery-operated generator. Parameters such as amplitude (amount of energy applied to skin), rate (number of times the nerve is stimulated per second), and pulse width (depth of stimulation) can be variably set depending on the effect desired. Electrodes are placed around the painful region or along peripheral nerve routes, acupuncture or trigger points, or at spinal segments. The mechanism of action is thought to be through stimulation of large-diameter cutaneous nerve fibers that inhibits nociceptive responses at the spinal cord and descending pathway. Low-frequency and high-frequency TENS also lead to the release of endogenous opioids. TENS is contraindicated in patients with pacemakers, over the carotid artery or eyes, or while driving (McCarthy, Shea, & Sullivan, 2003). Although clinical evidence indicates TENS is

effective at relieving pain, few studies have been done with children.

When used at conventional settings, TENS causes a tingling, buzzing sensation. This sensation, coupled with being unfamiliar with the machine, may produce fear in the child. Demonstrate use of the equipment on a parent, and then suggest the child try it on a nonpainful area. When the child appears comfortable with the machine, suggest using TENS for a painful area.

Management of Special Pain Situations

Managing procedural or chronic pain requires some of the same management strategies as acute pain, but additional techniques are important to consider. Other special situations include managing pain in the emergency department, in a child who is handicapped, and at home.

Procedural Pain

Managing procedural pain requires considering not only the type of procedure and the anticipated intensity and duration of pain, but also the meaning of the event, the coping style and temperament of the child, the child's pain history, and the family's ability to minimize the child's distress and provide comfort during the procedure. Limit the number of painful procedures to only those that are absolutely necessary. Painful procedures should be performed in the least painful manner and performed or supervised by the most skilled clinical personnel (AAP and APS, 2001). Use behavioral coping strategies and local anesthetics whenever possible. To help reduce fear and anxiety, which may increase perception of pain, prepare the child and parents for the procedure (see Nursing Interventions 10–5). To help decrease anxiety and increase comfort, address basic comfort measures such as hunger (if food and fluids are not restricted prior to the procedure) and thermal regulation; have the child void prior to the procedure.

Local Anesthetics

Local anesthetics can alleviate procedural pain (e.g., from lumbar puncture, venipuncture, or wound repair). Local anesthetics can be delivered in a number of different formulations. The topical (transdermal) route can be used to give medications painlessly or to reduce the pain of local infiltration. The onset of anesthesia of these local anesthetic solutions is between 2 and 60 minutes, varying by product and technique. Topical anesthetics should be applied when needles are to be used (e.g., IV insertion, lumbar puncture, bone marrow aspiration, laceration repair).

Apply skin anesthetics such as lidocaine–prilocaine, liposomal lidocaine, or amethocaine to intact skin before a procedure (Tradition or Science 10–4, Fig. 10–13). Properly timing administration can be accomplished by organizing nursing care or having the child or family apply the agent on an outpatient basis.

Local anesthetics can be injected subcutaneously with a small needle into the skin around the area to be manipulated. Do this 5 to 10 minutes before the procedure and test the area for insensitivity before beginning the

TRADITION OR SCIENCE 10–4

Which topical agents are most effective in reducing procedure-associated pain?

EVIDENCE-BASED PRACTICE

Lidocaine–prilocaine cream (e.g., EMLA [eutectic mixture of local anesthetics]) and lidocaine dispersed in liposomes (e.g., LMX4, Maxilene) have been demonstrated to be equally effective for topical anesthesia (Kleiber et al., 2002; Koh et al., 2004). Liposomal lidocaine is more effective than placebo (Taddio et al., 2005). Lidocaine–prilocaine requires covering with an occlusive dressing for 60 minutes prior to the procedure whereas liposomal lidocaine does not require occlusion and provides skin anesthesia within 30 minutes. Liposomal lidocaine also produces few adverse skin reactions (Taddio et al., 2005). Amethocaine (tetracaine), which requires occlusion for 30 to 45 minutes, is as effective as lidocaine–prilocaine (O'Brien et al., 2005) if not superior in reducing pain (Lander, Weltman, & So, 2006). In infants, topical tetracaine has not been demonstrated to reduce pain associated with venipuncture (Lemyre et al., 2007) or with peripherally inserted central catheter (or PICC) insertion (Ballantyne et al., 2003). Pretreating the skin with laser may reduce the time required to achieve anesthesia with transdermal agents (Koh et al., 2007; Singer, Weeks, & Regev, 2006).

The efficacy of injected buffered lidocaine and liposomal lidocaine are comparable (Luhmann et al., 2004). Needle-free jet injection systems also can be used to deliver lidocaine and prevent pain upon venipuncture better than placebo (Migdal et al., 2005) or lidocaine–prilocaine cream (Jimenez et al., 2006). Jet injection systems achieve a more rapid onset of action (2–3 minutes), than creams (Migdal et al., 2005). However, they are not pain free and they are more expensive than needles (Lysakowski et al., 2003); depending on facility charges, costs may be comparable with topical creams.

An advantage of skin refrigerants is their rapid onset of action, but they are equally effective as other topical agents such as amethocaine (Davies & Molloy, 2006; Soueid & Richard, 2007), lidocaine–prilocaine (Reis & Holubkov, 1997), placebo (Costello et al., 2006), or no intervention (Costello et al., 2006; Soueid & Richard, 2007). Applying an ice bag for 3 minutes prior to venipuncture reduced subjective and behavioral pain responses in school-aged children (Movahedi et al., 2006).

Evidence varies on the efficacy of lidocaine–prilocaine cream versus iontophoresis. Galinkin et al. (2002) found that they are comparable; others found that lidocaine–prilocaine cream provides better analgesia (Moppett, Szypula, & Yeoman, 2004; Squire, Kirchoff, & Hissong, 2000). Although erythema, pruritus, and tingling occurred in the iontophoresis group, pain scores and time required for adequate anesthesia were less than in the EMLA group (Squire et al., 2000).

Regardless of the use of topical agents, some children still report high pain levels that may be influenced by

genetics. Children reporting higher pain were younger, more active, had higher state and trait anxiety, and possessed a specific genotype (Kleiber et al., 2007).

The agent and method of topical analgesia is situation specific. Factors to consider when selecting local anesthetic agents for clinical use include efficacy, ease of use (factoring in time and technical requirements), minimal side effects, and cost. Walsh and Bartfield (2006) found that parents are willing to spend both time and money to reduce the pain of their child's IV catheter placement.

procedure. Arguments against using locals are that the “caine” stings for about 30 seconds after injection and the child is subjected to an additional injection.

caREminder

The stinging sensation caused by lidocaine can be reduced by buffering the solution (9 parts lidocaine to 1 part sodium bicarbonate), which raises the pH of the solution.

The small needle used for infiltration of the tissue with lidocaine most commonly causes less pain, however, than when the area is manipulated without the benefit of the local anesthetic.

Dermal anesthetics are intended for application to broken skin such as laceration repair, where they can reach dermal structures, blood vessels, and nerve endings (Shainhouse & Cunningham, 2004). In contrast to skin anesthetics, these agents (e.g., lidocaine, adrenaline, and tetracaine; lidocaine–epinephrine; tetracaine–phenylephrine) do not penetrate the dermis well. Follow the manufacturer's directions for use of the agent; some are not recommended for use on mucous membranes or body parts supplied by end arteries, such as the fingers or toes, because of the potential risk of ischemia from the vasoconstrictive effects of epinephrine. Apply agents to the wound 10 to 30 minutes prior to suturing. Look for blanching of the wound bed to assess effectiveness.

FIGURE 10–13. EMLA cream reduces the pain of IV catheter insertion and reduces the child's distress. Cover two potential sites in case the first stick is unsuccessful.

Iontophoresis of lidocaine uses an electric field to drive local anesthetics across intact skin. Iontophoresis provides analgesia in 10 to 25 minutes, depending on the amount of electric current used. The grounding electrode often causes a tingling sensation that children may not like; place the medication electrode on the child and the grounding electrode on a parent and maintain skin-to-skin contact between the parent and child.

Alert! Do not use iontophoresis on body parts supplied by end arteries. If the child complains of undue burning or pain during treatment, pause the treatment and inspect the site under the electrode. Stop the iontophoresis if excessive irritation is present or discomfort persists.

Vapocoolant sprays or skin refrigerants (e.g., Frigiderm, Fluro-Ethyl, Pain-Ease) cool the skin, which may decrease the number of pain impulses being transmitted. Spray the refrigerant for a few seconds onto the cleansed and prepared site immediately before needle insertion. It can also be sprayed onto a cotton ball. The cotton ball is then applied, using forceps, to the injection site for 15 seconds.

Sedation

Sedation is a depressed state of consciousness induced by the use of medications. It is generally used for painful procedures such as bone marrow aspiration, lumbar puncture, laceration repair, and fractures, but may be used for nonpainful procedures such as magnetic resonance imaging or computed tomography. When sedation is planned, nothing is given by mouth for 2 hours before the procedure. Clear liquids may be consumed up to 2 hours before the procedure; breast milk may be consumed up to 4 hours before the procedure; infant formula, nonhuman milk, and light foods may be consumed up to 6 hours before the procedure (American Society of Anesthesiologists, 1999).

Alert! When sedation is induced, one member of the healthcare team, proficient in pediatric basic life support, must continually monitor the child, with this being the member's only responsibility. Moderate sedation can readily progress to deep sedation, rendering the child unable to maintain protective reflexes and a patent airway.

Personnel competent to perform pediatric advanced life support, particularly airway management and intubation, and equipment for resuscitation must be readily available. Continuously monitor the child's oxygen saturation and heart rate; the use of capnography is encouraged (American Academy of Pediatric Dentistry, et al., 2006). Document vital signs such as heart rate, respiratory rate, blood pressure, oxygen saturation, and level of consciousness at least every 5 minutes (Nursing Interventions 10–8).

Chronic Pain

Pain that persists a month beyond the usual expected disease or injury course is considered chronic. In contrast to

NURSING INTERVENTIONS 10–8

Child Undergoing Procedural Sedation

- Ensure availability of appropriately sized resuscitation equipment and opioid receptor antagonist (naloxone) and benzodiazepine receptor antagonist (flumazenil), as appropriate. Administer as ordered or per institution protocol.
- Review child's health history. Note and inform prescriber of conditions that would make the child more vulnerable to the effects of sedating medications (e.g., hepatic, renal, or cardiovascular dysfunction). Ask about medication and latex allergies.
- Obtain information about medications that the child is taking.
- Elicit history of previous sedation.
- Verify that the child has fasted for the ordered length of time.
- Teach the child and family about the effects of sedation.
- Assess the child's level of consciousness and protective reflexes before sedation.
- Obtain baseline heart rate, respiratory rate, blood pressure oxygen saturation, and carbon dioxide level, as appropriate.
- Place an IV catheter, as appropriate.
- Administer medications as per prescriber's order or institution protocol.
- Monitor the child's heart rate, respiratory rate, blood pressure, oxygen saturation, carbon dioxide level, and level of consciousness and responsiveness per institution protocol.
- Monitor the child's electrocardiogram, as appropriate.
- Monitor the child for adverse effects of medication including excessive somnolence, respiratory depression, hypercarbia, hypoxemia, apnea, arrhythmias, and agitation.
- Position the child as appropriate for the procedure and ensure a patent airway.
- Provide airway and respiratory support (airway positioning, supplemental oxygen, bag-mask ventilations) if indicated.
- Evaluate whether the child meets discharge criteria: sufficiently recovered from the effects of medications and return to baseline leveling of functioning (stable cardiovascular function and airway patency, can be aroused, can talk and follow directions as age appropriate, has age-appropriate motor skills [e.g., infant can sit, older child can walk], and has an adequate state of hydration). Evaluate handicapped children for return to their baseline status.
- Give families written discharge instructions.
- Document all medications and fluids administered (dose, route, time), vital signs, monitoring devices used (continuous pulse oximetry), untoward or significant reactions and actions taken, child's response, and discharge instructions given.

acute pain, chronic pain does not have a biologically protective function. Some causes of chronic pain in children are cancer, sickle cell disease, juvenile rheumatoid arthritis, and recurrent pains (headache, abdominal and limb pain). Distinguishing between acute and chronic pain is important, because assessment and management differ.

Impact on the Child

QUESTION: It may not be possible to isolate the effect of chronic pain from the amputation and the effect of metastatic disease, but what are some of the most significant changes in George's life?

The effects of chronic pain on the child may include sleep disturbances, exhaustion, irritability, mood disturbances, and depression. These effects are probably related to depletion of serotonin and endorphins. Many children respond to chronic pain by regressing to earlier developmental stages. Another reaction may be an increased response to minor injuries. For example, an

exaggerated response would occur when a child bumps his or her knee and then reports that it hurts horribly and cries for 20 minutes.

The primary task of childhood is achievement of developmental milestones such as socialization and self-differentiation. Chronic pain may delay acquisition of normal skills. For example, an infant may experience feeding problems or motor development delays related to limitation of movement. A school-aged child may experience withdrawal, or delay in achieving self-care skills or achieving socialization skills involving school or peer involvement (Developmental Considerations 10–5).

The extent to which pain affects a child depends on the interplay between physical limitations caused by the pain and the degree to which physical and emotional factors interfere with activities of daily living. Children may restrict themselves to activities that are easy for them, not trying new activities that could promote a sense of success and accomplishment and enable them to acquire new skills. Achievement of milestones may also be delayed because parents are overprotective and may limit the child's experiences, for fear they may exacerbate the pain.

DEVELOPMENTAL CONSIDERATIONS 10–5

Potential Effects of Chronic Pain

Children of all ages respond to ongoing pain by regression to earlier stages of development.

Infant

Withdrawal or difficulties in social interactions
Feeding problems
Sleep pattern disturbances
Motor development delays related to limitation of movement

Toddler and Preschooler

Withdrawal, aggression
Motor lags
Loss of recently achieved developmental milestones (e.g., toileting, motor skills)

School-Aged Child

Withdrawal, aggression, out-of-control behaviors, depression
Delay in achieving self-care skills
Delay in achieving socialization skills (school and peer involvement)

Adolescent

Alteration in body image and peer relationships
Withdrawal, oppositional behavior, depression
May affect achievement of independent self-care skills

ANSWER: The greatest change for George is that he no longer attends school. He and his family have countered that loss by taking online high school courses as a means of achieving his developmental goals.

Effect on the Family

QUESTION: Who do you think is especially vulnerable in the Tran family?

Negative repercussions are usually seen in the family system when a member suffers from chronic pain. In addition to those of the patient, the needs of the parents and siblings must be recognized and addressed. The ongoing nature of the child's suffering may result in exhaustion and ensuing irritability. Parental employment may be jeopardized by the time and energy demands imposed by the situation. Other financial problems may occur because of expenditures related to the pain.

Siblings of the child in pain may feel neglected because of the increased attention focused on the child experiencing pain. Marital difficulties may be caused by the prolonged stress on the family system. The parents may feel inadequate that they are unable to help their child or prevent the child's suffering. This feeling of inadequacy can manifest itself as anger, directed inward as depression, directed at each other, or, not uncommonly, directed at healthcare providers. Feelings of inadequacy may also be manifested as controlling behaviors by the parents, such as stating that only a certain nurse can take care of the child. Remember that the parent is generally acting out of concern for the child and may use control as a coping strategy. Be sensitive to the parent's needs, recognizing that the parent knows the child better than other members of the healthcare team.

caREminder

Involve the family as fully as they wish to participate in healthcare decisions concerning management of their child. If a parent's controlling behaviors are interfering with the treatment regimen, convene a care conference to reevaluate the treatment plan and rationales for decisions, and maintain a consistent approach by the healthcare team.

Children experiencing chronic pain may find that others discredit their complaints or label them as psychosomatic. Assessment and management of these children require astute perception and a holistic approach, embracing the philosophy that the health team is working *with* the family in achieving the desired outcomes.

ANSWER: George's sister, Ashley, is particularly vulnerable. She has a previous history of depression (see Chapter 29), which may resurface with her family and brother's suffering.

Assessment of Chronic Pain

QUESTION: Assess and evaluate George's pain management assessment and treatment plan from the case study at the beginning of the chapter.

When pain is chronic, the methods and tools used for acute pain may assist in the assessment process. Often, because persistent pain results in adaptation, one does not see the more dramatic response behaviors that are seen with acute pain. Therefore, depending primarily on physiologic indices such as vital sign changes, which have since stabilized, may prevent the nurse from recognizing many instances of pain (Chart 10–2). The initial response to chronic pain can result in behavior and school problems before a diagnosis is even made. A common marker of the dysfunction caused by the pain is school avoidance (not attending school regularly).

CHART 10–2 SIGNS AND SYMPTOMS OF CHRONIC PAIN IN CHILDREN

Stable vital signs

Altered muscular movement leading to misused, tense muscles, which leads to decreased movement, which leads to altered sensory input

Disrupted sleep causing the child to tire readily, be more irritable, with decreased ability to concentrate

Developmental regression

Change in eating patterns

Behavior or school problems

Withdrawal from peer group activity

Depression

Aggression

Patients with neuropathic pain typically describe the quality of their pain with terms such as *burning, shocking, stabbing, shooting, tingling, or like pins and needles*. These sensations persist despite healing of an injury or surgical site and in the absence of physical signs of injury or tissue damage. Physical symptoms of nervous system dysfunction that may provide objective evidence of the neuropathic origins of the child's reports of pain include motor abnormalities, such as spasms, tremors, weakness and atrophy, as well as symptoms of autonomic dysregulation, such as cyanosis, erythema, mottling, swelling, and poor capillary refill of the painful area.

Children with chronic pain present their own unique assessment challenges. It is beneficial to use tools that use a variety of methods to provide a comprehensive pain assessment (see Table 10–2) (Hermann et al., 2008; Varni et al., 2007). Pain symptom diaries may provide useful information, particularly when assessing chronic pain. Identify the reason for collecting information so the child can focus the narrative. For example, if the aim is to identify the etiology of recurrent pain, the child should record events preceding pain onset, precipitating factors, and so forth. If the goal is to evaluate effectiveness of ongoing management, the child may record medications or psychological techniques used, record activity level, and rate the intensity at specified intervals during the day. Family, teachers, and healthcare team members need to remember that the body adapts to pain that is ongoing and that the child therefore may not demonstrate behaviors that are typical of acute pain. This should help avoid a common assumption that the child is not experiencing pain and is exaggerating the pain ratings.

Assessment of chronic pain should include a routine health history that encompasses aspects of the child's pain and functional ability. Elicit a description of a typical day. Identify difficult activities (e.g., comfortably positioning an infant for feeding, dressing self for a school-aged child), those that exacerbate pain (no nap for a toddler,

participation in sports for an adolescent), and activities that reduce the pain (position, distraction, medications). Keeping a symptom diary may help identify proactive steps to avoid exacerbating the pain. Also obtain a diet history, because chronic pain may cause loss of appetite. Evaluate aspects of family functioning such as parental mental health, stressors in the family, other siblings with the same disease, pain that started after a grandparent died of cancer, and perceptions such as that relatives have migraines and they “are genetic, so nothing can be done.”

Complete a thorough physical examination. This step serves a dual purpose. The first is to evaluate the child's baseline status. The second is to assure the child and family that the child's pain is being taken seriously and they are believed. When the child is monitored for a time, healthcare providers may feel comfortable that they know the situation and become biased in their assessments and conclusions.

Alert! A new disease or advancing pathology may have occurred since the last visit. This possibility should not be overlooked as a potential cause of pain. Complaints of increased or different pain must be investigated.

Management of Chronic Pain

Help the family to establish realistic goals and set priorities. The goals should not be too basic or easy, because the child needs to be challenged; however, they should not be so difficult that they cause frustration.

Many of the techniques previously discussed apply to the management of chronic pain in children. Obviously, strategies are influenced by the origin and type of pain. Pathology should be addressed and treated. The focus in acute pain is on rest, symptomatic treatment, and avoiding stress. The focus shifts with chronic pain to helping the child regain or achieve appropriate developmental tasks, decreasing attention to pain behaviors (while making sure that pain control is as good as possible), and emphasizing a productive role.

Children with chronic pain benefit from an interdisciplinary approach that combines behavioral, biophysical, and pharmacologic strategies. Interventions are planned on the basis of assessment findings, goals, and priorities of the family (see Nursing Interventions 10–9). Parents should reward positive behavior—that is, praise the child for performing activities of daily living even when having pain. Less attention should be paid to complaining, after it is determined that complaints are not caused by new or different pain.

The child should resume self-care and activity to the fullest extent possible. Strongly encourage school attendance, because it is a normalizing activity. If the child has missed school for a time, address school reintegration (see Chapter 12). Ensure that the teacher is educated, with parental permission to ensure privacy, about the biopsychosocial etiology of the pain. Teachers who attribute pain to physical causes respond more positively to the child than if they believe it is a psychological cause (Logan et al., 2007).

Treatment of neuropathic pain is extremely difficult. Multiple pharmacologic agents, such as antidepressants, anticonvulsants, local anesthetics, and opioids, may be

NURSING INTERVENTIONS 10–9

Chronic Pain

- Believe that the child has pain.
- Help the child and family establish realistic goals and work toward these goals steadily with small steps. Reinforce the fact that overexertion is usually counterproductive.
- Provide environmental manipulation:
 - Coordinate with physical therapy to evaluate need for and providing adaptive aids such as a cane or slip-on shoes, or adding a railing to the stairway.
 - Evaluate the effect of different positions to promote comfort and functional activity.
 - Rearrange the daily schedule to provide more time for difficult activities or to allow the child to perform them in the morning, when fatigue may be less of an issue.
 - Schedule rest periods and promote uninterrupted sleep.
- Optimize nutritional intake.
- Teach stress reduction techniques: biofeedback, exercise, relaxation.
- Implement biophysical interventions: transcutaneous electrical nerve stimulation (or TENS), cutaneous stimulation, nerve blocks.
- Provide pharmacologic interventions:
 - The oral route is preferable for chronic pain.
 - Medicate to provide pain relief or at least so child can participate in normal activities.
 - Single-drug therapy may be tried, but complex pain problems often require combinations of drugs (acetaminophen, NSAIDs, antidepressants, anticonvulsants, benzodiazepines, opioids).
 - Individualize schedule and promote around-the-clock dosing, with additional dosing available for breakthrough pain.
 - Watch for signs of withdrawal when discontinuing medications. Reduce dosage slowly to avoid withdrawal and acute exacerbation of pain; wean from sedatives first.

prescribed to reduce neuropathic pain intensity. Psychologic, cognitive–behavioral, and physical therapies are also used to restore function and provide coping strategies for children living with neuropathic pain.

Reassess pain and reevaluate the treatment program on a routine basis. The benefit of an interdisciplinary approach can be realized by using the strengths of different team members; the nurse should be a contact person for the family and coordinate team member activities. This role may involve coordinating with the healthcare prescriber and pharmacist for medication schedule, dose, or drug changes; the psychologist for behavioral and coping strategies; the physical therapist for functional activity and strength training; the nutritionist for diet modifications; or the social worker for family support issues (Clinical Judgment 10–3).

ANSWER: Although George’s condition is chronic, it is also progressive with increasing disability and increasing pain. His treatment plan, supported by the National Comprehensive Cancer Network clinical guidelines, offers regular assessment and continuous treatment.

Pain in the Emergency Department

Children frequently present to the emergency department in pain. Airway, breathing, and circulation (ABCs) must be addressed first. If defibrillation is not necessary, consider D a reminder to assess and treat discomfort.

Severe pain is considered an emergency in itself and requires immediate attention after all the ABCs have been evaluated and stabilized.

The child in the emergency department may experience pain resulting from pathology, from diagnostic or therapeutic procedures, or from some combination of these sources. If painful procedures are necessary, prepare the child before the procedure when possible. When interventions must be done on an emergent basis, explain what is being done as it is happening. Position the child securely for procedures. Children are routinely restrained without sedation or analgesia for painful procedures, something that would be unthinkable with an adult. If a child is unable to follow directions and allow a procedure to proceed safely with analgesia alone, the child should be sedated.

KidKare ■ ■ Tell children what they can do (“Squeeze your mommy’s hand as hard as this hurts.” “Count to 10.” “Make your arm like a noodle.”) versus what they cannot do (“Don’t tense up your arm.”).

Use a topical anesthetic for venipunctures, lumbar punctures, laceration repairs, urinary catheterization, and other painful procedures. IV opioids or sedation should be used for more painful procedures. Children undergoing sedation in the emergency department should be assumed to have full stomachs.

Address pain management early to avoid escalating the pain and the child’s and family’s distress. Always provide

CLINICAL JUDGMENT 10–3

An Adolescent in Pain

Charles is a 14-year-old with hemophilia who weighs 50 kg. He is well known to your clinic because he has a history of multiple bleeding episodes. He is not receiving routine medication, only factor XIII for acute bleeding episodes. He comes in today limping and complaining of joint pain at 8 points on a 10-point scale. Charles greets all the nurses with a hug and smile, but seems much less cheerful than normal. Vital signs are normal for age.

Questions

1. What more would you ask Charles about his current complaints?
2. Charles indicates that this pain is primarily in his left knee and ankle, although all lower extremity joints are painful intermittently. This pattern has been present for about 7 months, becoming increasingly painful until reaching its present level about 2 weeks ago. He has lost 2 kg since last weighed 6 months ago and is not sleeping well (“I can’t get comfortable”). He misses at least 1 day of school a week, and his grades are dropping. He still swims but can’t ride his bike to school anymore. On the basis of this history, what are your concerns?
3. What is his current problem?
4. How should Charles’ pain be managed?
5. When and how will you reevaluate Charles?

Answers

1. History of current pain complaint: Did he hurt himself recently? Does he think it is an acute bleed? Where is the pain? What does it feel like?

- How long has it been present? Is it always at this level or is it intermittent? Is pain interfering with activities of daily living, including eating and sleeping, school attendance and performance, and with activities that he enjoys (swimming, bike riding, and roping)? If pain is interfering, to what extent? Does anything help relieve the pain?
2. The pain is affecting Charles’ quality of life, as evidenced by sleeping and eating disturbances; it is also interfering with school, socialization, and potentially his ability to achieve independence and self-care skills.
 3. Chronic arthritic pain from previous bleeding episodes
 4. Start oral acetaminophen and an opioid around the clock. Advocate for a physical therapy consultation. Discuss biobehavioral methods of pain relief such as cutaneous stimulation (cold) and cognitive-behavioral methods (progressive muscle relaxation, meditation, guided imagery, self-hypnosis). Have Charles select one to learn and use until his next appointment. Have Charles keep a symptom diary.
 5. Reevaluate in 1 week. Charles should call the clinic sooner if the pain worsens or is not less than 4 out of 10 points in 2 days (Charles’ goal). At this time, review his symptom diary. Ask if Charles is satisfied with his pain management plan. Develop a plan to wean from the opioid if Charles has not already reduced his dosage. Is the behavioral technique working? Does he like it? Does he want to learn another?

psychological support and use biobehavioral techniques when possible. In the emergency department, drugs are usually given to control pain because of time constraints and the amount of pain experienced.

