Alert! Some children are chronic carriers of *S. aureus*. Children with recurrent impetigo should be cultured for the organism in nares, perineum, and axillae.

Interdisciplinary Interventions

Impetigo usually remains clinically stable for weeks, and many lesions heal spontaneously. In other cases, however, prompt therapy is crucial so that the impetigo does not spread to other children. Treating the child with impetigo involves performing daily hygiene to the affected areas, administering antibiotic therapy, and instituting measures to prevent further spread. Topical therapies may be used if the impetigo is superficial, nonbullous, or localized to one or two lesions. Some of the products available include Neosporin, Polysporin, Bacitracin, and Mupirocin applied three to four times daily. Topical antibiotics are effective if hygiene and general health are good, and the lesions are not widespread. Although many physicians treat impetigo only topically, others prefer to use systemic therapy for neonates and young children at risk for widespread disease and in whom no improvement is seen within 3 days of initiating topical therapy. Nursing responsibilities focus on educating the family about the treatment plan and helping the family to recognize the infection in case it recurs (TIP 25–4).

Cellulitis

Cellulitis refers to a fairly common, full-thickness, non-suppurative skin infection involving dermis and underlying connective tissue, often accompanied by lymphangitis and adenopathy. It affects slightly more males than females and occurs in all age groups. Any part of the body can be affected, but the most prevalent location is the legs.

Pathophysiology

Most cases of cellulitis develop in skin that has been compromised in some way, including debilitating disease, trauma (e.g., puncture wounds), lymphatic damage, pressure ulcers, immune compromise, and tinea infections. In some hospitalized children, complex nosocomial cellulitis develops at IV infusion sites, surgery wound sites, and joint replacement sites. Periorbital cellulitis is often precipitated by infecting organisms from wounds, bites, and sinusitis. In children younger than age 3 years, facial cellulitis is commonly associated with otitis media. *Haemophilus influenzae* facial cellulitis has a violaceous hue that is commonly associated with otitis media.

The most common causative agents of cellulitis are GABHS and *S. aureus*, acting alone or in combination. Other implicated microbes include *Escherichia coli*, *Proteus mirabilis*, group B streptococci, and anaerobes. *H. influenzae* and *S. pneumoniae* also can cause cellulitis, especially in children. The infecting agents, especially the streptococci, create a large amount of enzymatic spreading factors called *hyaluronidase*. These substances break down the fibrin network and other subcutaneous barriers that normally localize an infection. In addition, the hyaluronidase can also travel through the lymphatic system. As a result, severe cellulitis can rapidly progress to a life-threatening situation in a child if interventions are not prompt.

When sinusitis is the primary cause, the infection usually spreads from the ethmoid sinuses across the lamina papyracea and into the orbital area, causing periorbital cellulitis. Infection can also spread through the floor of the frontal sinus or the roof of the maxillary antrum. In all cases, the orbital septum is the only barrier protecting the infection from spreading from the eyelids to the orbit.

Prognosis

Prognosis for cellulitis depends on the promptness and efficacy of the interventions as well as on the child's general health status. If not eradicated, persistent cellulitis can lead to necrotizing fasciitis, bacteremia, or osteomyelitis.

Assessment

Characteristic health history and physical examination findings suggest the clinical diagnosis of cellulitis. Other signs include increased white blood cell count, positive blood culture (especially in facial cellulitis), and culturing of an organism from lesion aspirate.

Cellulitis is characterized by reddened or lilac-colored, swollen skin that pits when pressed by the fingertips (Fig. 25–11). The skin texture may resemble an orange peel, and the borders are usually indistinct and not palpable. Superficial blistering of the area is a common finding. Systemic symptoms include fever, chills, malaise, tachycardia, hypotension, and headache. Regional lymphadenopathy and lymphangitis may occur. The child may appear prostrate and listless, and may complain of severe pain over the affected area.

CLINICAL JUDGMENT 25–2

The Child With Impetigo

When Mrs. Sanchez picked up her daughter Ally from preschool, the teacher told her that Ally had a skin rash on her face that looked like impetigo. Mrs. Sanchez was informed that Ally could not come back to preschool until she had been seen by her health-care provider, with treatment initiated if needed.

Questions

1. If Ally has impetigo, how would you expect the lesions to look?
2. What other characteristics of the lesions and history of this situation could help you confirm the presence of impetigo?
3. The nurse practitioner agrees with the evaluation of the lesions and tells Mrs. Sanchez that Ally has impetigo. What are the primary goals of care at this time?
4. What interventions should be implemented to treat the lesions?
5. What information should Mrs. Sanchez repeat to you to demonstrate her understanding of how to prevent spread of this skin condition?

Answers

1. Nonbullous lesions are vesicles that rupture, leaving moist, honey-colored, crusty lesions on erythematous, eroded skin. Bullous lesions are pustular blisters that rupture, leaving a varnishlike coating.
2. The most common site is the face, as seen in Ally's situation. Satellite lesions may occur near the primary site and on other body parts, especially the extremities or perineum. Impetigo is most often seen in children younger than 6 years. A history of pruritus and an earlier skin disruption at the site also confirm the current physical findings. Determine whether any other children at school have impetigo.
3. Treat the bacterial infection and prevent spread of the disease.
4. Gently clean and remove the crusts on the skin. Use topical antibiotics (mupirocin) three times a day for 5 to 14 days. If there is no improvement in 3 days, the child should be seen again by a health-care provider, and oral antibiotics would be started and administered for a 10-day period.
5. Ally should be discouraged from touching or picking at the lesions. She should wash her hands frequently throughout the day. If she or anyone else touches the lesions, they should wash their hands immediately with antibacterial soap and water. Ally's fingernails should be cut short. Other members of the family should not use Ally's towel or washcloth. Ally can return to school after she has used the topical antibiotics for 48 hours.

FIGURE 25–11. Cellulitis.

Interdisciplinary Interventions

Hospitalization is required for children with large areas of cellulitis or cellulitis of the face, systemic toxicity, high fever, or hypotension (see [thePoint](#) Care Path: An Interdisciplinary Plan of Care for the Child With Periorbital Cellulitis). If the skin ruptures or tears, the physician may order treatment with a nonocclusive dressing with saline-dampened gauze. Moisture-retaining dressings, such as the occlusive films (e.g., Tegaderm Opsite) and hydrocolloids (e.g., Duoderm, Tegaserb) are contraindicated in active cellulitis because they may contribute to the development of secondary infections.

Treating cellulitis typically involves administering antibiotic therapy. The medication used depends on the infecting organism, the child's condition, and the site of infection. After the infection subsides, the antibiotic is typically changed to an oral anti-infective agent. Keep parents informed of the medication regimen to prepare for continuing care of the child in the home after discharge from the acute care facility.

Members of the interdisciplinary team can monitor and facilitate the healing process. If the child is debilitated or

TIP 25-4 A Teaching Intervention Plan for the Child With Impetigo

Nursing diagnoses and outcomes

Impaired skin integrity related to presence of vesicles, erosions, and exudates

Outcome:

- Child's skin shows evidence of healing within 42 to 78 hours of initiation of therapy.

Risk for infection related to transfer of skin lesions from child to others during close personal contact with family and peers

Outcomes:

- Child remains free from systemic infection.
- Family members and peers do not contract the skin infection.

Deficient knowledge: Treatment and prevention of impetigo

Outcomes:

- Family demonstrates measures to treat the child's skin condition.
- Family members participate in measures to prevent spread of the infection.

Teach Child/Family

Treatment of Lesions

- Apply warm water compresses to areas of lesions to remove crust and exudate several times daily.
- Clean lesions gently with mild soap to prevent secondary infection.
- Apply topical antibiotics or give oral antibiotics as ordered.

- Observe for treatment effectiveness such as decreased erythema and drainage.
- Follow-up appointment should be scheduled in 48 to 72 hours if there is no improvement and in 10 to 14 days.

Preventing Spread of Infection in Affected Child and to Others

- Observe skin carefully for signs of new infection (erythema, vesicles, erosions, exudate).
- Wash hands before and after caring for lesions, using antimicrobial soap.
- Trim the child's nails and keep them clean.
- Keep the child out of school or daycare activities until after 24 hours of treatment with oral antibiotics or 48 hours with topical ointments.
- Keep infected athletes who compete in close-contact sports from competition until contagious period has passed. Sterilize athletic mats and equipment.
- Keep child's personal care items (towel, washcloth) separate from other family items until the lesions disappear.

Contact Healthcare Provider if:

- Presence of lesions does not diminish within 48 to 72 hours of initiating treatment
- Fever develops
- Lesions begin to appear infected
- Other members of the household exhibit the presence of similar lesions

unable to take foods orally, consultation with a dietitian may be necessary to plan ways to ensure adequate nutritional intake to support tissue healing. In a severely ill child, parenteral nutrition may be warranted.

During hospitalization, a child life specialist can assist in providing diversionary activities for the child. In addition, the child life specialist can provide play experiences that encourage expression of the child's feelings about hospitalization and pain. Chapter 11 discusses this aspect of the child's care in more detail.

Community Care

Family teaching before discharge should include the expected outcomes, the prescribed treatment regimen, and the coordination of home care and return clinic visits. The child and family members may need to learn aspects of dressing care and sterile technique. Instruct parents to schedule outpatient visits, so that the health-care team can monitor the healing process, and to call the healthcare provider promptly if signs of progressing infection develop, such as increased body temperature, or increased swelling or pain near the lesion site.

Cat Scratch Disease (CSD)

Transmitted by asymptomatic young cats, cat scratch disease (CSD) is caused by a small gram-negative bacillus, *Bartonella henselae*. The condition is characterized by a benign subacute, chronic course of lymphadenopathy that usually resolves spontaneously in 2 to 3 months. Occasionally, CSD causes severe systemic sequelae; this development is seen more often in immunosuppressed children. CSD affects primarily children and adolescents, with the vast majority of cases in those younger than 20 years of age (Burns et al., 2008; Lamps & Scott, 2004).

Pathophysiology

In 87% to 99% of cases, a cat (usually a kitten) is involved, although other sources include dog scratches, monkey contact, and wood splinters (Burns et al., 2008; Lamps & Scott, 2004). The organism is believed to be spread from kitten to kitten. As the kittens age, they retain antibodies for *B. henselae* and the bacteremia subsides, which is why adult cats are less likely to be the culprits in transmission of this disease. The inoculation site

may be a scratch, puncture, or abrasion and is usually nonpruritic and nonscarring.

Assessment

Symptoms of CSD manifest in a classic sequence. Usually 3 to 10 days after cat contact, maculopapular lesions appear on the skin in the inoculation area and progress to vesicles and pustules. The lymph nodes draining the site of the cat scratch become swollen 14 to 50 days after the contact. The nodes are tender, warm, reddened, and indurated, and they remain enlarged for up to a year.

Mild systemic symptoms include malaise, anorexia, headache, body aches, sore throat, conjunctivitis, nausea, vomiting, abdominal pain, rashes, and arthralgia. Fever occurs in only about 25% of affected children, usually indicating systemic disease. More severe symptoms, such as central nervous system involvement, rarely occur. These symptoms can be severe and include seizures, myelitis, blindness, radiculitis, encephalitis, encephalopathy, paraplegia, cerebral arteritis, and coma.

Diagnosis is based on a history of contact with a young kitten, the presence of lymphadenopathy, positive skin test for *B. henselae*, and identified *B. henselae* organisms cultured from lymph nodes. The *B. henselae* immunofluorescent assay test is highly sensitive and specific for the detection of infection caused by this bacteria. A complete blood count may show leukocytosis and increased eosinophils; the erythrocyte sedimentation rate may be elevated early during the disease. Lymph node biopsy may also be performed.

Interdisciplinary Interventions

In most children, CSD resolves spontaneously in 2 to 4 months. Nursing care is supportive and children are rarely hospitalized. If desired, antimicrobial therapy may be ordered. Bed rest and analgesics may also be ordered if fever is present. Treatment of local lesions includes warm, moist soaks. Nursing care is supportive and children are rarely hospitalized.

VIRAL SKIN DISORDERS

Any skin eruption associated with an acute viral syndrome is called a *viral exanthem*. If the mucosa is involved, it is called a *viral enanthem*, which tend to be nondescript, diffuse, and symmetric maculopapular rashes, often indistinguishable from a medication reaction (Pride, 2001). Viral exanthems include measles, rubella, enteroviral and adenoviral exanthems, roseola, the mononucleosis syndromes, herpes simplex, and herpes zoster. These conditions are discussed in Chapter 24. The discussion in this chapter is limited to warts, which are caused by the human papillomavirus (HPV), and hand, foot, and mouth disease, which is caused primarily by the coxsackievirus.

Warts (Verrucae)

Warts are common, harmless skin growths (small epidermal tumors of the skin) caused by a virus. They do not have

“roots” or seeds as many believe; the dark specks sometimes seen in warts are actually the ends of capillaries. Verrucae, or warts, are one of the most common skin problems seen in children, and are usually self-limiting (Smolinski & Yan, 2005). The warts affecting children include the common wart (*verruca vulgaris*), flat warts (*verruca plana*), plantar warts, and, in adolescents, genital warts.

Pathophysiology

More than 150 types of HPV exist that can produce a broad spectrum of conditions ranging from asymptomatic warts to squamous cell carcinoma of the skin (Smolinski & Yan, 2005). The clinical manifestations of HPV depend on the type of HPV, the host, and the anatomic site affected.

HPV is transmitted through direct contact. Incubation periods range from 1 to 12 months, with an average of 2 to 3 months (Arndt & Hsu, 2006). The virus invades the skin or the mucous membranes, and then skin changes occur. Children who are immunocompromised are at greater risk for development of the disease because HPV is known to be a latent asymptomatic infection. That is, once infected, the virus may remain latent in the basal layers of the epidermis, demonstrating manifestations when the child has a weakened immune system.

Most warts resolve spontaneously within several months to years. Some may require extensive treatment to remove if they are considered unsightly or occur in an area in which they are irritated by friction against clothing. The therapy should eradicate the problem without causing scarring.

Assessment

Slightly raised above the skin surface, *common warts* are growths that can be very small, or they can be large and clustering. Warts usually occur on the hands, but they can also be seen on the face, knees, and elbows. They are usually elevated, flesh-colored single papules with scaly, irregular surfaces. This type is usually asymptomatic and multiple in number. *Plantar warts* occur on the soles of the feet. They are often surrounded by a collar of hardened skin, and they can cause pain with walking. Warts that are not raised or rough are called *flat warts* and are often seen on the face, neck, and extremities.

Genital “moist” warts (condylomata acuminata) are single or multiple soft masses that usually appear around the anus, the vagina, or the penis. Occasionally, they can obstruct the urethral meatus or vaginal introitus. The incubation period for genital warts ranges between 6 weeks and 6 months, although much longer periods are possible. The virus is transmitted predominantly through sexual contact. These warts are usually asymptomatic, but they can itch, burn, or cause local pain. When untreated, venereal warts resemble cauliflowerlike masses.

Alert! Warts of the genitalia in young children should raise the question of possible sexual abuse.

Interdisciplinary Interventions

Numerous healthcare modalities may be necessary, and the recurrence rate for warts is very high. Treatment usually involves either freezing the wart or chemically killing the skin that contains the wart virus. The decision to treat should be based on location, number, and size of the lesions; discomfort; and whether the warts are cosmetically objectionable. Active nonintervention is a viable option, given that many warts will resolve spontaneously (Smolinski & Yan, 2005; Torrelo, 2002).

To freeze the warts, liquid nitrogen (cryotherapy) is applied to the site for 2 to 10 seconds, which may or may not be followed by electrosurgery to remove the wart. A blister or blood blister may develop at the site within 1 to 2 days. The blistered skin is soaked in warm soapy water and then the blister can be gently opened, applying a thin layer of antimicrobial ointment to the area. Exposing warts to heat has been shown to clear the skin lesion. This treatment is completed by immersing the area in hot water, by applying exothermic patches, or by multiple 30- to 60-second exposures to heat at 122 °F (50 °C) (Smolinski & Yan, 2005).

Over-the-counter chemical agents (e.g., maximum-strength wart remover, Mediplast, Compound W, Wart-Away) can be applied to eliminate the wart. These work by causing topical peeling and an inflammatory response, and tend to turn the skin white. One study demonstrated that application of calcipriol cream (a vitamin D₃ derivative) shows promise in treating warts (Labandeira et al., 2005).

Warts that are cut off are likely to spread. Plantar warts may respond with intermittent flattening of the lesion with a pumice stone or callus file.

Alert! Concentrated drug store preparations of salicylic acid should never be used on venereal warts.

Other destructive interventions that eliminate the wart by causing necrosis and blister formation include surgical excision, carbon dioxide laser therapy, photodynamic therapy, antimetabolic agents (such as cantharidin), topical immunotherapy with contact sensitizers, immunotherapy modalities that stimulate an immune response to HPV, and intralesional injection of antigens (Clifton et al., 2003; Grussendorf-Conen & Jacobs, 2002; Serour & Somekh, 2003; Smolinski & Yan, 2005; Torrelo, 2002). Many of these surgical techniques are not preferred because, although they may remove the lesion, the resulting scar often becomes a more difficult problem than the wart itself (Tradition or Science 25–4).

Children and families need education about the cause and recurrence of warts. Parents need to know that warts can disappear spontaneously but, even when treated, can be unpredictable. Teach that the spread of warts to other body parts is possible and that repeated irritation of the wart usually causes enlargement. Also educate adolescents about the transmission of genital warts and the cancer risk associated with condylomata. Genital warts can be cosmetically disfiguring, and the affected adolescent has the responsibility of protecting his or her sexual partner from infection.

TRADITION OR SCIENCE 25–4

Can duct tape be used to eliminate warts?

EVIDENCE-BASED PRACTICE

Occluding warts with duct tape or waterproof medical tape, either alone or in combination with a topical agent, has been shown in some studies to be effective as a standard treatment for warts. However, the mechanism for its utility is unclear. Implementation involves leaving the tape in place for several days at a time, then simply changing the tape, for 1 to 2 months. One study demonstrated complete resolution of warts in 85% of adult patients treated with duct tape for 2 months compared with 60% of those treated with cryotherapy (Focht, Spicer, & Fairchok, 2002; Smolinski & Yan, 2005). Duct tape has been shown to be more cost-effective than cryotherapy (Keogh-Brown et al., 2007). Children have not been used in duct tape studies and thus it is unclear whether children would consistently follow the treatment plan. More vigorous trials are warranted utilizing a pediatric population, and larger samples.

Hand, Foot, and Mouth Disease

Hand, foot, and mouth disease is a highly contagious viral syndrome seen most frequently in children during the summer and fall months. It is transferred from person to person by the fecal–oral route and possibly by the oral–oral route. Children younger than age 5 years are most commonly affected. The incidence among close contacts in the same household is also higher. Hand, foot, and mouth disease is usually caused by the coxsackievirus A16. However, several other serotypes of enteroviruses such as A5, A7, A9, A10, B2, B5, and enterovirus 71 have been linked to outbreaks of the disease (Frydenberg & Starr, 2003; Pride, 2001).

Pathophysiology

The spread of hand, foot, and mouth disease is from child to child through the fecal–oral route or possibly the oral–oral route. The virus implants on the mucosa of the throat and ileum, followed by spread of the virus to the lymph nodes within 24 hours. By day 3, lesions on the oral mucosa appear, followed by extension of the disease to other secondary infection sites. Antibodies appear by day 7, with few newer lesions erupting at this time. The incubation period is from 3 to 6 days. Most cases completely resolve within 10 days.

Prognosis

Hand, foot, and mouth disease generally causes only mild difficulties for the child and is self-limiting. However, central nervous system involvement (paralysis, encephalitis,

and meningitis) has been noted to occur as a result of the disease. The condition may be dangerous to the newborn and has been associated with spontaneous abortions. The lesions of the coxsackievirus A16 may be chronic, reappearing at later dates.

Assessment

Hand, foot, and mouth disease is generally a mild, self-limited disease that manifests with mild, nonspecific symptoms such as low-grade fever, malaise, anorexia, and sore mouth, as well as symptoms of a cold. Mild abdominal pain and mild diarrhea may also be present.

Oral lesions are 3 to 6 mm in diameter, irregularly distributed on the buccal mucosa, tongue, gums, palate, and pharynx. Eruptions of lesions on other body surface areas generally occur within 48 hours after the appearance of the oral lesions. Painless, maculopapular eruptions, which may progress to vesicles 3 to 7 mm in diameter, are most frequently seen on the palms, soles, fingers, and toes. Lesions on the buttocks, extremities, and face are more likely to be evident in young children.

Diagnosis is made based on the clinical presentation and distribution of the lesions. The virus can be cultured from the cutaneous vesicles or the oral lesions.

Interdisciplinary Interventions

Symptomatic treatment is all that is usually required. Young children may need to be monitored for dehydration and fluid and electrolyte imbalance if the lesions interfere with their ability to eat and drink. A soft, nonirritating diet for a few days, and plenty of cool, clear fluids help prevent dehydration and food refusal. After meals, the child should rinse the mouth with warm water to prevent secondary infection of the oral lesions. Fever and discomfort can be managed with acetaminophen. Liquid Benadryl may be prescribed for the secondary lesion sites on the body if the child is particularly uncomfortable.

Community Care

Because hand, foot, and mouth disease is highly contagious, evaluate other family members who have had close contact with the affected child for signs of the condition. Spread of the disease is extremely difficult to prevent; therefore, infected but afebrile children may return to their daycare or school after their fever has subsided. If the child becomes confused or delirious, has a fever that persists for more than 3 days, refuses to eat, and shows signs of dehydration, then the child should be seen immediately by a healthcare provider.

Prevention is possible by teaching families, daycare providers, and teachers to use good hygiene practices. In child care settings in which caregivers are changing diapers, gloves should be worn during the diaper change, and hands should be washed with antibacterial soap after disposal of the diaper. Children should be taught to wash their hands with antibacterial soap before ingesting

any food. For children with pacifiers or who are bottle-feeding, nipples that drop to the ground or are touched by other children should be cleansed thoroughly before being used again by the child.

FUNGAL SKIN DISORDERS

Infections caused by fungi are common throughout the world, especially in areas where general hygiene measures are poor. Nearly everyone is colonized with some form of fungi. Fungal infections account for a large portion of pediatric outpatient visits. During childhood, infections of the scalp, hair, and body surfaces are common; fungal infections of the hands, feet, and nails are rare before adolescence.

Alert! Fungal skin infections can be life threatening when the child is nutritionally depleted or is immunocompromised.

Dermatophytoses (Tinea)

Formally called *dermatophytoses*, fungal skin infections are caused by the filamentous dermatophytes belonging to the classes Trichophyton, Microsporum, and Epidermophyton. These infections are commonly called either *ringworm* or, by their Latin term, *tinea*. Dermatophytoses, or tinea infections, are seen in several forms, depending on their body location (Nursing Interventions 25–4) (Arndt & Hsu, 2006; Roberts & Friedlander, 2005; Theos, 2007). At least 40 dermatophyte species exist, but in the United States, most human infection is caused by a relatively small number of species (Theos, 2007).

Pathophysiology

Dermatophytes infect the keratin—that is, the stratum corneum layer of the skin, hair, or nails. Because keratin is shed constantly, fungi must multiply rapidly to keep pace with keratin production. As a result, tinea infections spread rapidly. These superficial fungi form an enzyme that enables them to digest keratin, causing scaling skin, crumbling nails, and breaking hairs. Inflammation associated with tinea infections is the result of an allergic response to fungal antigens that diffuse through the keratin to underlying living skin cells (Erbagci, 2004).

Tinea infections are usually transmitted from one infected person to another. This organism is acquired from three sources: organisms that live in the soil, animal fungi, or, most common, pathogens that will infect only humans and cannot survive elsewhere. Tinea infections can also be transmitted by asymptomatic carriers (e.g., school children) who harbor the organism but lack clinical symptoms (Roberts & Friedlander, 2005). Poor nutrition and hygiene; a tropical climate; debilitating diseases; atopy; and contact with infected animals, persons, or fomites all increase the likelihood of fungal infection.

caREminder

Dermatophytes do not depend solely on humans for growth. Transmission can also occur from infected pets and practically any items that touch the scalp, such as combs, towels, hats, and pillows.