Children in shock should not be given opioids until hemodynamic stability is achieved. If severe pain is present in a child with potential hemodynamic compromise, small doses of short-acting opioids may be given repeatedly (e.g., morphine or fentanyl every 5 minutes). Headache associated with head injuries often can be managed with nonopioid analgesics. These agents are preferable, because opioids may mask signs of changing neurologic status. If opioids are required, use small amounts that do not affect level of consciousness. Aggressive pain management is required for children with burns. Opioids combined with nonopioids should be given as soon as possible. Dressing the wounds and applying cold compresses aid in pain relief. Fractures can be extremely painful; short-acting IV opioids

should be given. Ibuprofen or acetaminophen with codeine and application of cold may be effective for less severe fracture pain. Pain resulting from minor injuries may be managed with acetaminophen, ibuprofen, or another NSAID as age appropriate, or a weak opioid such as codeine. Reevaluate pain intensity and efficacy of interventions frequently, at least every time vital signs are taken.

Community Care: Focus on the Child in Pain at Home

The majority of children who experience pain are not seen in the healthcare setting. Well-child care can include anticipatory guidance for managing minor pain at home. Ice, massage, bandages, rest, distraction, or other biobehavioral interventions may be quite effective. Acetaminophen or ibuprofen, particularly effective for musculoskeletal pain, may be given.

Alert! Aspirin use is thought to be associated with an increased risk of Reye syndrome and should not be given, particularly when a viral infection is present, unless ordered by a healthcare provider.

Aspirin may be used to manage chronic inflammatory disease such as juvenile rheumatoid arthritis. Teach the child and parents to consult the healthcare provider if pain is accompanied by signs of systemic disease.

Always give written instructions to children being discharged from a healthcare setting and their parents. Instructions should include intensity of pain to expect with the condition or procedure and how long it might last; and how to use a developmentally appropriate assessment tool, preferably a method that was used in the healthcare setting, to assess pain level. Rank interventions in order of what to try first or what to do for certain pain levels (e.g., if pain is severe, give the opioid; if mild, give acetaminophen). Include activity restrictions, if any (e.g., after sedation, the child requires close supervision for at least 8 hours and should participate in no potentially dangerous activities such as bathing, use of tools, bike riding, skating, or using playground equipment). Teach parents to evaluate the effectiveness of interventions. If medications are used, emphasize that regular dosing is most effective. Describe side effects of medications, ways to prevent them, and what to do if

they occur (e.g., if receiving opioids, increase fluid and fiber intake to decrease constipation). Also provide the number of the person to call if pain management is inadequate.

ENSURING EFFECTIVE OUTCOMES OF PAIN MANAGEMENT

For the child experiencing mild to moderate pain, biobehavioral interventions alone may adequately manage the pain. For moderate to severe pain, use of medications coupled with appropriate biobehavioral strategies best supports the child. Pharmacologic management of pain can be achieved using a single drug or combinations. Dose must be titrated, and schedule, route, and drug combinations must be optimal. Side effects must be anticipated and managed. The adequacy of pain management must be evaluated on a routine basis (Nursing Interventions 10–10).

The Interdisciplinary Pain Team

Effective management of pain in children requires the efforts of many individuals sharing their expertise. These experts include nurses, pediatricians, anesthesiologists, pharmacists, psychologists, physical therapists, social

NURSING INTERVENTIONS 10–10

Checklist for Assessing Adequacy of Pain Management in Children

Pharmacologic Strategies

- Have the child and parents been asked about their previous experiences with pain and their preferences for use of analgesics?
- Does the child or parents have reservations about the use of opioids for pain treatment?
- Is the child being adequately assessed at appropriate intervals?
- Are analgesics ordered for prevention and relief of pain?
- Is the analgesic strong enough for the pain expected or the pain being experienced?
- Is the timing of drug administration appropriate for the pain expected or experienced?
- Is the route of administration appropriate for the child?
- Is the child adequately monitored for the occurrence of side effects?
- Are side effects appropriately managed?

- Has the analgesic regimen provided adequate comfort and satisfaction from the perspective of the child or parents?

Biobehavioral and Nonpharmacologic Strategies

- Have the child and parents been asked about their experience with and preferences for a given strategy?
- Is the strategy appropriate for the child's developmental level, condition, and type of pain?
- Is the timing of the strategy sufficient to optimize its effects?
- Is the strategy used with, rather than instead of, analgesics?
- Is the strategy adequately effective in preventing or alleviating the child's pain?
- Are the child and parents satisfied with the strategy for prevention or relief of pain?
- Are the treatable sources of emotional distress for the child being addressed?

Adapted from AHCPR. (1994). *Management of cancer pain*, p. 128. AHCPR publication no. 94-0592. Rockville, MD: Agency for Health Care Policy and Research, Public Health Service, U.S. Department of Health and Human Services.

NURSING INTERVENTIONS 10–11

Optimizing Pain Management

- Make sure that the currently ordered regimen has been followed and used to the fullest (highest doses, most frequent intervals) extent possible.
- Keep the focus on the child (not “what you ordered is not working” or “I cannot stand his crying anymore”).
- Believe that everyone is trying to provide excellent patient care.
- Offer objective physiologic and behavioral evidence of pain, not vague statements (“He has slept fitfully, for no longer than 20 minutes at a time; he lies stiffly in bed, grimaces and cries when moved; he is consolable with a pacifier but not for longer than 2 minutes” versus “he appears to be in pain”). Knowing the prescriber’s criteria for pain indicators is a benefit; the patient report can address these criteria (e.g., if the prescriber believes that all toddlers are irritable and cry after surgery because they are in a strange environment but takes vital sign changes as valid, emphasize vital sign changes).
- State current management regimen, both pharmacologic and biobehavioral (morphine at 1 mg IV is ordered every 2 hours, it was last given 90 minutes ago, his mother is holding him and his favorite video is on).
- Ask the prescriber or pharmacist for management suggestions. If the prescriber has no suggestions or is reluctant to change the regimen, reiterate your assessment that the child is experiencing pain and your suggestion for management (“What about increasing the morphine to 1.5 mg or adding an NSAID?”).
- Be persistent in advocating for the child, do not get angry, and remember everyone is working toward the same goal.

workers, child life workers, and others. Some centers are large enough to support a specific pediatric pain program. Such a program is optimal, because pain management is an expanding field of research, and practice patterns change with new knowledge. Some centers incorporate the pediatric population into the general pain program. Others rely on individuals with knowledge in the field.

Nurse’s Role in Pain Management

Nurses contribute substantially to managing pain in children and should take a lead role as part of the interdisciplinary team. Assess pain during initial patient contact and routinely when assessing vital signs. Work with the family to set realistic goals and a plan for action. For example: Ashley will walk to the end of the hall. She will take her pain medication 30 minutes before this walk and use cold packs. Reevaluate the interventions and goals at appropriate intervals.

The nurse is pivotal in ensuring the effectiveness of medications, and helps to educate the other healthcare team members who write the orders. To ensure that medications are optimally effective, be familiar with mechanism of action, peak and duration of action, and side effects. Plan care on the basis of this information. Prevent pain when possible, observe for effectiveness of and tolerance to medications, and schedule to keep pain intensity at a minimal level. Around-the-clock management is imperative.

The nurse must advocate for the child. Advocacy may involve convincing a parent that opioids are appropriate for the situation, or consulting with the prescriber

regarding an ineffective medication regimen. Healthcare team members need to collaborate to promote effective communication and to decrease the amount of frustration that may be involved in this process (Nursing Interventions 10–11). Nurses have assumed leadership roles in pain management through pain relief nurse programs and nursing-directed pain management services (McCleary, Ellis, and Rowley, 2004).

Documentation

However pain is managed, the plan must be clear, consistent, and well documented so that all team members can work efficiently together. An effective way to achieve these goals is to use interdisciplinary protocols for pain management. Standards for pain management have been developed by various organizations such as the Acute Pain Management Guideline Panel (Agency for Health Care Policy and Research [AHCPR]), APS, AAP, Oncology Nursing Society, and the World Health Organization. Protocols should include institution- or unit-specific guidelines for pain assessment for children of various ages. These guidelines should outline the specific behaviors to be included, tools to be used, frequency of assessments, interventions, and documentation requirements. Including psychosocial and developmental issues is particularly critical if the team cares for adults as well as children and the physician members are not pediatricians. Child life specialists can be particularly valuable in this situation, providing biobehavioral pain management such as relaxation, distraction, and procedural preparedness.

Assessment of pain by nurses is performed most consistently when pain is viewed as the fifth vital sign. To facilitate consistent documentation of pain assessments, the child's flow sheet should include a designated area next to the vital sign recordings for this purpose. Management of more complex pain problems, rapidly changing regimens, or weaning from opioids may best be documented on a separate pain flow sheet. Other issues that should be addressed by the pain team or person responsible for pain management in the institution are quality improvement and outcome monitoring; home care needs, community resources, and school integration; and research use or implementation of clinical research.

Assessment and management of pain in children are challenging. We must continue to meet this challenge; the comfort and well-being of children depend on it.

Acute Illness as a Challenge to Health Maintenance

Case History

Remember the Whitworth family and Cory Whitworth in Chapter 6? Cory has never been a good eater, but during the past few days he has refused to eat at all and has had a fever off and on, although he is still drinking. This morning he seemed more comfortable and playful, so Wendy sent him off to kindergarten. The school called when he began crying and guarding his abdomen. Wendy took him directly to the pediatrician's office; however, after an initial physical examination, the pediatrician sent them to the nearest hospital with a pediatric facility to determine whether appendicitis was the cause of the intense abdominal pain.

In the emergency room it is determined that Cory has a perforated appendix and will require surgery immediately, and more than a week of hospitalization with intravenous (IV) antibiotics. Although the Whitworths have had

children in the emergency room for various cuts and breaks, this is the first time one of their children has needed surgery. When Wendy hears the words *emergency surgery* and *hospitalization*, she becomes extremely anxious and overwhelmed. She feels as if she cannot absorb any more information. The Whitworth family had just changed insurance carriers and not only is the new insurance card not in Wendy's wallet, she is not sure of the name of the new insurance company. Her husband is out of town today and tomorrow. When she tries to reach him, she finds that his cell phone is turned off for a meeting. Her oldest son, Ken, attends community college on the far end of town, so she calls her second son, Collin, at high school to help her by going home to get the insurance card and bringing it to the hospital.

CHAPTER OBJECTIVES

1. Facilitate care during acute illness to minimize stress for the child and family.
2. Discuss the impact of hospitalization on the child's and family's coping and adaptation responses.
3. Select nursing interventions to provide basic care needs for the child during an episode of acute illness.
4. Select interventions that provide psychosocial support to the family during hospitalization.
5. Describe nursing care of the child having surgery.
6. Identify factors that prepare the child and family for a smooth transition from the acute care environment to a community setting.

See [thePoint](#) for a list of Key Terms.

Acute illnesses or conditions are those in which changes occur relatively rapidly, reach a certain level of acuity, then subside. Chronic conditions, in contrast, are present for a prolonged period of time, potentially never resolving. An acute illness is a threat to a child and his or her family characterized by suddenness, severity, and disruption of the normal patterns of everyday life. An acute illness is generally unexpected. Acute illness encompasses the minor illnesses that are frequent in childhood (e.g., viral respiratory infections, gastroenteritis, fractures) and those of a more serious nature (e.g., meningitis, congenital heart disease). The critical nature of the illness and the uncertainty regarding its outcomes challenge the child's emotional well-being and the integrity of the family system.

For some children, the acute illness may be an exacerbation of a chronic condition or the terminal stages of a life-threatening condition. The child's acute status may be an "expected" part of the disease process, or the result of a traumatic event such as drowning, poisoning, or injury. Regardless of the precipitating illness, admission to the acute care setting is stressful for all children and their families. Stress and family disruption can be reduced by implementing care based on the developmental and physiologic needs of the child and family, and by considering the environment, security issues, and specific care needs of the child.

THE ACUTE CARE EXPERIENCE

QUESTION: How would family-centered care benefit the Whitworth family? Who should be allowed to stay with Cory and who should be allowed to visit Cory at the hospital?

The hospitalization of a child is stressful for both the child and the family. An acutely ill child and his or her parents often experience removal from their familiar environment, restricted visiting hours of other family members (e.g., grandparents, siblings) and friends, disruption in routines, and lack of recognition of parents as

the primary caregivers who know the child best and their role in planning the child's care. Families may incur financial hardship as parents lose time from work and have expenses such as travel, parking, meals, and babysitters for their other children. Increased parental anxiety and stress have a negative affect on the child's outcomes (Melnyk, Feinstein, & Fairbanks, 2006).

Recognizing that illness and hospitalization are stressful events for families, the **family-centered care** approach has become the philosophical underpinning for the care of children and their families (see Chapter 1). As a partnership between healthcare providers, patients, and families, the family-centered care model emphasizes dignity, respect, open communication, collaboration, and the restoration of control to individuals and families. Parents want an interactive relationship with healthcare providers that offers information about their child's care and also demonstrates compassion and sensitivity to the parent's and child's needs (Hopia et al., 2005).

Family-centered care encourages liberal 24-hour visitation policies, sibling involvement in hospitalization, pet visitation policies, family conferences to promote shared decision making, assisting families to utilize support systems, and family education with regard to the care of the child. Family presence during healthcare procedures typically decreases anxiety for the child and the parents. Family presence, even during resuscitation, is supported by many professional organizations (Fullbrook et al., 2007; Henderson & Knapp, 2006) (NIC 11–1).

Include the family as an integral member of the healthcare team. Research demonstrated that parents wanted to actively participate in their child's care, but were limited by nurses' willingness to communicate and negotiate shared care (Corlett & Twycross, 2006). Parents' primary motive for being with the child is to provide emotional support; they are willing to help with care but experience ambiguous boundaries between parents' and nurses' roles (Coyne and Cowley, 2007). An expectation that parents are continually present to provide all care can increase parents' stress. Assess parents' desire for involvement and explicitly negotiate boundaries of care. Obtain family input in developing the plan of care for the child and family.

Children want to be involved in their care and decision making (Coyne, 2006b). Give the child as much control as developmentally appropriate. **Atraumatic care** is provision of care in a manner that minimizes the emotional and physical threat to the child. Regardless of the setting in which care is delivered, implement principles of atraumatic care (Nursing Interventions 11–1) to help minimize the negative effects that may result from interactions with the healthcare setting.

ANSWER: A benefit of family-centered care for the Whitworth family would include having a family member stay at the bedside and actively participate in Cory's care throughout the hospitalization. Cory's family should be allowed to identify those individuals whose presence and support will promote family coping. For example, all the members of the family as well as preidentified members of their church should be allowed to visit Cory.

NIC 11–1 Nursing Interventions Classification: Family Presence Facilitation

Definition: Facilitation of the family's presence in support of an individual undergoing resuscitation and/or invasive procedures

Activities:

Introduce yourself to the staff treating the patient and family
 Determine suitability of the physical location for family presence
 Obtain consensus from the staff for the family's presence and the timing of the family's presence
 Appraise the treatment team of the family's emotional reaction to the patient's condition, as appropriate
 Obtain information concerning the patient's status, response to treatment, identified needs
 Introduce yourself and other members of the support team to the family and patient
 Communicate information concerning the patient's current status in a timely manner
 Assure family that best care possible is being given to the patient
 Use the patient's name when speaking to the family
 Determine the patient's and the family's emotional, physical, psychosocial, and spiritual support needs and initiate measures to meet those needs, as needed
 Determine the psychological burden of prognosis for family
 Foster realistic hope, as appropriate
 Advocate for family, as appropriate
 Prepare the family, ensuring they have been informed about what to expect and what they will see, hear, and/or smell

Inform the family of behavior expectations and limits
 Provide a dedicated staff person to ensure that family members are never left unattended at the bedside
 Accompany the family to and from the treatment or resuscitation area, and announce their presence to the treatment staff each time the family enters the treatment area
 Provide information and explanations of the interventions, medical/nursing jargon, and expectations of the patient's response to treatment
 Escort the family from the bedside if requested by the staff providing direct care
 Provide the opportunity for the family to ask questions and to see, touch, and speak to the patient prior to transfers
 Assist the patient or family members in making telephone calls, as needed
 Offer and provide comfort measures and support, including appropriate referrals, as needed
 Participate in the evaluation of the staff's and the nurse's own emotional needs
 Assist in identifying need for critical incident stress debriefing, individual defusing of events, and so forth, as appropriate
 Participate, initiate, and/or coordinate family bereavement follow-up at established intervals, as appropriate

THE ACUTE CARE ENVIRONMENT

The acute care environment encompasses various settings including inpatient units, outpatient clinics, pediatric emergency rooms, same-day surgery centers, pediatric rehabilitations units, and palliative care units. For a discussion of specific care settings (see [thePoint](#) for Supplemental Information: Care Delivery Settings for Children). No matter the setting, the acute care environment is typically busy and full of unexpected and often unpleasant events for the child. Anxiety, fear, pain, discomfort, surprise, fatigue, frustration, mistrust, and anger are common experiences for the child and the family. Nurses must be sensitive to these experiences and develop a plan of care that enhances family function and reduces the stressors associated with interaction in the acute care setting. Room design, including waiting rooms, should address comfort, education and information needs, facilitation of social interaction, as well as privacy needs. Play area design should be appropriate to the ages and physical conditions of the children served. Excessive noise levels can have negative psychophysiological effects (Christensen, 2005)

and disrupt sleep patterns (Stremler, Wong, & Parshuram, 2007). Privacy and noise reduction are important factors in all designs, particularly treatment rooms, so that children are not frightened by what they see and hear in other rooms. The latter guideline holds especially true for emergency departments, which can be chaotic and consequently terrifying for children (Fig. 11–1).

Skilled interventions critical to caring for the child and family in the acute care setting include

- Facilitating entry into the acute care setting
- Integrating age-appropriate principles of growth and development in all care
- Supervising or implementing routine care and procedures in a nonthreatening way
- Maintaining, to the extent possible, the child's daily routines
- Maintaining safety
- Responding to the unique psychosocial needs of the child and family
- Addressing the needs of the child undergoing surgery
- Implementing effective discharge

NURSING INTERVENTIONS 11–1

Delivering Atraumatic Care

Aspect of Care	Interventions
Psychological	Always explain what is happening to the child—in his or her terms, not in adult and medical terms. Do not go into a lot of detail; keep it simple, direct, and honest. Do not tell the child it is not going to hurt if it is, but do not dwell on the pain factor. The use of topical anesthesia and medications assists in obtaining the cooperation of the child in the procedure. Ask the child to draw a picture of what is going to happen; you may find many misconceptions as well as open opportunities for discussion. Keep the parents involved as much as possible nurturing and supporting the child; do not isolate the child from the parent. The parent's absence may be more traumatic to the child than the procedure.
Environment	Keep the child's environment as nonthreatening as possible. Interpret the surroundings from the child's point of view. What does that large machine look like? Possibly a monster? Are there all types of implements out that cause pain or look scary? Is the room very sterile with no friendly items around? The machines can be draped with sheets or put in other areas; the implements can be put away. To soften the area and to distract the child from any potential procedures, add pictures (even hand drawn) of rainbows, butterflies, or flowers, or add a stuffed animal.
Restraints	Use restraints as minimally as possible and use the least restrictive one that provides safety (e.g., start with mittens first before a full arm restraint). Attempt, at first, to distract the child by playing games or with toys, singing songs, reading stories, or telling silly jokes. If the IV is in the child's right hand and the child is right handed, both the nurse and the child should draw left handed, and make designs, "silly" pictures, or play board games that only require one hand. If it is absolutely necessary to restrain a child, allow periods of freedom while supervised (e.g., during bath or meals).
Pain	Medicate freely. Do not withhold medication after surgery because the infant or child is not crying. Look for other signs of distress: pallor, furrowed brow, grimaces, shallow and rapid breathing, withdrawal of limb or area in pain, or thrashing around. Obtain the child's subjective rating of pain if possible.
Surgery	Prepare child prior to hospitalization if possible with a visit to see the environment and play with the items to be used to gain familiarity (blood pressure cuff, masks [both surgical and anesthesia], IV equipment, and so forth) and to have the schedule explained. Have the child draw pictures and tell a story about the experience to get a better idea of the child's true impressions.
Suturing	Use topical anesthesia prior to injecting the area with an intradermal anesthetic. Use as fine a needle as possible (30 gauge if possible). Cover the wounds with as small a dressing as possible, and decrease the size of the dressings as the wound improves. A child may correlate the size of the dressing with the severity of the wound.
Blood drawing	Draw blood as infrequently as possible. Attempt to draw as few specimens as possible for the maximum amount of tests. When doing heel sticks on infants, use a nontraumatic lancet such as a Tenderfoot rather than a regular lancet or a scalpel blade. When doing venous draws, apply a topical anesthetic in enough time prior to the draw to allow for sufficient anesthesia.
IVs	Prior to the insertion, use a topical anesthetic. Attempt to place the IV in a location where the child or infant will not need a lot of restraints or arm boards. If this is not possible, use padded or air-filled arm boards of the appropriate size, with a nonthreatening look (e.g., colorful covers with pediatric designs) to provide extra cushioning. Allow the older child to become familiar with the IV equipment by using tubing for play or creative endeavors. Soften the impact of IV poles and pumps by attaching pictures of animals, butterflies, or rainbows, or by adding stuffed animals to them.
Injections	Advocate for the child; ask if medications can be administered via a less traumatic route. Use the appropriate length and bore needle. Administer medication in the largest muscle mass possible, as deep as possible. Use a topical anesthetic in enough time prior to injection to provide local anesthesia. If medication is very irritating, mix with a small amount of lidocaine, unless it is contraindicated.

FIGURE 11-1. A child may be overwhelmed by the sights, sounds, and bustle of the emergency room. A parent's presence can help the child cope with this unfamiliar, sometimes frightening environment.

NURSING CARE OF THE CHILD AND FAMILY DURING THE ADMISSION PROCESS

QUESTION: Cory and his family had very rapid transitions: from pediatrician's office, to emergency room, to surgical suite, and then to the pediatric care unit. He did not have the benefit of a hospital tour nor have his parents had a child hospitalized before. How you could individualize nursing care during admission for the Whitworth family? For whom is the admission process most stressful?

The admission process is the beginning of the relationship between the child, the family, and the healthcare staff. It assumes great importance, because a positive first impression serves as a basis for establishing a trusting and supportive relationship among the healthcare team, the child, and the family, which generally leads to improved outcomes (Nursing Interventions 11-2).

With the increase in technology and use of bedside computers, some facilities have adopted a "bedside admission

process" that bypasses the admitting department (Fig. 11-2). This allows direct access to the pediatric setting where developmentally appropriate communication techniques are the standard of care; this can help relieve fears and anxiety associated with an unfamiliar environment.

Preparing the Child and Family for Admission: Hospital Tours

To meet the developmental needs of prospective patients and their families, they should have an opportunity to tour the acute care setting before hospital admission or surgery (Chart 11-1). A successful preoperative tour can create a positive impression of the surgical experience and defuse a potentially threatening event for the child and family. It lets the child and family meet the care providers and other staff members and become accustomed to the environment. This is particularly useful for children in early childhood who may be especially frightened by hospitalization but are old enough to benefit from the desensitization effects of a preadmission program (Fig. 11-3).

If an older child is especially anxious about surgery, the facility may arrange for a tour through an operating room (OR) that is not in use, a preoperative area, and a postanesthesia care unit. If the child is to be admitted to intensive care after surgery, a tour of this area may be warranted. Make the tour more child friendly by using a large doll or stuffed animal to help demonstrate machinery that the child will encounter. A child may be reassured to see a teddy bear on the operating table "have a special sleep for surgery" and then "wake up" to be hugged. Explain the purposes of hospital pajamas, masks, caps, shoe covers, and gloves, and let the child try them on. Let the child hear the beeps of an electrocardiograph (ECG) machine and feel the stickiness of the ECG pads, place a pulse oximeter probe on the child's fingers or toes, put a blood pressure cuff on the child, or let the child listen to his or her own heartbeat through a stethoscope.

If the facility cannot provide tours of the OR, substitute a photograph album, slide show, or a videotape presentation of a tour. No matter what form the tour takes, presenting a certificate to each child on completion of the tour gives the child a concrete reminder of his or her experience.

NURSING INTERVENTIONS 11-2

Guidelines for the Admission Experience

- Ensure that the child knows why he or she is coming to the hospital.
- Incorporate parents' feedback regarding methods or tools that have helped the child adjust to past experiences.
- Encourage use of familiar, comforting toys and belongings during the admission.
- Explain in age-appropriate terms the steps to the admission process (admission, laboratory work, patient unit, and so forth).
- Use multisensory mechanisms for education, such as play materials, books, and videos that illustrate aspects of hospitalization.

FIGURE 11–2. Bedside admitting can be easier and less stressful for the child and family.

Some facilities have taken the hospital tour to the local community. In this outreach program, healthcare personnel use a videotape and discussion to present the hospital tour to schools and other community organizations.

CHART 11–1 GUIDELINES FOR CONDUCTING A HOSPITAL TOUR

- Determine whether a preadmission tour would benefit or frighten the child.
- Keep groups small—about 10 children per group.
- Conduct the tour for 20 to 30 minutes, depending on the children’s attention span. The nurse or child life specialist conducting the tour should have time dedicated for the tour with no interruptions.
- Encourage parents to join the tour.
- Present the tour in a nonthreatening environment, such as the hospital playroom, school classroom, or child’s home.
- When unable to actually tour the site (e.g., emergency on unit, presenting at a school), use an indirect method of presenting the hospital tour, such as a puppet, film, or slide show.
- Present the tour and explanations at the child’s developmental level.
- Avoid dwelling on unpleasant or threatening events or intrusive procedures.
- Give the child and parents an opportunity to ask questions.
- Give the children an opportunity for therapeutic play, using dolls and hospital equipment.
- Give the children something to take home to remind them of the hospital tour, such as a coloring book, mask, or head cover.
- Encourage parents to discuss the tour afterward with the child and to clarify any concerns he or she may have about the hospital.

FIGURE 11–3. A hospital tour familiarizes the child with the new environment.

Conducting an Admission Assessment

Obtain physiologic and psychosocial data during the admission assessment. The data collected about the child and family allows the nurse to develop an individualized plan of care. Ideally, perform the assessment when the child’s primary caregiver is present. The caregiver is able to give historical information about the child’s health status, such as childhood illnesses and immunizations. Psychosocial assessments of younger children, especially during infancy and early childhood, cannot be completed without the assistance of a parent. The exception to this is the adolescent whose privacy and confidentiality needs may preclude the presence of a parent. However, parents can provide great insight into any age child.

Communicate with the caregiver in a context of respect for their role as the person most knowledgeable about the child, whether this individual is the parent, grandparent, or other legal guardian. Recognizing this, the term *parent* used in this chapter refers to all primary caregivers.

caREminder

The objective of the assessment is to learn the information needed to provide the best possible care for the child.

If the parent understands this point, he or she will most likely be more willing to cooperate with the assessment. Provide as much privacy as possible, with minimal noise or stimulation. Learning from the parent about how the child copes with new situations and what the child has been told about the current situation is important in planning how to approach the child. In addition, approaching the child with a communication style that matches developmental age is a key ingredient in completing an assessment that is most productive for the nurse and least frightening for the child (Developmental Considerations 11–1).

Most acute care settings have standardized forms for the admission assessment. These forms can cue the nurse to elicit all the important information in the most efficient manner possible. The tool’s design helps the nurse

DEVELOPMENTAL CONSIDERATIONS 11–1

Communicating With Children

Stage	Guidelines for Communication
Infancy	Allow the infant to keep the parent in view. Rely on the parent to interpret the infant's nonverbal cues. Use pacifiers and blankets for security.
Early childhood	Be concrete in verbal descriptions. Use visual aids such as puppets and dolls. Allow the child to handle instruments before you use them, when possible. Demonstrate the use of an instrument on a parent prior to using it on the child. Provide opportunities to ask questions. Encourage the parents to be present for interactions. Respect emerging sense of modesty.
Middle childhood	Allow time for composure and privacy. Use teaching aids such as dolls and diagrams. Provide explanations of function of equipment.
Adolescence	Provide assurance of privacy and confidentiality. Provide some time away from the parent. Respect the adolescent's privacy and opinions by not prying or being judgmental. Although the adolescent is capable of abstraction, do not overestimate this capability. Provide diagrams and models to ensure comprehension.

better understand the child's physiologic and developmental needs as well as the social, spiritual, and cultural practices that might be affected by hospitalization. The tool must be comprehensive and useful to serve as a sufficient mechanism for determining the child's condition on admission and should cover key assessment areas of the child's history including

- Present illness or reason for seeking healthcare
- Birth history
- Previous health challenges
- Childhood illnesses
- Immunizations
- Recent exposure to communicable diseases
- Allergies
- Current medications
- Pain history (acute and chronic)
- Nutritional assessment
- Elimination patterns
- Family medical history
- Environmental history
- Social history
- Growth and developmental history

At a minimum, the admission assessment should also include a general head-to-toe physical assessment of

- Skin, head, eyes, ears, nose, and throat
- Neurologic system
- Cardiovascular and respiratory systems
- Gastrointestinal system

- Genitourinary/reproductive system
- Musculoskeletal system

Based on this general examination, establish priorities for more in-depth assessment in a particular area. For example, if an infant has no bowel sounds, the need for further immediate assessment and intervention becomes the priority of the examination. The documentation of findings, reporting of variances from the norm to appropriate personnel, and the development of a plan of care are also key ingredients of admission care.

ANSWER: The admission process is most stressful for Wendy. She has never had a child hospitalized before, her husband is out of town, and her only immediate family support is her high school-aged son. Remember that stress decreases problem-solving abilities. Wendy's anxiety level and sense of being overwhelmed may affect her ability to answer extensive questions regarding Cory's history. The nurse should focus on the questions most pertinent to the surgery first (e.g., "Does Cory have any allergies?" and "When did he last eat or drink?"). Cory is sedated and prepared for surgery as soon as it is determined that the appendix has ruptured. Much of the physical assessment will be done without his awareness. Also, permission to use the extended support of their family and church will help to decrease some of the stress inherent in Cory's emergency hospital admission. Prompt the family with concrete examples: "Do you have a

religious affiliation?" "Is there someone in your church that you should contact?" "Do you have any other family or friends that you want to make aware that Cory is in the hospital?"

NURSING CARE OF THE CHILD AND FAMILY DURING HOSPITALIZATION

Soon after admission to an acute care setting, the child and family encounter routines related to that setting. These routines include procedures that are part of the child's diagnostic evaluation and treatment as well as care that affects activities of daily living (ADLs). The most common routines include hygiene, safety, routine procedures, medication administration, and infection control. Each of these provides an intrusion into the child's and family's privacy, because they represent and mandate a departure from the family's way of life at home. Continuity between home life and hospital life is often difficult to achieve; nonetheless, an admission assessment that reveals as much as possible about home routines, likes, dislikes, coping mechanisms, favorite toys, and activities can help the nurse assist the child and family in bridging the gap between home and hospital routines (Fig. 11–4). Many routines from the home environment (including various ADLs, sleep patterns, and nutrition habits) can be transferred, or adapted with minor changes, to the hospital environment.

Promoting Activities of Daily Living

QUESTION: For the Whitworth family, what are the steps you would take to delineate the role of family members and the role of the nurse regarding Cory's ADLs?

Perhaps the hospital routines that are most disruptive to home patterns are those regarding ADLs. Bathing, oral care, dressing, and toileting are such basic functions that the ways in which one performs them are taken for

FIGURE 11–4. Familiar objects and maintaining home routines normalize the environment and help the child cope with hospitalization.

granted. Having an acute illness changes the way in which these basic functions are performed as a result of the child's physical condition and restrictions caused by treatment devices.

ADLs are determined by culture as well as by family practices, rituals, and individual preferences. By assessing them thoroughly during admission, the nurse can enhance desired patient outcomes. This is true because much greater cooperation is achieved if care delivery mimics as closely as possible what was done at home. Communicating the child's and family's preferences to all involved care providers is a key part of developing an interdisciplinary plan of care for the child.

ANSWER: As soon as the child is stabilized, set aside time to meet with the parents for a care conference. The time taken is very worthwhile and saves time and emotional energy throughout the course of the stay. Ask the parents what aspects of Cory's care they would like to provide. Systematically go through specific examples of ADLs (e.g., "Would you like the nurses to give Cory his bath or is that something you prefer to do?").

Bathing

Safety and privacy are the greatest concerns in bathing. Infants through preschoolers should never be left alone when bathing. Infants who can sit alone may be bathed in a tub under constant supervision. Toddlers also need to be bathed, but they can help. Preschoolers can be more independent with bathing but still need assistance. Children of these ages are more comfortable if a parent or grandparent helps them with their bath, especially after they reach the stage of stranger anxiety, which begins around age 6 to 8 months. Middle-childhood aged children can bathe themselves, especially after age 8, barring developmental or physical disabilities, but may not be as thorough as they should. During middle childhood, children who have the physical strength to bathe alone are not at risk for accidents while bathing, unlike infants and those in early childhood. However, assess developmental capacities before making this professional judgment. Developmentally delayed children of middle childhood and older may require constant supervision during the bath. Adolescents are often preoccupied with hygiene and the primary concern becomes having the "space" and time to carry out the desired hygiene rituals in the most private, autonomous way possible. For patients who are too ill to get into a tub or shower, the bed bath becomes a necessity. Prepackaged single-use disposable baths reduce adult patient agitation and nursing time over basin and soap, and are cost-effective (Larson et al., 2004); more research is needed with children.

Frequency and timing of bathing are often culturally determined. Respect habits within the confines of standards acceptable for infection control and scheduling. Some children are accustomed to bathing in the morning, whereas others prefer to bathe before bed. If the child is fairly independent, arranging for a shower or bath before

bedtime may greatly increase their personal satisfaction. A bath every day is not necessary, provided that the patient is clean enough for infection control; however, cleanse face, hands, and perineal area daily.

WORLDVIEW: Not all cultures use the same types of products for bathing and hair care. Checking with the parents for assistance and asking them to bring in supplies is helpful. Bathing and hair care may be left to willing family members as long as it does not jeopardize patient safety.

For children hospitalized for longer than a few days, periodic hair washing is necessary. Wash an infant's hair daily or every other day to prevent cradle cap. Older children typically need one or two shampoos per week.

Oral Care

Providing oral care for children is a necessary and challenging aspect of hygiene. Young children often do not like to have their teeth brushed and thus resist. Children younger than the age of 8 need assistance with mouth care. Although it is important to permit preschool-aged children to begin brushing their own teeth, they need one thorough brushing per day with the assistance of an adult. Infants whose teeth have not erupted still need mouth care; this can be provided by using a washcloth or sponge-tipped applicators to rub the gums and oral cavity. After the teeth have erupted, use a soft toothbrush and dental floss to remove plaque. For a child at high risk of caries, such as living in an area without fluoridated water, a minute amount of fluoride toothpaste can be used. Children in early childhood often like to use a familiar brush, although supervision is required to ensure that the child does not ingest large quantities of fluoridated toothpaste and continue to need assistance with brushing and flossing. During middle childhood, children can brush their teeth but need reminders to be attentive to the back surfaces of the molars. After they demonstrate an ability to spit and not swallow, a fluoride mouth rinse is recommended at least once a day, especially at the night cleaning. Adolescents are usually sensitive about halitosis and how their teeth look, so they are usually compliant with brushing. Some may need to be reminded about flossing and the use of fluoride mouth rinse.

Children who have been treated with certain types of immunosuppressive or chemotherapeutic agents may experience stomatitis. Oral care for these children is key in minimizing the occurrence of infection and/or severity of the condition (see Chapter 22).

Dressing

Some hospitalized children are too sick to dress in anything other than a gown or pajamas. Parents may wish to select outfits for the infant or toddler to wear that are more attractive and warmer than the hospital gown. Older children may feel like donning clothes from home. Encourage the child to choose the clothes to wear. This may be especially important to adolescents, whose chief developmental concerns are body image and personal appearance.

Toileting

Many children regress developmentally during hospitalization. Toddlers who have just begun to master toilet training may revert to diapers. No interventions usually are needed. When children return home, they usually resume their former developmental level. If a child has recently been toilet trained, make a concerted effort to assist the child in maintaining continence. The key guideline in toileting is to ensure the patient's privacy and dignity, no matter what the age. Adolescents may be particularly embarrassed by the use of a bedpan, especially in a shared room. Male patients of school age and older may be embarrassed by assisted toileting from female nurses, particularly with regard to the use of urinals. Being direct and matter-of-fact, and allowing as much privacy as possible are the preferred interventions in these situations. Keeping toileting implements, such as urinals and bedpans, out of sight when not in use and keeping bedside commodes emptied, clean, and stored as covertly as possible are also commonsense interventions related to toileting. Promptly answering the call light promotes trust that assistance is available when needed. This decreases the sense of humiliation and anxiety.

Sleep

The hospital environment is notorious for promoting sleep pattern disturbances. Sleep is necessary to maintain and promote health. Sleep deprivation, however, has deleterious effects on the immune system and can impair healing. Because deep sleep is necessary to growth hormone secretion (Durmer & Chervin, 2007), sleep pattern disturbances are a serious concern for care providers in pediatric hospitals.

In the hospital, sleep pattern disturbances can result from three basic types of sources: physiologic, psychological, and environmental. Physiologic factors can include diseases that cause pain, such as juvenile rheumatoid arthritis, and medications that decrease rapid eye movement sleep, such as barbiturates, opiate derivatives, and benzodiazepines. Psychological factors include separation anxiety, which may be the most prevalent cause of sleep disturbance, along with having a preexisting stressor, such as a dysfunctional family. The hospital environment also has many factors that can precipitate sleep pattern disturbance; these include noise (such as monitors and alarms), too much light, and treatments and assessments that frequently wake the child.

Assessment of home preferences and routines for sleeping is a step toward eliminating sleep pattern disturbance in the hospital. Determining the child's bedtime, sleep duration, bedtime rituals, and nap pattern helps the nurse develop a plan of care that prevents sleep pattern disturbance (Developmental Considerations 11–2 and Nursing Interventions 11–3). Model measures to reduce the risk of sudden infant death syndrome, such as placing infants supine for sleep; do not use soft objects or soft bedding in the crib for infants or for children who are developmentally delayed until they can lift and turn their head (American Academy of Pediatrics, 2005).

DEVELOPMENTAL CONSIDERATIONS 11–2

Sleep Promotion in Hospitalized Children

Developmental Stage	Developmental Guideline
All ages	<p>Post a daily schedule at the child's bedside, include nap times and bedtime.</p> <p>Establish a light–dark cycle if the room has no window.</p> <p>Eliminate noxious stimuli (see Nursing Interventions 11–3).</p> <p>Synchronize hospital routines with the child's normal routines.</p> <p>Treat the child's pain.</p>
Infancy	<p>Provide a sense of security for the infant by rocking and holding during the evening; adhere to home bedtime rituals, such as taking a bottle while rocking.</p> <p>Swaddle a younger infant.</p> <p>Play a familiar lullaby using a musical toy.</p> <p>Place supine for sleep and “back to sleep.”</p>
Early childhood	<p>Adhere to home bedtime rituals, such as reading a story, having a snack, and brushing teeth.</p> <p>Use transitional objects from home such as toys, blankets, and clothes.</p> <p>If the parents cannot be present, encourage them to leave pictures of themselves and the family or tape-recorded stories.</p>
Middle childhood	<p>Arrange telephone calls to parents at bedtime.</p> <p>Allow the child to express fears of separation through imaginary play with puppets or dolls, or through drawings or writing stories.</p> <p>Adhere to bedtime rituals.</p>
Adolescence	<p>Arrange telephone calls to family at bedtime.</p> <p>Enforce mutually agreed upon bedtime.</p> <p>Encourage quiet activity in the hour before bedtime: relaxing music, reading, television.</p> <p>Give back rub.</p> <p>Maintain home bedtime rituals.</p>

NURSING INTERVENTIONS 11–3

Eliminating Noxious Stimuli

- Coordinate care to decrease noise.
- Place noisy equipment away from the head of the bed.
- Keep alarms turned low and promptly respond to them.
- Guard against loud talking, laughing, music.
- Decrease volume on overhead paging system.
- Provide acoustic design measures in the building (e.g., carpet, padded trash can lids, acoustic ceiling tile).
- Cycle light to maintain day and night differentiation.
- Control bright light through dimmed lighting.
- Replace white light with soft yellow lighting.
- Turn off overhead lighting when possible; use direct light at individual bedside as needed; use flashlights to check on children.
- Drape isolettes/cribs to prevent bright light.
- Shield child's eyes and ears.
- Evaluate benefit of providing soft music with a low pitch, slow tempo to promote relaxation.

caREminder

Arrange medication schedules, whenever possible, so they do not interrupt a child's sleep. Plan schedules for weighing and acquiring vital signs to coincide with sleep patterns. Weighing is typically performed on morning waking, prior to feedings. Frequency of assessment of vital signs is determined based on the child's condition; obtain assessments prior to putting the child to sleep and schedule periods of uninterrupted sleep.

Nutrition

Nutrition can become a major challenge in the care of the hospitalized child. Interruption of personal preferences, habits, or family and cultural practices along with malaise from illness can decrease the child's appetite. Certain medications and treatments can interfere with a child's appetite (e.g., methylphenidate [Ritalin] can suppress a child's appetite) and sense of taste (e.g., chemotherapeutic agents and clarithromycin [Biaxin] can result in a metallic aftertaste). Consider all these factors when planning care. Work with the dietitian to determine the optimal diet within the bounds of a prescribed diet. Select developmentally appropriate foods (see Chapters 4–7), with input from parents and children who are old enough. Foods may also be brought in by family members, ensuring that they meet the child's nutritional needs and restrictions, if present. Make provisions for appropriate storage and refrigeration of this food.

WORLDVIEW: The child may be accustomed to having certain staple foods at every meal. Accommodating these preferences may improve the child's intake as well as satisfaction with care.

Maintaining Safety

Providing a safe environment for children in the hospital is a particular challenge for the following reasons:

- Children are at risk for unintentional injury.
- Continuous visualization of the child may not always be possible.
- The environment is potentially harmful (equipment, toxic substances).

The challenge to providing a safe environment for a child while in the hospital is to maintain a developmentally appropriate approach. As the child matures, the safety risks and precautions change (Developmental Considerations 11–3). General safety principles include proper identification of the child and treatment to be performed, and engineering controls that contribute to overall environmental safety.

Patient Identification

Nurses are responsible for many aspects of care that require impeccable attention to correct patient identification. Examples include administering medications or blood

products, obtaining blood samples, performing and preparing children for a variety of medical and surgical procedures, and transporting children to and from various departments. Under any of these circumstances, the consequences of mistaken identity can range from mere embarrassment to personal and professional tragedy. Accurate identification serves two purposes: to reliably identify the individual as the person for whom the service or treatment is intended, and to match the service or treatment to that individual. It is not permissible to use a bed number or only verbally verify the child's name (e.g., "Are you Johnny?") before implementing medical procedures. Verifying the child's identity with two identifiers (e.g., name, date of birth, medical record number), and matching the service about to be performed (by checking the medication label, laboratory requisition, medical record) to the individual is a vital part of every nursing procedure. This is especially pertinent when dealing with preverbal infants or with children whose communicative abilities have been precluded by delayed development or impaired by illness or medical treatment. Document that these precautions have been taken. For example, record the identification bracelet number of a neonate and later note matching it with the birth record and the mother's matching name band.

Accurate identification of the child in the acute care setting is aided by placement of an ID band on the child's wrist or ankle on admission (Nursing Interventions 11–4). If the child has any known allergies, identify these in a similar manner. This is often done with a separate, brightly colored band placed on the same extremity as the ID band.

caREminder

If identification or allergy bands are removed (e.g., for IV placement in that extremity), replace them immediately.

Engineering Controls

General engineering controls that enhance environmental (electrical and mechanical) safety contribute to the child's overall safety. These include physical adjuncts such as cribs, side rails, and immobilizers and safe modes of transport. Close monitoring can prevent the child from getting into dangerous situations.

Cribs

Cribs are typically used for infants and toddlers. Ensure that the crib sides are locked at the highest level when the child is unattended. When providing care to an infant or toddler in a crib with the side down, stand next to the child to prevent him or her from rolling off the crib. If you must turn your back or reach for something, always keep one hand on the child's trunk to prevent him or her from falling (Fig. 11–5).

Covers for cribs such as Plexiglas domes, plastic, or netting are commonly used in the pediatric setting. Use them when the child is old enough to pull to stand and thus could conceivably fall out of the crib (Fig. 11–6).

DEVELOPMENTAL CONSIDERATIONS 11–3

Ensuring Child Safety in the Acute Care Setting

Developmental Stage	Age-Specific Activities and Risks	Guidelines During Hospitalization
Infancy	<p><i>Activities:</i> Rolls over Creeps Crawls Pulls to stand Walks</p> <p><i>Risks:</i> Suffocation Falls Choking Drowning</p>	<p>Keep the side rails up on the crib at all times. Always leave infant in a secure environment, such as a crib with side rails up or strapped in a stroller with wheels locked. Do not leave in prone position or propped with pillows. Do not use pillows or soft bedding. Do not allow parents to sleep while holding or rocking infant. Do not leave with bottle propped. Put a net or Plexiglas dome over crib after age 6 months. Never leave unattended near water, in stroller, or in highchair. Avoid wearing removable jewelry when caring for an infant. Do not leave small medical objects in bed or within reach of child</p>
Early childhood	<p><i>Activities:</i> Walks Explores environment Put objects in mouth Feeds self Continues to perfect gross and fine motor skills</p> <p><i>Risks:</i> Falls Burns Suffocation Poisoning Electrical shock from uncovered outlets Drowning Choking</p>	<p>Keep sharp objects out of reach. Keep out of reach any small, hard objects, such as buttons or coins, or balloons that could be aspirated. Keep medication and toxic substances out of reach. Ensure that the crib is covered and side rails are up. Evaluate motor skills for safety of using a large bed; keep side rails up when the child is in bed. Do not leave the child unattended near water. Do not leave the child unattended when not secured, such as with a stroller or wheelchair strap. Supervise feeding. Avoid foods that present a choking hazard, such as whole grapes, hot dogs, peanuts.</p>
Middle childhood	<p><i>Activities:</i> Continues to refine fine motor skills Participates in gross motor activities such as sports</p> <p><i>Risks:</i> Falls</p>	<p>Keep side rails up when the child is in bed. If parents/child do not wish this, obtain consent for release. Ensure that child understands mobility limitations. Supervise play activities to minimize risk taking that could lead to falls or other injuries. Discuss stranger safety as age appropriate to hospital setting.</p>
Adolescence	<p><i>Activities:</i> Demonstrates thrill-seeking behaviors Has a preoccupation with body image</p> <p><i>Risks:</i> Substance abuse Noncompliance with medical regimen that affects body image (e.g., not wearing splints)</p>	<p>Provide adolescent-oriented activity rooms that promote age-appropriate activities geared to interest, expression of feelings, and peer interactions. Discuss safety as appropriate to child's treatment, hospital setting, and safety off the unit.</p>

NURSING INTERVENTIONS 11–4

Pediatric Identification Strategies

- Ensure the presence of a name band in locations where direct physical care is provided (e.g., the emergency department, day surgery unit, or an inpatient setting). In the emergency department, the child's parent or caregiver may verify the child's name and date of birth. Place ID bands on the child as soon as possible to assist in accurate identification for all clinicians.
- Always verify the child's identification before performing any nursing procedure. Younger children may answer to any name. Older children may think it is funny to "switch" and trick the nurse. Identification verification requires two separate identifiers (e.g., name, date of birth, medical record number) to identify the child and match the service to be performed with that child.
- Identify and double-check the organ, extremity, or side of the body to be treated with other health team members taking "time-out" prior to treatment initiation to deliberately verify patient identity and the service to be performed.
- Double-check crib and wrist tags before removing or returning infants to crib or room.
- Be aware of more than one child with the same name. This occurs frequently in newborn nurseries prior to the infant acquiring a first name.
- Be aware of the child's whereabouts, on or off the unit.
- Check both ID bands from the delivery setting to match names and numbers in the case of handing a newborn to a mother. It is not realistic to expect newly delivered mothers to recognize their newborns, especially if they are exhausted, sick, or under the influence of mind-impairing medication.
- Ask the mother to keep her own ID band on her wrist when a newborn must remain hospitalized after the mother's discharge. Such ID bands are not removable without cutting them off, and any such handling of the ID band will be readily noticeable.
- Take immediately accessible photographs (digital, Polaroid) of the parents (especially the mother) and infant together in the event of an expected prolonged hospitalization of the newborn. Keep one for the chart, and give parents the other one. Have the parent bring his or her ID band at the time of discharge.

Side Rails

Side rails are commonly used in the hospital to prevent the patient from falling out of bed. Because side rails vary in design, learn how to operate them in that particular setting. Ensure that they are locked in place when leaving the bedside and know how to lower them quickly in an emergency.

FIGURE 11–5. Safety is always a priority. Keep at least one hand on the infant at all times when not properly secured.

Immobilizers

The terms *restraint*, *immobilization*, *clinical holding*, and *holding* are often used interchangeably in pediatrics (Brenner, 2007) but there is a distinction between restraining a patient for behavioral reasons and to reduce risk of interfering with treatments. Behavioral health care

FIGURE 11–6. A crib cover can be used to restrain a child who is old enough to stand up.

reasons for restraint are to protect the patient or others from injury because of violent or aggressive behavior (Joint Commission, 2007). Because restraints to protect surgical and treatment sites are not considered restraint by the Joint Commission (although some state regulations do), the term *immobilization* will be used to indicate actions used to restrict activity as part of the treatment plan (e.g., traction); to prevent interfering with tubes, dressings, or healing tissue (e.g., elbow immobilizers); or facilitate administration of medications or treatments.

The Joint Commission plays a leadership role in ensuring that hospitals are protecting consumer rights through the appropriate use of restraints. The Joint Commission requires that patients with arm, leg, or jacket restraints be checked periodically for neurovascular integrity and general safety, and that this assessment information be documented in the patient's chart. Hospital policy dictates the frequency of assessment, but assessment must be performed at least every 15 minutes in behavioral healthcare settings. Release immobilization devices, when able (e.g., elbow immobilizers), and restraints at least every 2 hours; document assessment of the child's overall status, including hygiene, elimination, and nutrition. A licensed independent practitioner's order stating the reason for the restraints, type of restraint, and duration of restraint is required and must be rewritten every 24 hours.

A serious infringement of patients' rights is the use of restraints for punishment. Never use a restraint to discipline a child, to place them in "time-out." Time-outs are used to help the child regain self-control of behavior. The use of restraints imposes an external control, rather than allowing the child to develop internal control.

Nurses report using physical restraint to promote inactivity or immobility, to prevent interference with tubes or dressings, to prevent touching or scratching healing tissue, to facilitate administration of medications or

treatments, to prevent children from getting out of bed or into dangerous places, or to protect staff from combativeness (Snyder, 2004). Nurses often use these devices because they *think* the child will interfere with treatment (Snyder, 2004).

Alert! Because use of restraints and immobilization can result in complications such as falls, incontinence, and pressure sore formation, it is prudent to minimize use of these while still providing a safe environment and preventing disruption of medical treatments (Nursing Interventions 11–5). Exhaust all alternatives to immobilization (e.g., distraction, parental or staff presence) before using any restraint, and implement the least restrictive methods first.

Limb Immobilizers

Limb immobilizers are used when children could harm themselves if not immobilized and they are used to prevent treatment interference, such as ensuring the integrity of IV sites, catheters, endotracheal tubes, feeding tubes, and surgical sites and dressings. Many commercial immobilizers are available; most include a soft sponge to protect circulation.

Alert! When immobilizing limbs, ensure that the immobilizer cannot tighten around the extremity. Use padding to protect circulation, and fasten it in a way that prevents impaired circulation. Never tie immobilizers to bed side rails because raising or lowering of the rail could injure the immobilized limb.

Elbow Immobilizers

Elbow immobilizers are sometimes used to prevent the child from reaching the face to do harm. They prevent elbow flexion but leave the hands free for play and

NURSING INTERVENTIONS 11–5

Alternatives to Using Immobilization

- Increase supervision of child by parents, family, friends, volunteers, or nurses.
- Have windows to increase ability to observe the child when not physically in the same room.
- Actively listen to the child.
- Ask the parent the most effective methods of obtaining compliance from and distracting the child.
- Take the child to the nurses' station or playroom, unless contraindicated by the child's condition.
- Provide activities to distract the child and to promote expression of feelings such as anger or aggression.
- Prepare the child for procedures as developmentally appropriate, because a prepared child may maintain better control and need less restraint.
- Hold the child's hand or foot; simple touch may comfort the child and help remind them to "hold still."
- Protect and cover the site (e.g., tape IVs well, cover with a cup or gauze); put clothes on the child, which make it physically more difficult to pull out a tube or disrupt a wound.
- Ensure that the child's hygiene, nutrition, toileting, and comfort needs are met.
- Minimize environmental stimuli if they trigger the child's loss of control.

exploration (Fig. 11–7A). They may be needed after cleft lip and palate repair or to prevent pulling out oral or nasal feeding tubes.