Prognosis

Prognosis for tinea infections is excellent, because current medical therapy usually eradicates the problem. Some forms, however, are resistant to therapy (tinea unguium). Underlying immune suppression can make treatment more difficult.

Assessment

The first sign of tinea in a child is scaling and hair loss on the scalp. Because treatment for any of the misdiagnoses differs substantially from that for tinea, patients may be treated incorrectly at first. Tinea lesions of the skin, nails, and hair are circular or annular (hence the name *ringworm*), with an active border that exhibits erythema and scaling. Nursing Interventions 25–4 summarizes the characteristics and healthcare interventions for the more common forms of tinea.

Diagnosis of a tinea infection can be confirmed by potassium hydroxide preparation treatment of lesion scrapings and then completing microscopic examination to confirm the presence of fungi. In some cases, cultures of the lesions or a skin biopsy may be necessary to confirm the diagnosis. Examination of infected areas under Wood's light was formerly routine in the diagnosis of tinea capitis; however, because the epidemiology is changing such that nonfluorescent *tinea tonsurans* is now the most common cause in the United States, Wood's light is helpful only under some circumstances (Arndt & Hsu, 2006).

Community Care

Nursing care focuses on educating children and their families on how to follow the prescribed healthcare plan. The lesion sites should be cleansed thoroughly with water before applying any medications. Oral antifungal medications must be taken appropriately, and any side effects must be reported to the healthcare provider. Griseofulvin, long considered the gold standard for the treatment of tinea corporis and tinea capitis, is best absorbed when taken with a fatty meal or glass of milk. Because of an increasing resistance and decreased cure rate, this drug is now being prescribed at increasingly higher doses (Roberts & Friedlander, 2005). To prevent recurrence, teach child and family that all medications must be taken for the entire prescribed period, even if the lesions have faded. Other medications include itraconazole (Sporanox), fluconazole (Diflucan), and terbinafine (Lamisil). These three oral antifungals may be ordered for children in whom griseofulvin treatment has failed or who have developed adverse reactions to this medication (Erbagci, 2004; Roberts & Friedlander, 2005; Theos, 2007).

School nurses assist in periodic screening of sports participants for tinea corporis to decrease the incidence of spread of the condition. Students participating in athletics should be encouraged to change their socks and shoes immediately after a sports activity, and to expose their feet to warm, dry air by wearing sandals or thongs.

Children with tinea infections should refrain from applying oils or petroleum jelly to their skin or scalp because these agents act as an occlusive medium and can promote more fungal growth. All affected children should be advised not to share personal articles to prevent transfer of the fungi (Clinical Judgment 25–3).

Candidiasis

Caused by the yeast *Candida albicans*, candidiasis (candidosis or moniliasis) is an infection that occurs in the mouth, eyes, and anywhere on the skin. When the yeast is present in the oral cavity, it is commonly called *thrush*. *Candida* is a normal flora, of which 20 species exist, but overgrowth can occur on the skin and mucous membranes. Most susceptible are newborns infected during the birthing process, chronically ill children, those receiving antibiotic therapy, and immunocompromised children.

Children with an immunologic deficit are at risk for development of chronic mucocutaneous candidiasis, a progressive infection characterized by large polycystic plaques, resembling ringworm or psoriasis, but with thick hyperkeratotic crusts. A defective cell-mediated immunity is a feature of this syndrome. After immunity is restored to normal, the cutaneous lesions resolve.

Pathophysiology

Congenital candidiasis is acquired in utero, affecting 1% of newborns. The infection is present at birth, characterized by pustular and vesiculopustular lesions that progress to a drying exfoliative stage. The lesions often clear within a few weeks. Lesions can be found anywhere, including the nails, oral mucosa (thrush), palms, and soles.

Neonatal candidiasis is acquired by the child during the birthing process by delivery through an infected birth canal. The mother usually has a history of a past or present vaginal yeast infection. Fungal infections are common during the newborn period, especially among premature neonates, and are responsible for considerable morbidity and mortality (Frattarelli et al., 2004; Pappas et al., 2003; Smolinski et al., 2005). A classic sign of the condition is the presence of a beefy, red, glazed, weeping dermatitis in the genital area. The lesions are well demarcated with raised borders and have slight scaling. Erythematous papules or vesiculopustular satellite lesions surround the periphery of the primary rash.

In infants and young children, candidal infections can develop as either an acute or chronic skin infection, and may be either generalized or localized. In young children, candidal infection of the diaper area often transfers to other areas of the body, most commonly the oral mucosa (thrush). In the oral cavity, the lesions appear as white plaques that adhere to the oral surfaces tightly and that bleed when scraped. The outer lips appear chapped and cracked.

NURSING INTERVENTIONS 25–4

Management of Tinea Infections

Name	Appearance of Lesions	Common Location	Nursing Considerations
Tinea capitis	<p>Round patches of hair loss that increase in size</p> <p>Broken hair shafts at surface, leaving a black-dot, stubbled appearance</p> <p>Scaling of scalp</p> <p>Mild itching</p> <p>Usually affects children ages 2 to 10 years, with males more often affected than females</p>	Hair and scalp	<p>Administer oral antifungal medication (Griseofulvin) for 6 to 8 weeks.</p> <p>Use antifungal cream twice a week for 8 weeks; use antifungal shampoos.</p> <p>There is no need to shave or cut hair to prevent spread; hair regrowth is slow.</p> <p>Lesions are mildly contagious. The child can return to school after medications and antifungal shampoos have been started.</p> <p>Affected children should not share combs, brushes, or head wear.</p>
Tinea corporis	<p>Round, pruritic, expanding red lesions with well-circumscribed borders and central clearing</p> <p>Scaling on lesion borders</p> <p>Single or multiple lesions</p> <p>Annular lesions</p> <p>Uncommon after puberty</p>	Entire body, especially face and extremities	<p>Apply topical antifungal cream twice daily for 2 to 4 weeks, continuing for several days after clinical cleaning.</p> <p>Continue application of cream for 2 weeks after the lesions have disappeared.</p> <p>Lesions are mildly contagious. The child can return to school after treatment with topical medication has been started.</p> <p>To control spread, direct contact with infected children and animals should be avoided.</p>
Tinea faciei	Erythematous, scaly lesions that commonly have a “butterfly” distribution	Face	Apply topical antifungal cream twice daily for 2 to 4 weeks, continuing for several days after clinical cleaning.
Tinea cruris (jock itch)	<p>Erythematous, scaly eruption</p> <p>Not usually seen before adolescence</p> <p>Often seen in athletes</p>	Inner thighs and inguinal creases	<p>Apply topical antifungal cream twice daily for 2 to 4 weeks.</p> <p>Keep area dry.</p> <p>Wear loose fitting cotton shorts.</p> <p>Cleanse area daily with water and carefully dry.</p>

Name	Appearance of Lesions	Common Location	Nursing Considerations
Tinea pedis (athlete's foot)	<p>Vesicles and erosions on the instep of one or both feet</p> <p>Fissuring between the toes, with scaling and erythema</p> <p>Itchy and burning rash</p> <p>Unpleasant foot odor</p> <p>Most forms found exclusively in the postpubertal adolescent</p>	Feet	<p>Lesions are mildly contagious and will not affect dry, normal skin.</p> <p>For acute episodes use open wet compresses (Burow's solution, 1:80).</p> <p>Apply topical antifungal cream twice daily for 2 to 4 weeks to clean feet.</p> <p>Keep feet dry by wearing sandals, thongs, or no shoes.</p> <p>Wear cotton socks only and change them twice daily.</p> <p>Thoroughly dry feet after bath or shower.</p>
Tinea versicolor	<p>Multiple annular to oval macules or patches with a fine scale</p> <p>On well-tanned or darkly pigmented children, lesions are hypopigmented</p>	Neck, upper back, shoulders, upper arms	<p>Lesions are not contagious.</p> <p>Wash affected areas with prescribed medicated shampoo of 1% selenium sulfide or 212% selenium blue over-the-counter shampoo (Selsun Blue) daily for 2 to 3 weeks.</p> <p>Apply topical imidazole antifungal agent twice daily for a week then tapering may be ordered.</p> <p>Not contagious.</p> <p>Recurrence is likely. For chronic recurrence involvement, systemic antifungals may be indicated.</p> <p>Monthly treatment with the shampoo can prevent recurrence.</p> <p>Normal skin color does not return for 6 to 12 months.</p>
Tinea unguium (onychomycosis)	<p>Distal thickening and yellowing of the nail plate caused by separation of nail plate from bed and entrapment of air between the two structures</p> <p>Usually found in adolescents</p>	Fingernails, toenails	<p>Topical agents have not proved effective as a cure.</p> <p>Oral antifungal agents may be used.</p>

CLINICAL JUDGMENT 25–3

The Adolescent With Tinea Cruris

Mrs. Law brings her 16-year-old son Kevin to the clinic because he is complaining that he has a pink rash on his inner thigh and groin areas. Kevin is embarrassed about being at the clinic for this problem. When his mother leaves the room during the examination, he asks you whether he got the rash from going skinny dipping in a neighbor's lake with some of his buddies.

Questions

1. As you complete a physical examination, what characteristics of the lesions would indicate that Kevin has tinea cruris (jock itch)?
2. Is Kevin's age a significant factor in confirming this condition?
3. Is the fact that Kevin was skinny dipping significant to the history of this skin condition?
4. What interventions should Kevin take to clear up the rash?
5. Kevin asks, "What do I do if this stuff doesn't go away?" What is your response?

Answers

1. The lesions should be symmetric, scaly with raised borders, erythematous, and slightly brown or pink. The penis and scrotum should have no lesions on them.
2. Tinea cruris is most common during adolescence.
3. No. Tinea cruris is most associated with hot, humid weather and wearing tight clothing. It is not associated with being in the water.
4. Keep the groin area dry. Wear loose-fitting cotton shorts. Wash clothes, towels, and athletic supporter daily. Using plain water, wash then carefully dry the rash site daily. Apply topical antifungal cream to the site as ordered.
5. If the rash does not begin to improve within 1 week or if it is not completely cured within 1 month, return to the clinic to be reevaluated. To prevent a reinfection, be sure to use the topical ointment for 1 to 2 weeks after the rash has vanished.

The breast-feeding infant can transfer this infection to the mother's nipples if good hygiene is not promoted.

Candidiasis is often an opportunistic infection made possible by the weakened defense system of the child who is immunocompromised. Other contributing factors include trauma, malnutrition, and administration of broad-spectrum antibiotics. Eruption of the lesions has also been associated with excess perspiration or metabolic dysfunction. Local predisposing factors are moisture, macerated folds of skin, and warmth. Diapers make children particularly vulnerable to this infection. The prognosis is excellent, given the efficacy of antifungal agents. Systemic involvement must be considered if any of the following conditions are present: immunodeficient states (HIV or cancer), prematurity with low birth weight, pneumonia or sepsis, or previous treatment with a broad-spectrum antibiotic.

Assessment

Candidiasis presents as a deep, livid, red area of macerated skin with small satellite papules and pustules along the margin. Warm, moist body folds such as the axilla or the genital areas are the most common site of the rash (Fig. 25–12). Diagnosis of candidiasis is confirmed by potassium hydroxide slide examination showing budding yeasts and pseudo-hyphae. A positive fungus culture demonstrates white mucoid growth within 48 to 72 hours.

Older children with candidiasis may complain of discomfort and itching. Infants and young children may display fretful behavior and may have trouble sleeping.

Interdisciplinary Interventions

Management involves three primary interventions: (1) removal of any predisposing cause, (2) application of topical or oral antifungal agents, and (3) keeping the affected area dry. Commonly used medications include topical anticandidal agents such as nystatin, miconazole, clotrimazole, and ketoconazole. Improvement should be noted within 3 to 5 days. Application of a low-potency corticosteroid cream, followed by a preventive petroleum, zinc oxide, or dimethicone water-repellent ointment to pre-

FIGURE 25–12. An infant with candidiasis.

vent the causative agent from continually reinfecting the area, may be required if inflammation is severe.

Oral infections are commonly treated with nystatin oral solution for 1 to 2 weeks. The solutions should be swabbed onto the mucous membranes using a cotton-tipped applicator (TIP 25–5). Older children may be treated with oral antifungals such as clotrimazole troches, itraconazole, or fluconazole. Systemic infections are treated with medications such as intravenous amphotericin B, itraconazole, fluconazole, and a new class of antifungals that includes caspofungin and Micafungin (Frattarelli et al., 2004; Smolinski et al., 2005; Wertz & Pretzlaff, 2004).

Keep the affected area dry. The nurse and parents can assist the healing process with frequent diaper changes or by leaving the child's diaper off at times, thereby exposing candidal lesions of the groin area to the air, which helps them to dry. If topical antifungal agents are ordered, they should be applied after each washing or each diaper change, and then covered with a protective cream as indicated earlier. Teach parents to recognize a candidal

infection, especially if the child is receiving antibiotic therapy or is immunocompromised.

REACTIONS TO ENVIRONMENTAL FORCES AND SUBSTANCES

Environmental forces and substances pose different risks and hazards for children than for adults. Pressure ulcers, formerly called *decubiti ulcers*, are a common reaction to environmental forces among long-term immobile patients. Poison ivy, oak, and sumac are plants that can cause cutaneous reactions ranging from mild to severe. Ambulatory and active children often come in contact with these environmental substances. In addition, reactions to medication can cause substantial alterations in skin integrity.

Pressure Ulcers

Pressure areas are localized areas of tissue destruction that occur when the tissue is compressed between a bony

TIP 25–5 A Teaching Intervention Plan for the Child With Oral Thrush at Home

Nursing diagnoses and outcomes

Impaired oral mucous membrane related to presence of candidiasis lesions

Outcomes:

- Child's oral mucosa remains intact with no further breakdown.
- Child will experience effective swallowing.

Risk for infection related to transfer of candidiasis from child to others during close personal contact with family and peers

Outcomes:

- Child remains free from systemic infection.
- Family uses hygienic practices to prevent spread of infection.

Teach Child/Family

Medication Administration

- The prescribed solution is applied to the oral mucous membranes.
- A calibrated measuring device should be used to measure the amount of oral solution to be applied. One half of the dose is placed in each side of the mouth.
- A cotton-tipped applicator can be used to apply the solution to the oral mucosa of the young infant.
- Older children should be instructed to hold the suspension in their mouth or swish it throughout their mouth for several minutes.
- The solution is applied after feeding and cleaning of the mouth.

- The child should not drink immediately after application of the solution.
- The infant may swallow some of the solution. This is expected and does not harm the infant.
- If a dose is missed, the medication should be taken as soon as it is remembered, but not if it is almost time for the next dose. Doses should never be doubled.

Medication Storage

- Oral solutions must be kept refrigerated.
- The solutions should be kept away from small children to prevent accidental ingestion.

Preventive Measures

- If the infant is bottle-fed, all nipples and pacifiers should be sterilized after each use.
- If breast-feeding, the mother should apply the solution or antifungal cream, as ordered, to her nipples to eliminate reinfection.
- The child's toothbrush should be cleansed thoroughly in hot water after each use.
- The infected child should not share drinking cups or eating utensils with others.

Contact the Healthcare Provider if:

- Irritation of the mucous membrane increases
- Child refuses to eat or drink
- Child shows signs of dehydration (poor urine output, lethargy, sunken eyes, sunken fontanel, poor skin turgor)
- Child shows other signs of illness (e.g., lethargy, fever, cold symptoms)

prominence and an external surface for an extended period. Pressure ulcers occur in children and adolescents whose mobility, activity, or sensory perception is severely restricted because of prolonged immobilization or conditions that may impede movement (e.g., a child with myelomeningocele).

Pathophysiology

A pressure ulcer arises secondary to tissue hypoxia caused by the prolonged pressure over a certain area. A critical relationship exists between time and pressure; a lower pressure over a longer time can generate an area of skin breakdown as easily as an area of high pressure for a short time. Preterm infants and children who are immobilized are two groups at high risk for pressure ulcers.

The high-risk areas for ulcer formation are the bony prominences all over the body, such as the sacrum, heel, and elbow, because subcutaneous fat and superficial fascia are thinner and greater pressures are generated. Pressure ulcer locations differ in children according to age. In infants, the occiput is the most likely spot; in older children, sacral pressure is greatest. Other factors, including shear, friction, and nutritional deficiencies, all contribute to pressure ulcer formation; however, pressure is the primary causative factor. Severity of the ulcer usually depends on the intensity and duration of the pressure and the tolerance of the affected tissue. Shear, the interplay between gravity and friction, results when gravity pushes down on the body while resistance (friction) occurs between the patient and a surface. Friction alone can cause minor or severe skin damage. Over time, however, friction and gravity may work synergistically to cause shear. Malnutrition, especially protein deficiency, should also be considered when assessing and managing pressure ulcers.

Assessment

The primary focus of the nursing assessment is to prevent alterations in skin integrity. Quigley and Curley (1996) developed a skin care algorithm to establish daily practices for assessment and prevention (see [thePoint](#), Evidence-Based Practice Guidelines). This tool identifies intrinsic and extrinsic factors such as immobility, incontinence, and health conditions that can precipitate a skin alteration. Upon recognition of altered integrity, immediate action should be taken to protect the skin.

If an ulcer has developed, the lesion must be continuously assessed for color, exudate, odor, and dimensions. Pressure ulcers are organized into stages based on their severity (Agency for Health Care Policy and Research, 1992; National Pressure Ulcer Panel Advisory Board, 1989):

- *Stage I:* Pressure ulcer is an observable pressure-related alteration of intact skin with indicators, compared with an adjacent or opposite area on the body, that may include changes in one or more of the following: skin temperature (warmth or coolness), tissue consistency (firm or boggy feel), and sensation (pain, itching). The ulcer appears as a defined area of persistent redness in lightly pigmented skin, whereas in darker skin tones, the ulcer may appear with persistent red, blue, or purple hues.

- *Stage II:* Partial-thickness skin loss involving epidermis or dermis. The ulcer is superficial and presents clinically as an abrasion, a blister, or a shallow crater.
- *Stage III:* Full-thickness skin loss involving damage to, or necrosis of, subcutaneous tissue that may extend down to, but not through, underlying fascia. The ulcer presents clinically as a deep crater with or without undermining of adjacent tissue.
- *Stage IV:* Full-thickness skin loss with extensive destruction, tissue necrosis, or damage to muscle, bone, or supporting structures (e.g., tendon or joint capsule). Undermining and sinus tracts may also be associated with stage IV pressure ulcers.

Assessment factors include location of the wound, staging (I–IV), size in centimeters (length, width, and depth), type of tissue at the wound base, presence of exudate or odor, presence and location of undermining or tracts, character of wound margins, condition of periwound skin, and dressing type.

Be cognizant of the child's nutritional status and relay all abnormal laboratory indices (especially decreased levels of albumin, low total protein, and altered serum electrolytes) to the physician.

Interdisciplinary Interventions

Recognizing the factors that predispose a child to pressure ulcer formation and providing pressure relief to children at risk is crucial.

The best nursing care related to pressure ulcers is to prevent their occurrence. Hospitalized or immobilized children are prone to their development because of the small amount of subcutaneous tissue and because these children are often debilitated by multisystem problems.

To standardize prevention and management, practice guidelines for treating pressure ulcers have been developed by the Wound, Ostomy, and Continence Nurses Society (2003) and the National Pressure Ulcer Advisory Board (Baharestani & Ratliff, 2007). Nursing Interventions 25–5 summarizes many of the research-based pressure ulcer guidelines for neonates and children. For more in-depth information, see [thePoint](#), Evidence-Based Practice Guidelines.

Poison Ivy, Oak, and Sumac

QUESTION: Would Nick also react to poison oak and poison sumac?

The significance and need to assess environmental risks during childhood has already been discussed. An important reason children's exposures are different from those of adults is their level of behavioral development. Most children actively explore their environments, as well as exhibit frequent hand-to-mouth and object-to-mouth behaviors. This may bring them into contact with poison ivy, poison oak, and poison sumac, which are three potent antigens that characteristically produce an intense dermatologic

NURSING INTERVENTIONS 25–5

Prevention and Management of Pressure Ulcers in Neonates and Children

Assessments

- On admission, perform a comprehensive skin assessment and risk assessment for pressure ulcers on all neonates and children.
- Perform a head-to-toe skin assessment daily.
- Perform comprehensive nutritional assessment.
- Assess for pain.

Pressure Redistribution

- Evaluate skin under blood pressure cuffs, nasal prongs, arm boards, plaster casts, traction boots, nasogastric tubes, and so forth.
- As child grows, adjust orthotics, wheelchairs, and wheelchair cushions to changes in child's size.
- Ensure tubing, leads, toys, and syringe caps are not under or on top of child's skin when child is in bed, crib, or isolette.
- Tape invasive tubes without tension to the skin.
- Use age-appropriate low-air loss beds or overlays.
- In neonates younger than 32 weeks, use water, air, and gel mattresses; and sheepskin and gel pads at the joints, behind the ears, and behind the occiput.
- Reposition the neonate every 4 hours and the older child every 2 hours.
- Use convoluted foam and gel pillows to reduce occipital and sacral pressure.
- Use draw sheet for lifting to minimize sheering.

Topical Treatments

- Select only those products that have been recommended for use in the neonate and pediatric population.

Wound Cleansing

- Use sterile water and normal saline for wound cleansing, with sterile water preferred for neonates.
- Warm cleansing solution to body temperature for use in neonates.
- Use a 20-mL syringe with a blunt needle or a polytetrafluoroethylene catheter to flush wound exudate.

- Avoid use of antiseptics because of potential for tissue damage and absorption.

Debridement

- Fine mesh gauze with saline dampening can be used on the ulcer in a “wet-to-damp” method. When removed, the dressing removes necrotic tissue.
- Use whirlpool therapy to debride.

Managing Bacterial Colonization and Infection

- If extensive colonization is suspected, use antibiotic ointments.
- If infection is suspected, obtain cultures and Gram stains.
- Avoid use of silver sulfadiazine cream in neonates because of its potential for toxicity.

Dressings

- Use hydrogels, hydrocolloids, and film dressings for noninfected ulcers.
- Avoid products not recommended for neonate or pediatric populations.
- Use pectin-based skin barriers or hydrocolloid adhesive barriers where adhesive tape will be repeatedly removed and reapplied.
- For neonates, use cotton balls soaked with warm water to assist in the removal of adhesives.
- Avoid use of solvent adhesive removers and bonding agents in this population.
- Avoid products containing dyes, perfumes, and preservatives.

Pain Management

- If necessary, premedicate the child with pain relievers prior to management of the ulcer site.
- Use pain relief measures as needed.

From Baharestani & Ratliff (2007); Butler (2006); and Noonan, Quigley, & Curley (2006).

inflammatory reaction upon contact with the skin. The source of the allergen is *urushiol*, a saplike oil, present on live or dead leaves. Sensitization to one plant produces cross-reactions with other plants containing urushiol.

The skin eruption is a form of contact dermatitis known as *rhus dermatitis*. One or 2 days after the encounter, the affected skin displays erythema, edema, and erythematous popular lesions in a streak or patchlike shape, representing the path in which the plant brushed across

the skin. The lesions are itchy. Within 2 to 3 days, vesicular lesions develop and quickly rupture, leaking fluid that forms a crust over the lesion site. Fluid from the ruptured vesicles is not antigenic and does not spread the eruption. However, the rash can spread more during the first 2 weeks as a result of the allergenic response of the host. In addition, antigen retained under fingernails and on clothing initiates new eruptions if not removed by washing with soap and water. The offending antigen may

also be carried on animal fur that comes into contact with the plants. The sap left on fur, clothing, and objects is contagious if not cleansed properly. Urushiol can remain potent for years, especially in dry environments, and becomes airborne when plants are cut with mowers. Lesions from the plant exposure usually resolve within 3 to 4 weeks. Complications from poison ivy, oak, and

sumac exposure are low, although secondary skin infections can occur and hyperpigmentation and/or lichenification of skin lesions may occur in darkly pigmented children.