Mummy Immobilization

Mummy immobilization is useful when performing procedures for which the infant or toddler must remain still. With appropriate teaching, they may be used by a parent who must perform procedures with the child at home, such as changing tracheostomy tubes or performing wound care. Place the child on the diagonal of a blanket with the feet and head at opposite corners. Wrap the sides over the child's chest and secure the feet by tucking the lower corner over them. Tape can be used to hold the folds in place (Fig. 11–7B). Papoose boards (manufactured boards with canvas flaps that attach in place by Velcro to secure the child during procedures) may also be used.

Safety Belts

Always use safety belts when young children are placed in infant seats, swings, or high chairs. A strap should be secured to the chair that runs between the child's legs up to the belt, to prevent the child from sliding down and injuring himself or herself.

FIGURE 11–7. Two types of restraints. (A) Elbow restraint. (B) Mummy restraint.

Transports

During transport or transfer of the child, several actions can increase safety. It is unsafe to carry a child for a long distance because of the risk of tripping, slipping, falling, or fatiguing. Walking for a distance is not an appropriate option for sick children. Use transport devices, such as wheelchairs and stretchers, to transport children from the pediatric unit to other areas of the hospital, such as radiology or the laboratory. Use a crib-type stretcher with side rails covering the entire length for infants and toddlers requiring stretcher transport. Never leave a pediatric patient alone when being transported. Also, have ready, easy access to the child's head at all times, should vomiting or respiratory distress occur. When the child is being transferred in or out of a stretcher or wheelchair, lock the wheels in place to prevent falls. Always secure the safety straps or “seat belts” on wheelchairs, strollers, and wagons.

Latex Allergies

Although measures are taken to provide a safe environment for children, families, and healthcare workers, the acute care setting poses an additional hazard for those who are allergic to latex, because the environment contains many products that contain latex as well as airborne latex allergens (particularly from powdered latex gloves). Those with increased exposure to latex are at highest risk of developing latex allergy. Early reports of latex sensitivity were from patients with myelomeningocele. It is now recognized that patients who have undergone multiple surgeries and those with a history of atopy are also at high risk for developing latex allergy (Guillet, Guillet, & Dagregorio, 2005) (Tradition or Science 11–1).

TRADITION OR SCIENCE 11–1

Is latex allergy more prevalent in children who are exposed to medical procedures? What are the risk factors?

EVIDENCE-BASED PRACTICE

Studies demonstrate a high incidence of latex allergy in children exposed to medical procedures including those with spina bifida, esophageal atresia, urogenital disorders (Cremer et al., 2007), chronic renal failure (Dehlink et al., 2004), hematologic and oncologic disease (Bostanci et al., 2003), and those requiring home ventilation (Nakamura et al., 2000). Sparta et al (2004) found a positive correlation between the number of operations and latex sensitivity, whereas Hourihane et al. (2002) found that a previous operation increased the odds of latex sensitization 13 times whereas multiple operations had a less marked effect. Spina bifida has a disease-associated propensity for latex sensitization (Ausili et al., 2007). More inquiry is needed to identify children most at risk, the factors involved, and how much latex exposure may result in sensitization.

The most common allergic reaction to latex is a delayed hypersensitivity presenting as contact dermatitis (Guillet et al., 2005). A less common but more serious reaction is an immediate response that presents as urticaria, rhinoconjunctivitis, bronchospasm, and anaphylaxis. Maintain a high index of suspicion regarding latex allergy because its symptoms are difficult to distinguish from other allergic reactions or causes.

The best treatment for latex allergy is identification of high-risk populations and minimizing latex exposure in these children. Latex is found in many products used both in the home and in the healthcare setting, such as tubing in blood pressure cuffs and stethoscopes, pulse oximeter probes, bulb syringes, catheters, disposable diapers, and some toys (see [thePoint](#) for Supplemental Information: Examples of Latex Items in Medical and Community Environments). Make latex-free substitutions when possible. The Spina Bifida Association of America maintains a current list of latex-safe alternatives (see the [thePoint](#) for Organizations).

Label the medical and dental charts of children at high risk for, or identified with, latex allergy. Notify the child's school or child care center to have nonlatex gloves and an EpiPen available, and notify healthcare providers in an emergency.

In the acute care setting, latex avoidance is particularly important because many products contain latex. Initiate latex precautions and teach the child and family about latex-containing products. In addition to using latex-free products such as latex-free IV tubing and injection ports, carefully administer medications to prevent latex exposure. It is questionable whether syringes with rubber stoppers on the plunger may leak latex into the medication. Therefore, draw up medications immediately before administration.

Schedule the high-risk child going to surgery as the first case of the day to minimize exposure to airborne latex. Notify the anesthesia care practitioner of the latex allergy. With early identification of children at risk for developing latex allergy and meticulous attention to latex avoidance, latex allergy and the resultant deleterious effects may be minimized.

Visitor Identification and Management

Despite how busy any pediatric setting may become, the nurse must be aware of every individual on the premises and also of visitors' or callers' relationships to specific children. Be aware of strangers on the unit and those asking questions about the children. The possibility of unauthorized adults trying to obtain information about a child's condition, or even of kidnapping and abduction, is very real. This is especially true in large and busy settings where visitor flow is difficult to control.

All visitors should receive prior parental permission; however, this is not the reality in most practice settings, especially with short-stay admissions. Determine information about visitor restrictions with the initial admission assessment. This alerts the nursing staff to situations in which custody issues may arise or in which there are restraining orders preventing specific individuals from seeing certain children.

Most of the missing children in the United States are abducted by one of their own parents (Finkelhor & Ormrod, 2002). Some of these abductions occur when the family is experiencing unusual circumstances, such as hospitalization for an acute illness. Proper patient and visitor identification policies along with a well-planned and structured infant and child security program within the hospital setting can prevent child abductions and provide a safe environment for the acutely ill child.

Infant and Child Security

Crime and violence against children have drawn much attention at the national level in recent years. Several cases of kidnapping of children from hospitals and nurseries have occurred. Gang violence has become a concern in the pediatric setting as younger and younger children are victims of gang crimes in urban settings and are hospitalized with injuries. Security measures to protect these victims from further retaliation have become necessary.

The safety and protection of patients and others must be secured in the acute care setting. A good security program combines several approaches. The facility must develop and adhere to policies that safeguard children; educate and promote teamwork by all staff, parents, and visitors; and provide physical and electronic security measures (Rabun, 2005).

Security policies vary according to setting. Most units that deal with newborns have strict policies regarding infant, mother, and father ID banding; saving cord blood; obtaining footprints and photographs of the infant shortly after birth; and identifying the person to whom the infant is discharged. Pediatric units must have similar policies in place (Chart 11–2). The institution should post and enforce the policy that parents are not allowed to leave children unattended in waiting rooms.

All staff, parents, and visitors must be familiar with security policies and adhere to them. Staff should be informed of the policies during orientation, and should inform parents and children (as appropriate) during the child's admission to the facility. Everyone must be alert for suspicious behavior and report it immediately. Abductors often do not target a specific child, but plan carefully, visit the facility, and seize the opportunity to take a child when it presents itself. The more obstacles a potential abductor encounters, the greater the chance to prevent the abduction (TIP 11–1). Teamwork is essential both to deter a potential abductor and to ensure rapid response if an abduction occurs. Critical incident response policies must be in place to ensure a rapid, coordinated response when an incident occurs. A rapid response increases the chance that the child will be found.

Physical and environmental controls can play a key role in preventing abduction. Carefully screen visitors who are allowed to gain entry to the facility's inpatient area, as noted earlier. In cases of individual need for increased protection, use visitor restrictions that designate who may and may not visit the child. In newborn nurseries, arrange visitation hours that permit viewing without physical access to the infants. Ensure that identifying data, such as mother's full name, are not displayed

CHART 11-2 SAMPLE SECURITY POLICIES FOR A PEDIATRIC UNIT

- All staff must wear the institution's photo ID above the waist; consider adding some other identification to indicate those who are allowed to transport the child.
- All staff are to monitor and report any suspicious behavior by visitors (e.g., visiting "just to see" infants, questioning the facility's procedures or physical layout, carrying a large package off the unit, taking hospital lab coats or scrubs).
- Keep staff locker rooms locked; do not let visitors borrow scrubs or lab coats.
- All visitors must enter and exit through an access-controlled corridor.
- Parents or visitors must wear an ID wristband or show a photo ID.
- Question anyone transporting a child without displaying the proper identification, either the institution's photo ID or an authorized ID band for that child.
- Upon admission, assess for high-risk children (e.g., custody issues, child abuse).
- At admission, footprint and photograph infants, and perform and document a complete physical examination.
- Assign infants to rooms close to the nurses' station, not near stairwells or exits; keep infants in line-of-sight supervision.
- Transport children via appropriate mechanism (bassinet, wheelchair, gurney); *never* carry the child in the halls.
- Transport only one child at a time.

on the crib card or where visitors could view it. The abductor may attempt to take the child from the home. Measures such as surveillance cameras and door alarms increase environmental security.

Alert! Specific photo IDs should be mandatory for personnel allowed to transport children. This policy makes it readily apparent when an unauthorized person is moving the child.

Healthcare facilities are also increasing their security staff. Emergency rooms are improving security by having armed personnel on guard at all times and limiting access through the use of locked doors that, with the exception of employees, can be entered only with permission. These constraints may seem excessive and annoying to the patients and families if they do not understand the reasons for them. Review the rationale for implementing security precautions; all staff should reinforce and comply with these precautions.

Performing Routine Procedures

Performing procedures, including specimen collection, on children can be time-consuming at best. At worst, it can be frustrating or even impossible without taking extreme measures, such as using restraints. Small children are afraid of procedures and often are very unwilling to cooperate. Knowing not only how to minimize trauma to the child and parent but also how to perform the task requires skill. Explain the purpose of, steps to, and outcomes expected from the procedure to the child and parent. This requires knowing the major fears of the child's age group, understanding the best time to give information as determined by the child's developmental level, providing preparation at that time, and addressing fears

TIP 11-1 A Teaching Intervention Plan for Parents to Deter Child Abduction From a Hospital

Nursing Diagnosis and Family Outcomes

- Ineffective protection related to child's age and vulnerability in acute care setting

Outcomes: Family will be knowledgeable about and comply with safety policies.

Child will not be abducted from healthcare facility.

Interventions

Educate the Parents

- Never let your child be taken from the room by anyone without a proper ID photo badge.

- Do not hesitate to question staff regarding their identity and the reason for taking the child.
- Stay with your child if possible.
- Do not give out personal information such as your address to anyone without him or her having a legitimate reason for needing it.
- Become familiar with hospital personnel who work on the unit; meet the nurse assigned to care for your child.
- Report suspicious behavior immediately.
- Observe the facility's policies regarding security, safety, and visitation.

by using language or props that the child can understand. Therefore, perform a developmental assessment of the child and intervene to promote coping and to preempt pain (see Chapter 10).

Use honest, understandable language when talking to children about pain and procedures. Ambiguity or unfamiliarity with language is particularly a problem in early childhood, but older children are also subject to misunderstanding, especially if ambiguous or unfamiliar terms are used (Table 11–1). Include explanations about what will happen and why, what the effects will be, and how the child can help during the procedure. Choose vivid language and sensory information for preparations, such as color, sound, size, or shape. Avoid jargon, fantasy, and ambiguity when asked if a procedure is going to hurt. Do not be dishonest about the outcome or the pain involved; try to describe it as well as possible.

A systematic review of the research indicates that parental participation during procedures may not positively or negatively affect child distress, but it is not detrimental (Piira et al., 2005). It may be that children are more likely to express distress to a parent or that benefits such as fewer postprocedure effects are not captured in the research. Parents who were present either had less distress and higher satisfaction or were no different from absent parents (Piira et al., 2005).

In addition to preparing the child and family, successful procedure performance also depends on knowledge of age-dependent variances and proper equipment selection and use (Nursing Interventions 11–6). Considerations for and techniques of medication administration to children are discussed in Chapter 9.

Maintaining Infection Control

Infection control is an increasingly important focus in healthcare settings. Hepatitis B, hepatitis C, and HIV are the most common risks to healthcare workers (Tarantola, Abiteboul, and Rachline, 2006). The spread of these diseases and others such as drug-resistant tuberculosis has increased the need for facilities to provide exposure control plans, and workplace and engineering controls that protect patients, visitors, and healthcare workers. It is essential to follow all hospital guidelines and policies designed to prevent the spread of infection.

Standard Precautions

The control of potential infections is of critical importance in pediatric care because nosocomial infections are important contributors to morbidity and mortality in young hospitalized patients (Couto et al., 2007). The most important way to minimize exposure to and transmission of pathogens is by following standard precautions.

caREminder

Handle all body fluid using standard precautions, regardless of whether it has been tested and identified as containing contagions. This includes wearing gloves to change diapers.

The overriding goal of infection control programs is the protection of all patients and staff at all times from infectious disease. Although healthcare providers can be infected by contact with patients, patients are more susceptible to infection. This is because hospitalization is more likely to occur when the general state of health is impaired, and the ability of the immune system to ward off infection is likely compromised. Furthermore, many patients experience invasive procedures, which allow a port of entry for exogenous bacteria to enter the body. To reduce the spread of microorganisms by direct contact with patients, perform hand hygiene before *and* after contact with each child.

Appropriately disinfect patient care materials between children, or use single-use disposal equipment to reduce the spread of microorganisms by indirect contact. Instruct children and employees to cover their nose and mouth when sneezing and coughing, using disposable tissues if possible, and then perform hand hygiene to reduce airborne contamination.

When following standard precautions, healthcare personnel wear gloves and other personal protective equipment as needed for protection from contact with blood and other body fluids. Perform hand hygiene after gloves are removed. Change gloves between patients and remove before contact with objects such as the telephone or a pen.

Strict adherence to standard precautions can become another stressor for the child and family in the acute care setting. Children and families may be approached by personnel wearing protective devices, such as gowns, masks, and goggles. Parents may be required to wear this personal protective equipment when caring for their children.

Furthermore, infection control measures may impede family and cultural practices. Some families may want to store food in the room. Others may want to keep plants, flowers, or small pets (e.g., fish). These items can harbor bacteria or act as vectors for insect infestations. To compound the problem, some families may belong to cultures that do not adhere to the germ theory of disease; they may not adhere to western standards of hygiene related to handwashing and food storage practices. In such cases, the nurse is challenged to educate the family in such a manner as to promote their compliance with infection control standards as well as their satisfaction with the acute care experience.

Isolation

Isolation refers to protecting the child and others from infectious agents. This may be done in a variety of ways, depending on the disease. Whatever isolation technique is required, the child usually must be sequestered from the environment at large. For example, the child may be confined to a private room, may need to keep a draining wound covered, or may need to wear a mask when leaving the room. Children in isolation may be sequestered from others in the environment. Such measures can be frightening for the child, and annoying and cumbersome for families. Sequestration can impair the child emotionally and socially. Toddlers and preschoolers cannot fully

TABLE 11-1

Language Considerations for Children

Potentially Ambiguous	Clearer
The doctor will give you some “dye.” <i>To make me die.</i>	“The doctor will put some medicine in the tube that will help her be able to see your _____ more clearly.”
Dressing, dressing change <i>Why are they going to undress me? Do I have to change my clothes? Will I be naked?</i>	“Bandages; clean new bandages.”
Stool collection <i>Why do they want to collect little chairs?</i>	Use child’s familiar term, such as <i>poop</i> , <i>BM</i> , or <i>doody</i> .
Urine <i>You’re in?</i>	Use child’s familiar term, such as <i>pee</i> .
Shot <i>Are they mad at me? When people get shot, they’re really badly hurt. Are they trying to hurt me?</i>	“Medicine through a (small, tiny) needle.”
CAT scan <i>Will there be cats? Or something that scratches?</i>	Describe in simple terms, and explain what the letters of the common name stand for (if child is old enough to understand).
PICU <i>Pick you?</i>	Describe in simple terms, and explain what the letters of the common name stand for (if child is old enough to understand).
ICU <i>I see you?</i>	Describe in simple terms, and explain what the letters of the common name stand for (if child is old enough to understand).
IV <i>Ivy?</i>	Describe in simple terms, and explain what the letters of the common name stand for (if child is old enough to understand).
Stretcher <i>Stretch her? Stretch who? Why?</i>	“Bed on wheels.”
Special, funny <i>It doesn’t look/feel special to me.</i>	“Odd, different, unusual, strange.”
Gas, sleeping gas <i>Is someone going to pour gasoline into the mask?</i>	“Medicine, called anesthesia. It is a kind of air you will breathe through a mask like this to help you sleep during your operation so you won’t feel anything. It is a different kind of sleep.” Explain differences.
Put you to sleep <i>Like my cat was put to sleep? It never came back.</i>	“Medicine, called anesthesia. It is a kind of air you will breathe through a mask like this to help you sleep during your operation so you won’t feel anything. It is a different kind of sleep.” Explain differences.
Move you to the floor <i>Why are they going to put me on the ground? Or to the (treatment room) table People aren’t supposed to get up on tables.</i>	“Unit; ward.” Explain why the child is being transferred, and where. “A narrow bed.”
Take a picture (radiographs, CT, and MRI machines are far larger than a familiar camera, move differently, and don’t yield a familiar end product.)	“A picture of the inside of you.” Describe appearance, sounds, and movement of the equipment.
Flush your IV <i>Flush it down the toilet?</i>	Explain in simple terms, “Put some water in your IV tube.”

As long as ... (e.g., for duration of a procedure)	“For less time than it takes you to ...”
As much as ...	“Less than ...”
You will have to say good-bye to your parents.	“That will be the time when you say ‘See you later’ to your parents.”
Lots of children feel sick to their stomachs and throw up when they wake up.	“Your stomach has also been asleep and resting. It may need time to wake up. As your stomach wakes up, you will slowly be able to drink and then eat food again. Some children say they feel sick while their stomachs wake up; other children say they feel fine.”
You will have a sore throat when you wake up.	“Your throat may feel very dry when you wake up.”
You are angry/scared/sad. That was very hard for you.	“How was that for you? Was it the way you thought it would be? Or harder or easier? Is there something else we should tell people about this?”

From Gaynard, L., Wolfer, J., Goldberger, J., Thompson, R., Redburn, L., & Laidley, L. (1998). *Psychosocial care of children in hospitals: A clinical practice manual* (pp. 62–65). Rockville, MD: Child Life Council. Adapted with permission.

understand these processes and, hence, have greater difficulty coping during periods of required isolation. Provide developmentally appropriate diversional activities for the child to enhance coping.

Perhaps the intervention of the greatest importance for promoting effective coping of the isolated child is that of educating the family. The family who understands the reason for isolation can become the nurse’s ally in finding ways to make the experience more acceptable to the child. Families are often the best source for learning what the child fears, which activities he or she prefers, and which measures he or she finds most comforting. Social isolation is an unpleasant experience usually accompanied by depression, fatigue, frustration, and anger. Therefore, minimizing the impact of isolation is an important challenge for the nurse. Additional tips for minimizing social isolation include the following:

- Discuss with the parents and significant others the importance of their visiting the child.
- Include parents in the process of explaining the isolation to the child when developmentally appropriate.
- Encourage picture videos of family, friends, and pets.
- Provide access to telephone or videophone where available.
- Arrange for the child life specialist to visit the child for therapeutic play.

Educating the Child and Family

Education is an integral component of nursing care and a standard of professional practice. To promote positive patient outcomes, the nurse must adopt education strategies that enhance learning readiness and facilitate effective

learning. The process of patient teaching resembles the nursing process. Teaching begins with an assessment of the problem and of readiness to learn. Then it progresses to development of a plan, implementation of the plan, and evaluation of its effectiveness.

Learning needs are affected by many factors, including prior experience with illness, cultural background, language skills, educational level, and developmental level. During the admission assessment, determine the factors that may influence learning and establish a rapport. Throughout the initial interview, collect data about the child’s physical and psychosocial needs. Then analyze the data to determine whether the child and family understand the situation. Identifying knowledge deficits on admission, enables the nurse to plan teaching strategies that address the family’s learning needs and promote coping.

caREminder

Every contact with the child and family is a teaching opportunity. After evaluating readiness to learn, barriers to learning, and preferred learning methods, present content at an appropriate level (e.g., if anxious, present simple, focused information; if asking appropriate questions, proceed to more complex topics). Issues taught may range from specific care of the child to anticipatory guidance and health promotion.

Promoting Coping: The Child

To provide support to children and help them cope with their experiences, one must first understand how children typically respond to hospitalization.

NURSING INTERVENTIONS 11–6

Procedures

Procedure	Variations	Nursing Considerations
All	<p>Children understand and react to situations based on cognitive maturity; gear teaching and support to cognitive level.</p> <p>Developmentally appropriate support helps child maintain control.</p>	<p>Prepare for procedure as developmentally appropriate.</p> <p>Give choices as appropriate.</p> <p>Offer coping strategies (e.g., pacifier for infant, distraction for toddler).</p> <p>Teach parents techniques to support child during procedure (e.g., distraction).</p> <p>Have another staff member available to hold/assist as needed.</p> <p>Do not perform procedures in the child's bed if possible, or the playroom; keep these safe areas.</p> <p>After the procedure, provide comfort measures and positive reinforcement.</p> <p>See Chapter 10 for considerations for painful procedures.</p>
Blood specimen collection	<p>Small total blood volume in young children increases risk of anemia and fluid volume deficit with frequent blood draws. Most laboratories can analyze values based on a small amount of blood.</p> <p>Infant's skin is thinner, does not provide a good barrier to toxic agents, and is susceptible to damage.</p>	<p>Use a topical anesthetic on site prior to nonurgent blood draws.</p> <p>Use a bandage to prevent bleeding after specimen collection, especially in preschoolers.</p> <p>In neonates and children requiring frequent blood sampling, maintain ongoing tally of the amount of blood extracted (in cubic centimeters).</p> <p>Collect minimal amount of blood required to perform laboratory analysis.</p> <p>In infants (<2 months) cleanse antiseptics from skin afterward.</p>
Venipuncture	<p>Common sites are veins on dorsum of hand, antecubital flexor surface of foot, and wrist (very sensitive area).</p>	<p>Help child maintain control of situation; if appropriate, offer choice of sites, have child help cleanse site.</p> <p>If unable to obtain venous access after two or three attempts, have another practitioner do the puncture.</p> <p>After procedure, apply pressure to site until bleeding stops, then cover as appropriate (e.g., no tape for premature infant, bandage for preschooler).</p> <p>Choose site carefully (check landmarks).</p> <p>Warm the extremity prior to drawing blood; wet a disposable diaper with warm water and wrap around the foot or hand.</p>
Capillary puncture	<p>Can use medial and lateral aspects of the heel up to about 18 months of age; do not puncture posterior curvature to avoid striking the calcaneus. Use side of finger in older children.</p>	<p>Do not squeeze extremity excessively when drawing blood (causes cells to hemolyze so may obtain false high K^+ level).</p>

Procedure	Variations	Nursing Considerations
Urine specimen collection	<p>Language used by the nurse may be misunderstood by the child.</p> <p>Adolescent may be unable to void on request or may be reluctant to have test completed because of concerns over body image; body functions, and privacy; suspicion that specimen is requested for drug testing.</p> <p>Urine may be aspirated from cotton balls for small-volume tests such as specific gravity, pH, or glucose; disposable diapers with absorbent gel are difficult to aspirate from and yield inaccurate results</p>	<p>Use child's words such as <i>pee-pee</i> to make request.</p> <p>Provide privacy for older child, adolescent.</p> <p>Clean area or teach child/parent correct cleaning method for clean-catch specimen.</p> <p>Provide potty chair or urine collector in toilet for preschool- or school-aged child.</p> <p>Explain to adolescent why test is needed.</p> <p>Offer child something to drink; most infants void shortly after feeding. Too much fluid may dilute the specific gravity of the urine.</p> <p>Place cotton balls near the urethra inside the diaper to squeeze out urine for small volume testing; do not aspirate urine from diaper.</p> <p>Run water in sink to trigger urge to void.</p> <p>Clean and dry perineal skin.</p>
<p>Urine bag</p> 	<p>Lack of bowel/bladder control does not allow young children to voluntarily cooperate with specimen collection. Use urine bag to collect urine for larger amounts (e.g., routine urinalysis).</p>	<p>Apply chemical adhesive (e.g., tincture of benzoin) to help maintain seal (do not use on premature infants, neonates).</p> <p>To place on female: position lower half of adhesive on bag on perineum first, then press on adhesive up toward symphysis.</p> <p>To place on male: insert penis and scrotum into bag opening; adhesive adheres to perineum and symphysis.</p> <p>Ensure bag does not cover anus, to reduce contamination.</p> <p>Cut a hole in the diaper, pull the urine bag through the opening; thus, when the child voids, it is easily visible and the bag can be removed immediately.</p>
Urine catheterization	<p>Swelling of the labia in female neonates, resulting from maternal hormones, makes it difficult to visualize urethral opening; may have excess tissue overlying opening.</p> <p>Choose urinary catheter size depending on child's age. Use of shorter length urinary catheters, not feeding tubes, and basing length of insertion on sex and age, can reduce incidence of knotting (e.g., for toddlers and younger females, insert 2 in; for male infants, insert 3 in; male toddlers, 3–4 in)</p>	<p>Have second person maintain child in frog-leg position.</p> <p>Use thumb and forefinger to spread labia.</p> <p>Exert slight pressure up and out to reveal urethral opening in female.</p> <p>Apply sterile lubricant, using specific adapter containing 2% Xylocaine around meatus and into urethra meatus.</p> <p>Have extra catheter ready; if the first is contaminated or inadvertently placed in vagina, leave it in place, and put the second catheter in other opening (urethra).</p> <p>Insert indwelling catheters to the hub of the catheter, and do not inflate balloon until urine is seen; after balloon inflation, pull catheter back to seat at bladder base.</p> <p>If indwelling catheter or urine bag with drainage tubing is used, ensure collection tubing is out of young child's reach, out of view.</p>

(Continued)

NURSING INTERVENTIONS 11–6

Procedures (Continued)

Procedure	Variations	Nursing Considerations
Stool collection	May be particularly embarrassing for school-aged child and adolescent.	Know the words the child uses for stool. With nontilet-trained child, scrape stool from a diaper using tongue blade and place in stool collection cup. Ask toilet-trained child to use a potty chair or place a collection container in the toilet. Provide privacy.
Sputum specimen collection	Infants/toddlers will not cough productively on command; must use suctioning to obtain specimen.	Do not exceed 80 to 100 mm Hg suction pressure. Limit suctioning time to 10 seconds.
Nasogastric/ orogastric tube placement	The young child cannot cooperate by swallowing during tube insertion.	Measure tip of tube from child's nose to earlobe to xiphoid process. Mark level on tube with tape, lubricate tip with water or soluble lubricant, and quickly insert. In young child, may need to angle tube toward occiput rather than up. Do not exert pressure on nares when taping tube to cheek.

See [thePoint](#) for information on the following procedures: Blood Drawing from Peripheral Sites: Heel Stick and Finger Stick, Urine Collection: Routine Voided, Urinary Catheterization: Insertion and Removal, Enteral Tube Placement and Management: Naso-/Orogastric Tubes

Child's Response to Hospitalization

Children tend to respond to hospitalization with emotional upset. Seminal work by Prugh et al. (1953) revealed how children react negatively to the stress of hospitalization with separation anxiety, loss of control, and fears. Since then, hospitalization has changed with higher acuity, shorter stays, and increased parental involvement. Still, negative consequences are common, such as aggression, hyperactivity, anxiety, depression, posttraumatic distress, and somatization (Melnyk et al., 2004; Murray, Kenardy, & Spence, 2007; Small & Melnyk, 2006). Be cognizant of the threat that hospitalization poses to normal development and intervene to reduce the risk.

Separation Anxiety

Hospitalized children between the ages of 6 months and 4 years are at the greatest risk for separation anxiety. Older children are still at risk, but increasing cognitive

abilities and concept of time help them cope. Classic work by Robertson (1958), who expanded on the work of John Bowlby, describes the phases through which young children progress when separated from their parents:

- *Protest*: In this phase, lasting hours to days, the child searches for the lost parent, angrily protests, cries frequently, and rejects hospital staff. When the parent returns, the child readily goes to him or her.
- *Despair*: In this phase, the child becomes more sad and apathetic, mourning the lost parent; however, he or she cries less and searches the environment less. The child makes few demands on the environment and those within it. When the parent returns, the child may not readily approach him or her or may cling to the parent.
- *Denial*: In this phase, the child becomes cheerful, interested in the environment and new persons, and seemingly unaware of the lost parent. The child is friendly with staff and begins to develop superficial relationships.

When the parent returns the child typically ignores them as a coping mechanism to avoid further emotional pain. Bowlby called this stage *detachment* (Alop-Shields & Mohay, 2001). This stage is more common to long-term separation. With rooming-in of parents, hospitalization rarely progresses to this stage. Because the child becomes increasingly “easier” to work with, it may be mistakenly interpreted that the child is coping effectively. Children who progress to denial, however, suffer long-term impaired parental relationships and impaired trust, which can lead to problems in establishing close relationships, attention deficits, self-centeredness, and decreased intellectual functioning. Therefore, the pediatric nurse must develop interventions that reduce separation anxiety (Developmental Considerations 11–4).

Separation anxiety is not unique to younger children. Although preschoolers exhibit fewer symptoms of restlessness, hyperactivity, and irritability, they do exhibit more somatic symptoms such as vomiting, urinary frequency, diarrhea, and dizziness (Clinical Judgment 11–1).

School-aged children manifest anxiety but exhibit fewer panic reactions than younger children. Children of this age have a concept of time and understand that parents need to leave and that they will return. In addition, school-aged children are separated from their friends and school, which play a major part in their psychosocial development. A school-aged child’s anxiety is related to fear of the unknown or the unexplained, and his or her coping mechanisms usually include denial and rationalization.

The adolescent suffers separation anxiety when separated from peers rather than parents, but it is still crucial that he or she is confident in the family’s personal commitment. The adolescent’s efforts to maintain peer contact may break hospital rules. For example, the adolescent may leave the hospital without permission, leave the unit after hours to meet peers in the lobby, use the telephone excessively (to the exclusion of participating in the hospital regimen), or refuse hospital treatments that are viewed as disfiguring or displeasing to peers.

To help prevent separation anxiety while a child is in the hospital, it is important to minimize separation of the child from support systems. Encourage open visitation and provide parents with the environment (e.g., sleep space, showers) and support (e.g., information, equipment) to facilitate their role as a member of the team caring for their child. Encourage friends and schoolmates to send cards and videotapes, and to visit when appropriate. Bringing in transitional objects, such as pictures of families and friends, to put in the room can help to decrease the separation anxiety that may be felt.

Loss of Control

Hospitalized children commonly experience loss of control (Rennick, Johnston, Dougherty et al., 2002). Unlike separation anxiety, which decreases as the child ages, control issues persist because the child is removed from the normal environment. Toddlers and preschoolers are at

highest risk for loss of control. The toddler has just gained the ability to explore the environment. Developmental milestones such as potty training and the ability to feed oneself may be initiated or mastered. Hospitalization may interfere with the toddler’s search for autonomy. A broken leg that is immobilized or a peripheral IV line in the dominant hand may place limitations on the child who can ambulate or feed him- or herself. A previously potty-trained toddler who is limited to bed rest and receiving IV fluids may regress to voiding in the bed. This loss of control can be very stressful for the patient. Nurses can help alleviate this stress by allowing choices whenever possible. If the toddler is being potty trained at home, continue with the routine when hospitalized. Allow the child to feed and dress himself or herself as much as possible. Keep the child on the home schedule and provide positive reinforcement when the child accomplishes tasks on his or her own.

Fears

Children’s fears are developmentally based (see Chapters 4–7). Children older than 4 years identify pain and discomfort as the worst aspects of hospitalization (Lindeke, Nakai, & Johnson, 2006).

Many fears are actualized in the hospital: separation, loss of control, unfamiliar environment body mutilation, and painful events (Coyne, 2006a). Provide developmentally appropriate explanations to counter unrealistic fears and intervene to minimize trauma caused by those fears that are real (e.g., encourage parental presence during procedures or in the postanesthesia care unit, allow choices and have the child make decisions whenever possible, use topical anesthetics to reduce pain from needle sticks ([Developmental Considerations 11–5; see also Chart 5–2]).

Strategies for Enhanced Coping of the Child

QUESTION: After the surgery, Cory will remain in the hospital for about a week. He will have an abdominal incision with a drain and will receive IV antibiotics. What aspects of the following programs would be beneficial to Cory?

The nurse must support the child in developing effective coping behaviors while in the hospital. Nursing diagnoses that may be applicable to the hospitalized child and family include the following:

- Family will exhibit adequate internal levels of cooperation to organize daily family activities during hospitalization.
- Family will verbalize need for hospitalization and adopt strategies for maintaining relationship with hospitalized child during hospitalization.
- Family will articulate an optimistic, but realistic, definition of the situation by discharge.

DEVELOPMENTAL CONSIDERATIONS 11–4

Minimizing Separation Anxiety and Loss of Control

Stage	Stressor	Intervention
Infancy	Separation	<p>Promote rooming-in of parents.</p> <p>Play peek-a-boo to promote mastery of the separation experience.</p> <p>Seek volunteer support for holding and stimulating the infant in the parent's absence.</p> <p>Provide tactile, auditory, and visual stimulation such as mobiles over the crib, cuddly toys, musical toys, or tape recordings.</p> <p>Minimize the number of caretakers; have consistent nurse assigned to care for the infant.</p>
	Loss of Control	<p>Provide comfort measures such as pacifier, holding, rocking, talking in a soothing voice, and cuddling.</p> <p>Heparin lock IV when possible. Use a crib with a canopy to allow freedom of movement in the crib.</p> <p>Alter the environment by using infant seat, buggy, or stroller and bringing the infant to playroom or nursing station when possible.</p>
Early childhood (1–4 years)	Separation	<p>Provide toys, such as stuffed animals, mirrors, and mobiles.</p> <p>Encourage rooming-in of parents.</p> <p>Teach parents to assess symptoms of stress, such as protest and withdrawal.</p> <p>Encourage parents to provide comfort measures.</p> <p>Play hide-and-seek with the child to promote mastery of the separation experience.</p> <p>Use doll play to demonstrate that parents will return.</p> <p>Give the child time frames when parent will return: "After <i>Sesame Street</i> is over."</p>
	Loss of Control	<p>Have parents bring in "transitional objects" from home to promote familiarity with the environment (e.g., favorite toys, clothes, tapes of family members' voices, photographs of family members, and pets).</p> <p>Promote home rituals, such as feeding and bedtime rituals.</p> <p>Promote dietary practices similar to those at home.</p> <p>Encourage autonomy by giving choices when possible, such as with toys or games.</p> <p>Take the child to the playroom.</p> <p>Provide opportunities for medical and therapeutic play.</p> <p>Teach the parents that regression is a typical response to hospitalization and will usually resolve when the child returns home.</p> <p>Be truthful with the child.</p>
Middle childhood (5–10 years)	Separation	<p>Promote communication with siblings and friends.</p> <p>Maintain normalcy by encouraging the child to do homework from school.</p> <p>Be available to talk to the child. Be supportive when the child expresses feelings of loneliness.</p> <p>Take the child to the playroom.</p>
	Loss of Control	<p>Explain to the parents the importance of frequent visits. Rooming-in may not be necessary for older school-aged child.</p> <p>Provide opportunities to discuss the medical situation. Encourage the child to discuss his or her understanding.</p> <p>Provide explanations of the medical situation, using diagrams, equipment, and concrete explanations.</p>

Stage	Stressor	Intervention
Adolescence (11–21 years)	Separation	<p>Allow opportunities for the child to achieve the developmental goal of “industry” by helping with tasks.</p> <p>Promote choices in care, if possible.</p> <p>Promote peer interactions.</p> <p>Promote parent visitation. Teach parents the importance of the adolescent’s need for control.</p> <p>Provide activities, such as “rap sessions,” dances, and make-up sessions.</p>
	Loss of control	<p>Develop the plan of care with the adolescent.</p> <p>Respect the adolescent’s need for independence. Offer choices in routines, if possible.</p> <p>Allow for privacy.</p> <p>Be open and forthright about the medical situation. Allow time to discuss this with the adolescent.</p>

CLINICAL JUDGMENT 11–1

Separation Anxiety

Cory never attended daycare, preschool, or a Mothers’ Morning Out program. He began attending kindergarten this fall, which was a difficult separation at first, but recently has become easier. Wendy and Cory are still in the emergency room when Wendy’s older son brings in the health insurance card. Wendy is asked to take the card to the admissions desk. When Wendy steps out of the room, Cory begins to scream, “Stay! Stay!” and kick despite the presence of his older brother. Wendy returns and sends the older brother to the desk with the card.

Questions

1. What is your assessment of Cory’s behavior and his mother’s response?
2. Which phase of separation anxiety is Cory manifesting?
3. Cory is 5 years old; will the nursing staff and family feel he is behaving appropriately?
4. What information should the nurse share with Cory’s family to help them understand Cory’s strong feelings about separating from his mother?
5. Which of Cory’s behaviors will the nursing staff on the pediatric floor use to evaluate the effects of hospitalization and separation on Cory?

Answers

1. Cory is having separation anxiety. Separating from a parent can be viewed as a learned skill. In the familiar setting of kindergarten, Cory is able to separate calmly; in unfamiliar circumstances, he

- regresses and displays separation anxiety. Wendy responds by staying and relieving Cory’s anxiety.
2. Cory is demonstrating the “protest” phase of separation. In most hospitalized children today, separations are short and the protest phase is the most commonly seen behavior.
3. The staff in the emergency room, especially if they do not work exclusively with children, may feel that Cory is not “being a big boy.” They may very well make their judgments known to Wendy. Cory’s family is not surprised by his behavior; in the past, Cory has been very vocal in his refusal to separate.
4. It is important that Wendy understands that a strong protest is indicative of a strong attachment and trust relationship. It will also be helpful to Wendy to explain the signs of the “despair” phase, especially the possibility that Cory may be angry and not greet her joyfully on her return.
5. The desired outcome is that Cory has minimal episodes of despair and anxiety. Cory’s rudimentary skills of separating and trusting a parent, particularly his mother, to return should be supported and encouraged. Initially short absences are helpful in establishing trust. Some children respond well to a security object (e.g., a blanket or stuffed animal). Children who do not have a previous attachment to an object may benefit from keeping something belonging to the parent until the parent returns.

DEVELOPMENTAL CONSIDERATIONS 11–5

Fears Experienced by Hospitalized Children*

Developmental Stage/Fears	Interventions
Infancy Loud noises Sudden movements Loss of physical, emotional support Strangers	Talk to in soft, soothing tones Handle with firm, confident movements Swaddle Have parents hold infant, perform care Keep parents in sight Maintain consistent caregivers Post sign with infant's behavioral cues
Early childhood (1–4 years) Dark Some machines (animistic thinking) Body mutilation Unknown Supernatural	Mimic home routines as feasible Maintain consistent routines Use a dim light for sleep Let child approach and handle equipment, safely Explain what is going to happen Keep parents in sight Reassure that taking specimens will not mutilate them Use bandages after intrusive procedures
Middle childhood (5–10 years) Bodily injury, pain Unfamiliar environments Death	Explain the environment and what will be happening Maintain routines, post schedule Reassure that taking specimens will not mutilate them Have them tell you why they are sick
Adolescence (11–21 years) Body disfigurement Pain and discomfort Loss of physical abilities Death	Explain the environment, treatments, expected outcomes Have them tell you about their illness Ask about concerns, clarify perceptions

*Separation and loss of control are issues in all stages (see Developmental Considerations 11–4).

- Family will recognize and utilize resources by discharge.
 - Child/family will be knowledgeable regarding disease process and necessary medical intervention during hospitalization and after discharge.
 - Child/family will be knowledgeable about and understand rationale for hospital routines.
 - Child will utilize developmentally effective coping strategies:
 - Engage in play or discussion to decrease fear of procedures
 - Feel a sense of trust and security in relation to parental support
 - Obtain sleep and rest necessary for achieving wellness
 - Child will engage in play to decrease fear of procedures.
 - Child/family will practice developmentally appropriate coping strategies.
 - Child will gain age-appropriate mastery of environment through play and establishment of routines that mimic home environment to the extent possible.
 - Child/family will perform ADLs in new environment.
 - Child/family will perform ADLs in new environment.
- Children use many different strategies to cope with the stress of illness, such as information-seeking, social support, emotional behaviors, information limiting or avoiding, and physical exercise. This reinforces the need for individualized intervention. Children appreciate nurses who have a positive affect; treat them as individuals; manage pain; provide advocacy, entertainment, and support; and meet basic needs (Schmidt et al., 2007).
- Preparation helps a child to cope (Brewer et al., 2006; Wennström, Hallberg, & Bergh, 2008). When teaching, be alert to the child's cues indicating how much information is desired, and prepare the child based on this. To promote coping, teach the child strategies that

can reduce stress, such as relaxation, imagery, distraction, and positive self-talk (see Chapter 10 for further discussion of these techniques). Parent involvement also helps the child cope (Melnyk et al., 2006).

Art

Children often reveal their fears and concerns through drawing. What children draw and how they draw it may be significant (Clatworthy, Simon, and Tiedeman, 1999). For example, very large things may imply aggressive tendencies (often the healthcare team or equipment, such as needles, are large); tiny things (the child in bed) may imply feelings of insignificance or inferiority. Based on knowledge of growth and development, the nurse can use drawings as an effective method of assessment and as vehicle for communication with the child. When identifying the child's concerns and perceptions, the nurse can correct misconceptions and support coping skills. Use drawings for psychotherapy only if trained for such. Supply drawing materials that are familiar to the child, are nonthreatening, and may support coping through distraction. Most children draw without prompting; some ask for guidance about what to draw. A broad, nondirective response may help elicit issues of concern to the child (e.g., "Why don't you draw what it will be like after surgery?" or "Why don't you draw what you are thinking of right now?"). Remember, however, that not every drawing has therapeutic significance—a picture may just be a picture.

Music

Music can also be used to promote coping (Liu et al., 2007; Whitehead-Pleaux et al., 2007). The child can select the music, giving him or her control over the situation and providing a familiar milieu and distraction (Fig. 11–8). Honor the child's preference, although music that has a slow tempo (60–72 beats per minute) with a soft tone, soft to moderate volume, notes that are close on the musical scale, and a smooth, consistent

FIGURE 11–8. This adolescent listens to soothing music to promote relaxation and coping during stressful procedures.

rhythm is more sedating (Stouffer, Shirk, & Polomano, 2007).

Play

Play is a mechanism through which children cope, learn, test new ideas, and test newly acquired psychomotor skills. It is the medium through which children grow and develop. Play also provides children with a sense of control. In the acute care setting, children might engage in normative or therapeutic play. Normative play is activity in which children spontaneously engage and from which they derive pleasure. Therapeutic play is activity directed by the nurse to promote emotional and physical well-being, such as playing with medical equipment during hospitalization.

Therapeutic Play

Therapeutic play can be used to promote coping by helping children work through hospital experiences (Li, 2007). This may be effective for a number of reasons: it provides the child with information, the child feels a sense of control and mastery when able to manipulate the equipment and play situation, and the nurse or child life specialist can use the session to model effective coping behaviors. Unlike normative play, therapeutic play is goal directed. Nevertheless, both types of play should be provided in the hospital.

Although the terms often are used interchangeably, therapeutic play is different from play therapy. Play therapy is play that helps a child express and work through emotional or psychological issues. It is usually considered a form of psychotherapy that is supervised by a professional educated in play therapy methods. Play therapy may be directed by the therapist or by the child with the therapist guiding the session. Nurses and child life specialists most commonly guide children during therapeutic play sessions.

Conduct therapeutic play sessions in a protected, non-threatening environment (NIC 11–2). Do not allow treatments, doctors, or other distressing interruptions during the play session. Be accepting of the child's play behaviors and avoid expressing approval or disapproval.

Therapeutic play includes instructional play (Fig. 11–9), emotional outlet play, and physiologically enhancing play (Fig. 11–10). Gear these types of play to the child's physical, emotional, and cognitive abilities (see Chart 11–3). The nurse must incorporate play into the plan of care and value this time as essential to the child's development and emotional well-being. Do not force the child to play, however, if he or she is not emotionally or physically ready.

The Hospital Playroom

This distinctive area should be equipped to meet the unique cultural and age-appropriate developmental needs of the population being served (Fig. 11–11). Children

NIC 11–2 Nursing Interventions Classification: Therapeutic Play

Definition: Purposeful and directive use of toys or other materials to assist children in communicating their perception and knowledge of their world and to help in gaining mastery of their environment

Activities:

- Provide a quiet environment that is free from interruptions
- Provide sufficient time to allow for effective play
- Structure play session to facilitate desired outcome
- Communicate the purpose of play session to child and parent
- Discuss play activities with family
- Set limits for therapeutic play session
- Provide safe play equipment
- Provide developmentally appropriate play equipment
- Provide play equipment that stimulates creative, expressive play
- Provide play equipment that stimulates role playing
- Provide real or simulated hospital or medical equipment to encourage expression of knowledge and feelings about hospitalization, treatments, or illness
- Supervise therapeutic play sessions
- Encourage child to manipulate play equipment

- Encourage child to share feelings, knowledge, and perceptions
- Validate child's feelings expressed during the play session
- Communicate acceptance of feelings, both positive and negative, expressed through play
- Observe the child's use of play equipment
- Monitor child's reactions and anxiety level throughout play session
- Identify child's misconceptions or fears through comments made during (hospital role) play session
- Continue play sessions on a regular basis to establish trust and reduce fear of unfamiliar equipment or treatments, as appropriate
- Record observations made during play session

From Bulechek, G. M., Butcher, H. K., & Dochterman, J. M. (2008). *Nursing interventions classification (NIC)* (5th ed.). St. Louis, MO: Mosby. Reprinted with permission.

and families should be encouraged to engage in activities there and should always feel welcome to enter.

caREminder

Do not perform any uncomfortable or painful procedures (such as an injection) in the playroom itself to promote the child's perception that, within the confines of this room, they are safe from intrusion and discomfort as much as possible.

To prevent the spread of infection in the playroom, follow standard precautions. Ensure that body fluids are

not spread in the playroom. If a child's infectious secretions cannot be safely contained, do not permit that child in the playroom. To help minimize spread of infection, wash toys with soap and water or a 10% hypochlorite (chlorine bleach) solution after use. Also, follow the facility's guidelines for infection control in the playroom (Nursing Interventions 11–7). Effective control is enhanced by consistent adherence to the policy. Toys brought from home can be contaminated with potentially dangerous bacteria and may provide unnecessary risks for nosocomial infection (Fleming & Randle, 2006); cleanse these toys appropriately to prevent the spread of infections via toys.

FIGURE 11–9. Instructional play can help prepare a child for surgery.

FIGURE 11–10. This example of physiology-enhancing play encourages deep breathing after surgery by using a pinwheel.

CHART 11-3 MATERIALS AND METHODS FOR USE IN PLAY

Instructional Play

Purpose: To prepare the child for procedures or to learn about his or her disease

- Dolls or stuffed animals dressed as doctors, nurses, children, and family members
- Hospital gowns and pajamas
- ID bracelets
- Surgical hats, masks, and booties
- Stethoscopes
- Blood pressure cuff, thermometers, and tape
- Large syringes without needles
- Bandages and dressing materials
- Equipment such as an IV pole, stretcher, and bed
- Oxygen masks
- Wash basin and towels
- Laboratory coats
- "Good Patient" stickers

Therapeutic Play

Purpose: To allow the child to express anxiety or articulate fears about his or her disease or hospitalization

- Punching bags
- Paints and crayons
- Inflatable bopper clowns
- Pegboard and hammers
- Dress-up clothes
- Puppets
- Blank books for writing stories or poetry
- Interactive video games
- Opportunities to play "doctor and nurse"
- Games such as peek-a-boo, hide-and-seek
- Sessions for telling "hospital stories"
- "Rap" groups
- Skits
- Song-writing sessions
- Water play
- Aggression play toys, such as blocks, clay, Play-Doh, punch pillows, squirt guns, and tin cans

Physiology Enhancing Play

Purpose: To allow the child to improve his or her physical health

- Lung expansion—straw blowing, tuned bottle blowing, blowing bubbles, blowing up and popping paper bags, pinwheel spinning, kazoo or woodwind instrument playing
- Pain management—reading stories, pop-up books, telling jokes, playing musical tapes, playing video games
- Improve range of motion/muscle strength—leave toys just out of reach, take a doll on an airplane ride, arm wrestle, reach to hang up decorations, throw bean bags

FIGURE 11-11. It is important to provide safe, age-appropriate activities in the hospital playroom.

Child Life Programs

Child life programs are designed to minimize stress for children and families during hospitalization, to promote the hospitalized child's continued growth and development, and are an essential component of quality pediatric care (American Academy of Pediatrics, 2006). To help the child cope successfully with hospitalization, child life programs organize interventions in the following categories:

- Preparation for hospitalization, procedures, and surgery
- Play
- Diversional activities during invasive, painful procedures (e.g., lumbar punctures, IV starts)
- Emotional support for parents and siblings
- Patient advocacy with hospital staff
- Promotion of family-centered environment

The child life specialist is responsible for designing and implementing interventions in each category that meet the needs of the patients and their families. To do this, child life specialists must be trained in child development and in techniques to address anxieties and fears regarding a child's condition, impending procedures, and hospitalization. Child life specialists also must be able to work in an interdisciplinary setting so that therapeutic activities incorporate all aspects of care.

Because child life specialists are one of the few health-care professionals who do not cause the child pain or discomfort, this specialist is often the one with whom the hospitalized child feels most comfortable. The child life specialist may become the primary healthcare professional to whom the child expresses feelings of anxiety, fears, and anger.

For hospitalizations lasting more than a few days, a teacher may be provided through the local school district or the child life program. Teachers provide programmed instruction and assist children in keeping current in the homework they would be completing if they were in school with other children.

NURSING INTERVENTIONS 11–7

Infection Control for Recreational Activities in the Acute Care Setting

All personnel and visitors must perform hand hygiene

- Upon entering and leaving the unit
- When serving food to patients
- After assisting patients with toileting or diapering
- After blowing or wiping a patient's or own nose
- After removing gloves used for handling body fluids
- When leaving an isolation area or handling articles from that area
- When leaving the toilet

Prevent toys and equipment from becoming vectors for infectious agents by

- Not allowing stuffed or unwashable toys in the playroom
- Scrubbing all toys handled by infectious or drooling patients in warm, soapy water and rinsing for at least 30 seconds with manual friction; spray with disinfectant; leave on surface for amount of time specified by manufacturer; rinse with water
- Wiping all nonsubmersible toys with cloth saturated with disinfectant, leave on surface for amount of time specified by manufacturer, wipe with water-moistened cloth

Pet Therapy

Pet visitation or animal-assisted therapy involves the touching, holding, or cuddling of animals to promote therapeutic results (Fig. 11–12). Pet visits distract children from the confines of their illness. Children can openly display affection and joy toward the pet. Pet visits also give children an opportunity to learn about animals. Organizations exist that provide trained animals expressly for this purpose. The animals need to be well cared for, with careful veterinary support and health screening (Chart 11–4). With the proper screening, the child's own animal may visit (Hemsworth and Pizer, 2006). When developing such a program, however, some key points must be addressed (NIC 11–3). If pet visitation is not possible, the videophone or use of videotapes may provide some comfort to the child while in the hospital.

ANSWER: Therapeutic play and normative play will be important for Cory. The suddenness of his illness may be best understood through reenacting similar events in imaginative play—for example, a toy ambulance rushing someone to the hospital. A doll with an incision and drain may help decrease anxiety about his incision. Normative play will be an essential outlet for a 5-year-old boy accustomed to active play with four athletic brothers.

Promoting Coping: The Family

Family coping is just as important as the child's coping during acute illness. Hospitalization of a seriously ill child can precipitate a crisis for the family. Family coping skills are important factors to consider during a child's acute illness and hospitalization, because families who face serious illness in a child (or family member) are at risk for psychosocial maladjustment (Melnyk et al., 2006). Fam-

ilies who use effective coping skills tend to adjust to the child's hospitalization and do much better. Therefore, assess the family's coping skills, promote the use of effective skills, and teach additional skills if needed.

Family's Response to Hospitalization

Family members typically are affected by hospitalization based on their relationship to the child and their role in the family. Parents may exhibit responses that include stress, fear, anxiety, helplessness, anger, uncertainty, guilt, and a sense of having no control (Coyne and Cowley, 2007; Hopia et al., 2005). The parents' coping abilities may be reduced by financial, emotional, or physical stressors; the severity of the child's condition; and the need to care for their other children as well as the hospitalized child (Diaz-Caneja et al., 2005). Assess the parents' response and provide intervention and support

FIGURE 11–12. Pet visits can help reduce the stress of hospitalization for a child.

CHART 11-4 GUIDELINES FOR PET AND ANIMAL VISITATION

- Establish a mechanism for screening and approval of animals.
- Obtain parent's consent for the child to participate in the pet program.
- Ensure that the choice of animals complies with state and local health department regulations.
- Identify designated areas for animal visitation.
- Identify key personnel who will manage animals on location in the facility.
- Consult with the infectious disease or immunology department to determine patient restrictions regarding pet visitation.

to help the family cope with the acute hospitalization of a child.

Siblings' coping skills can be affected by misperceptions about the sick child's condition and feelings of loss, parent neglect, isolation, or loneliness (Rozdilsky, 2005; Wilkins and Woodgate, 2006). The sibling may exhibit anxiety, depression, or acting-out behaviors. Difficulty in school and altered roles within the family may be apparent for the affected sibling. To practice family-centered care, the nurse must understand the effects of hospitalization on the patient and family, and intervene to promote effective coping by all family members.