Learning to recognize the plants and to avoid contact with them is an important aspect of education for families. Community Care 25–2 describes the plants and summarizes the care that should be initiated if the child or

COMMUNITY CARE 25–2

Protecting Children Against Poison Ivy, Poison Oak, and Poison Sumac

Recognize the Plant

Poison Ivy

Small plant, vine, or low shrub with shiny green leaflets that grow in groups of three. The leaf stems have waxy, yellow-green flowers and, later, greenish berries. In the autumn months, the leaves turn red. Poison ivy grows all over the United States, except California and parts of adjacent states.

Poison Oak

Shrubs or vines with oak-shaped leaves that have a hairy, light-green underside and darker green surface. The leaves grow in groups of three. Some shrubs or vines have clusters of greenish or creamy white berries. The plant grows on the west coast of the United States and from Mexico to Colombia.

Poison Sumac

Colorful woody shrubs that grow from 5 to 25 ft tall, most commonly found in the eastern United States in swampy areas. A branch of the shrub contains 7 to 13 long, smooth, paired leaves, topped with a single velvety leaf. The plant is bright orange in the spring months, and then turns to a glossy dark green with a pale underside, and then to a reddish orange color in the fall. Poison sumac has drooping clusters of green berries. The nonpoisonous variety has upright red berries.

Protect the Child From Exposure

- Children should wear long pants and enclosed shoes with socks when walking in the woods or swampy areas.
- Rubber gloves and rubber boots are not considered protective because the catechols in urushiol are soluble in rubber.
- Apply Ivy Rest to the skin prior to the child's outing.
- Oil residue on clothes, pets, toys, and garden and sports equipment should be removed with liberal soap-and-water washing.

If the Child Is Exposed

- Immediately wash and rewash the affected area with yellow or brown laundry soap, or nonperfumed bath

soap and cold water. Do not use a brush on the skin, to avoid scratching the skin surface.

- Wash and rewash any clothes that came into contact with the plants.
- Wash any pets that came into contact with the plants. Wear gloves and do not touch the animal's fur with bare hands. Dispose of the gloves afterward.

To Help With Itching and Treatment of the Lesions

- Keep lesions clean by daily washing with mild soap and water.
- Do not use occlusive dressings. Allow vesicles to be open to drain.
- Apply tap water or Burow's or Domeboro solution with a dressing to blistered or oozing lesions for 20 minutes, twice a day.
- Apply over-the-counter preparations to reduce itching and dry lesions (e.g., calamine lotion, Ivy Rest).
- Place the child in tepid baths with colloidal oatmeal (Aveeno). Hot water baths or showers will increase pruritus.
- Apply topical steroid creams as ordered by the healthcare provider.
- Administer antihistamines as ordered by the healthcare prescriber. Medications are usually given three to four times a day unless sedation interferes with the child's school work and other activities.
- Administer glucocorticosteroids if ordered by the healthcare provider.
- Administer antibiotics if ordered by the healthcare provider to treat secondary bacterial infections.

Call Healthcare Provider if:

- Face, eyes, or lips become involved
- Signs of infection appear, such as redness, oozing, or pus at lesion sites
- Rash begins to blister
- Itching interferes with child's sleep

other family member comes into contact with urushiol. The only preventative product approved thus far by the Food and Drug Administration to protect the skin from potential exposure is Ivy Block, a 5% quaternium-18 bentonite lotion that leaves a visible film on the skin. The lotion interferes with absorption of urushiol by physically blocking contact of the oil with the skin. Washing thoroughly with soap and water immediately after skin contact is also essential, because if even 10 minutes have elapsed with the oil on the skin, only 50% will be removed.

ANSWER: Because Nick has been sensitized to poison ivy, he will most likely also react to poison oak and poison sumac, even if it is his first exposure.

Adverse Drug Reactions (ADRs)

Adverse drug reactions (ADRs) are undesired effects arising from the appropriate use of medications. The actual incidence of ADRs is not known. The sudden eruption of skin lesions is the most common clinical feature of an ADR (Fig. 25–13).

Several factors have been associated with a high risk for ADRs in children. These include age younger than 12 months; the presence of serious, concomitant disease; the use of multiple drugs; and an increase in dose (Developmental Considerations 25–4). In many cases, ADRs are preventable by more carefully monitoring the administration of harmful drug–drug combinations and drug–food combinations.

Pathophysiology

Mechanisms that cause ADRs include dose-related reactions, drug interaction reactions, idiosyncratic reactions, and allergic or immune-mediated reactions. *Dose-related reactions* are those experienced by a child because the dose ingested was either below or above the therapeutic level desired. A child may also have a dose-related toxic effect of a drug that is being given at a therapeutic level (e.g., hair loss with Accutane therapy). *Drug interaction reactions* are those caused by drug combinations that produce toxicity or lethal side effects. For instance, morphine and diazepam used together place a child at higher risk for apnea than if the drugs were used alone. *Idiosyncratic reactions* are attributed to an unusual characteristic specific to a certain child that causes him or her to have an adverse response to a certain medication. Allergic or immune-

FIGURE 25–13. (A–C) Adverse drug reactions can manifest in various skin eruptions. For example, a systemic eruption of itchy wheals (A) or measles-like lesions (B) might occur, or a fixed eruption might occur as a single oval lesion at the identical site where it had occurred previously (C).

DEVELOPMENTAL CONSIDERATIONS 25–4

Why Children Are at Greater Risk for Adverse Drug Reactions

- The child's neurologic system is responsive and susceptible to impairment, because it is still developing after birth (e.g., first-generation antihistamines are sedating in adults but are associated with paradoxical excitation in some children).
- Drugs given to mothers during pregnancy, delivery, and lactation can lead to adverse reactions for the child as a result of their teratogenic, pharmacologic, and toxic processes.
- Topical absorption of medications is enhanced in neonates and young children because of the increased permeability of their skin.
- The sick neonate and children with chronic conditions (e.g., cancer, asthma) are exposed to a large number of medications, thereby increasing their risk of an ADR.
- Symptoms of an adverse reaction may go undetected because the child's condition masks the side effects or are similar to those of an ADR.
- Premature infants and full-term neonates have a lesser capacity for renal elimination of drugs because of decreased glomerular filtration and tubular secretion.
- Many liquid medications for children contain excipients designed to improve the stability and tested acceptability of the medication. These additives can cause adverse side effects.

mediated reactions are created by immunologic mechanisms that produce a wide variety of systemic responses to the drug.

Assessment

Skin eruptions caused by a drug reaction are diverse in nature, and it may be difficult to identify the exact cause. For example, in the seriously ill child, the appearance of an unusual rash may be an allergic response to a drug or may be the result of a newly acquired viral infection. Ask the child and their parents if the child is receiving any over-the-counter medications. Determine whether the child has had any changes in medications. Has the child had any allergic reactions in the past? Are there any other agents or processes that could be causing the skin lesions?

Morbilliform (measleslike) rashes are the most common type of skin manifestation seen in children in response to an ADR. However, drug reaction rashes can also assume several other forms (Table 25–6). The lesions may be accompanied by itching, malaise, fever, nausea, vomiting, and liver or kidney damage. Severe anaphylactic reactions can lead to respiratory compromise and shock. Anaphylaxis is discussed in more detail in Chapter 31. Any acutely occurring rash should be evaluated for a drug reaction. Common drug offenders include penicillins, cephalosporins, sulfa drugs, phenytoin, barbiturates, diazepam, isoniazid, and carbamazepine.

Interdisciplinary Interventions

The most immediate measure to take when an ADR occurs is to stop using the suspected drug. Treatment is individualized and may vary from simply monitoring the child with no special interventions provided, to treating the severe manifestation of anaphylaxis. If itching and rash formation are severe, oral antihistamines, oral ste-

roids, or both may be ordered. If blistering occurs, the child's fluid and electrolyte, as well as infection status should be monitored.

Review signs of an ADR with the family to assist in the early identification of problems that may reoccur in the future. Medication derivatives from the same family as the agent that caused the adverse reaction should be avoided. Recommend that the child wear a MedicAlert bracelet to notify others that the child has a medication allergy.

GENETIC AND IMMUNE-RELATED DISORDERS WITH DERMATOLOGIC MANIFESTATIONS

Several skin conditions appear linked to genetic susceptibility or to a systemic immunologic response. The conditions discussed in this chapter include urticaria and angioedema, and Stevens-Johnson syndrome (SJS). Two other conditions, neurofibromatosis and dermatomyositis, are rare disorders that may be encountered in the pediatric population (see [thePoint](#), Supplemental Information: Neurofibromatosis and Dermatomyositis). Neurofibromatosis is a common autosomal dominant disorder in which affected children develop benign and malignant tumors. Childhood dermatomyositis is a multisystem inflammatory disease of uncertain origin that affects primarily skin and muscles.

In many cases, the exact mechanisms that trigger the dermatologic clinical features are unknown. The underlying insult that causes skin injury is likely to produce other clinical manifestations that can be severe. The child is cared for by an interdisciplinary team that includes support from dermatology, rheumatology, physical therapy,

TABLE 25-6
Clinical Features of Drug Reactions

Type of Drug Eruptions	Drugs Associated With the Reaction	Clinical Signs	Interdisciplinary Interventions
Morbilliform	Allopurinol Amoxicillin Ampicillin Barbiturates Carbamazepine Cephalosporins Chloramphenicol Erythromycin Gentamicin sulfate Gold Isoniazid Nonsteroidal anti-inflammatory drugs Penicillins Phenytoin Sulfonamides Trimethoprim	Measleslike (morbilliform) or exanthematous lesions that start on the trunk and move to extremities Areas of normal skin may surround areas of eruption. Initial lesions become papular and then form plaques from joining of several individual lesions Fever Malaise Arthralgia	Remove offending drug. Rash may fade with time, requiring no treatment. Give antihistamine therapy.
Urticarial	Acetylsalicylic acid Amoxicillin Ampicillin Cephalosporins Horse serum Penicillins Sulfonamides	Edematous, flat, erythematous papules that last less than 24 hours As lesions resolve, may leave a macular, brown, bruised appearance Angioedema of mucous membranes	Remove offending drug. Give antihistamine therapy. If needed in severe cases, give systemic steroids to maintain airway and diminish swelling associated with angioedema.
Serum-sicknesslike reaction	Cephalosporins Hydantoins Penicillins Sulfonamides Streptomycin Thiouracils	Fever Malaise Large urticarial plaques that resolve, leaving the skin areas with a dusky or bruised appearance Lesions may be accompanied by angioedema Arthralgia Lymphadenopathy Edema Albuminuria	Remove offending drug. Take fever reduction measures. Apply symptomatic treatment using combination of analgesics, glucocorticoids, and antihistamines.
Fixed	Barbiturates Carbamazepine Phenazone derivatives Phenolphthalein Sulfonamides Tetracycline Trimethoprim	Solitary or multiple sharply demarcated erythematous lesions that may look like urticaria or become bullous As lesions fade, skin remains hyperpigmented with residual, sharply demarcated outlines of the lesions	Remove offending drug. Give antihistamine therapy.
Vasculitis	Allopurinol Barbiturates Gold Penicillins Sulfonamides	Soft, small erythematous papules or urticarial papules that blanch when pressure is applied	Remove offending drug. Give antihistamine therapy.

(Continued)

TABLE 25-6

Clinical Features of Drug Reactions (Continued)

Type of Drug Eruptions	Drugs Associated With the Reaction	Clinical Signs	Interdisciplinary Interventions
	Thiazide derivatives	Over several hours to several days, lesions become firm and dark red or purple	
Exfoliative dermatitis (Lyell's syndrome, toxic epidermal necrolysis syndrome)	Allopurinol Barbiturates Hydantoin derivatives Penicillins Phenazone derivatives Sulfonamides Sulindac	Diffuse erythema followed by bullae and loss of large portions of epidermal tissue	Remove offending drug. Give cyclosporine therapy. Give intensive, specialized care similar to that given to a child with severe burns.

Data from Weston, W., Lane, A., & Morelli, J. (2007). *Color textbook of pediatric dermatology*. St. Louis: Mosby.

and nutrition specialists. Treatment is aimed at controlling skin lesions, preventing or reversing other systemic manifestations, and supporting the child and family through long-term therapy if required.

Urticaria and Angioedema

Urticaria, a hypersensitivity reaction commonly called *hives*, is manifested by well-demarcated, raised erythematous lesions that blanch with pressure. The lesions are usually pruritic and involve the superficial layer of the dermis. Urticaria is a symptom that might be triggered by several disease states, as well as medications, foods, animal stings, pollen, infections, heredity, and physical environment (cold). Urticaria and angioedema may occur at any age, although incidence is higher in young adults. Although in many cases the exact causative source may not be known, approximately 15% to 25% of the population has a history of one or more episodes of urticaria, with most of these cases acute and self-limiting, and not extending beyond a 6-week period. Acute or transient urticaria is more common in children and young adults. In some cases, the urticaria extends beyond the 6 weeks and may display periods of exacerbation for years.

When the urticaria extends deep into the dermis (subcutaneous or submucosal layers), it is known as **angioedema**. Angioedema is usually characterized by a tingling, burning sensation in normal-appearing skin with overlying swelling. Although urticaria is relatively common in children, angioedema is much less so.

Pathophysiology

Generally speaking, urticaria is caused by a complex interplay of immunologic-mediated antigen-antibody responses to the release of histamine from mast cells as a

result of the trigger agent or toxin. The histamine release causes vasodilation and edema of the skin and mucous membranes, with vasodilation and increased vascular permeability causing the erythema and characteristic wheal (Arndt & Hsu, 2006). Urticaria may be the result of an immune-mediated reaction (IgE), a complement-mediated reaction, or a nonimmunologic-mediated mechanism (Chart 25-4). In the physical urticarias (those caused by cold, heat, and so on), histamine levels appear normal. The chemical mediator of physical urticarias appears to occur through cholinergic fibers of the autonomic nervous system.

Assessment

Begin evaluation of the child with a thorough family history of hives, angioedema, arthritis, atopy, and itching. Elicit information that specifically identifies when the lesions occur, how long the lesions last, and the events that might precipitate a flare-up. Note any association between some type of food or medication (such as aspirin) and occurrence of the lesions.

Acute urticaria and angioedema are defined by the sudden appearance of lesions or attacks of sensation (tingling). The location of the lesions may assist in determining the cause. The lesions are pruritic with erythematous raised wheals, 2 to 15 mm in diameter, scattered over the body. The center of the lesion is pale in color and has tense edema.

The wheals usually persist for 20 minutes to 3 hours, disappear, and then reappear at another location. An episode generally lasts 24 to 48 hours, although it may extend up to 6 weeks. When lesions appear for longer than 6 weeks, the urticaria is considered to be chronic. The subcutaneous extensions of the lesions, or angioedema, appear as large swellings around the eyelids, lips, face, trunk, genitalia, and extremities.

CHART 25-4 MECHANISMS THAT CAUSE URTICARIA

IgE-Mediated Urticaria

Allergic reactions (drugs, food, insect venom)
Physical urticaria (cold, heat, pressure, vibration, solar exposure, exercise)
Atopic diathesis

Complement-Mediated Urticaria

Collagen vascular diseases
Transfusion-related reactions
Hereditary angioedema
Acquired angioedema
Serum sickness (type III)
Necrotizing vasculitis

Non-IgE-Mediated Urticaria

Direct mast cell-releasing agents (opiates, muscle relaxants, radiocontrast media)
Histamine-releasing agents
Intolerance reactions (aspirin, nonsteroidal anti-inflammatory medications)

The physical urticarias are characterized by large (10–20 mm) blotchy erythematous areas surrounded by small (1–3 mm) central wheals. Heat, exposure to cold, ingestion of hot or spicy foods, a febrile illness, hot baths, and exercise sufficient to raise the body temperature 0.5 °C induce an attack. Delayed-pressure urticaria can initiate angioedema 4 to 6 hours after the pressure, which can last up to 24 hours. This condition is most commonly seen in adolescents who wear backpacks to carry their schoolbooks. If these lesions are fixed longer than 48 hours, it is most likely not urticaria. Angioedema has thick, edematous plaques usually involving the face. These are not associated with pruritus but rather with pain, burning, or both. This edema may last up to 72 hours, with gastrointestinal or laryngeal symptoms present (Arndt & Hsu, 2006).

The physical examination for urticaria involves light stroking of the skin with a blunt object, which may cause an intense wheal and flare reaction known as *dermatographism*. Applying a warm or cold stimulus that causes the appearance of wheals and intense itching can help to diagnose cold- or heat-induced urticaria. An exercise challenge may be used to help elicit exercise-induced urticaria.

Interdisciplinary Interventions

An acute attack of angioedema can be treated with oral antihistamines for 3 to 4 weeks until the antigen is eliminated. Hydroxyzine hydrochloride or diphenhydramine hydrochloride are most commonly used. Severe acute

cases may require the use of subcutaneous or intramuscular epinephrine; in a few cases, systemic corticosteroids may also be needed.

If airway involvement results from angioedema, close monitoring in an acute care facility is indicated until the attack has been resolved. Opioids may be required for relief of abdominal pain, and nasogastric suction may be needed if the child has emesis. H₂-receptor antagonists may be useful in some children in controlling airway or bowel reactions.

Pharmacotherapy may include H₁ antihistamines. A prolonged course (3 months or longer) utilizing second-generation drugs (e.g., cetirizine [Zyrtec], fexofenadine [Allegra], loratadine [Claritin]) may be needed to induce a remission. Failure to induce a remission may require dosage recalculation or change to a different antihistamine. Medication withdrawal must be gradual to prevent a rebound effect. If the urticaria recurs, the medication must be restarted at full strength.

Community Care

Because all triggers cannot be avoided, an anaphylactic emergency kit must be available to the child. Long-term care for the child should include avoidance of certain foods from the diet and avoidance of medications that contain aspirin or related compounds. A daily diet and symptom record can be initiated to help identify precipitating events. If a clear precipitating factor is not found, an elimination diet of lamb, chicken, rice, and water for 2 to 4 weeks may be tried. If the child's symptoms do not improve, the urticaria was probably not caused by a food substance. A dietitian may provide suggestions for how nutritional requirements may be met through the diet phase and whether certain foods should be avoided for a long-term period.

Physical triggers should also be avoided. For example, thermal protection is important for children with cold-induced urticaria, and the generous use of sunscreen is helpful for the child with solar urticaria. The child with exercise-induced symptoms should be encouraged to decrease or stop the activity at the first sign of symptoms. Exercise-induced urticaria has been reported to be more pronounced in individuals who exercise after ingestion of certain foods such as shellfish, celery, peaches, grapes, and wheat. Therefore, some children must avoid exercise for 4 to 6 hours after ingesting a known offending food or medication.

No major complications arise from urticaria that is confined to the skin. Urticaria with respiratory manifestations, or involving vital structures by angioedema, is a more serious condition.

Childhood dermatomyositis is a multisystem inflammatory disease of uncertain origin that affects primarily skin and muscles.

Stevens-Johnson Syndrome (SJS)

SJS (also called *erythema multiforme major*) is the severe bullous form of erythema multiforme characterized by lesions of the skin and mucous membranes, fever, sore

throat, headache, and systemic toxic effects. The lesions begin as macules and can develop into papules, vesicles, bullae, or urticarial plaques. The most extreme cases are called *toxic epidermal necrolysis syndrome* or *Lyell's syndrome*; in these cases, the entire skin surface is affected.

SJS occurs in children and young adults, and affects males more frequently than females. Acute and sudden onset often follows an upper respiratory infection, whereas the actual syndrome is generally triggered by medications. The drugs most commonly associated with SJS include sulfonamides, anticonvulsants, penicillin, antimalarial sulfadoxine–pyrimethamine, and barbiturates. Increasing evidence indicates that SJS may be the result of genetic susceptibility, although both the etiology and exact mechanism is not known (Vanfleteren, Van Gysel, De Brandt et al., 2003). Finally, the association of SJS with patchy pneumonia, increased titers or cold agglutinins, and the isolation of *Mycoplasma pneumoniae* have suggested a relation to mycoplasma infection.

The mortality rate of SJS may be as high as 10% during the acute phase, particularly in children with pulmonary involvement. Subsequently, the disease is self-limiting; skin lesions gradually subside without scarring in 1 to 4 weeks, although mucous membrane lesions may persist for months. Recurrences are rare (Vanfleteren et al., 2003).

Assessment

Most children with SJS have a prodrome of fever, headache, sore throat, and malaise; nonspecific respiratory infection; and possibly petechial rash. The hallmark of the syndrome is an erythematous papular skin lesion that enlarges by peripheral expansion and usually develops a central vesicle. This eruption may involve cutaneous surfaces, including the palms and soles. Lesions may be scattered or confluent, and new lesions appear for 2 to 4 weeks after onset. Cutaneous lesions tend to rupture, leaving the child at risk for fluid loss, anemia, bacterial superinfection, and sepsis. Vesiculobullous lesions also occur on mucous membranes of the conjunctivae, nares, mouth, anorectal junction, vulvovaginal region, and urethral meatus. Lesions have been described in the larynx, trachea, bronchi, bladder, and gastrointestinal tract. Esophageal stricture or visual impairment from corneal scarring may produce long-term sequelae such as eating difficulties and impaired vision. The diagnosis of SJS is made by history, presence of vascular lesions on at least two mucous membranes, fever, presence of systemic toxic effects, and appearance of classic cutaneous iris or target lesions.

Laboratory tests are not helpful in diagnosing SJS, so diagnosis is made clinically. However, complete blood count with differential; blood urea nitrogen; creatinine; electrolytes; urinalysis; and culture of lesions, blood, and urine are useful in supportive evaluation.

Interdisciplinary Interventions

The goals of therapy are to provide supportive care while the epidermis regenerates and to minimize the potential for subsequent morbidity. An interdisciplinary specialty team of healthcare providers is required to adequately

assess and manage SJS, including critical care intensivists and ophthalmologists. Nursing care is aimed at supportive measures and includes meticulous skin care, early detection and treatment of infection, careful attention to fluid balance, nutritional support, and alleviation of symptoms.

Pharmacologic Interventions

Antimicrobial silver sulfadiazine cream is generally not used because of the risk that the sulfa will trigger further eruptions. Use age-appropriate pain assessment tools for pain management. Viscous lidocaine may be used for pain relief on oral mucosa and in the perineal area.

Alert! When applying viscous lidocaine to the oral cavity with a cotton-tipped swab, do so sparingly. Swallowing viscous lidocaine interferes with the child's gag reflex and ability to swallow.

Antibiotic therapy is indicated only when sepsis is diagnosed or strongly suggested. Neutropenia has been shown to indicate a poor prognosis, and has been suggested as a criterion for prophylactic antibiotic therapy. Systemic steroid use is not indicated and may increase the risk of complications such as sepsis and gastrointestinal hemorrhage. Antimicrobials used may include macrolides, amoxicillin–clavulanic acid, and even acyclovir (Vanfleteren et al., 2003).

Nutritional Interventions

Nutritional management is based on severity of symptoms and ranges from a soft or liquid diet in mild cases to IV fluid management in severe cases. The child may require parenteral nutrition during acute phases of the illness.

Surgical Management

Surgical consultation is required for children with severe skin lesions; treatment is similar to that for a child with burns, and the child may be managed in a burn unit or a pediatric intensive care unit. For severe damage, operative wound debridement and xenografts may be required.

Supportive Interventions

These children are usually admitted to a pediatric intensive care unit, where supportive care for children who are potentially unstable, and particularly those with hypovolemia, can be cared for. Therapy includes daily bathing with saline, antibiotic ointments applied to eroded areas, and antibiotic mesh gauze applied to denuded areas.

Skin care includes use of sheepskin or air-fluid beds to reduce pressure on blistering or eroding skin. Lesions should be bathed daily with normal saline or Burow's solution compress and dressed with antibiotic or mesh gauze, depending on the extent of lesions. The child should be repositioned frequently. Children with extensive lesions should be placed in reverse isolation. Mucous membranes should also be cleansed with normal saline,

followed by application of petroleum jelly ointment. Saline compresses can be used on eyes to reduce crusting of eyelid margins. Be alert to early symptoms of infection, such as elevated temperature, positive blood culture, change in vital signs, or increased irritability.