Strategies for Enhanced Parental Coping

Building a supportive relationship, communicating effectively, and encouraging parental involvement in the care of the ill child are integral to the implementation of family-centered care.

Rapport and Communication

QUESTION: What communication techniques would you use to support the Whitworth family? How would you assess the coping skills of the Whitworth family? What are some examples of specific questions to ask that promote family coping?

Rapport between parents and nurse results in more individualized care for the child. The degree of rapport is influenced by the nurse's knowledge of the child and the parent's knowledge of the nurse. The nurse's demonstration of interest in learning about the child as a person and the child's condition is important in establishing rapport.

Communication or sharing of information is the cornerstone of building a trusting, supportive relationship with a family. Successful coping is dependent on timely information delivered in a coordinated, knowledgeable manner. Parents have a need to protect their children. In their role as "protector" of their child, having information might help them maintain control.

Communication and building a trusting relationship begin during the admission assessment. Ask the child and family why they have come to the acute care setting and what their expectations are of the healthcare team, then share information about what the family may expect dur-

NIC 11-3 Nursing Interventions Classification: Animal-Assisted Therapy

Definition: Purposeful use of animals to provide affection, attention, diversion, and relaxation

Activities:

- Determine patient's acceptance of animals as therapeutic agents
- Determine if any allergies to animals
- Teach patient/family purpose and rationale for having animals in a care environment
- Enforce standards for screening, training, and grooming of animals in therapy program
- Enforce standards for health maintenance of animals in the therapy program
- Fulfill health inspector's rules concerning animals in an institution
- Develop/have protocol that outlines appropriate response to accident or injury as result of animal contact
- Provide therapy animals for patient such as dogs, cats, horses, snakes, turtles, gerbils, guinea pigs, and birds
- Avoid animal visits with unpredictable or violent patients

Monitor closely animal visits with patients with special conditions (e.g., open wounds, delicate skin, multiple IV lines, or other equipment)

Facilitate patient's holding and petting therapy animals

Encourage repeated stroking of the therapy animal

Facilitate patient's watching therapy animals

Encourage patient's expression of emotions to animals

Arrange for patient to exercise, as appropriate

Encourage patient to play with therapy animals

Encourage patient to feed/groom animals

Have patient and others who pet or contact an animal to wash hands

Provide an opportunity to reminisce and share about previous experiences with pets/other animals

From Bulechek, G. M., Butcher, H. K., & Dochterman, J. M. (2008). *Nursing interventions classification (NIC)* (5th ed.). St. Louis, MO: Mosby. Reprinted with permission.

ing their visit. Assessment and sharing of expectations should occur during the prehospital visit or at the time of admission to the acute care setting. If this exchange does not occur in a timely fashion, the family's trust of the hospital staff can be undermined.

Throughout the acute care experience, assessing an individual's readiness for communication becomes a key component of effective communication, which is integral to providing support to the child and family. Parents and children are involved in a stressful situation, so determining the level at which they can participate is a vital skill (e.g., if they are anxious, discuss only simple, basic concepts or they may need to discuss what is distressing them before progressing to other topics). Receptivity to feedback from the child or family is key in this determination. Some families use maladaptive coping mechanisms such as anger, criticizing the care delivered, and demanding special treatment to deal with the stress of a child's hospitalization. The nurse must recognize the maladaptive behavior, interpret it as such, and respond therapeutically. For example, when a parent criticizes the care the nurse delivers, the parent may be angry or frustrated. Defending oneself may lead to further confrontation. Conversely, acknowledging the emotion (e.g., "You sound like you are angry. Tell me about it.") might address the parent's issues and lead to effective problem solving.

Parents need to understand and be informed of treatments and procedures in terms they can understand. Having staff communicate with the parent and child when providing care helps to create a sense of comfort and reassurance. Talk directly to the child as well as the parent. Inadequate communication and excluding the child of middle childhood and older reduces trust of the child (Kelsey, Abelson-Mitchell, & Skirton, 2007). Interventions for facilitating communication between parents and staff are presented in Nursing Interventions 11–8.

ANSWER: Cory and his family had very little time for communication and to absorb information as they went from pediatrician to emergency room to surgical suite. The nurses will need to give consistent and concise answers, and be active listeners. Remember that Cory's parents may need to hear the same information several times to absorb it. Questions such as "Is there someone to help you with your other children while Cory is in the hospital?" or "Is there someone you can call to support you?" may be helpful to promote family coping.

Parental Visitation and Participation

QUESTION: Wendy has not left the hospital or slept since Cory's admission. What might you say to help Wendy? Based on Wendy's previous answers, identify extended support networks available to Wendy. What do you think is a beneficial pattern of visitation and family participation for the Whitworth family?

Parental involvement helps reduce the child's anxiety, promote parent coping, and improve satisfaction with care (Fig. 11–13). Family-centered care reflects the importance of parental involvement. True family-centered care views parents as partners in care, not as visitors.

Include the parent as an active participant in developing the plan of care. Parents have varying expectations of their role in caring for their hospitalized child (Power and Franck, 2008). For example, one parent may regard a nurse's action as a relinquishment of parental control. Another parent may see parental participation in the child's care as a shirking of the nurse's duty. Assess the parents' needs and preferences for participation in care when planning interventions. Also, discuss the healthcare team's expectations regarding parent participation in the child's care with the parent at the onset of the hospital stay.

Today, most facilities that care for children have 24-hour open visitation for parents and grandparents (Bradley, 2001). This policy encourages parents and grandparents to participate in their child's care and to room-in when possible. Although evidence demonstrates the importance of liberal visitation policies (see Tradition or Science 11–2), this might be a source of conflict between the family and the healthcare team members. The healthcare providers might have concerns about increased physiologic stress on the child, interference with ability to provide care, and physical and emotional exhaustion of the family members. Conflicts might also arise over who may visit the child, the number of visitors, visiting hours, and inconsistent enforcement of the policies (Griffin, 2003). Guidelines that define how the hospital can meet the family's visitation needs can serve as a useful communication tool. Guidelines can also maintain infection control and safety standards and enhance the family's satisfaction with the facility.

If parents cannot be present to support the child in person, do not assume they do not care or are "bad" parents. Encourage parent visitation in the child's care to the extent possible, and encourage the participation of significant others. If parents are reluctant to visit because the child cries and protests when they leave, explain that this is a normal response to separation. If parents are absent as a result of work, sibling care, or other responsibilities, reinforce that the child will be attended to in their absence. Provide the family with the name and telephone number of a contact person knowledgeable about the child; the nurse can also initiate regular telephone contact with the family. When appropriate, assist the child in calling home. Assisting the family with logistics (e.g., handouts regarding hospital visitation policies and support services; transportation, meal, and lodging assistance) may help to increase visitation.

For a family who does not have a cell phone, assisting the family in obtaining a temporary pager may also enhance coping and satisfaction for children and families. Treatment of acute illness frequently involves waiting, which exacerbates anxiety and frustration. Having a pager may enable the child and family to leave the clinic or child's room to go to the cafeteria or playroom and return when paged. Having a pager also lets the parents run errands, eat, or just leave the room while the child sleeps,

NURSING INTERVENTIONS 11–8

Facilitating Communication With Parents of Acutely Ill Children

- Use active listening techniques:
 - Convey an unhurried demeanor and minimize interruptions.
 - Position self at same level when communicating (e.g., sit down).
 - Be aware of nonverbal messages conveyed in body stance and voice inflection.
 - Consider cultural background of parents when using some techniques (e.g., maintaining eye contact is considered disrespectful in many Asian cultures).
 - Clarify what you think you heard (e.g., “You are angry because the doctors did not talk with you this morning.”).
 - Encourage and accept expression of feelings (use statements such as “This is a difficult time for you.”).
 - Reflect parents’ statements (e.g., “You feel guilty because you didn’t call the doctor sooner.”).
 - Ask the parents specific questions about their needs (e.g., “Do you need to go get something to eat? I will sit with Sandy while you are gone.”).
 - Do not take anger personally.
 - Provide information:
 - Give honest, accurate information.
 - Use short, simple explanations.
- Be tactful in stating information, but do not try to minimize the seriousness of a situation.
- Avoid letting long periods of time pass without giving information, especially in critical situations, even if it is only to tell the parents that the child’s condition has not changed and what is being done to support the child.
- Volunteer information freely and in a timely manner to promote trust.
- Teach and reinforce knowledge of disease process, treatments, and how parents can support their child.
- Be consistent:
 - Give same information over time and by different health team members.
 - Minimize the number of health team members interacting with the parents.
 - Reinforce importance of the parent’s role:
 - Acknowledge parents’ expertise in knowing their child.
 - Encourage and provide opportunities for parents to provide physical care for the child; parents may need to be shown how they can do this (e.g., demonstrate how to bathe a child with an IV).
 - Ensure parent involvement in care conferences.

knowing they can be paged when the child awakens. In addition, parent coping can be enhanced by sharing the unit phone number and encouraging the parent to call and speak to the nurse at any time when they are away from the hospital. These options allow the family choices that increase their control and promote coping.

FIGURE 11–13. Visitation helps reduce the parent’s anxiety and improve coping.

TRADITION OR SCIENCE 11–2

Should open visitation in acute care facilities be allowed?

EVIDENCE-BASED PRACTICE

The presence of family and friends at the bedside has been shown to decrease stress and provide reassurance to the child and parent (Board, 2005; Smith, Hefley, & Anand, 2007). Parents want to protect their child (Dudley & Carr, 2004) and view their participation as essential for the child’s emotional welfare (Coyne, 1995). Chinese parents view participation as an unconditional aspect of being a parent (Lam, Chang, & Morrissey, 2006). Family presence allows for increased opportunity for education and communication with the healthcare team. Although in some cases exhaustion of family members may occur, studies have shown that open visitation often allows family members to relax and be less anxious during times they are not with the patient (Berwick & Kotagal, 2004). Using principles of family-centered care in the implementation of visitation policies that give guidelines, not rules, and recognizing first that the family is the constant in the child’s life, and second that hospitals must be flexible in their visitation policies, best meets the needs of children and families.

ANSWER: Assessment of Wendy's coping includes asking her, "What will be the hardest aspect of this hospitalization?" Wendy identifies separation from her children as the most stressful aspect of the hospitalization. Parents need to know they are welcome to stay with their child as much as they would like. Sometimes parents may need to be given "permission" to go home. An example of what to say is, "You are welcome to stay as long as you like, but it is important that you take care of yourself too. Under what conditions could you go home and relax and sleep?" It is very easy for the entire focus to be on the child who is sick. You can also assist this family to identify a combination of family, church, and neighborhood support to decrease the entire family's level of anxiety and enhance their coping with this hospitalization. You can encourage the Whitworth family to work out a schedule whereby there is always one member of the family with Cory. John and Wendy can plan to take turns spending the night. Wendy's older children are in school, so she can spend the school hours at the hospital with Cory.

Strategies for Enhanced Sibling Coping

QUESTION: How would you assess the coping and the needs of Cory's siblings? What is an example of a question you could ask Wendy about her other children? What questions could you ask Cory's siblings? Prior to Cory's hospitalization, his siblings each had an assigned afternoon to watch Cory. What do you think might be a beneficial pattern of visitation for Cory's older brothers?

Family-centered care also addresses the needs of siblings. Assess each sibling for risk factors that affect coping, and signs of stress and ineffective coping (Developmental Considerations 11–6). Children who perceive more changes in their parents' behavior and negative interpersonal effects on their lives often experience more adjustment problems (Murray, 2002; Simon, 1993). Siblings often may feel neglected or jealous of the attention that is being given to the ill sibling. The nurse can help facilitate the sibling's understanding of the illness. Child life therapists, social workers, and psychiatrists might also help the sibling cope, especially in the case of life-threatening or terminal illnesses.

KidKare ■ Ask the siblings how they think things are different since the child has been sick or in the hospital. Early identification of those children at high risk enables the nurse to arrange intervention and to follow up with the primary healthcare provider.

Parent perceptions of effects of illness on the siblings have not been found to correlate with siblings' self-report; therefore, it is more accurate to obtain information directly from the sibling (Houtzager et al., 2005). On the basis of assessment findings, implement interventions to promote sibling coping (NIC 11–4). Siblings who received education about the patient's hospitalization, illness or injury, and treatment demonstrated less anxiety than siblings who received no intervention (Gursky, 2007). Encourage parents to include siblings in

DEVELOPMENTAL CONSIDERATIONS 11–6

Sibling Coping With Hospitalization

Risk Factors in the Sibling

- Sibling is undergoing stress in other areas, such as school or peer relationships.
- Sibling had a poor relationship with the parents or the ill child before the illness began.
- Sibling has not developed effective coping skills as part of general life strategies.
- Sibling is cared for outside of own home.
- There is an increased change in the parents' behavior.

Risk Factors in the Ill Child

- Ill child is developmentally delayed.
- Ill child has multiple handicaps.
- Ill child has chronic or genetically transmitted disorder.

- Ill child has an altered body image, such as that caused by amputation, burns, disfigurement, or scars.
- Ill child has a terminal condition.
- Ill child is in an intensive care unit.
- Ill child is undergoing prolonged or repeated hospitalizations.

Signs of Stress

- Somatic symptoms—vomiting, diarrhea, or abdominal pain
- Change in appetite
- Change in academic performance
- Change in temperament—irritability, nervousness, sorrow, difficulty concentrating

activities and conversations, to inform them about what is happening, and to teach them about their sibling's condition. Ideally, the routine for the siblings is disturbed as little as possible and they are able to play with their friends.

Encourage parents to have the sibling visit (Fig. 11–14). Sibling visitation helps normalize hospitalization for the patient, especially a child with a condition that requires a prolonged stay. For prolonged hospitalizations, videophones can play a key role in supplementing sibling visitation to promote increased contact among siblings on an ongoing basis. Sibling visitation also helps the sibling adapt to the situation. It dispels misconceptions the sibling may have about the hospitalized child, such as things are “worse” than reported or the child is dead. It helps reduce separation anxiety of siblings when parents

spend time at the hospital. Sibling visitation also provides opportunities for nurses to intervene directly, educate, allay fears, and promote a realistic understanding of the situation. Finally, it eases the strain on parents who often face conflict between being in the hospital and supervising the children at home. Some hospitals have developed special play areas in the hospital for siblings. These areas allow the sibling to visit the patient and provide a safe and developmentally appropriate environment to play while the parents are with the patient.

Reduce Chaos by controlling the hours for sibling visitation and limiting the number of persons who visit a child at any one time. Although sibling visitation has not been shown to be related to greater cross-infection (Rozdilsky, 2005), screening siblings for infectious symptoms or exposures may protect vulnerable patients and their

NIC 11–4 Nursing Interventions Classification: Sibling Support

Definition: Assisting a sibling to cope with a brother or sister's illness/chronic condition/disability

Activities:

- Explore what sibling knows about brother or sister
- Appraise stress in sibling related to condition of affected brother or sister
- Appraise sibling's coping with illness/disability of brother or sister
- Facilitate family members' awareness of sibling's feelings
- Provide information about common sibling responses and what other family members can do to help
- Perform sibling advocacy role (e.g., in case of life-threatening situations when anxiety is high and parents or other family members are unable to perform that role)
- Recognize that each sibling responds differently
- Encourage parents or other family members to provide honest information to sibling
- Encourage parents to arrange for care of young sibling in their own home, if possible
- Assist sibling to maintain and/or modify usual routines and ADLs, as necessary
- Promote communication between well sibling and affected brother or sister
- Value each child individually, avoiding comparisons
- Help child to see differences/similarities between self and sibling with special needs
- Encourage sibling to visit affected brother or sister
- Explain to visiting sibling what is being done in care of affected brother or sister
- Encourage well sibling to participate in care of the affected brother or sister, as appropriate
- Teach well sibling ways to interact with affected sister/brother
- Permit siblings to settle own difficulties
- Recognize and respect sibling who may not be emotionally ready to visit an affected brother or sister

- Respect well sibling's reluctance to be with or to include child with special needs in activities
- Encourage maintenance of parental or family interactional patterns
- Assist parents to be fair in terms of discipline, resources, and attention
- Assist sibling to clarify and explore concerns
- Use drawings, puppetry, and dramatic play to see how younger sibling perceives events
- Clarify sibling concern for contracting the illness of the affected child, and develop strategies for coping with concern
- Teach pathology of disease to sibling, according to developmental stage and learning style
- Use concrete substitutes for sibling who is unable to visit affected brother or sister (e.g., pictures and videos)
- Explain to young siblings that they are not the cause of illness
- Teach sibling strategies for meeting own emotional and developmental needs
- Praise siblings when they have been patient, have sacrificed, or have been particularly helpful
- Acknowledge the personal strengths siblings have and their abilities to cope with stress successfully
- Provide referral to peer sibling group, as appropriate
- Provide community resource referrals to sibling, as necessary
- Communicate situation to the school nurse to promote support for younger sibling, in accord with parental wishes

From Bulechek, G. M., Butcher, H. K., & Dochterman, J. M. (2008). *Nursing interventions classification (NIC)* (5th ed.). St. Louis, MO: Mosby. Reprinted with permission.

FIGURE 11–14.

visitors. This type of screening can limit potential exposures to varicella, measles, and respiratory syncytial virus. A sibling visitation policy provides a consistent approach that the staff can follow and present to families (Nursing Interventions 11–9).

ANSWER: A question the nurse could ask Wendy is, “What time of day is it most important for you to be home with your other children?” This type of question turns Wendy’s focus to her family, “gives permission” to leave Cory, and validates the needs of the other family members. Although Cory’s siblings are teenagers and preteens, they continue to have needs of their own. The nurse should include them in the assessment of family coping, such as asking them,

“What has been the hardest part of having Cory in the hospital?” They may have questions about Cory’s experience, appendicitis, and his surgery. They may be reluctant to voice their concern that this could happen to them, but they are probably thinking it! Continuing the siblings visitation pattern normalizes Cory’s afternoon routine.

Support Groups

Parents usually find it helpful to discuss concerns about their ill child with other parents who have similar experiences (Buarque et al., 2006; Hurst, 2006). To facilitate this, the nurse can introduce parents to each other or refer them to a specific support group. Many types of support groups exist, ranging from disease-specific support groups to support groups for siblings and grandparents, and online support groups.

The unit-based support group is a particular type of support group. It is especially useful during hospitalization because it can provide a brief escape from the stress of the hospital environment. In this support group, parents can discuss their immediate concerns about hospitalization. The presence of other parents makes it easier to discuss issues that they may have difficulty addressing individually with a staff member. These support groups usually are led by a professional such as a nurse, child life specialist, or social worker. The group leader must have an understanding of group theory and excellent communication skills.

Having a hospital staff member lead the group helps parents solve problems that they identify in the group, such as displeasure with routines or concern over a child’s behavior. In a support group for an infant special

NURSING INTERVENTIONS 11–9

Sibling Visitation

- Find out if a sibling would like to visit. Respect the child’s feelings.
- Establish specific times for sibling visitation, preferably times when siblings will be out of school and when many procedures are not being carried out. Screen siblings every 24 hrs to identify symptoms of communicable disease, such as rash, runny nose, cough; many institutions have a standard form. Teach the family about sibling screening policy. Indicate clearance of sibling for visitation on the unit.
- Explore the visiting child’s understanding and provide age-appropriate information before the child comes to the unit. Visual aids can familiarize children with what they will see.
- If visiting children must wear isolation clothing, allow them to dress in gowns, gloves, and masks and role play before the visit.
- Ask parents if they want help responding to sibling’s questions, concerns, anger, frustrations, or fears during the visit.
- Control the environment to make it as familiar and nonthreatening to the visiting sibling as possible.
- Use drapes or dividers to provide privacy and shield the visiting sibling from confusing or disturbing sights.
- Avoid interrupting the visit for intrusive procedures or examinations.
- Be sure the sibling is always accompanied by a family member.
- Ensure that the sibling performs hand hygiene upon entering and leaving room.

care unit, for example, the group may be led by the unit-based social worker and a translator to provide a means for families, as needed, to better understand hospitalization and vent their frustrations with it. Each week, a member of a different discipline attends the support group so parents can discuss specific questions with that representative. This type of group helps parents feel like part of the team.

NURSING CARE OF THE CHILD GOING UNDERGOING SURGERY

Surgery is a frequent reason for children to interface with the acute care setting. Although it may be unexpected, most admissions to the hospital for surgery are planned. Thus, families and children anticipate their entry into the acute care setting. Coordinated care and preparation of the child and family for their surgical experience can decrease the stress and anxiety associated with a sick child.

Preoperative Care

Preparation of the child and family for surgery can be a highly specific process, tailored to the child's needs and developmental status, and to the procedure required. In many facilities, the nurse is a primary source of information for the child and family. The nurse may need to clarify information and misconceptions or counsel the child and family as the emotional impact of the need for surgery is understood.

caREminder

Clarify family understanding by routinely reviewing discussions the family has had with the surgeon, anesthesiologist, and other members of the health team.

Teaching

QUESTION: How much preoperative teaching is appropriate for Cory and his mother?

Preoperative anxiety has been identified as a universal phenomenon and can be expected to affect young children as well as older patients. Children's anxiety is related to their parents' anxiety (Kain et al., 2006). A goal of preparing children and families for surgery is to minimize the impact of the unexpected and to endeavor to make the unknown known in a nonthreatening manner. By doing so, the anxiety of facing the unfamiliar can be reduced. Adequate preparation may also bolster feelings of control. Preparation for procedures by providing

adequate information can positively influence children's coping and the outcome of the child's hospitalization (Brewer et al., 2006).

Individualize preoperative teaching strategies based on the child and family's developmental level, anxiety level, and previous experiences, and whether the surgery is done emergently or as a planned event (Developmental Considerations 11–7). Keeping in mind that children usually regress when stressed and that high anxiety levels interfere with information processing, present information in simple terms and provide sensory descriptions (e.g., what the child will feel, see, taste, smell, or hear). Ask the child what he or she knows about the surgery and what they want to know. Explain the expected sequence of events and what will happen. Considering the literal, concrete thinking in early childhood, use simple, brief language. Children during middle childhood are in the psychosocial stage of industry versus inferiority and have an increased ability to process information. Speak directly to the child and actively engage them (e.g., selecting a scented anesthesia mask); explain activities (e.g., “The purpose of the belt on the stretcher is to prevent you from falling, not to tie you down.”) (Dreger and Tremback, 2006). During adolescence, as the capacity for abstract thinking develops, ensure that the level of information and detail matches the adolescent's ability and needs by periodically asking what their understanding is and if they want different information.

Help identify appropriate coping strategies; demonstrate relaxation methods, distraction, and deep-breathing techniques so that the child can practice them in advance and they may be sufficiently useful for the child to maintain control (see Chapter 10 for a discussion of these techniques). Use a peer model to demonstrate coping skills (MacLaren and Kain, 2007).

caREminder

Build on the previous experiences of the child when presenting new information. For example, if the child has been hospitalized before, explore what the child remembers of the experience and use that information in presenting the new information. Written material alone is not effective (MacLaren & Kain, 2007). Use videos, tours, pictures, manipulation of medical equipment, or role playing to increase the effectiveness of the information and to help allay fears and correct misconceptions.

Provide opportunities for the child and family to express emotions, fears, and anxieties, and to ask questions. Evaluate understanding and clarify misperceptions. When surgery is planned, prepare children younger than 6 years no more than a week in advance, prepare children older than 6 years at least 5 days in advance (MacLaren & Kain, 2007), which gives them time to incorporate the information and practice coping techniques. When surgery is done on an emergent basis, condense teaching and

DEVELOPMENTAL CONSIDERATIONS 11–7

Preparation of the Child for Surgery

Infancy

- Avoid making changes in an infant's routine prior to surgery (e.g., starting to introduce solids or changing sleeping schedules).
- Infants who are used to being around a variety of people will be less cranky in the unfamiliar environment of the acute care setting.
- Place familiar items in bed with the child, such as a music box or stuffed animal.

Early Childhood (1 to 4 years)

- Provide detailed information to parents; give simple and brief information to the child.
- Allow time to play, and space for exploration.
- Encourage contact with security object.
- Utilize imitation.
- Dispel misconceptions.
- Reinforce that there will be parental presence.

Middle Childhood (5–10 years)

- Give more detailed explanation.
- Reinforce peer involvement.

- Introduce to hospital units and equipment.
- Dispel myths.
- Respect privacy; reduce exposure of body.
- Provide simple reading materials.

Adolescence (11–21 years)

- Encourage peer interaction, and telephone access when possible.
- Emphasize positive attributes; consider body image changes.
- Use reading materials/videos/CDs.
- Explain all activities; include patient in all decisions.
- Respect need for privacy and allow for private teaching.

All Age Groups

- Provide diversional activities when stable (videos, CDs, TV, books, toys).

present essential information, perhaps just as events are occurring.

ANSWER: Cory and his family had very little time for preoperative teaching. Before surgery, the nurses should give consistent and concise information, and be active listeners. Expect that Cory's parents may need to hear the same information several times to absorb it.

Consents

During admission, the family is generally required to sign a bewildering array of forms, most of which contain a large amount of material in relatively small type. One of these forms requiring signature is a general consent form, which is required before any patient is admitted. The amount of information provided to the family at this time varies greatly depending on the facility or the person who asks the family to sign.

Informed consent is the standard for all patients who are admitted to the hospital or undergo medical procedures. When the patient is a child, it is particularly important to keep the parents informed, so that they can make treatment decisions for their child based on the most complete information available. The explanations

should be comprehensive and should describe the potential benefits and risks of each procedure or regimen (see Chapter 2 for more information on consent and assent).

The parent or legal guardian is asked to sign a consent form for any specific procedure to be performed, whenever possible. In an emergency, when a delay in obtaining consent is likely to lead to loss of the patient's life or significant functioning, the physician can authorize an emergency procedure. The institution should have a clear written policy for these cases.

Generally, the procedural or surgical consent form is more detailed than the general consent form required for hospital admission. These specific authorizations are used in obtaining informed consent. Informed consent is based on the concept that the child, parent, or guardian has the right to receive details and information about the child's health, as well as the expected risks and benefits of the specific procedures and alternative methods of treatment. The informed consent form gives the child and family clear explanations, in language that they can comprehend. Based on this information, the family can weigh the implications, analyze expected outcomes, consider alternatives, and then decide to approve or refuse the procedure based on the child's best interests. Informed consent requires the physician and family to collaborate with respect to healthcare.

Preoperative Assessment

QUESTION: Based on the case studies featuring Cory, can you identify any preoperative risks that Cory may have?

One of the nurse's principle responsibilities when caring for a child before surgery is the preoperative assessment of the child and family. The goal is to identify those factors that might put the child at risk for adverse perioperative outcomes and inform the parents of the potential risks.

Children have a higher incidence of perioperative cardiac arrest and mortality than adults (Braz et al., 2006). The most common causes of anesthesia-related cardiac arrest in children are cardiovascular then respiratory (von Ungern-Sternberg & Habre, 2007). Most children who have cardiac arrest have severe disease; children who experience other critical incidents are healthy and have respiratory events. Risks for perioperative critical incidents are higher American Society of Anesthesiologists status (American Society of Anesthesiologists physical status classification), age (infants), emergency surgery, and presence of underlying disease (von Ungern-Sternberg & Habre, 2007).

Assess for preexisting respiratory and cardiovascular disease, prematurity, neuromuscular disease, and chronic steroid therapy because these children are at increased risk for perioperative complications. Also consider the child's age, developmental level, surgical procedure to be performed, presurgical preparation, and the psychological status of the child and family. Identifying the factors that may influence a child's surgery and recovery aid the nurse in developing and implementing strategies to facilitate the most positive outcome.

Because children have a higher incidence of respiratory events, evaluate for a history of a recent upper or lower respiratory infection that might cause potential respiratory complications. In some cases, the surgery may be postponed, especially if endotracheal intubation is necessary. Use of a laryngeal mask airway to administer general anesthesia can decrease the child's incidence of respiratory adverse events over tracheal tube (Homer et al., 2007). The decision to proceed with surgery rests with the surgical team; if postponed, a delay of 4 to 6 weeks is typical (Burd, Mellender, & Tobias, 2006).

Children with asthma are at risk for perioperative complications, most often bronchospasm (Ireland, 2006). To decrease the incidence of respiratory complications, corticosteroids such as prednisone and a beta-agonist may be administered prior to surgery.

Premature infants are at increased risk for developing postoperative apnea during the first 6 months of life (Walther-Larsen & Rasmussen, 2006). Although the use of regional anesthesia in this high-risk group has been shown to decrease the risk of apnea, continuously monitor these infants for complications for 12 hours postoperatively. Administration of caffeine decreases the incidence of postoperative apnea in this high-risk group (Walther-Larsen & Rasmussen). In addition, infants

with bronchopulmonary dysplasia are at risk for hypoxemia and right heart failure, and will also require admission to a pediatric intensive care unit for close observation postoperatively.

Because innocent heart murmurs are common in children, a heart murmur may be detected during the presurgical assessment (see Chapter 8 for discussion of innocent murmurs). It is important to identify children with cardiac anomalies prior to anesthesia because of the changes in vascular resistance that occur, potentially altering intracardiac shunts. If signs of a potentially pathologic murmur are detected, then further follow-up with a cardiologist is warranted (Burd et al., 2006). In the child with a known cardiac anomaly, obtain details of the type of defect, previous surgeries, and current status, and notify the anesthesia care provider prior to surgery. Antibiotic prophylaxis to prevent bacterial endocarditis may be ordered.

Children with neuromuscular disorders may be at risk for increased intracranial pressure as a result of cerebral vasodilation during induction. Impaired airway function and decreased reflexes postoperatively may be present in children with preexisting neuromuscular weakness such as muscular dystrophy. Children receiving anticonvulsants should have therapeutic drug levels checked preoperatively to avoid perioperative complications related to nontherapeutic drug levels.

Patients with sickle cell anemia are at increased risk for postoperative complications related to general anesthesia. Preoperatively, assess the type of sickle crises, date of most recent crisis, and organ involvement. Transfusion and hydration may be indicated preoperatively to prevent sickling related to hypoxia, hypothermia, and hypovolemia and hypoperfusion states that can occur during the perioperative and postoperative periods.

Routine preoperative laboratory testing is not recommended; it should be individualized (Ireland, 2006). A hematocrit level is typically obtained in infants younger than 1 year of age, in menstruating girls, or in those with chronic conditions; pregnancy testing of menarcheal females is controversial (Burd et al., 2006). A type and crossmatch for packed red blood cells in case of the need for a blood transfusion may be indicated. Obtain the laboratory results 24 to 48 hours before surgery and ensure that the values are available in the medical record. The parents and patient should be counseled on potential complications, and informed of the reason for the testing.

caREminder

Review the laboratory test results during the presurgical assessment and notify the surgeon of abnormal findings. A decision will be made whether to cancel the surgery.

ANSWER: No surgical risks were identified during Cory's preoperative assessment. However, his radiographs identified previously undiagnosed scoliosis. Cory's mother and older brother also have scoliosis.

Preoperative Fasting

Surgical patients must remain on NPO (nothing by mouth) status for a minimum time before scheduled surgery. This practice is based on the need for the patient to have a relatively empty stomach, which reduces the risk of aspiration if vomiting occurs after anesthesia administration. Allowing the child to drink *clear* fluids until 2 hours prior to the operation does not result in any increased gastric volume (Brady et al., 2005). Withholding fluids and solids can often result in a fussy, agitated, and possibly dehydrated, hypoglycemic child. In light of this finding, the standardized order of “NPO after midnight” is increasingly being replaced with shorter, more individualized time frames. Although the American Society of Anesthesiologists recommends the following NPO guidelines: 8 hours for solids, 6 hours for formula, 4 hours for breast milk, and 2 hours for clear liquids (American Society of Anesthesiologists, 1999), newer evidence supports shortened fasting periods 6 hours for light meals, 4 hours for formula, and 3 hours for breast milk (Cook-Sather and Litman, 2006). Patients undergoing emergency surgery may not have the opportunity to be NPO for the recommended time frame. In these cases, the risk of aspiration must be assessed against the need for surgery.

caREminder

To avoid misunderstanding and potential delay or cancellation of surgery, give specific written instructions regarding fasting to the family (Community Care 11–1).

These guidelines apply to healthy children. The anesthesiologist orders the specific time period the child is to remain NPO. Children who are at higher risk of aspiration

include those with delayed gastric emptying, esophageal reflux, obesity, pregnancy, a tenuous airway, systemic disease, previous vomiting during induction, and emergency surgery. Except when surgery is unanticipated, high-risk patients have food withheld for 12 hours and clear fluids withheld for 8 hours. An IV line may be started to avoid dehydration.

Skin Preparation

Because skin ordinarily sustains a wide variety of potentially infectious bacteria and other microorganisms, many sanction skin cleansing prior to surgery to reduce surgical site infections (SSIs). The rationale is that mechanical scrubbing with an antimicrobial soap solution removes microbes, flakes of dead skin cells, oils, and other debris that foster the growth of the bacteria. Even with the most thorough skin cleansing, however, live human skin can never be completely “sterilized” of all microorganisms.

To reduce SSIs, some facilities aspire to achieve such a progressive reduction of bacteria that children are instructed to begin antimicrobial skin preparation before admission to the hospital for elective procedures. However, research is conflicting whether preoperative washing more effectively reduces SSIs over no washing and does not demonstrate that chlorhexidine is more effective than other cleansers (Webster & Osborne, 2007).

The evidence is inconclusive whether hair removal reduces SSIs (Tanner, Moncaster, & Woodings, 2007). Regardless, hair removal is rarely deemed necessary in prepubescent children because they have scant amounts of body hair. If hair removal is necessary, it is completed with the goal of preserving skin integrity. Clippers and depilatories result in fewer SSIs than a razor (Tanner et al., 2007). Razors, although able to remove hair closer to

COMMUNITY CARE 11–1

Preoperative Fasting Instructions

- Normal meals and snacks may be eaten until bedtime on the evening before the day of surgery.
- A light meal of dry toast may be eaten up to 6 hours before the start of surgery.
- Clear fluids may be ingested until 2 hours before the start of surgery. Clear fluids are fluids you can see through such as water, apple juice, cranberry juice, Jell-O, ginger ale, and so forth. Fluids that should *not* be ingested include milk, orange juice, and other fluids that contain particulate matter and are not clear.
- Infants who receive formula should finish their last feeding 6 hours before the start of surgery. Like older children, they may drink *clear* fluids up to 2 hours before coming to the hospital.
- Infants who are breast-fed may nurse until 4 hours before they are scheduled for surgery.
- Exceptions to these rules may be made by the anesthesiologist, taking into account the health status and special considerations of the individual child.
- If the child must take any oral medication, generally it may be taken with a small sip of water. Medications that are important to continue include antibiotics, anticonvulsants, bronchodilators, as well as other drugs ordered by the surgeon or anesthesiologist. Inform the healthcare team of these and any other medications that your child is currently taking.

This is an example of information the nurse may provide to the patient and family before surgery. Specific instructions may vary; check your facility’s protocol.

the root than clippers, are more apt to produce microscopic abrasions and nicks in the skin that serve as a port of entry and thus a potential source of infection. Because many individuals are sensitive to depilatories, their use requires testing on a patch of skin 24 hours prior to use. Children, in particular, because of their skin structure, develop adverse reactions to depilatories; therefore, their use is rarely indicated. There is insufficient evidence to determine the optimal time for hair removal (Tanner et al., 2007). Advantages of hair removal after the child is anesthetized, although prolonging anesthesia time, are reduction of anxiety in the child and minimizing scratches and nicks because the risk for the child making sudden movements is eliminated.

Ensure removal of body-piercing jewelry before surgery because electrical burns can occur with electrocauterization. The skin tract may close with temporary removal, so a nonmetallic spacer may be substituted.

Surgical Suite

QUESTION: Given Cory's behavior in the emergency department, would you advocate his mother's presence prior to anesthesia and in the postanesthesia unit?

Just prior to transporting the child to the OR, one last assessment is performed. Most facilities have a form that must be completed that covers standard assessment parameters (Table 11-2).

To eliminate wrong site, wrong procedure, wrong person surgery, perform a preoperative verification process and “time-out” before the start of any surgical or invasive procedure (Joint Commission, 2003). Prior to moving the child into the room where the procedure will be done, mark the site according to institutional protocol. The parent or whoever has authority to provide informed consent for the child should participate in the site-marking process. A final verification process or “time-out” involving active communication of all team members must occur in the location where the procedure is to be performed. This verifies the correct patient, correct procedure, and correct site.

Some facilities may allow parents to be present during the initial administration of anesthesia in a designated “anesthesia induction area” or preoperative holding area (Fig. 11-15). A few facilities allow parents to be present when the initial anesthesia takes place in the sterile environment of an operating room. These practices attempt to address the child's fear and separation anxiety, and cultivate a smoother induction, because preoperative anxiety is related to the occurrence of postoperative maladaptive behavioral change (Wright et al., 2007). The parents' anxiety is a factor; a calm parent can alleviate child anxiety during anesthesia induction, but an anxious parent has no benefit and may even increase the child's anxiety (Kain et al., 2006; Wright et al., 2007); further research is needed. Some legal and other concerns may argue against parents in the OR. For one, parents may not fully comprehend the OR routine and may interpret an unremarkable event or comment as malevolent circumstance. Another concern is

the reaction of a “civilian” in the OR and the possibility that an unpredictable reaction (such as fainting) may occur. These concerns may have some basis, but may be addressed with proper screening of the child, parent, and situation, and with adequate preparation.

To determine the appropriateness of parental presence during induction, consider the child's developmental level, age, willingness to cooperate, previous hospital experiences, and level of anxiety. Parents are good predictors of their child's preoperative behaviors; solicit their input about potential preoperative interventions (Voepel-Lewis, Tait, & Malviya, 2000). Parents' desire to be present must also be considered. Prepare the parent who wishes to be present for how the OR will look, the sequence of events, how the child may react (e.g., eyes rolling back, drooling, involuntary movements), and specific actions they can do to support the child (e.g., sitting next to him or her, maintaining physical contact, talking to the child). A preoperative information videotape can help reduce parental anxiety (McEwen et al., 2007). This can be an emotional experience for the parent; provide support before and after the induction.

When the facility does not permit parents into the OR, the anesthesiologist may administer sedation (e.g., midazolam, ketamine) either nasally or orally to the child in the preoperative holding area. These agents relax the child and create an amnesiac effect, so that the child separates from the parent and remembers little about it. Preoperative sedation may reduce preoperative anxiety, but, because of amnesic properties, children may be anxious postoperatively because they do not realize the surgery is completed. Some studies note postoperative negative behaviors with midazolam premedication (Wright et al., 2007); others noted it to be protective (Karling, Stenlund, & Hägglöf, 2007). Midazolam may be most beneficial for anxious children who are not rated by parents to have an impulsive temperament (Wright et al., 2007).

ANSWER: Nurses should advocate and facilitate Wendy's presence in the preoperative setting during the initial administration of anesthesia and also in the postanesthesia unit. Cory has demonstrated strong separation anxiety and this family has had a very rapid sequence of frightening events. The nurses in both areas can help this family gain an understanding of the situation, decrease the sense of loss of control, and establish a pattern of positive and helpful relationships throughout the acute care experience.

Postanesthesia Care

After surgery, most patients are taken to the postanesthesia care unit (PACU, also called the *recovery room*) or the ICU (intensive care unit). This unit provides resources and skilled nursing personnel to closely monitor the child who is emerging or recovering from the effects of the anesthesia. Intensive surveillance and immediate effective intervention are essential because the surgical patient is physiologically unstable as a result of the anesthesia.

TABLE 11-2

Pediatric Presurgical Check

Aspect of Care	Nursing Action	Rationale/Considerations
Identification verification	Verify that ID band corroborates with patient/family statement and chart documentation.	The ID band functions as a safety measure so that the proper patient receives the correct surgery.
Preoperative workup within hospital parameters (often 72 hours)	Check that laboratory values are in the chart. Assess laboratory values for relationship to normalcy, and identify any values that lie outside normal ranges.	Pay special attention to potentially significant outliers that may indicate change in patient status or electrolyte imbalance.
Consents completed: General consent Surgical consent Surgical attire	Confirm that all required consent forms are fully filled out, with dates, proper procedure identified, and witness. Dress child per facility's policy regarding perioperative attire.	Lack of properly signed consents can result in litigation and refusal of reimbursement to the institution. Some facilities allow children to wear underwear to the operating room (OR) to reduce anxiety.
Family notification	Verify that the family/guardian is informed regarding location of surgical waiting room, anticipated length of surgery, and areas to obtain amenities such as coffee and refreshments.	Concerned family members generally want to remain nearby when possible, so they may be notified regarding the ongoing status or outcome of surgery as soon as possible.
Allergy status	Prominently note known or suspected allergies in the chart.	Ask patient or family members about any allergies, including episodes of hives and food or medication allergy.
Familial history of problems with anesthesia	Elicit family history of reaction to anesthesia.	Intolerance or adverse reactions to anesthesia can be life-threatening and may be hereditary.
Vital signs	Chart current vital signs; identify any unusual trends or values outside the norm.	Unusual patterns or change in vital signs may indicate change in patient status.
Body weight and height	Document current height and weight.	Height and weight are the primary parameters used to determine drug dosages, blood volume, and fluid requirements.
Urine	Encourage child to void prior to surgery, and document; note any changes or unusual appearance in urine.	The opportunity to void in the OR may be limited, and the child will receive generous amounts of IV fluids intraoperatively.
NPO status	Keep the child NPO as ordered; inform family of underlying rationale.	Stomach contents may be aspirated during intubation. Anesthesia may reduce gastric motility, as well as cause nausea and vomiting.
Removal of foreign objects or personal belongings	Check for and ask the child about the possible presence of hair pins, jewelry, and so forth. Remove these prior to transport to the OR. If items (e.g., a ring) are not removable, notify the OR nurse of their presence, so that any hazard that these may produce can be minimized.	Metal or other materials may be a risk factor for burns from the cautery used in surgery or from pressure sores during prolonged surgery. Check even infants for earrings; older children may have other body areas pierced, such as umbilicus.
Removal of prostheses	Remove contact lenses, eyeglasses, and orthodontic appliances prior to transport to the OR. Note any exceptions.	Items such as contact lenses and orthodontic appliances are commonly encountered in the preadolescent and adolescent population.
Nail bed assessment	Remove any nail polish from fingers and toes prior to transport to the OR.	Nail polish can obscure the ability to accurately assess for oxygenation and capillary refill.
Dentition	Examine the mouth, and inquire about potentially loose teeth. If identified, note and report to the OR nurse or anesthetist.	Children intermittently loosen their primary teeth, which can pose a hazard should the child be intubated.
Preoperative medication	Administer any prescribed medications prior to transport to OR. If intramuscular medications are ordered, check with anesthesia care practitioner to give via different route.	Light sedation is often desirable to allay anxiety associated with surgery. Administer medication with enough time to achieve desired effect and monitor the patient for any adverse reactions.
Operative site preparation	Comply with facility standards for skin preparation for cleansing or hair removal of operative site skin.	The skin at the operative site should be as free of oil and debris as possible, to reduce risk of infection.

FIGURE 11–15. A parent’s presence in the preoperative area can help reduce the child’s separation anxiety. The child must be prepared for the parent’s appearance in operating room garb.

The Child’s Response to Surgery

Children differ from adults in their response to surgery in several ways (Nursing Interventions 11–10). For example, children are at greater risk of surgical hypothermia than adults; this stems from four reasons. First, the mechanism responsible for thermoregulation is immature and developing, as are most of the child’s physical systems. Second, a child is prone to increased heat loss from the body because there is relatively little subcutaneous tissue. Third, a child has a relatively large proportion of body surface area to body weight, which further facilitates heat loss. Fourth, a child loses more heat through respiration than the adult. The ability to achieve and maintain optimal body temperature is inversely proportional to age; that is, the younger the child, the more likely he or she is to have difficulty maintaining body temperature.

Postoperatively, children can suffer many of the same sequelae as adults. They may suffer headache, especially after receiving an inhalational agent. Nausea and vomiting are common, particularly in children who have undergone strabismus surgery, have a surgery duration longer than 30 minutes, are older than 3 years, and those with a history of postoperative nausea and vomiting in the child or relatives (mother, father, or siblings) (Eberhart et al., 2004). Postoperative bleeding, dizziness, vertigo, loss of appetite, muscle soreness and pain, and sore throat, even after surgery that did not involve endotracheal intubation, are also prevalent. At times during the postoperative period, the child’s normal movements may need to be restricted to ensure safety or to keep IV lines or nasogastric tubes in place (see previous Engineering Controls section).

Monitor for signs of malignant hyperthermia: tachypnea, tachycardia, and chaotic dysrhythmias. Later signs are increased temperature, muscle rigidity, hyperkalemia, hypercalcemia, and myoglobinuria. Malignant hyperthermia is an inherited syndrome in which succinylcholine and inhalation agents trigger a fulminant hypermetabolic state (Rosenberg et al., 2007).

Visitation in the Postanesthesia Unit

The presence of a parent or other trusted family member in the PACU provides invaluable support and can reduce the hospitalized child’s sense of isolation and separation anxiety. Thus, many PACUs encourage one parent to visit at the bedside when the child is physiologically stable. At times, facilities may restrict parental visitation, especially when the child is not fully recovered from the effects of anesthesia or when patient acuity level requires a high level of technical interventions.

Same-Day Surgery

For many types of surgeries and patients, outpatient procedures can be performed safely and efficiently. The major disadvantage of same-day surgery is the abbreviated contact with healthcare providers. Provide thorough postoperative assessment and interventions to compensate for this shortened time for patient and family interactions. It is not mandatory that the child ingest and retain fluids (Awad and Chung, 2006). Letting the child choose whether to drink reduces the incidence of vomiting immediately postoperatively (Schreiner et al., 1992; Tabaei et al., 2006) (Chart 11–5, TIP 11–2).

PREPARING FOR DISCHARGE FROM AN ACUTE CARE SETTING

QUESTION: What are some aspects of discharge preparation that Cory’s family will need to know before Cory’s discharge?

A common philosophy is that “discharge planning begins on the day of admission.” On admission, assess the child’s and parent’s readiness to learn, barriers to learning, and learning preferences. Because patients are now discharged earlier and often require home care, discharge may be complex and require more family preparation, including education, skill development, and supply acquisition. To prepare families for discharge in the limited time available, use every interaction, formal and informal, with the patient and family as an opportunity to assess, teach, and evaluate learning. To increase effectiveness, make the teaching individualized, meaningful, and family focused. A casual conversation can turn into a teaching and learning opportunity. For example, when entering the room to administer an oral medication, the mother may ask what medication you are giving. This inquiry offers the opportunity for the nurse to teach the parents about the child’s current medications and potential discharge medications. Parents are often “information overloaded” at admission and discharge. Recognizing and using teaching opportunities throughout the hospitalization will result in more successful discharge teaching.

All teaching must be in collaboration with and communicated to other members of the healthcare team. A

NURSING INTERVENTIONS 11–10

Postanesthesia Concerns for the Pediatric Patient

Aspect of Care	Reasons for Concerns	Interventions
Airway management	Laryngospasm after extubation	Position the child to maintain airway; head midline, may need to displace mandible anteriorly, open mouth. Administer 100% oxygen via positive pressure ventilation if laryngospasm occurs. Anesthesia care practitioner may administer a dose of succinylcholine. Assist with reintubation, if needed.
	Postintubation croup	Provide humidified mist to child. Give racemic epinephrine treatment via aerosol nebulizer as ordered. Give corticosteroids before extubation, if ordered. If croup persists longer than 2 to 4 hours, expect to hospitalize the child overnight for observation.
	Apnea	Use a cardiac monitor, apnea monitor, and pulse oximeter to monitor the child's status. Provide assisted ventilation as necessary.
	Airway complications caused by bleeding after nasopharyngeal surgery	Keep appropriate pediatric resuscitative equipment available at the bedside. Assess the oral and nasal cavities for bright-red blood. Observe for excessive swallowing. Monitor for changes in vital signs. Provide fluid resuscitation. Elevate the head of the bed. Apply an ice pack to neck or nose. Keep the child as quiet as possible. Do not remove clots.
	Aspiration	Administer pain medications as needed. Suction the mouth, pharynx, and trachea if vomiting or excessive accumulation of secretions occurs. Administer oxygen.
	Delayed return to consciousness	Position the child prone or on the side. Before extubation, assess child's muscular strength, respiratory effort, airway protection, and eye opening. Identify any residual effects of drugs.
Fluid maintenance	Preexisting volume depletion resulting from illness	Closely monitor intake and output. Urine output should average 1 to 2 mL/kg/hour.
	NPO status before surgery Fluid imbalance resulting from child's higher basal metabolic rate than adults and greater body surface area; during illness, trauma, or stress, the child's extracellular fluid is easily depleted Although child has relatively greater fluid demands than the adult, actual amount of fluids required is small.	Establish and protect venous access. Administer maintenance fluids that are hypotonic and contain glucose. Prevent fluid overload by administering all fluids, blood, and blood products with a volumetric infusion pump.

Aspect of Care	Reasons for Concerns	Interventions
Seizures	<p>Accelerated hypoglycemic reactions due to fluid loss and stress of illness and surgery</p> <p>External loss of fluid from vomiting, diarrhea, and nasogastric suctioning</p> <p>Postoperative hemorrhage resulting from bleeding of an open vessel, continuous third-spacing fluid shift, or coagulopathy</p> <p>Risk factors, such as previous history of seizures; intracranial injury, hemorrhage, or tumor; increased intracranial pressure; or metabolic or nutritional disorders that may result in electrolyte imbalances, such as hypoglycemia, hypocalcemia, and hyponatremia</p>	<p>Monitor for symptoms of hypoglycemia; check blood glucose if symptoms present.</p> <p>Administer isotonic replacement fluids.</p> <p>Monitor circulatory status by assessing vital signs, urine output, central venous pressure, and pulmonary artery pressure.</p> <p>Give blood or blood products as ordered.</p> <p>Assess the child for predisposing factors that increase risk for seizures.</p> <p>Treat seizures promptly with diazepam or lorazepam as ordered.</p> <p>Ensure that the child's airway is maintained. Provide additional respiratory support after drug therapy begins.</p> <p>Keep resuscitation equipment immediately available.</p> <p>Prepare the child for a complete diagnostic workup as needed to determine the cause of the seizure.</p>
Thermoregulation	<p>High ratio of body surface area to body mass, and large head in relation to body size, thus lose heat readily</p> <p>Hypothermia with increased risk of apnea, hypoventilation, hypotension, hypoglycemia, and metabolic acidosis (in neonates)</p> <p>Cool operating room</p> <p>Postoperative shivering, which can increase oxygen requirements by 400% to 500%</p> <p>Hypothermia causes slowed recovery from anesthetic agents and may delay elimination of muscle relaxants</p> <p>Heat loss via vasodilation, lack of muscle tone, and inhibition of temperature regulation caused by general anesthesia and neuromuscular block</p>	<p>Use warming lights and warming blankets; increase the room temperature.</p> <p>Warm intravenous fluids.</p> <p>Wrap the child's head and extremities to preserve body heat.</p> <p>Administer supplemental oxygen.</p> <p>Use pulse oximetry to monitor the adequacy of oxygen therapy.</p> <p>Treat shivering with small dose of IV meperidine as ordered, or place heat on the child's skin.</p> <p>Frequently assess the child's temperature to evaluate the effectiveness of warming measures.</p>
Emergence delirium	<p>Increased prevalence in children and young adults</p> <p>May be exacerbated by hypoxia, nausea, dizziness, inability to move, pain, fear, anxiety, full bladder, hypotension, gastric distention, and pharmacologic agents or postoperative medications</p>	<p>Involve the parents in recovery by having them hold, reassure, and comfort the child.</p> <p>Immediately rule out hypoxia as the cause.</p> <p>Give opioids to treat pain.</p> <p>Catheterize the bladder if warranted.</p> <p>Use a soft, soothing voice and light touch to calm the child.</p> <p>Protect the child from self-injury by padding the bed or crib rails.</p> <p>Relax physical restraints if they cause the child to fight harder.</p> <p>Secure all venous access devices, tubes, drains, and dressings.</p>
Emergency resuscitation	<p>Equipment too large for the child</p> <p>Immediate need for pediatric dosages of resuscitation medications</p>	<p>Use equipment specifically designed for pediatric patients.</p> <p>Organize resuscitation equipment for pediatric patients on a cart, including defibrillator</p>

(Continued)

NURSING INTERVENTIONS 11–10

Postanesthesia Concerns for the Pediatric Patient (*Continued*)

Aspect of Care	Reasons for Concerns	Interventions
		<p>paddles, intraosseous and IV needles, and oxygen equipment.</p> <p>Ensure that the staff is competent in using pediatric equipment.</p> <p>Keep essential resuscitation medications immediately available in pediatric dosages.</p> <p>Ensure that the child's age and weight are easily retrieved from the medical record.</p> <p>Keep pediatric emergency drug dosage calculation cards handy.</p>

documentation system, such as an interdisciplinary patient-teaching tool, enhances communication among the healthcare team on the child's progress toward reaching discharge teaching goals.

Include follow-up care during discharge preparation. Because hospital stays are relatively brief, follow-up appointments or arrangements are crucial to the patient's health and safety. Follow-up appointments are used to periodically assess the child's progress toward wellness or adaptation. Assist with arrangements for schooling; outpatient therapies; home health referrals; and in-home equipment, supplies, services, and medications as indicated (see Chapter 12 for more discussion).