As for a burn patient, careful monitoring of fluid balance is required. Fluid resuscitation with colloids or crystalloids may be required for hypovolemia or sepsis-induced hypotension. Urine output should equal 1 to 2 mL/kg/hour. A Foley catheter may be required for children with difficulty voiding or with urethritis.

The ophthalmologist should examine the child's eyes daily, mechanically separating the lids and the palpebral from the bulbar conjunctiva, if necessary, and removing pseudo-membranes obstructing vision. Children may need systemic as well as topical analgesia for this procedure. Topical antibiotics are prescribed for children with positive eye cultures. A follow-up appointment should be made with the ophthalmologist after discharge to ensure that no permanent visual impairment has occurred.

Community Care

If the onset of SJS is thought to be linked with a particular drug, the child and family should be taught to avoid that agent in the future. Long-term follow-up is necessary for children with mucosal or skin-scarring complications. Ophthalmologic consultation and follow-up visits are an important aspect of the overall plan of care.

THERMAL INJURIES

Thermal injuries are caused by hot and cold environmental forces that range from redness of the dermis to loss of circulation and cellular functioning in an extremity or other part of the body. Severe burns are among the most debilitating and disfiguring of all skin alterations. The third most common accidental injury in children, all but the most minor burns can have a traumatic effect on the child and the family. Even sunburn, although it is a type of minor burn and is substantially less ominous than major burns, may have long-term carcinogenic effects. Cold injury can also cause disfigurement and long-term discomfort to the child if exposure to cold-wet or cold-dry conditions is prolonged.

The most important interdisciplinary management strategy for thermal injuries is to teach prevention. Wearing proper attire, using protective skin creams and lotions, and regulating the time exposed to very hot or very cold weather conditions are important interventions to prevent thermal injury.

Fire and Burn Injuries

Burn injury to children may be accidental or nonaccidental. Nonaccidental injury involves child abuse by burning or by neglect. Accidental burns in children younger than 5 years of age are likely to occur as a result of environmental situations that are not controlled by parents. Natural curiosity and increasing mobility in the child at this

age contribute to the risk. For ages 3 to 14 years, many injuries are caused by clothes catching fire. The percentage of body surface area burned remains one of the most important factors associated with predisposing morbidity and mortality.

WORLDVIEW: Skin lesions and irregular markings on the child's body may be a result of folk practices used by the family to treat a specific illness. For instance, in the Chinese culture, the practices of cupping, skin scraping, and moxibustion can injure the child's skin. Cupping is a process that creates a vacuum in a cup by placing a heated material in the cup. The cup is then placed on the child's skin until easily removed. The treatment leaves a burn mark. Skin scraping is the process of applying oil to an area of the skin, then scraping the area with a coin repeatedly, leaving linear bruising on the skin. In the folk practice of moxibustion, the ignited moxa plant is applied to specific areas of the body to treat diseases that are caused from an excess of yin. This causes burn marks on the child. The nurse should emphasize to the parents that, although these practices are meaningful, they can further injure the child. In addition, the burns and lesions on the skin caused by these folk practices can become infected.

Incidence and Etiology

Thermal injuries are the second most common cause of death in children in the United States, second only to motor vehicle accidents. More than 600 children die every year in fires, or from other burn injuries. The most common burn injury in a child is from scalding, by either spilling of hot liquids or from bath water.

Alert! At 140 °F (60 °C), it takes 5 seconds for hot water to cause third degree burns. A temperature of 104 °F (40 °C) is the recommended maximum bathing temperature for children.

Nearly 75% of all scalding burns in children are preventable. Flame burns cause about 15% of injuries, and the remainder of burns are contact, electrical, chemical, and radiation (Safe Kids, 2004) (see [thePoint](#) Supplemental Information: Types of Burn Injuries).

Pathophysiology

Burn injury causes a multisystem cascade of effects. Many of its manifestations and outcomes are unique in the pediatric population because of physiologic differences between adults and children (Developmental Considerations 25–5). In addition to skin injury, the lungs, cardiovascular system, fluid and electrolyte balances, and metabolism may be damaged or altered; the potential for infection and sepsis also increases as the percentage of burned body surface area increases. Immediately after the injury, blood flow increases in the area around the injury. The burned tissue releases vasoactive substances, which increase capillary permeability. This increased permeability creates a fluid shift to the interstitial space (i.e., third spacing) with edema. This phase precedes the diuretic phase, which generally occurs 48 to 72 hours after burn injury, when the patient becomes more stable (Langford & Thompson, 2005; Smith, Doctor, &

Boulter, 2004). Managing fluids and electrolytes thus becomes vitally important.

Respiratory Compromise

Many noxious substances may be inhaled. The consequences of inhalation usually depend on the types of chemicals being released by the burning substance, the duration of contact, and whether the person was in a confined space. Obvious signs of inhalation injury include burns of the mouth, lips, nose, and face as well as sooty material deposited in those areas. Other signs include a hoarse voice, cough, wheezing, and dyspnea—all signs of respiratory distress.

Three types of respiratory system injury can occur with a burn: upper respiratory tract injury, pulmonary injury, and carbon monoxide inhalation and hypoxia

injury (Table 25–7). As with all trauma patients, the first priority in managing the pediatric burn patient is to assess airway and breathing. Pulmonary complications of burn injuries account for a large percentage of patient deaths.

Upper respiratory injury leads to swelling of the tissues in the throat and the upper airway, resulting in mechanical obstruction of the airway. Swelling starts within a few minutes of the injury, and the airway may occlude within a few minutes to a few hours. The edema remains in the tissues until it is slowly reabsorbed over a period of 2 to 5 days. Respiratory distress may be exhibited by abdominal breathing, head bobbing with respiratory efforts, nasal flaring, coughing, stridor, or wheezing. The young child may exhibit paradoxical inspiratory efforts, which draw the chest wall inward while thrusting out the abdomen. The

TABLE 25–7

Types of Respiratory Injury

Type of Injury	Cause	At Risk For	Interdisciplinary Interventions
Upper airway obstruction	Edema of upper airway secondary to direct burn injury from inhaling superheated air, swallowing extremely hot liquids, or as a consequence of massive tissue swelling associated with extensive burns and burn shock therapy	Mechanical obstruction of upper airway	Intubation of airway; administration of warm, moist mist with oxygen as needed
Inhalation injury	Inhalation of toxic products of combustion (smoke), resulting in chemical irritation and trauma to lung tissue	Impaired gas exchange related to acute pulmonary failure 24 to 48 hours after burn injury	Early diagnosis of inhalation injury by bronchoscopy, or xenon-133 ventilation/perfusion scan, followed by intubation of airway and ventilatory support using a mechanical ventilator and oxygen as needed
Carbon monoxide	Carbon monoxide released as a by-product of combustion (especially common in structure fires) Carbon monoxide replaces oxygen on the hemoglobin molecule, leading to cellular hypoxia.	Systemic hypoxia, brain damage, death	Administration of 100% oxygen by mask if the child is awake, alert, and able to protect the airway until carboxyhemoglobin level returns to normal range; otherwise, intubation and ventilatory support as required Continued monitoring of blood oxygen levels and oxygen administration until hypoxia resolves

small size of the pediatric airway may become occluded by tissue edema or mucous plugs, which increases the chance for a respiratory infection.

Burn Shock

Burn shock is a type of hypovolemic shock that begins to develop shortly after a burn injury of more than 15% to 20% total body surface area (TBSA) in children. In burns of up to 30% TBSA, the fluid leakage is around the injured area; when more than 30% is involved, the leakage becomes generalized (Bosworth-Bousfield, 2005). Mechanisms of burn shock are not well understood, but the sequence of major burn injury followed by massive capillary leakage of circulating fluid into the surrounding tissues is well recognized.

Alert! Untreated burn shock leads to death from hypovolemia. The larger the total body surface burned, the greater and more rapid the fluid loss.

Within minutes of a major burn injury, all the capillaries in the circulatory system—not just those in the area of the burn—lose their capillary seal, resulting in leakage of intravascular body fluid into the interstitial spaces; this process is called *third spacing*. This leakage, which peaks during the first 18 to 24 hours after a severe burn, creates a tourniquet effect and results in compartment syndrome. Should this syndrome occur, surgical incisions of the burned tissue (escharotomy) or muscle sheaths (fasciotomy) most likely will be performed. Erythrocytes and leukocytes remain in the circulation and produce an elevated hematocrit and leukocyte count. The process of burn shock gradually decreases after 48 to 72 hours, at which time the capillary seal is generally restored, and more fluid stays in the circulating system, with increasing diuresis.

As with any other trauma patient in hypovolemic shock, concurrent systemic changes also occur after the burn injury, including the following events:

- Ileus, which persists for about 48 hours after the burn
- Decreased blood flow to the stomach and intestines, resulting in bacterial translocation into the peritoneum
- Curling's ulcer, or true duodenal ulceration, which usually develops 10 to 14 days after burn injury
- Increased heart rate to increase cardiac preload
- Increased respiratory rate to meet the increased metabolic needs of the stressed body
- Decreased urinary output and increased specific gravity
- Increased blood urea nitrogen and creatinine
- Decreased hemoglobin and hematocrit

Fluid and Electrolyte Deficits

In addition to the large amount of intravascular fluid volume lost during burn shock, a child has a larger body mass-to-surface area ratio than an adult, thus increasing the extent of heat and evaporative water loss (Bosworth-

Bousfield, 2005; Langford & Thompson, 2005). After the initial 24 hours—even though the capillary seal is restored and circulating volume is maintained—major fluid and electrolyte losses continue to occur through the burn wound until wound closure is achieved. Fluid loss through the skin after burn injury peaks after the fourth day but continues to be a concern until the area heals. Fluid and electrolyte imbalances can occur rapidly. Whenever hypotension develops in burn patients, the body's ability to fight infection at the tissue level is compromised by inadequate tissue perfusion to the skin. Infection usually develops quickly, and infected wounds lead to more tissue destruction. Overwhelming infection rapidly leads to sepsis.

Both renal blood flow and urinary output are curtailed after a severe burn. Conditions such as acute tubular necrosis may follow inadequate fluid replacement; glycosuria occurs in patients who are metabolically stressed; and urinary output is severely curtailed, which alters blood urea nitrogen and creatinine levels. This oliguric phase commonly persists for the first 24 to 36 hours after burn injury, followed by a diuretic phase. During these times, monitoring serum electrolytes, especially sodium and potassium, is essential.

Metabolic Alterations

The major metabolic responses to burn injury include

- Hypermetabolism
- Elevated catecholamine levels
- Hyperglycemia
- Increased nutritional needs
- Growth delay

Hypermetabolism characterizes the metabolic response to burn injury and occurs in proportion to the extent of the burn. Energy expenditures may increase from 40% to 100% above basal levels in children with burns of more than 30% TBSA. Core body temperature for a child with a major burn injury will reset at about 99.5 to 100.4 °F (37.5–38 °C), and will remain at that level or higher until skin coverage is achieved. When exposed to cooler temperatures, the child begins to shiver, increasing the oxygen and energy demands of the body tremendously. A warm environment minimizes the hemodynamic and metabolic stresses associated with major burn injury.

Elevated catecholamine levels result from the child's increased core temperature and metabolic rate. In addition, the stress associated with treatments, including the surface water evaporation that occurs with exposure of the child to room temperature air, increases catecholamine release, metabolic stress, and energy demands.

Hyperglycemia is common after burn injury, because glucose metabolism is also altered. The elevation of fasting blood glucose levels above normal is related to the severity of the injury or to the presence of systemic infection. Young children may quickly deplete their glucose stores and may become hypoglycemic unless they receive adequate nutritional support.

Increased nutritional needs are associated with the hypermetabolic state required to heal a major wound. Major

injury and infections can lead to weight loss and severe alterations in body composition, even when calories and protein are supplied in substantial amounts. Nitrogen imbalance is associated with failure to meet increased nutritional needs. Wound healing cannot occur when the child is in negative nitrogen balance; thus, the provision of adequate nutrition is essential to recovery. However, overfeeding results in increased carbon dioxide production that requires increasing respiratory rates to clear and, in addition, can cause fatty liver and other hepatic dysfunction. Thus, one goal of nursing care is to provide sufficient nutritional support.

Growth delay follows depression of growth hormone levels after major burn injury. The child will not increase in height for many months after the injury, while the body focuses on restoring and healing damaged tissue. A growth spurt is usually noted about a year after the recovery phase.

Infection and Sepsis

The warm, moist environment of a major burn wound is an ideal location for bacterial growth. Wound infection is a great risk, because a burn injury presents a source of organisms capable of producing disease, a mode of transmission, and a susceptible host. The most common bacteria are found in the burn wound patient's own body, especially those bacteria normally present on the skin and in the gastrointestinal tract. Other bacteria can easily be spread to the patient by staff members who do not wash their hands after caring for other patients (nosocomial infection). Topical burn creams are used because the local blood supply to the area of burn injury is destroyed with the burn, and systemic antibiotics thus are not delivered to the burn wound.

Infection in partial-thickness burn wounds converts the area to a full-thickness injury, which then requires skin grafting. Hypovolemia for any reason, especially in children, greatly increases the incidence of wound conversion.

Systemic infection can result from aspiration of gastrointestinal fluid into the lungs, which may lead to pneumonia. Alternately, anaerobic bacteria may develop at the interface between the burn wound and the healthy tissue. If bacterial levels increase to the extent that invasion into the underlying tissue occurs, infection results. Bacteria then gain entrance into the systemic circulation and spread into other organs, causing sepsis.

The child's immune system is impaired after major burn injury and cannot protect the child from infection and sepsis caused by previously benign bacteria (Langford & Thompson, 2005). Monocyte and macrophage components of the immune system are not functioning well, nor are white blood cells such as neutrophils, granulocytes, and basophils. Phagocytosis, the normal mechanism for removing debris from a wound, does not occur.

Scarring and Disability

Although scarring is part of the healing process, burn scars can create substantial problems. Hypertrophic scarring results in an elevated, raised, reddened, and painful

FIGURE 25–14. Child with burn scarring. Courtesy of Shriners Hospital for Children. Reprinted with permission.

area that is very susceptible to traumatic injury from routine daily activities. Keloid scars form in the area of the burn and then expand onto unburned tissue (Figure 25–14). Burned areas become stiff and, without therapy, range of motion can become severely limited. Muscles tend to shorten, and skin contracts in burn areas involving the joints. Extension muscles are not as strong as flexor muscles, and injured areas over joints (especially the elbows, axillae, and knees) tend to become permanently fixed in the flexed position.

Assessment

The type and extent of burn injury will guide the assessment process. For instance, when child abuse is suspected, additional assessment factors to evaluate include parent and child's descriptions of how the burn occurred, location (palms, soles, flexor surface of thighs or perineum), and patterns.

Physical Assessment

If the burn injury is severe, the physical assessment should begin with a primary assessment of the airways (the ABCs). The most common cause of death during the first hour after an acute burn injury is respiratory impairment. Next, consider fluid and electrolyte parameters, appropriate fluid treatment, and pain issues. Finally, evaluate the extent of skin injury. This evaluation is based on many criteria. Burns can be described as superficial (first degree), partial (second degree; Fig. 25–15), or full thickness (third degree), depending on the depth to which the skin has been destroyed (Table 25–8). The percentage of the TBSA must also be considered and can be calculated using the Rule of Nines. This method divides the surface area of the body into areas of 9% or multiples of 9% equal to 18%. When all body areas of 9% are summed, 1%

FIGURE 25–15. Child with second-degree burn. Courtesy of Shriners Hospital for Children. Reprinted with permission.

remains, which is assigned to the genitalia and perineum. The Rule of Nines is less accurate for children, however, so a modified version is presented in Figure 25–16.

For patients younger than 15, a second, more precise method of estimating burn size is used. (1944) Burn estimation tables subdivide body areas into segments and assigns a proportionate percentage of body surface to each area based on age (Fig. 25–17). The head of a newborn baby, for example, is proportionately much larger than any other area of the body. As a child grows, the lower extremities assume more body surface area; the head becomes relatively smaller compared with the rest of the body. Also, rather than being viewed as a whole, the lower extremity is divided into foot, leg, and thigh areas.

A third method of estimating burn injury extent uses the size of the patient’s hand, assuming the palmar surface of the hand is roughly 1% of the total body surface.

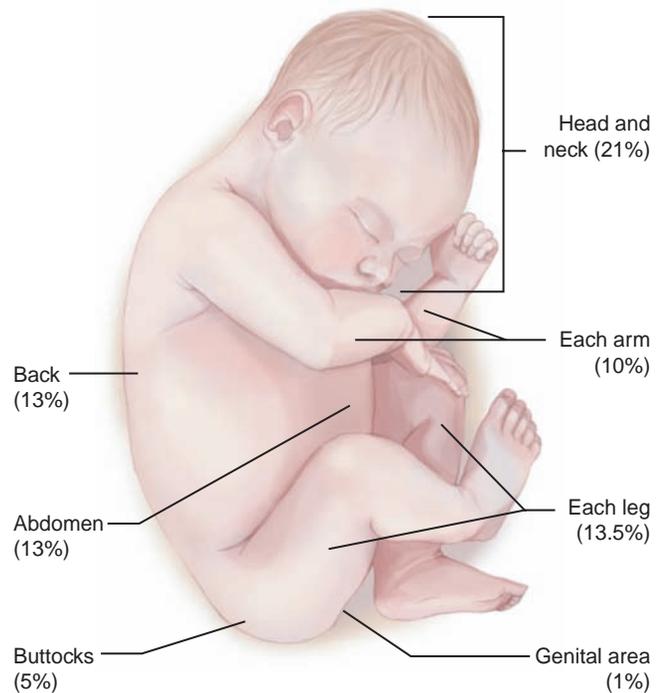

FIGURE 25–16. Rule of Nines for babies and young children.

Visualizing the patient’s hand covering the burn wound approximates the amount of body surface involved, especially if the burn areas are scattered.

Diagnostic Tests

A complete blood count should be obtained to establish baseline levels; many blood levels will be altered during

TABLE 25–8

Severity of Burns

Depth of Burn	Thickness	Appearance of Burn	Sensation	Example of Cause
First degree	Superficial epithelium	Erythema	Painful	Sunburn
Second degree	Partial thickness Destruction into, but not through, epidermis	Blisters Peeling epidermis Swelling White or red mottling Weeping, wet	Painful Hypersensitive to air, touch	Very deep sunburn Scalds
Third degree	Full-thickness destruction of skin into hypodermis Death to all skin appendages and subcutaneous tissue	Translucent Mottled white or tan Waxy Leathery Basically dry	Painless (initially)	Fire Prolonged exposure to hot liquid Electricity
Fourth degree	Full thickness through all layers of skin down into the muscle and bone	Looks like third-degree burn	No sensation because of nerve damage	Prolonged flame contact High-voltage electrical injury

CALCULATION OF EXTENT OF BURN

FIGURE 25-17. Child burn size estimation table. Lund, C. C., & Browden, N. C. (1944). Estimation of burn size. *Journal of the American Colleges of Surgeons (Surgery, Gynecology, and Obstetrics)*, 79, 352-358. Reprinted with permission.

the first 24 to 48 hours as a result of tremendous fluid shifts. For example, hematocrit will often be elevated secondary to fluid loss; also, white blood cell counts may also be elevated as an acute-phase reaction, but later could indicate infection. Assessing actual or potential pulmonary injury in children with flame injury involves measuring arterial blood gas and carbon monoxide levels. In addition, basic renal function tests, baseline clotting studies, type and cross-match, chest radiographs, and pulse oximetry should be included (Arndt & Hsu, 2006; Langford & Thompson, 2005).

Nursing Diagnoses and Outcomes

The following nursing diagnoses are appropriate for the child with a burn injury. Additional information regarding care management for the child with an acute condition can be found in Nursing Plan of Care 12-1.

Impaired skin integrity related to effects of burn

Outcome: Child's skin will heal without infection, as evidenced by restoration of the epithelial layer in partial-thickness injury or adherence of skin graft to area of full-thickness injury.

Acute pain related to response to thermal injury and related procedures

Outcome: Child will experience pain relief, as evidenced by age-appropriate behaviors, adequate nutritional intake, and appropriate sleep patterns.

Ineffective airway clearance/impaired gas exchange related to upper airway edema, smoke inhalation injury, or carbon monoxide/hypoxia

Outcome: Child will maintain normal oxygen saturation, will have unlabored respirations at a rate appropriate for age, and will have clear bilateral breath sounds.

Ineffective tissue perfusion (peripheral) related to burn shock

Outcome: Child will maintain a urine output of 1 to 2 mL/kg/hour for the first 24 hours after the burn and will remain alert and oriented.

Risk for deficient fluid volume related to loss of skin integrity in the area of the burn and systemic shifting of plasma and plasma components from the circulatory system into interstitial and intracellular spaces secondary to impaired capillary integrity

Outcome: Child will maintain normal fluid and electrolyte balance, as evidenced by intake and output measurements and serum electrolyte values that are within normal limits.

Risk for infection related to burn wound contamination or to pulmonary complications

Outcome: Child will achieve wound closure without developing infection, systemic sepsis, or pneumonia.

Imbalanced nutrition: Less than body requirements, related to hypermetabolism and the increased energy requirements of wound healing

Outcomes: Child will maintain muscle mass and protein stores appropriate for age.

Child's nitrogen balance and energy expenditure studies will consistently yield balanced results.

Disturbed body image related to perception of appearance

Outcomes: Child will reenter previous social settings and will express a feeling of comfort in these areas.

Family will provide emotional support for the child.

Child will discuss feelings related to reactions of others to the child's change in appearance.

Interdisciplinary Interventions

Minor burn injuries (first-degree burns) are generally treated on an outpatient basis. Moderate burns include second-degree burns that cover 10% to 20% of the body on a

child (15%–20% of the body on an adult) and third-degree burns covering 2% to 10% of the body. All other burn injuries are considered major and require hospitalization and intensive interventions. Therapy for all burn injuries is designed to promote wound healing, prevent infection, and provide pain relief (Nursing Interventions 25–6). The goals

of burn wound management are to close the wound and to prevent infection. Wound closure is determined by depth and extent, and is accomplished either by supporting spontaneous healing or by initiating surgical repair.

Many of the normal functions of the skin are altered by burn injuries (see [thePoint](#)). Supplemental Information:

NURSING INTERVENTIONS 25–6

Management of the Child's Burns

Eyes/Eyelids

On admission, irrigate the eyes with sterile solution. Eyelids will swell shut for 3 to 5 days. Cleanse the area gently; do not attempt to force the eyes open. After the edema resolves, wash the area every 8 hours and apply ointment and eye drops per physician's order. Inform the child that vision may be blurred because of the application of medications.

Ears

On admission, perform a gentle cleansing and use a cotton-tipped applicator to remove debris/eschar and blisters, and secure hair away from the burned area. Position the child without using a pillow to prevent further trauma to the ears, because wounds tend to adhere to pillows or bed linens. Apply Sulfamylon ointment every 12 hours as ordered by the physician.

Face

On admission, remove blisters and shave face (if age appropriate), except for eyebrows, as indicated. Apply bacitracin or other ointments per physician's order. Cleanse the area every 8 hours and reapply topical ointment. The area will heal quickly (7–10 days) if it is a superficial burn because of an abundant blood supply. Deeper burns are skin grafted early to decrease scarring. Pillows are not used with anterior neck burns to minimize scarring from chin to neck.

Hands

On admission, remove rings or other jewelry. Remove blisters and apply a topical antibiotic ointment (silver sulfadiazine), wrapping each finger individually and wrapping the entire hand in a manner that permits full range of motion. Cleanse the area every 8 hours, and reapply ointment and dressings. Encourage full range of motion and use of the hand. Elevate the child's hand above the level of the heart to promote edema reabsorption. Administer pain medication to facilitate use of the hand. The area will heal quickly (7–10 days) if it is a superficial burn because of abundant blood supply. Deeper burns should be skin grafted early to decrease scarring.

Feet

On admission, remove blisters. Apply topical antibiotic ointment (silver sulfadiazine) per physician's order. Wrap the toes individually; wrap the foot so that full range of motion is possible; and apply an elastic bandage, distal to proximal, over the dressing to promote comfort and reduce dependent edema. The patient should ambulate at least every 4 hours during the day unless contraindicated; pain medication should be administered to be effective at ambulation times. Elevate the patient's lower extremities when at rest.

Joints

On admission, remove blisters and shave areas with hair. Apply topical ointment per physician's order. Wrap the area to permit full range of motion. Cleanse the area every 8 hours, and reapply ointment and dressings. Shave areas of hair growth every 3 to 4 days. Encourage full range of motion. When at rest, joints should be kept in extension to prevent contracture formation.

Perineum

On admission, perform thorough cleansing and rinsing of the area, remove blisters, and shave the area. Insert a bladder catheter before edema accumulates. Apply silver sulfadiazine, per physician's order, directly to the perineum or onto diapers before application. Maintain the bladder catheter until the edema subsides. Cleanse the area after each stool/voiding, and reapply silver sulfadiazine. Scrotal edema can accumulate and may impair walking until resolved.

Circumferential Burns

On admission, identify areas of full-thickness circumferential burn. Cleanse the area, remove blisters, and shave as needed. Monitor distal pulses every 15 minutes using a Doppler monitor. If distal pulses diminish or disappear, notify the physician immediately and prepare for escharotomy or fasciotomy. After the procedure, check for pulses every 15 minutes for 24 hours postburn. If pulses diminish or disappear again, notify the physician. Apply silver sulfadiazine and dressings to the area. Cleanse the area and change dressings every 8 hours.

Functions of Skin Altered by Burn Injury). Treatment of major burn injuries must correct respiratory compromise, burn shock, fluid and electrolyte deficits, and metabolic alterations; prevent infection and sepsis; and minimize scarring and disability.

Pharmacologic Interventions

For any burn, check the child's tetanus immunization status on admission and ensure that tetanus toxoid is given if the child's immunizations are not up to date, because anaerobic and aerobic bacteria can grow at the interface between burned and healthy tissue.

For minor burns, the burned area is covered with an antimicrobial ointment (usually bacitracin or silver sulfadiazine [Silvadene]) and a nonadherent dressing and light gauze (see [thePoint](#)). Medications and Administration: Administering Topical Agents Commonly Used for Burns). Dressings are usually changed twice daily, with the patient premedicated for pain. Medications such as ibuprofen or acetaminophen are usually effective as an analgesic for minor burn injury, but the actual wound care will be very painful until healing is well established.

For major burn wounds, topical antibacterial agents are used to penetrate the **eschar** (necrotic skin and subcutaneous tissue) and to reduce bacterial growth in and around the wound. Silver sulfadiazine (Silvadene), the topical agent most commonly used, is not typically used on the face or for electrical burns. Facial burns are covered with a light layer of antimicrobial ointment. For burns to the ear or for electrical burns, mafenide (Sulfamylon) is the topical agent of choice because of its deep penetration into the eschar; do not apply it to the face. In a few burn units, protocol requires ointments to be placed on the wounds without a protective dressing. However, in most units, dressings are applied over the wound to keep the area moist and the topical agents in place. Systemic antibiotics are not used to control burn wound bacteria, because there is no blood supply to the wound to deliver the drug. If systemic sepsis is diagnosed, systemic antibiotics are administered to eliminate the source of the sepsis, if possible.

caREminder

If systemic sepsis occurs, children exhibit all the signs of hypovolemic shock, but the actual timing of the symptoms depends on the volume status of the child at the time of onset of sepsis.

Pain and itching are both active components of recovery from a burn injury. With partial-thickness burns and in areas used for skin graft donor sites, nerve endings are exposed, and the areas are highly sensitive to pressure pain. Also, the joints underneath develop an arthritic type of pain that is activated with movement. Burn patients awaken each day with chronic pain, stiffness, and aching in the burned areas for many months after the burn is healed.

Itching occurs in all healing areas and causes great distress unless it is relieved with medication. Itching persists for several months after burns heal, as new nerve endings and dermal elements reestablish themselves. Alterations

in sweat glands after burn injury result in excessive sweat production, which leads to dry skin and itching, adding to the problem.

The perception of pain in the burned child varies widely, but it is usually related to procedural pain from dressing changes or physical therapy, or from attempts to remain still to avoid the pain of movement. Chronically abused children learn not to verbalize pain and often withdraw into a trancelike state during painful procedures. Other children protest against each painful procedure with every bit of volume and energy available to them. The amount of protest a child manifests in response to painful procedures should not be the criterion for pain management. Procedural pain can be minimized by administering adequate analgesia 20 to 30 minutes before the procedure (to achieve maximal effect by the time the procedure is started), additional analgesia during the procedure, and analgesia at the completion of the procedure to allow the child to rest and recover. One effective method of pain control is the patient-controlled analgesia pump, which can be used by children as young as 6 years of age. For especially painful procedures, short-acting, memory-altering medications may be used so that the child does not recall the procedure.

caREminder

Administer pain medication before painful procedures, so that maximal effectiveness coincides with the procedure. When the child undergoes a procedure, such as skin grafting, that is known to produce prolonged pain, administer pain medication on a scheduled basis, rather than as needed after pain is reported.

Morphine is the analgesic of choice. It should be administered by IV rather than intramuscularly, because it will not be rapidly or evenly absorbed if it is injected into edematous tissue. Oral medications such as acetaminophen with codeine may be used to diminish pain between dressing changes.

In older children, anxiety and anticipatory stress may respond to antianxiety medications. Ensuring adequate sleep and uninterrupted quiet time is essential to allow the child to restore inner resources. Parental visiting should be unrestricted and individualized to the child's needs and to those of the family.

Itching of healing skin can be controlled by medications, such as diphenhydramine hydrochloride (Benadryl), and by applying soothing lotions, such as Nivea or Eucerin.

Nutritional Interventions

The child with a minor burn should increase fluid intake to replenish loss. However, the caloric requirements in the child with major burn injury are two to three times the normal basal requirements and necessitate aggressive nutritional support. In addition, healing cannot occur in the presence of negative nitrogen balance. Therefore, establishing and maintaining adequate nutritional intake is essential to survival. Several formulas have been proposed for estimating caloric requirements (see [thePoint](#)). Supplemental Information: Estimating Calorie Requirements in

Burned Patients Using the Galveston Formula). Correct estimates are important, because too little nutritional intake causes weight loss and protein mobilization from muscle, whereas administering excess calories can cause hyperglycemia, liver abnormalities, and increased carbon dioxide production. Weight, calorie and protein counts, and nitrogen balance are monitored daily; when possible, indirect calorimetric measurements of resting energy expenditure are obtained.

caREminder

Burn wounds cannot heal if the child is in negative nitrogen balance. Nutritional support is essential.

Most children with burns exceeding 25% of the TBSA are unable to consume an oral diet sufficient to meet their nutritional requirements. The child may refuse to eat because of the unfamiliarity of hospital food, because of pain, or in an effort to gain control over the environment. Many children require enteral tube feeding with supplemental liquid nutrition with vitamins (A, B, B₆, C, and E) and trace elements (iron, zinc, copper, and magnesium) to promote wound healing. If enteral feeding does not meet all of the child's nutritional needs, parenteral hyperalimentation can be administered. This route is used only as a last resort because of the risk of catheter-related infection and the desire to maintain intestinal integrity.

Surgical Management

Early burn wound excision is indicated for minor burns in which the wound would be slow (taking longer than 2–3 weeks) to heal. Only superficial burns with bright pink wounds that indicate dermal circulation are suitable for conservative treatment (Bosworth-Bousfield, 2005; Langford & Thompson, 2005). Early surgery provides further benefits, which include removing potentially harmful bacteria, reducing the degree of scarring, and accelerating healing.

caREminder

Meticulous and regular performance of appropriate debridement and use of antimicrobial topicals and cover dressings are the cornerstones of successful burn wound management.

Major burn injury produces eschar, which releases chemical mediators that stimulate leukocytes to digest debris, but this digestion also damages capillaries and skin elements. Necrotic tissue within a wound prolongs inflammation and slows healing and epidermal coverage (Bousfield, 2002).

Debriding a wound removes this necrotic tissue. Initial debridement can be performed in the emergency department or on the unit in the **hydrotherapy** treatment room. Every 12 hours, burns are cleaned, old creams and ointments are removed, and loose tissue is trimmed from around the wound.

Full-thickness burn injuries and most deep partial-thickness burn injuries are managed surgically. Burn tissue is removed by excision. Wound coverage is achieved

over healthy, unburned tissue. The skin used to cover the burn wound is harvested from an unburned area (donor site) of the child's own skin in a procedure called an **autograft**. The skin that is used is a paper-thin section of the upper layers of the skin (split-thickness skin graft). To cover a greater area, autograft skin is usually prepared with a skin mesher, which cuts small slits into the graft, enabling it to be stretched to cover an area 1½ to 9 times larger than the original graft. The slit pattern disappears as the graft heals (Fig. 25–18). If blood collects between the excised area and the skin graft, the skin graft will not adhere. Infection can also cause loss of skin grafts.

If the child does not have sufficient unburned skin for autografting, temporary coverage can be achieved by using a **homograft** (cadaveric skin) or **xenograft** (pig skin) that has been specially prepared for that use. A xenograft is applied when extensive early debridement is required; it is replaced every 2 to 3 days. These biologic skin coverings markedly reduce pain and facilitate movement of joints until suitable donor sites become available. Cultured epithelium, cell culture grafts, and synthetic skin substitutes such as BCG matrix, Biobrane, Apligraf, and Bio-occlusive also are available.

In some burn units, the burn eschar is removed in a two-stage excision and grafting procedure. On the first day, the burn is surgically excised, and the area is covered with antibiotic-soaked dressings. On the second day, the child is returned to surgery, where the autograft is obtained and applied to the previously excised burn areas. In other burn units, excision and skin grafting are accomplished in one procedure, with an interval in between to enable control of blood loss. Blood loss with excision of large burns is massive and may require replacement of as much as one half of the child's circulating blood volume. Burn patients receive many blood transfusions during their hospital course.

Supportive Interventions

For minor burns, first ensure airway patency and evaluate hydration status. Then, remove any restrictive clothing or jewelry; keep the patient warm. If the burn is chemical, remove contaminated shoes and clothing, and flush the area with water. Clean the wound with mild soap and tepid water and debride the area of loose debris and necrotic tissue.

For severely burned children, initial treatment consists of establishing an airway and administering higher concentrations of oxygen to treat respiratory compromise until an assessment and treatment plan are completed.

Upper airway edema is managed by airway intubation and administration of humidified oxygen until the edema subsides, usually about 2 to 5 days later. When initial assessment indicates that airway edema is accumulating and will lead to airway compromise or to occlusion, early, planned intubation is preferred over emergency intubation. Inhalation injury is managed by airway intubation and ventilation support at settings appropriate to the child's lung size. A full-thickness burn encircling the chest may limit full expansion of the lungs. In such cases, an escharotomy of the chest may be necessary to enable chest wall expansion.

Alert! Children who are severely burned and who do not have other injuries are awake, alert, and oriented. Loss of consciousness in a child with burn injuries is the result of factors other than the burn itself. The most common cause of unconsciousness in flame injury is hypoxia associated with smoke inhalation. If the child is unconscious, implement the ABCs, notify appropriate personnel, and prepare for possible intubation.

Carbon monoxide inhalation and hypoxia are treated by administering high concentrations of oxygen by mask until the condition is resolved. Using a Venturi mask—type of oxygen delivery device will enable high-flow, high-concentration oxygen. When the inspired concentration of oxygen is increased, the half-life of carbon monoxide decreases. With 100% inspired oxygen, the half-life is reduced to approximately 50 minutes (Bosworth-Bousfield, 2005). Hyperbaric therapy (100% oxygen given at 2½ times normal atmospheric pressure) reduces the half-life to approximately 20 to 25 minutes. No further treatment is needed for the hypoxia, although there may be other related problems, such as neurologic damage.

Alert! Beware of extra cooling interventions, such as wet dressing or ice applications, which promote vasoconstriction and impair circulation.

Therapy for burn shock is aimed at supporting the child through the period of hypovolemic shock until capillary integrity is restored. To maintain adequate circulating volume, fluids are administered intravenously at a rate greater than the rate of fluid loss. Many formulas can be used to calculate the rate of fluid administration, the most common of which is the Parkland formula of fluid resuscitation (see [thePoint](#), Supplemental Information: Parkland Formula of Fluid Resuscitation for Burn Shock). Because urine output reflects end-organ tissue perfusion, IV fluids are administered at a rate sufficient to keep the child's

urine output at 1 mL/kg body weight/hour—a rate that reflects adequate tissue perfusion. A Foley catheter is used to measure hourly bladder output. Ringer's lactate (crystalloid) most closely approximates the composition of the extracellular fluid being lost. Children younger than 5 years of age handle free water poorly, making them susceptible to pulmonary and cerebral edema.

caREminder

Major burns with large amounts of denuded skin should not be cooled. Additional heat loss will further decrease the core temperature and potentiate circulatory collapse.

If a child's urine output during burn shock is inadequate, the reason is insufficient administration of resuscitative fluids. Renal failure is not a component of burn shock if adequate fluids are administered. Burn shock fluid resuscitation formulas are only guidelines; individual children may require more than 4 mL/kg per percent of TBSA burned during the first 24 hours.

Sensorium is an important guide to the adequacy of fluid resuscitation. The burn injury itself does not affect the sensorium, so any changes in mentation should be investigated. When burn shock fluid resuscitation is delayed, cerebral hypoperfusion and hypoxia may occur, predisposing the child to cerebral edema when massive fluid infusion is initiated.

caREminder

Elevating the head of the child's bed 10 to 15 degrees to decrease cerebral edema fluid accumulation, along with monitoring for clinical signs of increased intracranial pressure, is essential to diminish the amount of cerebral edema during shock resuscitation.

Placing the head of the bed on wheel blocks to elevate the entire bed on a slant is preferable to elevating only the head of the bed, which results in edema accumulating in the groin and legs.

In certain cases, children may require fluid in excess of the calculated amount. Some of these exceptions include burn size that has been underestimated, pulmonary injury that sequesters fluid in the lungs, electrical injury with more tissue destruction than is visible, extremely deep injury, and delayed fluid resuscitation.

After burn shock has resolved, the child is given a colloid-containing solution to replace plasma lost from the circulating volume. When burn shock resuscitation is completed, a maintenance fluid plan is formulated using normal basal fluid requirements plus calculated evaporative water loss from the burn wound. The fluid infused is changed from Ringer's lactate to an electrolyte-free solution of 5% dextrose, with or without saline, depending on the patient's electrolyte status. A liter of dextrose solution contains 200 calories and is used to meet some of the patient's elevated caloric needs. Potassium may be added to the IV infusion as indicated for hypokalemia. The child's intake, output, and serum electrolyte balance are monitored closely. Fluids are administered in amounts

equally divided throughout each 24-hour period. IV fluids are administered until the child's bowel function returns, usually within 48 hours after the burn. The child can then be started on oral fluids. The child must continue to maintain adequate fluid intake until wound closure is achieved.

At times, fluid losses may increase, especially when the child's core body temperature exceeds 102.2 °F (39 °C), when tracheal intubation is required, when a paralytic ileus necessitates prolonged nasogastric suction, when perioperative procedures are accompanied by massive blood loss, and when diarrhea occurs.

Alert! Fluid and electrolyte imbalance lasting for only a few hours can lead to sepsis, seizures, and death in burned children. It is imperative that ongoing nursing assessments and appropriate interventions be implemented to prevent unnoted fluid and electrolyte imbalances.

Major burn wounds receive daily care until closure is achieved. Wounds are cleaned using mild soap before being covered with topical antimicrobial agents. Dressings are changed one to three times daily, depending on the agents used and on specific protocols. Dressings can be changed in hydrotherapy tanks, in bathtubs, in showers, or, if the child is too ill to be moved, at the bedside. Hydrotherapy (placing the burned area in water) makes cleaning easier and softens the eschar, thereby promoting range of motion. After debridement, the wounds are redressed.

Aseptic technique is used during dressing changes. In addition to pain control, measures to maintain the child's core body temperature, minimize shivering, and conserve energy must be part of wound care. To the degree possible, the child should engage in self-care. After dressings are applied, isolation is not necessary, and the child need not be restricted to an area of the hospital.

Hydrotherapy is used to clean the wound and the child, and to engage in active range-of-motion exercises. Some facilities use disposable plastic hydrotherapy liners to prevent cross-contamination between patients. To prevent electrolyte loss through the skin into the water, hydrotherapy should last no longer than 20 minutes. The room should be very warm, and the child should be covered and should be dried immediately after hydrotherapy.

Burn scars form in healed areas, including those that received skin grafts. Scarring starts when healing starts and continues for about 8 to 12 months. Preventing hypertrophic scarring is essential for optimal cosmetic and functional recovery.

Within 1 or 2 weeks after a wound is closed, scarring is minimized by applying pressure to the area using specially made antiscarring compression garments. Garments such as gloves, shirts, pants, or face masks are individually measured and fitted to the burn area. They are worn 24 hours a day, except during bathing, for about 10 to 12 months after the burn. The time that children wear the special garments varies, depending on the rate at which the scar matures. For many years, these garments were available only in tan, but several manufacturers are now creating them in bright, interesting colors with attractive appliquéd figures and designs. Because

donning and wearing these garments can be a difficult and painful process, adherence is often an issue, and the child's level of cooperation depends almost entirely on the attitude of the adult supervisor. Facial burns can be treated with rigid masks to restore a normal contour to the central face and chin.

Active range-of-motion therapy is continued for several months until the scars mature. Frequent exercise is required to prevent flexion contractures, which severely limit mobility and may require surgical correction. If the child is able and willing to cooperate, active range of motion and use of the burned areas promote optimal functional recovery. If the child is unable or unwilling to cooperate, passive range of motion, performed by staff, will help maintain function. The parents and the child will be taught the physical therapy exercises before the child is discharged from the hospital, because therapy must continue for about 12 to 18 months after the burn, until scar formation has peaked.

Immediate psychosocial stresses for the burned child include separation from parents and from home, as well as all of the known psychological traumas associated with hospitalization. Children who are intubated cannot speak or cry out, and often their arms and legs are restrained to prevent pulling on IV lines and tubes. Physical restraint is terrifying to a young child. Older children, who may better understand the rationale for restraint, may experience anger and a lack of trust.

Children must be allowed "safe time" during the day when no medical procedure, painful or not, is performed. Identify the period as "safe" through a statement, such as, "I am going to sit and read to you for the next 15 minutes and nothing else will happen during that time." Daily periods of uninterrupted sleep must be planned so that the child has time to rest and regain mental and physical strength.

Infants manage stress by sucking. If the child cannot take liquids by mouth, provide a pacifier. Children who have recently given up bottles or pacifiers tend to regress during hospitalization; make these items available to them if desired. The feelings of safety and comfort afforded by their use far exceed any problems associated with weaning after discharge from the hospital.

Recently mastered toileting skills will be lost with the stress of a major burn injury, so children should be placed in diapers until they are once again able to invest effort in independent toileting. Reassure the child that this behavior is acceptable during burn treatment, that punishment will not occur, and that diapering is not intended as a punishment. After discharge, at a time that the child and the parents feel is appropriate, toilet training can begin again at home.

Discharge Planning

For children with minor burns, teach the parents or the child to wash the burned area with mild soap and tepid water, to apply the prescribed ointment and a light dressing, and to promote use of the affected area. Instruct the parents to soak the dressing in tepid water before removing it, to loosen the dressing and to decrease the child's discomfort. Completing the wound care as quickly as possible reduces the pain, because the contact of air and

water on the exposed wound causes much of the pain. Burns of the face are usually left exposed, and antimicrobial ointment is applied twice daily. Inform parents of the importance of returning for follow-up visits.

Also provide instructions for meeting the child's nutritional needs and increasing caloric and protein intake. If the child is still receiving tube feedings, instruct the family on the procedures of tube feedings, on checking residuals, and on recognizing and reporting any complications. Provide the family with access to support groups for burn victims and their families. Be sure that the family members clearly understand the instructions for administering prescribed medications. Also instruct the parents on the signs and symptoms that should be reported to the physician, the home healthcare nurse, or the clinic. To promote the child's normal growth and development, assess the parents' understanding of the normal parameters for their child's age. If the parents are not able to provide needed care, indicate community and hospital resources.

The long-term effects of burn injury are related to physical changes resulting from the healing and scarring process, developmental issues specific to burns in young children, or psychosocial alterations in the relationship between the child and family members (see Developmental Considerations 25–5).

After the acute crisis of major burn injury is over and the child is nearing the time of discharge, short trips can be taken to nearby parks or shops to help the child and the parents adjust to public reactions to the burn injury. The child may never look unburned, but the location of the burn and whether it can easily be covered with clothing during daily activities will affect the child's and the family's adjustment. Some severely burned children lose all facial features, including ears, and going out in public becomes an ordeal that they

and their family avoid. Other children lead well-adjusted lives despite major disfigurement. The inner strengths of the family and the value they ascribe to the child both before and after the burn appear to be deciding factors in the level of adjustment. More specifically, children appear to respond to the burn and to give it a meaning in a manner similar to the mother's reaction. Nevertheless, disfiguring burn scars have a tremendous long-term effect on the child and the family. Occasionally, family members will not be able to accept the child and will request foster placement.

Community Care

Involving the family in the care of the child facilitates acceptance and eases the transition to the provision of care in the community. As soon as possible after discharge, the child and the family should resume normal daily activities. Most burn units have a formal program designed to facilitate the child's return to school. A staff member may accompany the child on the first day back to school to explain what has happened to him or her and to describe the purpose of pressure garments or other therapeutic interventions. Age-related issues of intimacy and sexuality will eventually arise, as will self-esteem issues. Social workers and psychologists monitor the child's and the family's adjustment during return clinic visits the first year after burn injury.

In the case of nonaccidental burn injuries, the child's placement after hospital discharge is determined by the legal system. Be prepared for the fact that the child may be returned to the home environment if it is believed that the child's safety can be ensured. The younger child does not understand the concept of child abuse and loves and depends on the parents just as much as any other child.

DEVELOPMENTAL CONSIDERATIONS 25–5

Pediatric Differences in the Effects of Burn Injury

- Very young children who have been severely burned have a higher mortality rate than older children and adults with comparable burns.
- Because a child's skin is thinner than an adult's, lower burn temperatures and shorter exposure to heat or chemicals can cause a deeper burn.
- A larger body surface area compared with adults places severely burned children at increased risk for fluid and heat loss. Children are also at increased risk for dehydration and metabolic acidosis secondary to diarrhea, evaporative water loss, and increased fluid requirements.
- The highest proportion of body fluid to mass in children increases the risk of cardiovascular problems because of their less effective cardiovascular response to changing intravascular volume.
- Burns involving more than 10% of total body surface area require some form of fluid resuscitation.
- Infants and children are at increased risk for protein and calorie deficiency because they have smaller muscle mass and lower body fat reserves than adults. If they are not eating and their metabolism is increased, their protein and calorie needs will not be met.
- Hypertrophic scarring is more severe and scar maturation is prolonged.
- An immature immune system means an increased risk of infection for infants and young children.
- A delay in growth may follow extensive burns.
- In children, Curling's ulcer occurs during the third or fourth week postburn, which is later than in adults.

The goal of protective services is always to restore and to maintain the family unit if the child's safety can be ensured by close supervision by the agency.

Many burn prevention programs are taught in schools and youth groups, but nurses can implement these programs by contacting their local fire department or burn center. Public education emphasizing the importance of smoke detectors can also significantly decrease the incidence of burns. Children can be taught to evacuate the house in the event of a fire using fire drills that identify two or more exits from each room and a location for the family to meet outside the house. Other measures, such as the "stop, drop, and roll" program, can greatly decrease the severity of a burn injury. Public campaigns to educate adults to turn hot water heater thermostats down to 120 °F and to check the temperature of the water before placing a child in the bath can also reduce the number of accidental scald burns. Further educational tips should include the following:

- Caution children about touching heated radiators, space heaters, and floor furnace grates.
- Never leave a child unattended near a campfire or wood stove.
- Store all matches and lighters securely so they are inaccessible to children.
- Keep all chemicals in their original container and inaccessible to children.
- Ensure that all electrical outlets are inaccessible to young children.

Electrical Injury

Electrical injury is a major injury that not only burns tissue but often results in instant death, because the electrical current disrupts the electrical rhythm of the child's heart, causing lethal arrhythmias. A common cause is household current, whereby the child inserts a conductive object into an electrical outlet. Other sources include defective electrical equipment, direct contact with either high- or low-voltage current, and lightning strikes.

The child who does not die instantly from contact with the electrical current is at risk for four major complications during the acute phase: cardiac arrest or arrhythmia, tissue damage caused by interrupted blood flow, myoglobinuria (urinary loss of globulin from muscles), and metabolic acidosis.

Pathophysiology

Entering through the skin, an electrical current follows a path of least resistance through the body, damaging skin layers, bone, nerves, tendons, and blood vessels. The heat of the current coagulates blood vessels and leaves the affected area without a blood supply. Gangrene develops in necrotic tissue unless it is removed, often requiring amputation.

The location of the damage depends on the child's position and exposure. Electricity may enter one hand and exit from the other, for example; or it may travel through the body and exit from one or both legs. The greatest damage occurs at the entrance and exit sites.

Myoglobinuria develops when products that are found in normal muscle are released into the blood after electri-

cal injury. Myoglobin is a large molecule that mechanically obstructs the renal tubules and leads to acute tubular necrosis unless large amounts of IV fluid are administered to flush the myoglobin out of the kidney.

Metabolic acidosis follows electrical injury because of the associated cellular destruction and hypovolemic shock.

Cardiac arrest, tissue damage, myoglobinuria, or metabolic acidosis usually resolve within 24 hours after the injury. Other complications that follow electrical injury include loss of short-term memory and altered emotional states. The child can usually remember events up to the time of injury, including the names of family members and his or her address, telephone number, and personal information, but is unable to recall more recent events. This loss of memory can be distressing to the child and frustrating to the family. For example, the child may be unable to remember visits by the family and may feel abandoned by them. The child may also be unable to follow instructions because he or she is unable to retain them, and this inability may lead to difficulty with planning care. Altered emotional states may include an absence of affect and blank stares or may include the opposite type of emotional response, such as hyperactivity and feelings of paranoia. Emotional responses usually become normal after about a week, but they may persist longer in some children. The electrical injury need not be to the head for these altered states to occur.

Interdisciplinary Interventions

The immediate risk to the child is cardiac arrest or arrhythmia. If cardiac arrest occurs, standard cardiac life support measures are initiated.

Osmotic diuretics may be administered to promote increased urine volume. IV fluid is administered at a rate that maintains urine output at 2 mL/kg/hour until the myoglobinuria resolves.

Ringer's lactate contains sufficient bicarbonate to manage the acidosis that accompanies burn shock, but not enough to correct the acidosis associated with shock after electrical injury (i.e., pathophysiologic hypovolemic shock, not a "shock" from the electrical current). Thus, sodium bicarbonate is added to the IV infusion to maintain pH balance.

Community Care

Long-term sequelae to electrical injury include development of ocular cataracts and gait-pattern instability resulting from neurologic deficits and alterations in spatial orientation. Ocular cataracts may occur in one or both eyes at varying times from within 3 months to 18 months after the injury. The very young child may not notice changes in visual acuity; therefore, eye examinations should be scheduled every 3 months for the first year after the injury.

Sunburn

Sunburn, one of the most common skin injuries, results from excessive exposure to UV radiation in the sun's rays. Human skin has several defenses against UV radiation, including the stratum corneum, which absorbs some UV

rays, and melanin, which increases pigmentation in the skin and protects against UV damage. Generally, children with darker skin pigmentation do not burn as quickly as fair-skinned children. Nonetheless, any child can be sunburned with sufficient sun exposure. The greatest risk of exposure is between 10 AM and 2 PM. Of increasing concern is the use of indoor tanning beds; dermatologists have expressed concern with the lack of regulation of this industry because these products emit up to 26 times more damaging UV light than an equivalent amount of sunlight (Arndt & Hsu, 2006).

Most people receive 80% of their lifetime exposure to sun by the time they are 21 years of age.

Pathophysiology

The cutaneous photosensitivity in sunburn is a result of overexposure to UV radiation, particularly to the radiation of the UVB wavelength. The UVA wavelength can also cause burns, but does so only after much longer exposure. The epidermis reflects 10% of the UVB rays, and 20% will penetrate to the dermis. UVA penetrates deeper, markedly accentuating UVB damage (Arndt & Hsu, 2006; Bell, 2004; Zacharyczuk, 2004). The exact cause of UV radiation damage is unknown. It is thought to result from a combination of direct effects, generation of toxic oxygen species, and the production of inflammatory mediators. Most children respond to UV radiation with increased skin pigmentation (tanning). Thus, tanning is one sign of cumulative UV injury to the skin. Cutaneous cells may demonstrate these cumulative effects many years later with fine and deep wrinkling of the skin, scaly red patches, and the potential for skin cancer formation.

Acute UV radiation exposure induces erythema secondary to vasodilation and increased blood volume in the dermis. Metabolic changes within the epidermis cause the cells to change shape and morphologic makeup. Peak reactions to sunburn occur 24 hours after the initial symptoms and may last up to 72 hours.

WORLDVIEW: Approximately 15% of white children have skin that never tans. These fair-skinned children should be taught to wear sunscreen throughout the summer and to avoid direct sun exposure whenever possible.

Prognosis

The prognosis for sunburn is good, as long as the child is removed from sun exposure and receives prompt treatment. The more serious issue related to chronic sunburn is the increased risk of skin cancer. UV radiation is the primary cause of skin cancer. UV radiation also damages the connective tissue of the dermis, causing premature skin sagging and wrinkling later in life. Furthermore, chronic UV-induced damage actually causes changes in the skin's immune function. Although acute sunburn may be treated adequately, parents and older children must be taught about the aging and carcinogenic effects of chronic sun damage and overuse of tanning beds. It has been estimated that if sun protective clothing and sunscreens were used from early childhood on, then the

incidence of nonmelanoma skin cancer in adulthood would decrease by 75% to 80% (Brown, 2007).

Assessment

Sunburned skin appears tender, reddened, and possibly slightly swollen. Severe sunburn may produce tense edema, vesicles, and bullae. On the head, the most prominent areas affected include the nose, cheeks, forehead, and ear lobes. On the extremities and trunk, skin areas unprotected by clothing are most affected.

Children with sunburn may have difficulty sleeping because of their discomfort. Sunburn over large areas of the body may result in systemic symptoms such as vomiting, headache, fever, chills, and malaise. In severe cases, extensive sunburn reduces the child's ability to sweat and may contribute to collapse from heat stroke.

Nursing Diagnoses and Outcomes

In addition to the nursing diagnoses presented in Nursing Plan of Care 25–1, the following diagnoses may apply. Additional information regarding care management for the child with an acute condition can be found in Nursing Plan of Care 11–1.

Impaired tissue integrity related to reddened, tender, and swollen epidermis in response to overexposure to the sun

Outcome: Child will experience comfort and healing to areas that have been sunburned.

Health-seeking behaviors regarding sun exposure protection and prevention

Outcome: Parents and child will initiate preventive measures to protect the child's skin from excessive exposure to the sun.

Interdisciplinary Interventions

Cool water soaks or wet dressings can be used to reduce the pain and erythema of sunburn. Aspirin and indomethacin, inhibitors of prostaglandin synthesis, can modify the intense epidermal response of sunburn if given within 48 hours of exposure. Topical glucocorticosteroids can relieve pain or inflammation, but must be used with caution because they are absorbed more readily through damaged skin. When skin peeling occurs, a moisturizing cream or aloe vera gel may be applied. Jojoba oil and vitamin E are also sometimes helpful. Petroleum, butter, and other occlusive ointments may intensify the burn and should be avoided. The child also must be given plenty of cold water or a flavored sports drinks, both during physical activity in the sun and afterwards. Acetaminophen or ibuprofen will soothe the discomfort. Severe blistering requires professional care.

Community Care

The best management for sunburn is to prevent it by limiting sun exposure and using an effective sun-screening agent on exposed skin (Fig. 25–19). Skin types dictate protection needs (Arndt & Hsu, 2006; Burns et al., 2008):

- Skin type 1: Always burns, never tans. Requires sun protection factor (SPF) of 15 or greater.
- Skin type 2: Usually burns easily, tans minimally (fair skinned). Requires SPF 15.

FIGURE 25–19. Sunscreens can be used to protect the skin through absorption, reflection, and scattering of UV radiation.

- Skin type 3: Burns moderately, tans gradually (lightly pigmented, dark white). Requires SPF 8 to 10.
- Skin type 4: Burns minimally, tans readily (pigmented; for example, Mediterranean, Asian, Hispanic). Requires SPF 4.
- Skin type 5: Rarely burns, tans profusely (moderately pigmented; for example, American Indian, Hispanic, Middle Eastern). Requires SPF 4.
- Skin type 6: Never burns (darkly pigmented, black; for example, African American). No or low SPF needed.

The American Academy of Pediatrics recommends that children younger than 6 months of age should not be exposed to direct sunlight, because their sensitive skin and decreased sweating rate places them more at risk for heat stroke. If avoiding direct sunlight is not possible, dress infants in lightweight long pants, long-sleeved shirts, and brimmed hats (Zacharyczuk, 2004).

Most sunscreens contain some combination of para-aminobenzoic acid, cinnamate, salicylates, and anthralin. A broad-spectrum sunscreen that protects against both UVA and UVB radiation should be used. Products with titanium dioxide or zinc oxide tend to provide the broadest protection. Sunscreens protect the skin by absorbing, reflecting, and scattering UV radiation. The quantifiable effectiveness of the sunscreen is expressed as the “sun protection factor,” or SPF. SPF is based on the UV-absorbing properties of the active chemical ingredient in the sunscreen. SPF reflects both duration and level of protection against UVB (Bell, 2004; Zacharyczuk, 2004). For example, if a child normally burns within 15 minutes of exposure to the sun without sunscreen, use of a sunscreen with SPF 15 enables the child to stay in the sun 15 times 15 minutes or 225 minutes (3 hours 45 minutes) before achieving the same degree of erythema or burn. Reapplying the sunscreen does not prolong this time. SPF 15 sunscreen protects the child for only 225 minutes, no matter how many times it is applied during that period. Sunscreen agents that are waterproof with SPF 15 or more are recommended for children. Few data exist to show that any protection over SPF 30 renders any additional benefits (Zacharyczuk, 2004). All sunscreens should be applied 30 minutes before sun exposure, and then reapplied every 2 hours or sooner, depending on the child’s activity.

caREminder

Perhaps the most important consideration for using sunscreens effectively is not product characteristics, but proper application and use. Applying an insufficient amount can decrease a product’s SPF rating by 50%.

Instruct parents and older children on management and prevention of sunburn (Community Care 25–3). Research suggests that although most parents are fairly knowledgeable about the relation between sun exposure and skin cancer, many do not have a solid understanding of practical preventive strategies, such as how to choose the best sunscreen. Although no data from clinical trials directly indicate that sunscreens prevent skin cancer, the products continue to be a major component of a complete sun protection program (Bell, 2004). In addition, many parents use poor sun protection practices themselves, and their own habits have been found to reflect the degree of protection practiced for their children. Thus, the nurse needs to teach parents to protect themselves and serve as an example to their children. Point out that sunscreens do not protect the child’s skin from all UV radiation; even with sunscreens, tanning or burning will occur if exposure is of sufficient duration.

Cold Injury

In cold–dry and cold–wet weather, children who play outdoors are at risk for cold injury and hypothermia (Community Care 25–4). In addition, one must be aware of the effects of windchill, which can significantly lower core body temperature.

Frostnip is a superficial cold injury that causes no damage to the skin tissue. *Frostbite* may be superficial or deep and can cause significant tissue damage or even tissue death. Exposed areas of the face are at greatest risk. *Immersion foot (trench foot)* occurs in cold weather when the feet are exposed to damp or wet, poorly ventilated shoes, causing tissue maceration and infection. *Hypothermia*, defined as a core body temperature of less than 95 °F (35 °C), is discussed in more detail in Chapter 31.

Extreme cold is an external force that freezes the cells of the skin. Ice crystals may form between or within cells, interfering with the activities of the normal sodium pump. This event leads to rupture of the cell membranes. Red cells or platelets may clump at the damaged site, causing microemboli or thrombosis. Blood may be shunted from the injured area, eventually causing cell death if not treated. The offending agent is not only the cold temperature but also the rapid motion of the surrounding wind or the presence of damp, cold conditions (Petroni, Kuncir, & Asensio, 2003).

Alert! Butane and propane propellants that are widely used in spray aerosols (e.g., hair spray, air fresheners) can cause moderately severe frostbite when sprayed directly on the skin at close range. Spray aerosols are a source of a variety of injuries and should be kept safely out of reach of children. Community and family education can help prevent occurrences.

COMMUNITY CARE 25–3

Fun-in-the-Sun Safety: A Checklist

1. Choose a sunscreen that blocks both ultraviolet (UV) A and UVB radiation.
2. Choose a product that includes a sun protection factor (SPF) rating of 15 or greater.
3. Do not use sunscreens on children younger than 6 months of age. Instead, use hats, bonnets, and light-colored clothes to protect the skin, and keep the infant away from direct exposure to the sun.
4. For children older than age 2 years, choose a sunscreen product based on the child's previous history of response to sun exposure. Sun-sensitive children should not remain outdoors for a long period of time, and an SPF product of at least 30 should be used to protect them.
5. Apply the sunscreen indoors, before exposure to sun (some product labels recommend at least 30 minutes, and others recommend up to 2 hours).
6. Reapply sunscreen after bathing, swimming, or perspiring if exposure to the sun is resumed. However, reapplication does not prolong the time frame of initial protection, which is provided by the selected SPF.
7. Some sunscreen products are labeled to denote that they offer protection in special circumstances:
 - Sweat resistant: Protects for up to 30 minutes of continuous, heavy perspiration, then must be reapplied
 - Water resistant: Protects for up to 40 minutes of continuous water exposure, then must be reapplied
 - Waterproof: Protects for up to 80 minutes of continuous water exposure, then must be reapplied
8. Minimize exposure to the sun near the hour of noon.
9. Know whether any medication the child is taking causes photosensitivity.
10. Encourage children to wear lightweight, long-sleeved shirts and broad-brimmed hats during prolonged sun exposure.
11. If the child's skin feels warm, it is.
12. Take one or more of the following actions to protect the child's skin:
 - Cover the skin.
 - Apply sunscreen.
 - Remove the child from sun exposure.

COMMUNITY CARE 25–4

Preventing Cold Injury

Parents and older children, especially those living in cold climates, must be educated about the hazards of cold injury. *The best healthcare management for cold injury is prevention.*

- Children should wear several layers of clothing under appropriate outerwear garments (including two pairs of socks, mittens, and a hat that covers the ears) to ensure warmth when playing outdoors.
- Outer garments should be waterproof, insulated, and offer protection against the wind.
- Children should wear well-fitted, insulated, waterproof, nonconstricting footwear in cold weather. Clothing that contains such products as polypropylene or Gore-Tex, wool, treated polyesters, or blends of synthetic wool fibers is best.
- If the child's hands, feet, or other body parts become wet while outdoors, a change to dry clothing or footwear should be made immediately.
- Children should rub their hands together or scrunch up their face when they are feeling cold to help warm up their bodies.
- Ample food and fluid should be provided during the time of outdoor activities.
- The child's exposure to extremely cold temperatures should be monitored and supervised by an adult with timely and appropriate rewarming opportunities.
- An adult who is feeling cold can be certain that children are also feeling cold, and should bring them indoors.
- Children who participate in outdoor sports activities should be alert to the presence of numbing of body parts, particularly the nose, ears, fingers, and toes.

Susceptibility to cold injury may be increased by dehydration, fatigue, hunger, anemia, ingestion of alcohol or illicit substances, and the presence of other illnesses. Therapy for any type of cold injury should begin as soon as the injury is noticed.

Frostnip

Frostnip lesions are usually manifested as firm white patches on the face, ears, and extremities that are numb. As the body is warmed, erythema develops with no immediate blistering. Over the ensuing 24 to 72 hours, blistering and peeling may occur. The affected area may have a residual hypersensitivity to cold that lasts for several days to weeks.

Care for the child with mild frostnip primarily involves providing first aid and teaching prevention measures. The child should be removed to a warm area quickly and examined for the possibility of more serious damage.

As the affected area rewarms, it can cause a stinging sensation, which may frighten the child. Explain by comparing the situation to that of a hand or foot “falling asleep.” As the foot “wakes up,” it tingles, almost to the point of hurting, but the feeling soon goes away.

Frostbite

Frostbite is the acute freezing of tissues when exposed to temperatures below the freezing point of intact skin. The severity of injury is related both the temperature at the skin surface and to the duration of exposure. Frostbite first develops as an initial erythema of the skin, which progresses to cold, hard, white, waxlike areas, commonly at the ears, fingers, and toes. The skin sensation of cold progresses from numbness or warmth followed by a burning feeling. This initial response to tissue cooling by alternating cycles of vasoconstriction and vasodilation is referred to as the *hunting reaction* (Murphy et al., 2000). Vasodilation reestablishes blood flow and, thus, thawing; this partial thawing and refreezing causes the most damage. Eventually, the joints and extremities are immobilized, and a progressive thrombotic phase occurs. If tissue damage is severe enough, even prompt management will not avert amputation of the damaged area.

When frostbite becomes more involved, it requires more aggressive therapy. The three levels of treatment include the following:

1. Mild hypothermia: Passive external warming. Wet clothing removed; patient covered with blankets or other forms of insulation
2. Mild to moderate hypothermia: Active external warming. Use warm blankets, heating pads, radiant heat, forced warm air, or warm baths. (A risk of this process is core temperature afterdrop. When the extremities and trunk are warmed simultaneously, cold acidic blood, which has pooled in the vasoconstricted extremities, returns to the core and causes temperature and pH to decrease. At the same time, removal from the cold environment results in peripheral vasodilation, potentially contributing to hypotension, inadequate coronary perfusion, and even ventricular fibrillation. For patients

suffering from this degree of hypothermia, the trunk should be warmed initially, and then the extremities.) Also be aware of the potential for surface burns.

3. Severe hypothermia: Active internal rewarming; intubation with warmed oxygen, continuous arteriovenous or venovenous rewarming, hemodialysis, and cardiopulmonary bypass (Murphy et al., 2000)

caREminder

Assess for core temperature afterdrop, a condition that occurs as peripheral vasoconstriction is reversed and blood is circulated through cold extremities, returning cold blood to the core.

Rubbing a frostbitten area may cause further damage. While the child is being transported to an acute care facility or clinic, the affected area can be warmed against an unaffected hand, abdomen, or axilla area. Dry heat should not be applied; rather, the affected area should be bathed in warm water (approximately 104–107.6 °F [40–42 °C]). A return of pink color should be observed. Blisters may develop on the affected area after thawing is initiated. The extremity should be kept elevated to avoid swelling, and the affected area should be wrapped aseptically to avoid secondary infection. Anesthetics may be necessary if painful swelling occurs. Vasodilating agents such as reserpine or oxpentifylline may be administered to patients who have not been rapidly rewarmed, but the data are still not conclusive (Murphy et al., 2000).

Prognosis can be very good, especially if secondary infection does not occur. Amputating tissue may be necessary, however, in the absence of vascular improvement.

Immersion Foot (Trench Foot)

When the feet, covered by poorly ventilated shoes, become damp or wet in cold weather, the extremity can become cold and numb. The foot becomes pale, edematous, and clammy. Tissue maceration and infection can occur, as can long-term hypersensitivity to temperature changes. As soon as the child's feet (or shoes) are known to be wet, the child's footwear should be changed. Treatment includes drying the skin, keeping the area well ventilated, and preventing or treating infection.

DISORDERS OF THE HAIR AND NAILS

Disorders of the hair and nails may result from such diverse causes as growth pattern disturbances, hereditary variances, disease, nutritional deficits, or trauma. A hair or nail problem is rarely the primary reason for a child to seek healthcare; rather, the problem is usually discovered by an astute nurse during routine or focused assessment.

Hair Disorders

Inspect the hair for distribution, color, texture, amount, and quality. Hair color changes in response to certain

TABLE 25-9

Disorders of the Hair

Disorder	Definition
Hypertrichosis	Excessive hair growth in inappropriate locations
Hirsutism	Male-type secondary sexual hair growth in the female
Hypotrichosis	Deficient hair growth
Alopecia	Partial or complete hair loss, which may be hereditary or acquired, diffuse or patchy, scarring or nonscarring
Occipital alopecia of the newborn	Hair loss on the occipital area of the scalp resulting from friction between the child's head and, for example, a mattress or sheets
Telogen effluvium	Loss of scalp hair resulting from the premature conversion of hair loss in <ul style="list-style-type: none"> • The newborn during the first few years of life • Postpartum women • After an acute febrile illness • After discontinuation of oral contraceptives
Congenital circumscribed alopecia	Localized areas of hair loss present at birth, usually overlying a birthmark or a sebaceous or epidermal nevus
Friction alopecia	Patchy hair loss caused by a variety of hairstyles: ponytails, curlers, rollers, tight braids
Toxic alopecia	Hair loss as a side effect of radiation therapy and certain drugs, such as chemotherapeutic agents
Trichotillomania	Hair loss with broken hairs resulting from the habit of pulling or twisting the hair
Alopecia areata	Rapid and complete loss of hair in round or oval patches on the scalp; cause unknown; 20% of patients have family history of the illness; increased incidence in patients with Down syndrome
Trichorrhexis nodosa	Structural defect that appears as a node or swelling on the hair shaft; defect caused by a fracture of the hair shaft with derangement of the cells in the cortex
Monilethrix	Autosomal dominant hair shaft defect in which the hair appears dry, lusterless, and brittle and fractures spontaneously or with mild trauma; affects eyebrows, lashes, body, and sexual hair; spontaneous improvement may occur at puberty
Trichorrhexis invaginata (bamboo hair)	Feature of Netherton's syndrome; hair is dry, fragile with no apparent growth; thought to result from a transient defect in keratinization; hair growth may improve significantly at puberty
Trichoschisis	Hair shaft defect in which affected children have brittle hair; hair shaft is actually fractured
Pili torti	Autosomal dominant condition in which a structural defect of the hair shaft causes it to be twisted on its own axis; hair is normal at birth, but is replaced by abnormal hair that becomes evident between ages 2 and 3 years; affected hairs have a spangled appearance, are fragile, and are often ash blonde in color
Pili annulati	Ringed hair that is characterized by hair shafts banded with bright rings when viewed in reflected light, not fragile; can be a familial or a sporadic defect
Woolly hair disease	Tightly curled, abnormal hair seen at birth; may occur as autosomal dominant condition in which most other hair is normal, as an autosomal recessive condition in which all hair is affected and appears short and pale, or in sporadic form (woolly hair nevus) in which localized areas of the scalp are affected
Menkes kinky hair syndrome	X-linked recessive disorder in which twisting of the hair is a result of a copper deficiency
Pityriasis amiantacea	Thick mat of scale on the scalp; reaction pattern of the scalp to inflammation, infection, or trauma
Tinea capitis	Fungal infection of the scalp caused by <i>Microsporum canis</i> or <i>Trichophyton tonsurans</i> ; thick, white, scaling, broken hairs and areas of alopecia

TABLE 25-10

Nail Abnormalities

Name	Definition
Anonychia	Absence of the nail plate
Koilonychia	Flattening and concavity of the nail plate with loss of normal contour
Macronychia	Abnormally large nail
Micronychia	Unusually small nail
Leukonychia	White opacity of the nail plate, which may involve the entire nail plate, may be punctuated, or may be striated; can be the result of trauma, infection, dermatosis, malnutrition, anemia, heavy metal poisoning, or a benign hereditary defect
Onychogryposis	Acquired nail defect in which the nail plate is thick, overgrown, and distorted
Onycholysis	Separation of the nail plate from the nail bed resulting from trauma, psoriasis, fungal infection, contact dermatitis, porphyria, drugs, or drug-induced phototoxicity
Beau lines	Transverse grooves in the nail plate that represent an inability of the nail matrix to produce a nail plate of normal thickness as a result of periodic trauma or secondary to systemic disease
Yellow nail syndrome	Yellow nail, slow to grow; associated with congenital abnormalities of the lymphatic vessels and chylothorax
Pachyonychia congenita	Autosomal dominant disorder characterized by gross nail thickening
Pigmented nevi of the nail	Longitudinal band of pigment in the nail plate that is common in dark-skinned individuals
Lichen planus	Common longitudinal ridging of the nail plate; nail thinning and pterygium formation may occur
Twenty nail dystrophy	Characterized by longitudinal ridging, fragility, distal notching, and opalescent discoloration of all the nails; tends to be self-limiting and reversible; eventually affects all 20 nails
Paronychia	Acute infection of the nail fold, which can be very painful, and is seen commonly in thumb or finger suckers; usually caused by staphylococcal, streptococcal, or pseudomonas infections; usually requires removal of the nail bed
Herpetic whitlow	Primary infection of the nail fold with herpes simplex
Ingrown toenail	Caused by incorrect cutting of toenail or ill-fitting footwear; produces pain, bacterial paronychia, and overgrowth of granulation tissue around the soft, pliable nail plate

dietary changes, ingested substances, or disease processes. For instance, kwashiorkor and zinc deficiencies can cause depigmented hair. Ingesting copper can turn the hair green, and ingesting cobalt can turn the hair blue. Discoloration can also be caused by the dithranol therapy for treatment of psoriasis. Premature graying (before age 20) can be an early sign of pernicious anemia or thrombosis.

Delayed or absent hair growth may indicate an ectodermal dysplasia. Alopecia (loss of hair) may occur for various reasons, including hair pulling, tinea capitis, and the use of chemotherapeutic agents. Hair disorders, including alopecia and structural anomalies of the hair shafts, are briefly described in Table 25-9. In most cases, disorders of the hair can be corrected by addressing or treating the underlying cause.

Nail Disorders

Disorders of the nails can cause changes in normal nail color, shape, texture, and size. Inspect the nails for these changes and for the presence of nail biting, skin picking, and infection. Nails can become discolored from antimalarial agents and certain other drugs, bacterial or fungal infections, and skin disorders such as alopecia areata, lichen planus, and psoriasis. Nail discoloration can also occur secondary to a systemic problem such as jaundice or cyanosis. Clubbing of nails may indicate chronic respiratory or cardiac disease. The curve of the nail in a convex or concave fashion may simply be hereditary or indicate injury, iron deficiency, or infection. Nail abnormalities in children that may reflect generalized skin diseases, systemic disease, bacterial or fungal infections, or trauma are reviewed in Table 25-10.

The Child With Altered Endocrine Status

Case History

Remember Lindsay Jenkins from Chapters 2 and 12? Lindsay was first diagnosed with type 1 diabetes when she was 6 years old. Right before Thanksgiving, her parents noticed that she seemed very thirsty and often would leave the dinner table to use the bathroom, but she did not seem sick. She had the energy of a normal 6-year-old. On Thanksgiving day, Lindsay romped with her cousins, although she was still very thirsty and her aunts commented on how thin Lindsay looked. The next day Lindsay vomited and her parents decided to take her to the doctor. Their pediatrician tested her urine for glucose and ketones, and within 5 minutes she was diagnosed with type 1 diabetes. He told them they would need to go to the hospital. Lindsay's initial blood sugar was more than 500 mg/dL. Lindsay and her family were in the hospital for 3 days to regulate Lindsay's glucose level and to teach Lindsay's parents the basic skills of diabetes care.

Lindsay was discharged home on three insulin injections each day. Initially, Lindsay's parents drew up her insulin and gave her injections. Lindsay gave herself her first injection with a syringe when she was at diabetes camp at age 7; she had learned to draw up her own insulin by age 8. Her parents always supervised her during this process. She checks her blood sugar before breakfast, midmorning, before lunch, before her afternoon snack, before dinner, and at bedtime. Her dad checks her at midnight and her mom

checks her at 3:00 AM if she has had a really active day. Lindsay uses an insulin pen of rapid-acting insulin at school, which greatly reduces the risk of an incorrect dosage.

Lindsay is now 8 years old and has reached an important milestone. For the past 3 months she has been proving to her pediatric endocrinologist that she is ready for an insulin pump. Lindsay has been counting her carbohydrates and giving herself five shots a day of rapid-acting insulin to cover meals and snacks, and to mimic the manner in which the insulin pump will work. Lindsay has been wearing the pump with just a saline solution in it this week to prepare her for wearing the pump. The night before, to prepare for the pump start in the morning, Lindsay does not give herself the long-acting insulin. The next day, Lindsay checks her blood sugar, injects her morning rapid-acting insulin, eats breakfast, and heads off to the endocrinologist's office with her parents. The pump is started that morning right after breakfast. Lindsay's parents will write down all of her blood sugars and pump settings, and fax them to the diabetes nurse educator daily for a couple of weeks. Their goal is to keep her blood sugars within a targeted range of 70 to 140 mg/dL. Over time, their control improves and they are closer to the desired range of blood glucose. The nurse who works for the manufacturer of her insulin pump is coming to Lindsay's school to talk to the health technician and the school nurse about her new insulin pump.

CHAPTER OBJECTIVES

1. Describe the functions of the endocrine system.
2. Describe the symptoms associated with disorders of each endocrine gland.
3. Identify diagnostic tests used to assess the disorders associated with each endocrine gland.
4. Describe the interdisciplinary interventions unique to selected endocrine disorders, including the role of the nurse in managing the child's care.
5. Describe the educational plan for a child with a newly diagnosed endocrine disorder that encompasses both acute healthcare needs and long-term home management needs.

See [thePoint](#) for a list of Key Terms.

The endocrine system is a network of glands that work in parallel with the nervous system to regulate growth, development and homeostasis. The glands of the endocrine system include the pineal, hypothalamus, pituitary, thymus, thyroid, parathyroid, adrenals, pancreas, and ovaries or testes. Endocrine glands secrete **hormones** directly into the bloodstream. Hormones are chemical messengers that exert physiologic effects on target cells in other endocrine glands, organs, or tissues. Thus, hormones transfer information and instructions from one set of cells to another set of cells that are genetically programmed to receive the message. Increased or decreased hormone levels are influenced by factors such as stress, infection, and changes in the balance of fluid and minerals in blood.

Endocrine function is regulated largely by negative feedback. One endocrine gland produces a hormone (tropic hormone) that affects another endocrine gland (the target organ). In response, the target gland produces a hormone that inhibits the release of tropic hormone. The reverse is seen when the stimulating endocrine gland detects low levels of target gland hormone. In that case, tropic hormone secretion increases, which causes increased secretion of the target gland hormone. For example, the pituitary gland (hypophysis or master gland) controls the release of at least seven different hormones, including thyroid-stimulating hormone (TSH). This pituitary tropic hormone stimulates the thyroid gland (target gland) to release thyroxine (T_4) and triiodothyronine (T_3) (target gland hormones). Elevated levels of these hormones then, in turn, inhibit secretion of TSH, the tropic hormone.

Endocrine disorders are mainly of two types: hypofunction and hyperfunction. **Hypofunction** causes deficient target hormone secretion, and **hyperfunction** causes excessive target hormone secretion. Normal levels of hormones vary widely, and this range may overlap deficient and excessive hormonal blood levels. Analysis of hormones at various times may be necessary to establish glandular hypofunction or hyperfunction. Endocrine gland dysfunction may be attributable to disease of the

gland itself (primary defect) or to increased or decreased secretion of its tropic hormone (secondary defect). A summary of the endocrine glands and their hormones is given in Table 26–1.

DEVELOPMENTAL AND BIOLOGIC VARIANCES

The endocrine glands are all present at birth; however, endocrine functions are immature. As these functions mature and become stabilized during the childhood years, alterations in endocrine function become more apparent. Thus, endocrine disorders may arise at any time during childhood development (Fig. 26–1). The endocrine disorders most prevalent in infancy are those that are congenital: hypopituitarism, congenital hypothyroidism, congenital adrenal hyperplasia (CAH), aplasia of the parathyroid glands, and nesidioblastosis. Although disorders of the pancreas are less common in infancy, hyperinsulinism and insulin-dependent diabetes occur. Poor feeding, irritability, and poor growth (weight, length) may all be indicators that an infant has an endocrine disorder.

Growth disorders may begin in the early childhood. Children who are walking are now compared with their peers in height, and discrepancies become evident. In middle childhood, the youth may present with a growth disorder or with signs of early puberty. During routine school health assessments, they may be measured in the school health setting or in the physician's office during routine visits. School-based health settings should refer children with perceived growth issues back to their primary care providers for evaluation.

Many endocrine disorders are detected during adolescence because of early pubertal onset or a delay in pubertal onset (see Chapter 3). Normal female adolescents begin pubertal development with development of breasts, growth of pubic and axillary hair, and **menarche** (the start of menstruation). In males, enlargement of the testes and growth of pubic and axillary hair begin (see Figs. 3–16 and 3–17 for a review of pubertal staging). Girls with irregular menses may present to the primary care provider, gynecologist, or endocrinologist. A variety of autoimmune endocrine disorders may appear during this stage in development, including Hashimoto's thyroiditis, Graves' disease, autoimmune hypoparathyroidism, Addison's disease, and type 1 diabetes. With the exception of type 1 diabetes, autoimmune disorders rarely occur before adolescence.

ASSESSMENT OF THE CHILD WITH ALTERED ENDOCRINE STATUS

Because the endocrine system varies greatly in its structures and functions, each gland requires its own specific assessment. The embryology, physiology, assessment, and disorders of each gland are discussed specifically and separately in this chapter.

TABLE 26 – 1**Hormones and Their Actions**

Gland and Hormone	Major Target Organ	Effect
Pituitary, Anterior		
Growth hormone (GH)	Bones, muscles, organs	Promotes growth of bone soft tissue. Increases gastrointestinal absorption of calcium, reduces sodium and potassium excretion, raises plasma phosphate levels. Mobilizes free fatty acids from adipose tissue. Induces hyperglycemia. Stimulates milk secretion.
Thyroid-stimulating hormone (TSH)	Thyroid	Increases iodine uptake and iodide clearance from plasma. Promotes growth of the thyroid. Stimulates release of thyroid hormone from thyroid.
Prolactin	Breasts	Initiates and maintains lactation. Stimulates the formation and function of the corpus luteum.
Adrenocorticotropin (ACTH)	Adrenal cortex	Stimulates release of cortisol from the adrenal.
Melanocyte-stimulating hormone (MSH)	Skin	Promotes skin pigmentation.
Follicle stimulating hormone (FSH)	Ovary (female) Testis (male)	Stimulates ovarian follicle growth and oogenesis. Stimulates the activity of the seminiferous epithelium. Controls spermatogenesis.
Luteinizing hormone (LH)	Ovary and corpus luteum (female)	Aids in maturation in ovarian follicles. Causes ovulation in the mature ovum. Causes formation of the corpus luteum. Stimulates progesterone secretion by the corpus luteum.
	Testis (male)	Stimulates Leydig cells of the testes to produce testosterone.
Pituitary, Posterior		
Antidiuretic hormone (ADH)	Renal tubules	Increases kidney tubule permeability thus increasing water reabsorption.
Oxytocin	Uterus, mammary glands	Stimulates contraction of smooth muscles of the uterus. Causes compression of the alveoli of the mammary glands (milk letdown reflex).
Thyroid		
Thyroxine (T ₄) and triiodothyronine (T ₃)	All tissues	Accelerates cell metabolism. Works with growth hormone to stimulate growth (very essential to development of nervous tissue). Increases glucose uptake by cells. Increases rate of cholesterol removal by liver.
Calcitonin	Bone and renal tubules	Lowers serum levels of calcium and phosphorus; decreases kidney excretion of calcium and phosphorus. Increases calcium and phosphorus deposition in bone.
Parathyroid		
Parathyroid hormone (PTH)	Gastrointestinal tract, bone, renal proximal tubules	Increases absorption of calcium, phosphorus, and magnesium from the intestine. Promotes reabsorption of bony tissue and release of calcium into the bloodstream.
Adrenal Glands, Cortex		
Aldosterone	Primarily renal distal tubules	Increases the reabsorption of sodium from distal tubule of the kidney. Promotes water retention and potassium loss.

TABLE 26 – 1

Hormones and Their Actions (Continued)

Gland and Hormone	Major Target Organ	Effect
Cortisol	All tissues	Increases protein catabolism, gluconeogenesis, and glycogenesis. Is antagonistic to insulin and androgens. Aids in erythrocyte formation and in maintenance of normal brain activity.
Androgens	Many tissues, especially gonads and muscles	Increases retention of nitrogen, potassium, phosphorus, and sulfur. Promotes growth and the development of male secondary sex characteristics. Promotes axillary and pubic hair development in females.
Adrenal Glands, Medulla		
Norepinephrine	Adrenergic receptors	Increases rate and strength of heart activity. Dilates coronary vessels; constricts vessels in other organs (increases blood pressure). Stimulates alertness. Mobilizes fatty acids from storage areas.
Epinephrine	Heart, liver, lungs, brain, kidneys, and arteries	Dilates vessels to skeletal muscle. Stimulates glycogenesis.
Pancreas Islets of Langerhans		
Insulin	Liver, muscle, adipose tissue	Increases glucose uptake by cells. Stimulates the conversion of glucose to glycogen. Promotes fatty acids and amino acid transport into cells. Promotes lipogenesis and protein synthesis.
Glucagon	Liver	Increases glycogenesis in the liver, thereby increasing blood glucose.
Somatostatin	Alpha and beta cells in pancreas	Inhibits insulin and glucagon release.
Ovaries		
Estrogen	Uterus, breasts, and bone	Causes initial stages of uterine regrowth during menstrual cycles. Increases mammary duct growth. Stimulates contraction of the uterus and uterine tubes. Promotes development of female secondary sex characteristics. Accelerates epiphyseal closure. Increases fat deposition in subcutaneous tissues. Causes salt and water retention.
Progesterone	Uterus	Prepares the uterus for implantation of fertilized ovum. Develops the secretory potential of the mammary gland. Increases basal body temperature. Promotes retention of salt and water.
Relaxin	Pelvis	Softens pelvic ligaments before labor. Creates sleepiness during pregnancy.
Testes		
Testosterone	Spermatogenic tubules, penis, bone, and many other tissues	Ensures development of the male reproductive organs. Promotes development of secondary sex characteristics. Increases protein anabolism and calcium retention. Increases rate of bone growth and epiphyseal closure.

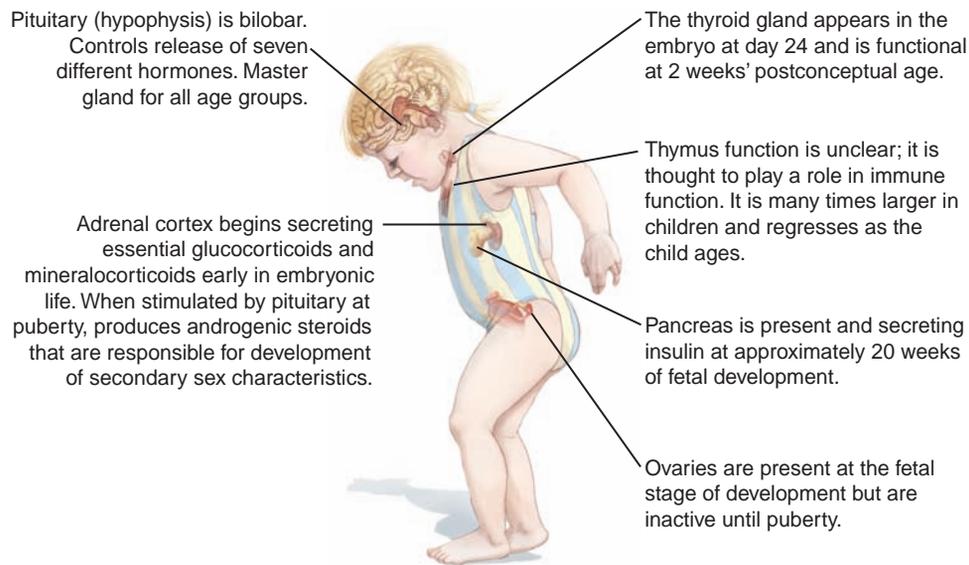

FIGURE 26–1. Developmental and biologic variances: endocrine.

Focused Health History

QUESTION: Review Focused Health History 26–1. What are the aspects of the case study that contain pertinent information for Lindsay's focused health history?

Endocrine disorders are not generally suspected as a primary clinical condition when a child presents with complaints of gastrointestinal, neurologic, or musculoskeletal problems in an outpatient setting. The serious nature of endocrine conditions means that most children are likely to present in the emergency department with severe metabolic distress. However, because endocrine dysfunction can affect all aspects of the child's growth, development, and physiologic functions, the healthcare provider must always keep a high index of suspicion for the possibility of endocrine dysfunction, especially in cases in which no other acute condition appears to be present.

Endocrine disorders often cause changes in normal growth and activity patterns. Good records of general health assessment, including serial recording of growth parameters using Centers for Disease Control and Prevention (CDC) growth charts, are especially helpful in making a diagnosis of endocrine dysfunction (Focused Health History 26–1).

Most general health assessment records in primary care settings include the child's height and weight, plotting growth parameters against norms. Correct measuring techniques must be used to complete these linear measurements (Tradition or Science 26–1). Parents' memories are often foggy and incomplete, but careful and thorough questioning by clinicians, and family photographs of the child at various developmental ages, can help pinpoint the origin and timing of problems with presenting symptoms. In addition, symptoms can be localized to individual glandular dysfunction more easily. Neonatal growth

parameters, including weight, length, head and chest circumferences, and appearance at birth, are also useful to know when reconstructing a health history focused on possible endocrine dysfunction. When an endocrine dysfunction is suspected, primary care providers should seek the assistance of pediatric endocrinologists for diagnosis and further recommendations for treatment. Endocrinologists can also work as a team with the primary care provider to provide guidance for health surveillance throughout the child's growth and development.

ANSWER: Critical information in Lindsay's case study includes sudden onset of symptoms, increased thirst, increased voiding, slight and gradual weight loss, and one incidence of vomiting.

Focused Physical Assessment

QUESTION: If you were to conduct a head-to-toe physical assessment of Lindsay at age 8 after she obtained her pump, what physical signs do you anticipate finding?

Dysfunctions of the endocrine system can result in a variety of physical changes because of the influence that circulating hormones have on growth and development, fluid and electrolyte balance, use of nutrients, and regulation of sex hormone levels. To pinpoint the exact systems affected by the dysfunction and thereby more accurately determine the actual endocrine disorder, perform a systematic physical assessment (see Chapter 8). Inspection, palpation, and auscultation reveal specific findings that indicate certain conditions (Focused Physical Assessment 26–1).

FOCUSED HEALTH HISTORY 26–1

The Child With Altered Endocrine Status*

Current history	<ul style="list-style-type: none"> Gradual versus sudden onset of symptoms Changes in child's lifestyle because of symptoms Changes in the child's physical appearance or general affect Recent changes in growth velocity or weight gain or loss Changes in sleep patterns Changes in appetite or thirst, food preferences Changes in vision Changes in voiding or stool patterns All medications the child is currently taking (prescribed, over the counter, or home remedies)
Past medical history	<p>Prenatal/Neonatal History</p> <ul style="list-style-type: none"> Birth history Results of neonatal screening tests Feeding difficulties noted at birth and during infancy Child's size at birth Maternal factors that may have affected weight and height of growing fetus (e.g., tobacco or alcohol use) <p>Previous Health Challenges</p> <ul style="list-style-type: none"> Treatment in the past for the current problems or symptoms Recent minor illness such as gastroenteritis or a viral syndrome Current immunization status Any allergies to medications, food products, milk, or formula products Exposure to exogenous steroids or gonadotropins
Nutritional assessment	<ul style="list-style-type: none"> Recent change in diet, food intake Unusual hunger or thirst Recent weight loss or gain Current intake, usual intake
Family medical history	<ul style="list-style-type: none"> Family history of any endocrine disorders (e.g., thyroid disorders, diabetes mellitus) Family members who have had growth or development difficulties (e.g., very short or very tall)
Social and environmental history	<ul style="list-style-type: none"> Normal daily activities Activity level (note fatigue vs. hyperactivity) Family resources to maintain a healthy diet, purchase needed medications, continue with consistent healthcare follow-up
Growth and development	<ul style="list-style-type: none"> Growth and development plotted on height and weight growth curves Achievement of age-appropriate developmental tasks Presence of learning disabilities or cognitive delays

*This history is focused on the endocrine system. See Chapter 8 for a comprehensive format.

Inspect the child's general appearance for abnormalities of facial structures and features; alterations in the appearance of the skin and hair; and the presence of abnormal, premature, or late secondary sex characteristics. Evaluate the child's size for his or her age.

Further evaluation of the child's respiratory, cardiac, gastrointestinal, and urinary functions is likely to reveal dysfunctions consistent with specific endocrine disorders. Serial serum hormone assays are performed for most endocrine conditions, and blood levels of these hormones often pinpoint the problems.

ANSWER: There are very few physical signs of diabetes. The presence of the insulin pump is the most obvious. On her abdomen or hips you can see small punctures at the previous insulin pump insertion sites. The insertion sites take a long time to fade and there may be as many as 10 old ones visible at any time. Her fingertips are calloused on both sides from multiple finger sticks; otherwise, her physical assessment reveals no clues to her diabetes.

TRADITION OR SCIENCE 26–1

Can nurses use strategies to ensure better accuracy of linear measurements?

EVIDENCE-BASED PRACTICE

Accurate measurements are essential for early detection of growth disorders in children, yet measuring linear growth is technically a difficult task (see Chapter 8 for measurement methods). A multisite study by Hench et al. (2005) used a didactic education program to teach appropriate linear measurement techniques to nursing staff. In 3- and 6-month follow-up evaluations, the treatment group (those who received education) showed significant improvement in accurately completing linear measures compared with the control group (no educational intervention). The educational background of the measurer was also found to be associated with accurate measurement, with registered nurses 1.8 times more likely than licensed practical nurses or nurses' aides to measure children using correct technique. The investigators demonstrated that correct technique and accurate measurement equipment are essential to ensure that a child's growth is monitored correctly.

Diagnostic Criteria for Evaluating Alterations in Endocrine Status

As with a focused physical assessment, no specific diagnostic criteria exist for general health challenges to the endocrine system. Tests and Procedures 26–1 for evaluating endocrine status summarizes the hormones of the endocrine system and the diagnostic tests used to determine whether the presenting symptoms are endocrine related or of some other clinical origin.

TREATMENT MODALITIES

QUESTION: Briefly, what are the treatment modalities for type 1 diabetes?

Treatment modalities replace or block the hormonal hypofunction or hyperfunction that occurs in the child's body. They are calculated based on the child's own serum blood levels of the hormones in question and on the child's physical appearance (e.g., short stature or premature development of secondary sex characteristics). Treatment options may involve surgical removal of a gland or portion of a gland that is oversecreting a hormone. If a tumor is causing endocrine dysfunction, surgical removal of the tumor is required. Many endocrine conditions require dietary modifications to manage the child's condition. Nursing Interventions 26–1 provides examples of endocrine conditions and their associated dietary management.

Treating most pediatric endocrine conditions requires the expertise of a team that is well versed in handling

numerous cases—the child's ability to reach full growth and development hangs in the balance. With input from the endocrinology team, maximal growth potential can be realized. Normal well-child healthcare and appropriate surveillance of the endocrinologic issue may be administered by a primary care clinician, with oversight by the pediatric endocrine team.

ANSWER: The treatment for type 1 diabetes is to replace the insulin, which enables glucose uptake to the cells and maintains a desired range of serum glucose.

NURSING PLAN OF CARE FOR THE CHILD WITH ALTERED ENDOCRINE STATUS

QUESTION: Which of the general nursing diagnoses found in Nursing Plan of Care 26–1 are most applicable to a family whose child has type 1 diabetes?

Fortunately, with modern science and pharmacotherapy, most endocrine dysfunctions can be treated. Although the child with an endocrine condition and his or her family may have to manage the problem on a long-term basis, the outcomes of management are generally successful when treatment regimens are carefully followed. General nursing diagnoses for a child experiencing health challenges with the endocrine system are presented in Nursing Plan of Care 26–1. In addition, Nursing Plan of Care 12–1 provides additional diagnoses addressing family issues and home management concerns for the child with a chronic condition.

ANSWER: Nursing Diagnosis: Risk for ineffective therapeutic regimen management is applicable for every family with a child with type 1 diabetes.

ALTERATIONS IN ENDOCRINE STATUS

Alterations in endocrine status can be categorized as disorders of the pituitary gland, alterations in the thyroid gland, alterations in parathyroid function, disorders of the pancreas, alterations in function of the adrenal glands, and gonadal disorders.

DISORDERS OF THE PITUITARY GLAND

Disorders of the pituitary gland depend on the location of the physiologic abnormality. The posterior lobe is called the *neurohypophysis* because it is formed of neural tissue. It secretes antidiuretic hormone (ADH; vasopressin) and oxytocin. The anterior pituitary, or *adenohypophysis*, is made up of endocrine glandular tissue and secretes growth

FOCUSED PHYSICAL ASSESSMENT 26–1

Endocrine System

Assessment Parameter	Alterations/Possible Clinical Significance
General appearance	Abnormal growth velocity (i.e., too short or tall/large): hypopituitarism, pituitary disorders Weight loss: pancreatic, thyroid and adrenal disorders Weight gain or obesity: thyroid disorders, syndrome of inappropriate antidiuretic hormone (SIADH)
Integumentary system (skin, hair, nails)	Cold intolerance or cold extremities: hypothyroidism Change in color or texture: pituitary, adrenal and thyroid disorders, Cushing's syndrome Easy bruising and striae: Cushing's syndrome Sweating: thyroid disorders
Head and neck	Enlargement in anterior neck: goiter Brittle hair: hypothyroidism Hirsutism (excessive growth of hair): cortisol or androgen excesses
Eyes	Changes in vision: pituitary tumor, pancreatic disorders, precocious puberty
Face, nose, and oral cavity	Rounded face: Cushing's syndrome Deformities or abnormal features: hypoparathyroidism, hypothyroidism Delay in dentition: hypocalcemia, hypopituitarism
Thorax and lungs	Fruity odor to breath: ketoacidosis Kussmaul respirations: type 1 diabetes
Cardiovascular system	Palpitations: thyroid disorders Tachycardia: hyperthyroidism Hypertension: Cushing's syndrome
Gastrointestinal system	Nausea: parathyroid disorders, type 1 diabetes Vomiting: parathyroid disorders, diabetes insipidus Changes in bowel habits (constipation or diarrhea): thyroid and parathyroid disorders, type 1 diabetes Polydipsia: diabetes insipidus, type 1 or type 2 diabetes Dehydration: SIADH, type 1 diabetes
Musculoskeletal system	Muscle weakness or lethargy: SIADH, hypothyroidism, parathyroid disorders, hyperinsulinism, congenital adrenal hyperplasia (CAH) Hyperactivity: hyperthyroidism Pathologic bone fractures: adrenal disorders Gait disturbances: hyperparathyroidism Diminished deep tendon reflexes: hypercalcemia, parathyroid Hyperflexia/twitching: hypocalcemia, parathyroid disorders
Neurologic system	Confusion: parathyroid disorders Increased irritability/behavioral changes: diabetes insipidus, SIADH, precocious puberty Headaches: type 1 or 2 diabetes, adrenal insufficiency, Cushing's syndrome Changes in sleep patterns: pituitary disorders
Genitourinary system	Polyuria: pancreatic disorders, type 1 or type 2 diabetes, diabetes insipidus, parathyroid disorders Hematuria: parathyroid disorders
Genitalia	Onset, timing, deviation of menses: gonadal and thyroid disorders Testicular mass or pain: gonadal disorders Small genitalia: hypopituitarism Ambiguous genitalia: CAH Presence of early pubertal changes or abnormal pubertal changes: precocious puberty, premature thelarche, gynecomastia Delayed pubertal changes: delayed puberty, adrenal insufficiency

hormone (GH), adrenocorticotropic hormone (ACTH), TSH, follicle-stimulating hormone (FSH), luteinizing hormone (LH), and prolactin. Usually, several target organs are affected when there is a disorder of the pituitary

gland, especially the adeno-hypophysis. Specific disorders are discussed with respect to their anatomic locations of origin and the effects of hyperfunction and hypofunction on target organs and the child as a whole.

Tests and Procedures 26 – 1 Evaluating Endocrine Status

Test or Procedure	Purpose	Finding and Indications	Healthcare Provider Considerations
Blood Tests			
Serum chemistries (blood urea nitrogen, creatinine, electrolytes, glucose)	Evaluates fluid and electrolyte status in presence of endocrine disorder.	Elevated levels indicative of renal involvement, diabetes insipidus and other endocrine conditions.	Sodium can be decreased with polyuria or urinary-concentrating defects.
Random hormone blood levels	Assesses function of endocrine glands.	High levels indicate hyperfunction. Low levels indicate hypofunction.	Lab work can be drawn at the same time as other serum chemistries to help decrease number of times child has to experience a needle stick.
Stimulation studies	Stimulate the hypothalamic–pituitary axis with drug to evaluate hormone secretion. Assess growth hormone level.	Low levels indicate hormone deficiency.	Advise parents to keep child NPO. Explain procedure to child. Establish venous access. Obtain blood samples at precise times.
Urine Tests			
Urinalysis	Assesses for glucosuria, ketonuria, concentration of electrolytes such as sodium, urine osmolality, highly concentrated urine or dilute urine.	May indicate diabetes, ketonuria, syndrome of inappropriate antidiuretic hormone secretion, or diabetes insipidus.	Describe procedure to child. Attach urine bag to a child who is not toilet trained.
Fluid deprivation study	Evaluates the effect of fluid restriction on urine concentration, specific gravity, and urine volume. Monitors serum sodium and osmolality.	Concentration of urine more than 600 mOsm/kg is a normal response. Concentration of urine plasma (>300 mOsm/kg) and signs of dehydration are an abnormal response indicating diabetes insipidus.	Do not perform this test in children as an overnight study, because severe dehydration may occur, leading to CNS damage. Monitor input and output carefully. Assess vital signs every hour (blood pressure and pulse). Measure urine specific gravity and osmolality with each void. Obtain serum specimens for sodium, ADH, hematocrit, and osmolality. Monitor the child's weight closely (twice daily in some). Terminate the test and give desmopressin (DDAVP) if the patient loses more than 3% of the baseline body weight or if tachycardia and substantial hypotension occur.
Other Tests			
Radiography	Compare radiographs of the left hand and wrist against standards for age to determine bone age.	Delayed maturation indicates growth will continue for a longer time than normal.	Radiography is easily available and an inexpensive testing method.

Test or Procedure	Purpose	Finding and Indications	Healthcare Provider Considerations
	Evaluate skeletal maturation.	Accelerated maturation indicates growth will continue for a shorter time than normal. Skeletal age is more advanced than chronologic age in precocious puberty.	Inform child and parents that the child will need to be positioned properly.
Computed tomography	Evaluates and diagnoses a large number of clinical conditions with radiographs taken at multiple angles of the body to provide cross-sectional anatomic display.	Abnormalities visualized include tumors, cancer, lesions, abscesses, fluid collection, and inflammation.	Obtain informed consent. Assess for allergies to contrast agent, which may be used; observe for reaction to contrast media. Determine whether child is claustrophobic or unable to remain still. Administer sedation if ordered.
Magnetic resonance imaging	Evaluates growth hormone deficiency or precocious puberty.	May detect a brain lesion as the cause of growth hormone deficiency or precocious puberty.	Obtain informed consent. Determine whether child is claustrophobic or unable to remain still. Administer sedation if ordered. Remove all metal objects from child's body. If parents allowed to stay with child during procedure, ensure that they remove all metal objects from their bodies. Explain to child that machine makes various noises as the radio waves are turned on and off. Provide child with earplugs if necessary.
Thyroid scan and radioactive iodine uptake test (RAIU)	Scan is used to determine the size, shape and position of the thyroid gland. The RAIU is performed to evaluate the function of the gland by measuring how much radioactive iodine is taken up by the thyroid gland in a given time period.	Enlarged gland may indicate goiter. Small thyroid may indicate a congenital defect. Increased uptake of iodine would indicate hyperthyroidism, decrease uptake would indicate hypothyroidism.	Performed by giving a radionuclide intravenously 2 hours before the scan. Ensure child has good intravenous access. ^{99m} Tc-Technetium is the preferred radionuclide in children because it has the advantage of low radiation exposure.
Ultrasonography	Assesses thyroid.	Could indicate ectopic, enlarged, absent, or nodular thyroid.	Tell the child and parents that no sedation is needed. Explain that the test is painless. Explain that an ultrasound lubricant will be applied to the area being viewed. Remove the lubricant after test is completed.

Diabetes Insipidus (DI)

QUESTION: Compare diabetes insipidus with diabetes mellitus. Why do they share part of the same name? What do they have in common?

Central diabetes insipidus (DI), also called *neurogenic*, *vasopressin-sensitive*, or *hypothalamic DI*, is a disorder of the posterior pituitary that results from deficient secretion of ADH. Nephrogenic DI is a result of the inability of the kidney to respond to ADH. Distinguishing between central DI and nephrogenic DI is important, because treatment may vary. Central DI may result from

NURSING INTERVENTIONS 26–1

Nutritional Management of Selected Endocrine Disorders

Endocrine Disorder	Dietary Management	Rationale
Addison's Disease	High-protein, low-carbohydrate, high-sodium diet Small frequent meals	Because of inadequate production of hepatic glucagons, the recommended diet prevents fatigue, hypoglycemia, and hyponatremia.
Cushing's syndrome	Low calories, carbohydrates and sodium diet Ample protein and potassium Reduced fluid intake	Helps control development of hyperglycemia, edema, and hypokalemia.
Type 1 diabetes	Adherence to American Heart Association Guidelines in addition to meeting guidelines for growth and development in child's age group	Helps prevent long-term effects of diabetes, including cardiovascular, neurologic, and renal effects.
Type 2 diabetes	Individualized meal plan	Meal plan is aimed at improving eating habits, restricting caloric intake, achieving moderate weight loss, maintaining consistent carbohydrate intake, and decreasing fat intake.
Hypothyroidism	Low-calorie, low-cholesterol, low-saturated fat diet	Because of decreased metabolic rate, child requires fewer calories to support metabolic activity. Individuals with hypothyroidism tend to have high cholesterol levels.

many different causes, including accidental or surgical trauma to vasopressin neurons; congenital anatomic hypothalamic or pituitary defects; neoplasms; infiltrative, autoimmune, or infectious diseases; increased metabolism of vasopressin; and genetic causes. Nephrogenic DI, in contrast to central DI, may have a genetic cause or can be acquired or caused from such conditions as polycystic kidney disease, an electrolyte imbalance, or a kidney defect. This section focuses on central DI, because it is more commonly seen.

Pathophysiology

The hypothalamus produces ADH. After synthesis, the hormone is transported to the posterior lobe of the pituitary gland where it is stored for later release. The purpose of ADH is to concentrate the urine from the kidneys and to conserve water. ADH works directly on the renal collecting ducts and distal tubules to increase membrane permeability for water and urea. A deficiency in ADH causes the kidney to fail to reabsorb water, which instead diffuses into the urine. Subsequently, a decrease in ADH secretion allows massive water loss, resulting in sodium retention in the serum.

Prognosis

The prognosis of children with central DI depends on the cause. Most children with proper treatment and follow-up can live fairly normal lives.

Assessment

The most common symptoms of central DI are **polyuria** (excessive urination) and **polydipsia** (excessive thirst). Children with central DI typically excrete 4 to 15 L urine/day, despite fluid intake. The onset of these symptoms is usually sudden and abrupt. Ask about repeated trips to the bathroom, nocturia, and enuresis. Other symptoms may include dehydration, fever, weight loss, increased irritability, vomiting, constipation, and, potentially, hypovolemic shock.

caREminder

The first symptoms of central DI seen in children, especially in infants, are irritability and incessant crying that can only be alleviated with feedings of water. Formula or breast milk does not quench the child's thirst.

The child with diabetes mellitus also has polydipsia but is satisfied with any type of fluid. With central DI, the child's urine is extremely dilute and often colorless, with a specific gravity usually not more than 1.005. Central DI may often be confused with diabetes mellitus because of the symptoms; however, in DI no glycosuria occurs.

Diagnostic Tests

Diagnosis of central DI is usually confirmed by low urine specific gravity, serum osmolality greater than 300

NURSING PLAN OF CARE 26–1: FOR THE CHILD WITH ALTERED ENDOCRINE STATUS

Nursing Diagnosis: Risk for excess or deficient fluid volume related to altered endocrine function

Interventions/Rationale

- Monitor and record vital signs.
Retention or loss of sodium and water can cause dramatic shifts in fluid volume. Hypertension and edema can occur from expanded fluid volume with sodium and water retention. Hypovolemic shock (e.g., tachycardia, tachypnea, and hypotension) and dehydration can occur because of disturbances in water metabolism.
- Weigh child daily.
Assists in detecting excessive fluid loss or gain.
- Monitor intake and output.
With many endocrine conditions, urine volume is independent of fluid intake.
- Complete blood and urine analysis as ordered.
Indicates electrolyte imbalances related to fluid volume excess or deficit. Indicates ability of kidneys to concentrate urine.
- Monitor fluid intake and provide access to fluids as warranted by the child's condition.
Conditions such as Cushing's syndrome may require restricted fluid intake, whereas the child with diabetes should have an easily accessible fluid source.
- Administer medication as prescribed.
The goal of medication therapy is to return the child to normal hormone levels and/or maintain normal electrolyte levels.
- Instruct child and family in administering medications and managing fluids and nutrition. Include expected effects, dosage, and side effects when child does not adhere to regimen and monitor fluids and nutrition.
Knowledge of the disease process and of the regimen for medication, fluids, and nutrition will promote adherence.

Expected Outcomes

- Child will remain well hydrated.
- Child will have normal serum hormone or electrolyte levels.
- Child and family will understand the need for replacement hormone or other medical therapy and long-term follow-up.
- Child and family will administer the hormone therapy as prescribed.
- Child and family will seek intervention when fluid volume excess or deficit occurs.

Nursing Diagnosis: Imbalanced nutrition: More or less than body requirements related to intake insufficient or in excess of activity expenditure and/or inability of body to utilize nutrients available

Interventions/Rationale

- Monitor trends in weight.
Provides documentation of weight loss or gain that may indicate a need to change therapeutic regimen.
- Assess child's nutritional status, including appetite; presence of nausea, vomiting, or diarrhea; food intake; and food preferences.
Endocrine dysfunction can impair gastrointestinal function, causing nausea, vomiting, and diarrhea. Appetite may increase when food preferences are determined and incorporated into regular meals and snacks.
- Provide diet specific to complement the metabolic hormonal excess or deficiency and thereby the nutritional needs of the child.
The regimen to manage specific endocrine disorders may include specific dietary requirements. For instance, the child with Addison's disease needs a high-protein, low-carbohydrate, high-sodium diet. The child with Cushing's syndrome needs a diet low in calories, carbohydrates, and sodium, with ample protein and potassium (see Nursing Interventions 26–1).
- Provide child and family education regarding child's nutritional needs and the complications that may arise when dietary plan is not followed.
Lack of knowledge or nonadherence to dietary guidelines can lead to severe complications of the child's condition.

Expected Outcomes

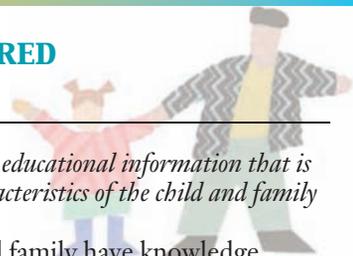

- Child and family will understand the need for specific nutritional therapy and long-term follow-up.
- Child will maintain weight within parameters for age and gender.
- Child will adhere to prescribed meal plan.

Nursing Diagnosis: Disturbed body image related to perception of changes in physical appearance resulting from hormonal imbalances

Interventions/Rationale

- Assess for changes in personal appearance caused by endocrine imbalance (e.g., obesity, increased body and facial hair, acne).
Evaluation of physical changes may assist in diagnosis of the condition.
- Assess child's feelings about changed appearance and evaluate coping mechanisms.
Provides information about specific areas of concern for the child to help develop plan of action to help bolster child's esteem.
- Promote coping mechanisms that deal with changes in child's appearance (e.g., selecting flattering clothes, improving personal grooming and hygiene).
Learning methods to compensate for changes in appearance can help improve child's self-esteem.

NURSING PLAN OF CARE 26–1: FOR THE CHILD WITH ALTERED ENDOCRINE STATUS (CONTINUED)

- Provide atmosphere of acceptance, including environment in which child feels supported.

Child should feel that family, friends, and healthcare providers are providing care in an accepting manner. Child can be referred to a support group to learn additional coping strategies and to gain support from interacting with others who have a similar condition.

Expected Outcomes

- Child will express positive feelings about self.
- Child will use appropriate coping mechanisms to manage changes in physical appearance.
- Child will have access to support groups as needed.

Nursing Diagnosis: Risk for ineffective family therapeutic regimen management related to presence of chronic condition

Interventions/Rationale

- Evaluate child and family learning needs, self-management skills and abilities.
Determines the amount and type of education and demonstration needed.
- Determine child and family members' ability (including developmental readiness) and willingness to learn.

Assists in presenting educational information that is tailored to specific characteristics of the child and family members.

- Ensure that child and family have knowledge about causes of symptoms, treatment, management regimen (e.g., dietary, medication). Instruct child to wear medical alert bracelet at all times.
Allows others to identify the child as having an endocrine condition and provide appropriate care in an emergency.

Expected Outcomes

- Child and family will report ability to cope and adjust adequately.
- Child and family will show ability to accept and adapt to new health status and integrate learning.
- Child and family will identify factors that influence inability to adhere to plan.
- Child will demonstrate a level of adherence that promotes physiologic safety.

Nursing Diagnosis: Anxiety related to response to prognosis; actual or perceived loss of body integrity; threat to self-concept

See Nursing Plan of Care 12–1.

mOsm/kg with urine osmolality less than 300 mOsm/kg, excessive urination despite fluid restriction, and elevated serum sodium levels when fluid is withheld. A water deprivation test may be ordered if the serum osmolality is less than 300 mOsm/kg, yet intake and output records in the home cannot be attributed to primary polydipsia. The water deprivation study can help to establish the diagnosis of central DI and to differentiate between central and nephrogenic causes (see Tests and Procedures 26–1). Magnetic resonance imaging may be completed to help determine the underlying disease that is affecting pituitary function.

Nursing Diagnoses and Outcomes

In addition to the nursing diagnoses presented in Nursing Plan of Care 26–1, the following nursing diagnosis may apply to a child with central DI:

Activity intolerance related to dehydration, excessive thirst, and frequent need to urinate

Outcome: Child will regain strength and desire to have increased level of activity.

Interdisciplinary Interventions

Treatment for central DI involves careful monitoring and management of the child to prevent fluid and elec-

trolyte imbalances, providing nutritional support and administering desmopressin (DDAVP), a synthetic analogue of ADH.

Monitoring

Monitor the child with central DI continually for signs and symptoms of dehydration (poor skin turgor, dry mucous membranes, sunken fontanel, weight loss, absence of tears, tachycardia, and decreased urine specific gravity) and hypernatremia (tachycardia, poor skin turgor, weak pulses, low blood pressure, cool skin, increased body temperature, dry mucous membranes, and changes in mental status). Administer sufficient fluids to maintain balanced intake and output over 24 hours. Record strict intake, output, and specific gravity measurements while the child is hospitalized. If urine output is more than 100 mL/hour for two consecutive voids, notify the healthcare prescriber. Weigh the child on the same scale every day.

Nutritional Interventions

Encourage high-calorie beverages, such as milk and juice, for children with central DI who are underweight because of inadequate calorie consumption. Instruct parents to note drinking patterns at home and to report changes to

the healthcare prescriber. Parents need to understand the symptoms of water intoxication and dehydration to prevent acute episodes of decompensation that could require hospitalization (see Chapter 17 for a discussion of fluid and electrolyte status). In addition, remind parents and school nurses that adequate replacement fluid is needed during increased physical activity or extremely hot weather.

Pharmacologic Interventions

If postoperative or acute central DI cannot be controlled with fluid management alone, pharmacologic treatment is instituted. DDAVP may be administered intravenously, subcutaneously, intranasally, or by mouth. Long-term home therapy usually entails administration twice daily by the oral or intranasal route. The healthcare prescriber initially orders small doses and titrates the dose as needed. DDAVP acts immediately and lasts between 8 and 24 hours. Headaches, nasal congestion, and abdominal discomfort are rare side effects. Vasopressin (Pitressin) is usually administered parenterally in the acute treatment of central DI because of its shorter half-life.

Community Care

Provide education before discharge regarding home administration of DDAVP and fluid management (Tip 26–1). Ensure that the child's school nurse knows that the child is receiving treatment for central DI. It is unlikely that DDAVP will be administered in the school setting, but if the parents struggle with adherence to medication administration, the school nurse may be asked to assist. Any fluid intake guidelines should be clearly stated in a school healthcare plan that is on file with the school health office. Advise parents to inform teachers and coaches that their child needs liberal bathroom privileges and extra fluids to prevent embarrassing accidents or dehydration. All children should be encouraged to wear MedicAlert bracelets that indicate that they have DI.

caREminder

Parents must educate teachers thoroughly on the symptoms of dehydration and hypernatremia, so they do not mistake these signs as bad or unruly behavior. A teaching session with the school nurse can prevent this misconception.

ANSWER: The word *diabetes* is derived from the Greek word for “passing through.” It is used medically to describe diseases characterized by excessive urination. Both diabetes mellitus and central DI are a result of deficient secretion of a hormone by a gland; both, when untreated, result in excessive urination. The excessive urination in DI is from inadequate ADH to stimulate the absorption of water

and thereby concentrate urine; excessive urination in diabetes mellitus is from excess glucose causing a hyperosmotic situation in both the bloodstream and the urine, which results in increased urination.

Syndrome of Inappropriate Antidiuretic Hormone Secretion (SIADH)

The syndrome of inappropriate antidiuretic hormone (SIADH) secretion results from hypersecretion of ADH. In SIADH, the negative feedback mechanism fails to regulate ADH release and inhibition. SIADH may occur with brain tumors, central nervous system (CNS) disease (meningitis), head trauma, or after certain surgical procedures on the brain. It may also stem from the use of certain medications, such as chlorpropamide, imipramine, vincristine, and phenothiazines. SIADH may also be caused by excessive administration of vasopressin, whether the drug is used for treating central DI, bleeding disorders, or enuresis.

Pathophysiology

Normally, ADH is not secreted when excess fluid is in circulation, because the fluid must be excreted. When ADH is hypersecreted, it shuts down the normal kidney function of water filtration and loss. Decreased sodium levels cause water to move into the cells, which causes brain cell swelling and increased intracranial pressure. Water remains in circulation, diluting all blood components. Metabolic toxins accumulate in the blood instead of being excreted. Hypokalemia and hypocalcemia develop from the dilutional effects of SIADH. Weakness, lethargy, anorexia, nausea, vomiting, and behavioral changes develop as the fluid and electrolyte balance deteriorates and serum sodium levels decrease. CNS changes associated with hyponatremia include confusion, convulsions, and coma. Death may occur if treatment is not immediate and aggressive.

Alert! SIADH is a transient, but life-threatening, emergency that is usually treated in the intensive care setting after head trauma or intracranial surgery.

Prognosis

Without immediate and effective interventions, CNS damage from the disorder can impair the child permanently. When the underlying disorder is corrected, the child should no longer be at risk, and the symptoms usually dissipate.

Assessment

Monitor weight, input, and output. The child with SIADH gains weight and has decreased urine output, because fluids are retained. Assess the child's level of consciousness with vital signs assessment. Symptoms in SIADH result from dilutional hyponatremia and include

TIP 26–1 A