Follow-up after discharge helps parents obtain more information regarding care of their child and provides support to parents in reassuming (or assuming) their role as caregiver. Support after discharge may be more effective because parents may be less anxious, better able to assimilate information, and have had an opportunity to identify specific

questions and issues. Postdischarge follow-up can be performed through a telephone call or a home visit if needed.

ANSWER: For Cory's family, preparation for discharge will include demonstrating competence and confidence in their ability to care for his surgical incision, discussing Cory's diet and appropriate foods for Cory to eat, as well as scheduling his follow-up appointment with the pediatric surgeon.

CHART 11–5 DISCHARGE CRITERIA FOR SAME-DAY SURGERY PATIENTS

Child must

- Have vital signs stable, similar to preoperative baseline vital signs, with no signs of respiratory distress
- Have no signs of complications as related to anesthesia or specific to type of operation (e.g., no excessive bleeding from wound; minimal nausea, vomiting, dizziness)
- Have pain well controlled
- Regain preoperative cognitive functioning; may still be very sleepy and need assistance with motor functions
- Have parents state understanding of postoperative care and signs of complications and when to call healthcare provider, and be given written instructions and prescriptions as indicated

PROLONGED HOSPITALIZATION

Advances in technology have made it possible for many children to survive critical illness who years ago would have died. Some of these children are acutely ill for a period of time, and although their health status stabilizes, they continue to have care needs that necessitate hospitalization. These children may remain in the hospital for many months, or even years. To a child and his or her family, the hospital environment can be confusing and overstimulating. Periods of rest are often broken by painful events and procedures. The hospital certainly is not an environment that is conducive to normal parenting or achievement of tasks that promote growth and development in the child. Also, incorporation of the family's cultural mores is hampered during prolonged hospitalization because exposure to the foods, language, and traditions of the culture is usually limited.

Effect on the Child

Growing up in the hospital may lead to delayed development of psychosocial skills. Prolonged hospitalization may interfere with the development of trust and attachment (Freund et al., 2005). This is of particular concern in infants, who may not form a primary attachment with parents as a result of multiple caretakers meeting the child's needs in often inconsistent ways. It is important to have consistent caretakers, who all follow a consistent plan, maintain the child's routine, and set consistent limits on behavior.

TIP 11–2 A Teaching Intervention Plan for the Child After Same-Day Surgery

Nursing Diagnoses and Family Outcomes

- Deficient knowledge: Postoperative care, expected postoperative course, signs of complications

Outcome: Child/family will verbalize and demonstrate appropriate postoperative care and state signs of complications.

- Acute pain related to effects of surgery

Outcome: Child will have pain adequately managed and verbalize or display minimal pain behaviors.

- Risk for infection related to effects of invasive procedures, break in skin integrity

Outcome: Child will not develop infection.

Interventions

Educate the Parents

- *Activity restrictions:* Usually restrict to quiet activities for 24 hours because of effects of anesthesia; no unsupervised activities for 24 hours that require coordination (e.g., stair climbing, sports), then as appropriate to the procedure (e.g., when myringotomy tubes placed, child must wear earplugs when in water, such as during bathing and swimming)
- *Intake:* Clear liquids, then increase as tolerated or as specific to procedure (e.g., posttonsillectomy

soft foods); how to tell if drinking enough, if voiding once every 8 hours probably has sufficient intake; tips to promote fluid intake: popsicles, serve fluid in small cups, encourage a few sips with every television commercial

- *Voiding:* If the child has not voided prior to discharge, notify the healthcare provider if the child does not void within 8 hours after discharge
- *Incision/wound care:* If appropriate, whether to change dressing; amount and type of drainage expected; any special site care; elevation, ice, cleansing
- *Pain management:* How to assess as age and child appropriate; pharmacologic and nonpharmacologic management strategies with potential side effects of drugs and actions to minimize these (e.g., drink plenty of fluids with codeine to counter constipating effects)
- *Proper use of any equipment:* For example, using crutches

Contact Your Healthcare Provider If

- *Signs of complications pertinent to procedure:* Excessive bleeding; acute onset, excessive, or poorly controlled pain; unable to tolerate oral fluids; insufficient urine output; altered motor or cognitive functioning, lethargic, unable to arouse

Develop a plan jointly with the parents, health team, and child if he or she is old enough to participate in the discussion.

Early developmental intervention to prevent the negative effects of prolonged hospitalization is preferable. Encourage developmentally appropriate tasks, even though they may take longer to perform. For example, a toddler needs to learn to feed himself, whereas a preschooler needs to dress herself. Performing tasks themselves fosters a sense of control, which often is difficult to achieve in the hospital. This bolsters self-esteem and socialization skills. It is also important to create personal space for the child, even if it is only a small area, which also helps develop a sense of control. Help the child identify acceptable outlets for expressing negative feelings such as gross motor activity, pounding toys, or words to use. Take infants to the playroom; provide school for older children; children of any age benefit from trips outside. Remember to treat the child as a child, not as a disease.

Effect on Parenting

Prolonged hospitalization imposes different parenting demands than those in the home. Initially, parents need to deal with the child's illness and uncertainty regarding the outcome (see Chapter 12 for a discussion of chronic conditions). Parents may feel that their role is less impor-

tant because the healthcare team has the technological expertise to care for the child's physical needs.

Implement interventions to strengthen the parent-child bond. Identify a few key staff members for the family to communicate with. This enables these staff members to become familiar with the family's needs and strengths, and how to best support them. If parents are unable to stay with the child, minimize interruptions when they do visit. Encourage them to perform normal parenting tasks (e.g., providing physical care, promoting acquisition of developmental tasks, setting limits) and reinforce how important they are to their child. Offer information freely to make parents feel they are an integral part of the child's care. There will be times when parents cope better than at other times; negotiate with them about how involved they want to be in the child's care. When hospitalization is prolonged, families often become close to each other and close to the nursing staff, sharing information about themselves and their child.

caREminder

Keep information confidential. If families want to share information with the families of other patients, it is the parents' prerogative.

Financial concerns often become more of an issue with prolonged hospitalization. Initially parents may have been given a paid leave from work. After a period of time, they may need to return to work to maintain insurance benefits and income. They may feel powerless and guilty because they must work and thus cannot be with the child as much as they would like. Parents may feel stuck in a position, unable to change jobs because of preexisting condition exclusions on much-needed insurance. All these factors may make the parent less able to support the child during his or her hospitalization.

Care Conferences

Patient care conferences are useful in the coordination of care for children with prolonged hospitalization. A care conference is a meeting that is set up before the discharge of a medically complex patient. The social worker or case manager usually assembles the healthcare team members to meet to discuss the physiologic and psychosocial needs of the child and family during the hospitalization through discharge. The nurse plays a vital role in providing information to the healthcare team regarding the child's course of illness and future needs. Care conferences should include all members of the healthcare team involved in the child's care (e.g., parents, nurses, social workers, medical staff, nutrition counselors, child life specialists, pharmacists). This interdisciplinary team approach helps to promote understanding and trust between the family and healthcare team. Focus the conference on the needs of the child and family, and how they can be met. Debrief the family after the meeting to ensure their understanding of the discussion and future steps (Lewis and Noyes, 2007). The advantages to the implementation of care conferences include

- Promoting clear, effective communication between the family and members of the healthcare team
- Facilitating collaboration between the family and healthcare team
- Facilitating the identification of priorities and development of a comprehensive plan of care to address psychosocial, physical, and developmental needs of the hospitalized child and family
- Ensuring adequate preparation for discharge and transition to home

Discharge

After a prolonged hospitalization, discharge presents a greater challenge than normal. The child must adjust, or readjust, to the home environment, with resulting changes in lifestyle. Parents often need to change their schedule and demands of care. Family routines and dynamics will change with the introduction or reintroduction of the child who has been hospitalized. Siblings may need to adjust to changing behavioral expectations, household chores, and routines.

The child and family benefit from a period of transition prior to the actual discharge. Assess what will be needed in the setting the child will be going to; not all children may

be able to be discharged home. Determine what equipment, schooling, therapy, respite care, home care, and transportation will need to be arranged (see Chapter 12). Have the parents assume total care of the child in the hospital for 24 hours to gain familiarity and comfort with the process while still having medical support close by.

Remember to talk to the child about the planned discharge. When medically stable, the child may be able to leave the hospital for brief periods of time. These home passes may help the child and family adjust to the change. When the child returns to the hospital, talk concretely about how it was—what he or she did, ate, saw; sleeping arrangements; and so forth. This will make the impending discharge more real to the child and help ease the transition.

Acute illness and hospitalization of a child are stressors that jeopardize the emotional and physical well-being of the child and threaten family cohesiveness; prolonged hospitalization exacerbates the situation. Using developmentally and culturally appropriate approaches to provide information and emotional support while addressing the child's physiologic needs in the most atraumatic manner possible, the interdisciplinary team can minimize the negative consequences of acute illness and hospitalization.

See [thePoint](#) for a summary of Key Concepts.

Chronic Conditions as a Challenge to Health Maintenance

Case History

Lindsay Jenkins went to the doctor with her father, Tom, on the Monday after her family returned from Thanksgiving with her grandmother and relatives. She had been unusually thirsty for days now, excusing herself to the restroom often. Sunday evening she had vomited. Her grandmother and aunts had commented on how thin she looked. Her pediatrician had her urine tested for ketones, took her history, and diagnosed her with type 1 diabetes. She and her father were given a choice between two nearby medical centers and Lindsay was admitted to the hospital. Lindsay's mother, Jean, had left town that morning on business.

When Tom called his wife to tell her they had to go to the hospital, Jean was devastated. "It was almost like hearing that she was dying. I just kept thinking, 'Why couldn't it be me and not my child?' I joined them at the hospital the next day, but I felt so guilty for not being there when they first heard the diagnosis. Lindsay's blood sugar was still running very high when I arrived at the hospital and Lindsay said hateful things to me. I know now how belligerent and

out of character she can be when her blood sugar is high, but at that time it just added stress to the situation. I remember thinking that she could never be in anyone else's care again and that we would never again have a night away."

"The first year of having a child with diabetes takes over your life. Every meal focuses on the numbers: the number of carbohydrates, the blood sugar numbers, and the amount of insulin. The first time she was away from us was at a weekend camp run by the American Diabetes Association. They separate the kids from their parents. Tom and I attended classes given by diabetes educators, nutritionists, and insulin pump manufacturers. The kids swam, played games, and had a camp experience while the camp doctors and nurses managed their insulin and intake. I don't think I slept but about an hour that first night. I was so anxious to know that Lindsay was all right. But I am so glad that we did go to camp. It proved to me that she could be okay without my constant vigilance, and she has gone to diabetes camp every summer since then."

CHAPTER OBJECTIVES

1. Define chronic condition.
2. Discuss the broad spectrum of disorders that can be defined as chronic conditions.
3. Discuss reasons for the disparity in determining the prevalence of children with chronic conditions. Analyze the impact of chronic conditions on children and families.
4. Understand interventions to promote health and normalization for children with chronic conditions and their families.
5. Discuss issues related to having a child with a chronic condition.
6. Contrast pediatric rehabilitation and habilitation from adult rehabilitation.
7. Delineate nursing interventions and strategies to assist the child in gaining independence during the rehabilitative and habilitative processes.
8. Discuss the impact of having a chronic condition on the child/adolescent.
9. Discuss the advocacy role of the nurse related to the laws protecting children and adolescents with chronic conditions.
10. Describe nursing strategies to improve the transition from pediatric settings to adult services.

See [thePoint](#) for a list of Key Terms

An acute illness is temporary and episodic; it is treated and resolves, usually without sequelae. Acute illnesses, such as otitis media, influenza, gastroenteritis, lacerations, or appendicitis, typically last a few days or a few weeks. Sometimes the recovery may take longer, such as for pneumonia or a fractured bone. Many conditions, however, can last for years and sometimes for a lifetime; these conditions are termed *chronic conditions*. The definition of a **chronic condition** is one that lasts at least 6 months and requires long-term monitoring and management “to control the symptoms and to shape the course of the disease” (Corbin, 2001, p. 1). It includes physical, cognitive, psychological, and social disorders that can range from mild (such as allergies or learning disabilities) to significant impairments (such as autism or cerebral palsy) (van der Lee et al., 2007). Chronic conditions are usually caused by irreversible pathologic alterations. Although some chronic conditions may alternate between periods of **remission** (times when no symptoms are evident) and **exacerbation** (times of acute symptomatology related to the condition), the condition still exists.

TERMINOLOGY RELATED TO CHRONICITY

QUESTION: Which of the following groups of children most accurately describes Lindsay?

Multiple terms are used to refer both to certain conditions and the children who have them. This section attempts to differentiate and define this terminology.

Chronic Condition Versus Chronic Illness

The terms *chronic illness* and *chronic condition* are not necessarily the same, and some confusion exists regarding the difference between them. Although all chronic illnesses are chronic conditions, very few chronic conditions are chronic illnesses. A **chronic illness** “implies being sick and needing to recover” (Selekman & Gamel-McCormick, 2006). In other words, the individual is perceived as being sick and not in a state of wellness, and is treated as though he or she is not well. An example of a chronic illness is cancer, for which the goal is remission of symptoms. Often, the healthcare community begins to use the term *cured* after 5 years or more without symptoms, although it is used with caution.

The vast majority of chronic conditions, however, are *not* chronic illnesses. Conditions such as mental retardation, Down syndrome, myelomeningocele, cerebral palsy, cystic fibrosis, asthma, diabetes, sickle cell disease, blindness, and attention deficit hyperactivity disorder are all chronic conditions but are not considered chronic illnesses, because the condition is always present. Although children with such conditions might be ill during a period of exacerbation, their chronic condition is *not* an illness from which they can recover. They are not ill because of their condition and should not be treated as such, except perhaps during periods of exacerbation (Selekman & Gamel-McCormick, 2006). Therefore, it is strongly recommended that nurses and families use the term *chronic condition* rather than chronic illness.

Person-First Language

Since the 1990s, there has been an emphasis to ensure that children and adolescents with chronic conditions are not referred to “as” their condition. It is inappropriate to speak about “the cystic,” “the diabetic,” or “the asthmatic”; rather, the healthcare provider should use **person-first language**. This type of language focuses on the fact that patients are people first who, by chance, happen to have a chronic condition. Thus, we refer to “the adolescent with asthma,” “the child with diabetes,” or “the infant with cystic fibrosis.” This allows the healthcare team to focus on the child or adolescent as a person, rather than on the child’s disorder. As one adolescent stated to a healthcare provider, “I am *not* my condition and my condition is *not* who I am. Just because I have a chronic condition, do not treat me like I am sick.”

Disability and Other Related Terms

Numerous terms are used to refer to the population of children and adolescents with chronic conditions. These terms include *disabled*, *children with special health care needs*, *handicapped*, *compromised*, *impaired*, and *technology dependent*.

The term **disability** has at least two official definitions: an educational definition according to the Individuals with Disabilities Education Improvement Act (IDEA) (2004) and a broader definition as detailed in the Americans with Disabilities Act (ADA) (1990). The IDEA definition of *disability* is characterized by disorders that will qualify a student for special education and related services (e.g., autism, mental disabilities, speech and language impairment, and traumatic brain injury).

The ADA definition of *disability* focuses on key life functions that are expected of a child of a particular age (Chart 12–1). This law states that a person with a disability is one who has a physical or mental impairment that substantially limits a ‘major life activity’ *or* has a record of such impairments, *or* is regarded as having such an impairment (Americans with Disabilities Act, 1990). ADA includes the same disabilities noted in IDEA, but expands the list to include those with chronic contagious and noncontagious diseases, including tuberculosis and HIV, cerebral palsy, epilepsy, muscular dystrophy, multiple sclerosis, drug addiction, and alcoholism (Americans with Disabilities Act, 1990). Major life activities include the ability to care for one’s self, perform manual tasks, walk, see, hear, speak, breathe, learn, or work.

These definitions will have a significant affect on who will qualify for various services. There are also multiple chronic conditions that are not listed in these definitions. A discussion of the broad spectrum of chronic conditions appears later in this chapter.

Developmental Disability

When a disability has an impact on the development of a child, it is called a **developmental disability**. According to the Developmental Disabilities Assistance and Bill of

Rights Act Amendments (1996), a person with developmental disabilities has substantial limitations in at least three of the following life activities: self-care, mobility, learning, capacity for self-direction, capacity for independent living, receptive and expressive language, and economic self-sufficiency. Frequently, children younger than 9 years of age with these conditions are referred to as *having developmental delays* rather than *disabilities*. This might be because of the concern about labeling a child with a condition that might disappear as the child matures or because of the difficulty in making an accurate diagnosis in a young child. A delay implies a maturational lag and being slower in achieving developmental tasks than children of the same age. There is, however, no clear differentiation between a developmental delay and a developmental disability, and neither of these general terms provides guidance to the healthcare team in planning care.

Children With Special Health Care Needs

Children with chronic conditions also are often referred to as **children with special healthcare needs**. The American Academy of Pediatrics uses the definition of the federal Maternal and Child Health Bureau’s Division of Services for Children with Special Health Care Needs, which states: “Children with special health care needs are those who have or are at increased risk for a chronic physical, developmental, behavioral, or emotional condition and who also require health and related services of a type or amount beyond that required by children generally” (McPherson et al., 1998, p. 138; as cited in Kastner and the Committee on Children with Disabilities, American Academy of Pediatrics, 2004).

In essence, this population uses and needs healthcare and related services more than the general pediatric population. The definition “focuses on the criterion of need for additional services instead of an identified medical condition or functional impairment, recognizing the variability in disease severity, degree of impairment, and service needs among children with the same or differing diagnosis” (Allen, 2004, p. 8).

Terms to be Avoided

Although many of the previous terms are used interchangeably to refer to children with chronic conditions, other terms have a more negative connotation. For instance, the term *handicap* should be avoided. A **handicap** is a limitation imposed on the individual by environmental demands and is related to the individual’s ability to adapt or adjust to those demands (Selekman & Gamel-McCormick, 2006). In other words, one is not born with a handicap; a handicap is imposed on someone by society. Telling a child that he or she cannot do something because of a chronic condition, preventing a child access to places and opportunities, treating a child differently, using derogatory labels to describe a child (e.g., *retarded* or *crippled*), and not allowing a child to strive for and reach developmental milestones all play a part in developing a handicap. It should be noted, however, that the term *handicap* was once very acceptable and was used in a number of federal laws.

CHART 12–1 DEFINITION OF A CHILD WITH A DISABILITY

A child with a disability means a child with “mental retardation, hearing impairments (including deafness), speech and language impairments, visual impairments (including blindness), serious emotional disturbance . . . , orthopedic impairments, autism, traumatic brain injury, other health impairments or specific learning disabilities; and, who, by reason thereof, needs special education and related services” (Individuals with Disabilities Education Improvement Act, 2004).

For children who are between the ages of 3 and 9 years, the phrase *child with a disability* “may, at the discretion of the State and the local education agency, include a child experiencing developmental delays, as defined by the State and as measured by appropriate diagnostic instruments and procedures, in one or more of the following areas: physical development, cognitive development, communication development, social or emotional development or adaptive development; and who, by reason thereof, needs special education and related services” (Individuals with Disabilities Education Improvement Act, 2004).

Another phrase used frequently in the past has been to refer to children who are **technology dependent**. Use of this term puts an emphasis on the technology rather than on the child, thus impersonalizing the child. It is interesting to note that this term is never used to refer to children who wear glasses, hearing aids, insulin pumps, or braces; it most commonly is used related to respiratory and feeding tube equipment.

When children with chronic conditions are referred to as **compromised children** or **impaired**, it implies that they are less than whole and had to settle for less. Although families may *feel* they have had to compromise their hopes and dreams for the reality of their situation, the children are *not* compromised as human beings (Selekman & Gamel-McCormick, 2006).

Nursing education promotes the individuality of each person and stresses the holistic nature of a person's being. It encourages support of the wellness components and treating individuals with respect. Emphasis has always been placed on promoting the self-esteem and self-worth of children, especially those with a chronic health concern. Therefore, it is essential to focus on children's wellness, their strengths, and their potential, rather than their limitations and technology (Fig. 12–1).

ANSWER: Lindsay is a child with a chronic illness that is also a chronic condition. Lindsay is not a child with a developmental delay, nor does she meet the ADA definition of disability, because she does not have “a physical or mental impairment that substantially limits a ‘major life activity.’” Lindsay is a child with special health needs. She will need access to medical care and services more than other children.

THE SPECTRUM OF CHRONIC CONDITIONS

Chronic conditions take many forms in children and adolescents, and these forms might change as the child ages

FIGURE 12–1. Sick or well, the focus should be on promoting the child's strengths and providing opportunities for enhancing developmental milestones.

or may change even from day to day. Some chronic conditions are genetic or congenital (e.g., Down syndrome or being born without a body part), some are acquired (e.g., traumatic brain injury, traumatic physical injury, or HIV disease), and some are idiopathic with no known cause. Some conditions are caused by high-risk behaviors in which the parents engaged prior to conception or during the pregnancy. Others are the result of conditions of the mother during the pregnancy (e.g., maternal infections). Some genetic conditions are obvious at birth (e.g., Down syndrome) and some are not (e.g., sickle cell disease or cystic fibrosis).

Some conditions affect only one organ system (e.g., clubfoot or blindness) and some affect multiple organ systems (e.g., cystic fibrosis, which affects the pulmonary, pancreatic/gastrointestinal, reproductive, and electrolyte systems). Some conditions progress during childhood, often causing death (e.g., muscular dystrophy), some are static (e.g., epilepsy and cerebral palsy), and some alternate between periods of remission and periods of exacerbation (e.g., inflammatory bowel disease and asthma). Some will result in a shortened life span (e.g., cystic fibrosis and muscular dystrophy) and others will have no effect on the life span (e.g., deafness or blindness).

Some conditions or the treatments for them put the affected individuals at risk for serious complications from the condition. For example, those with sickle cell disease are at a higher risk for stroke, those treated for cancer may be at risk for secondary cancers, and individuals with corrected myelomeningocele have a higher risk for latex allergy. Some chronic conditions may result in numerous hospitalizations during exacerbations or disease progression, whereas those with other conditions may never set foot in a hospital (Fig. 12–2).

Some chronic conditions result in little or no impact on the child and family (e.g., the need to wear glasses or to take a daily medication for a condition such as hypothyroidism); some have significant impact on the child's development and his or her potential for eventual independence, as well as on the family (e.g., having both severe mental retardation and cerebral palsy). In such

FIGURE 12–2. The child who is frequently hospitalized develops a warm rapport with the nursing staff. Developing a trusting relationship is important in helping the child feel secure.

TRADITION OR SCIENCE 12–1

What will be the long-term sequelae of fetal surgery on development and on the way chronic conditions present?

MORE INQUIRY NEEDED

Fetal surgery attempts to correct or treat selected conditions in utero, such as hydrocephalus, myelomeningocele, and diaphragmatic hernia. These conditions usually present with certain symptoms and progress in a particular, predictable fashion. Will the outcomes be different for those who have had this surgery in utero compared with those who have surgery after birth? The relative newness of these procedures has not given healthcare providers enough time to determine the answer to this question. This is a case where more inquiry and investigation are needed to determine the long-term benefits of fetal surgery to correct or treat acute and chronic conditions in children.

cases “habilitative” and rehabilitative services may be needed for the child. It should be noted that the ability to cope with and adjust to the chronic condition is not necessarily related to the severity of the condition. This concept is covered later in this chapter.

Some chronic conditions are secondary to or complications of another risk factor. Premature birth is a high risk factor for numerous long-term health problems. Approximately 11% of those born weighing less than 1,000 g develop serious conditions, such as cerebral palsy, mental retardation, and blindness. Another 15% are at risk for developing seizure disorders and learning disorders (Mayes, 2003). Still others might have alterations in their physical growth, intellectual development, language development, and behavior and socialization later in life (Tradition or Science 12–1).

The vast majority of chronic conditions present in a mild or minor form, resulting in minimal negative impact on the child’s ability to engage in the usual childhood activities, perform regular school work, and achieve independence (Allen, 2004). All chronic conditions have an impact on the family and on the child. Most also have an impact on the schools and the community. It is essential for the pediatric nurse to understand the spectrum of chronicity and to be able to support the family and the child through the experience.

THE PREVALENCE OF CHRONIC CONDITIONS

The numbers used in the professional literature to indicate the prevalence of chronic conditions in the pediatric population are confusing and contradictory. In essence, they depend on the definition used for disability and what constitutes a chronic condition. The most commonly used statistic to identify those with disabilities estimates that 18% of those younger than age 18 have a disability

(Kuhlthau et al., 2002). However, the prevalence of children and adolescents with chronic conditions in the United States is reported to range from 2% to 32% (Centers for Disease Control and Prevention, National Center for Health Statistics, 2003; Ireys, 2001; van der Lee et al., 2007). This means that anywhere from approximately 1 in 50 to 1 in 3 children and adolescents has a chronic condition that should be considered when completing health assessments, setting goals and planning for care, and delivering care.

PSYCHOLOGICAL ADJUSTMENT TO A CHILD WITH A CHRONIC CONDITION

In addition to having a solid knowledge of the physiologic components of chronic conditions affecting children and adolescents, pediatric nurses need a keen understanding of family dynamics as well as child and adult psychology. Having a child with a chronic condition adds additional challenges and stressors to a family’s life.

Although there is a variable amount of adjustment and coping with the ongoing demands of having a child with a chronic condition, there are specific times when stress has a greater chance of being at a high level for families of a child with a chronic condition (Melnik et al., 2001). These times include

- The period before the diagnosis is made
- The time surrounding getting a diagnosis
- The period when the family is adjusting to the ongoing care demands of the child
- Times of exacerbations requiring hospitalization, and deterioration of the child’s condition

Be aware of all the potential stressors that could interfere with the psychological health of the family, and take measures to facilitate and support successful coping and psychological health.

The Period Prior to a Diagnosis Being Made

Some children are born with physical signs that are visible and clearly fit a pattern for an immediate diagnosis, even while in the delivery room. Down syndrome and many congenital anomalies are examples. Myelomeningocele is obvious at birth, and a diagnosis can be made on day 1 of life. How the healthcare team responds to the parents in the delivery room and in the postpartum area can result in an aura that “something is very wrong with your baby.”

Still other conditions appear with such diffuse symptomatology, such as asthma, cystic fibrosis, sickle cell disease, cancer, and autism, that identifying that a pathologic problem exists might be difficult to discern and often takes years for the condition to develop and be accurately diagnosed. Parents of children with chronic conditions might sense that something is wrong with their child, sometimes years before a diagnosis is made. The symptoms might be

subtle, but of sufficient concern to the parents, yet the parents might delay seeking a medical evaluation as a result of fear of the unknown, lack of confidence in their assessment skills, and concern that they will be labeled as an overly concerned parent by the healthcare provider. They might first try a variety of home remedies or a change in behavior or dietary management. They might also compare their child with their friends' children or with their other children to note any differences.
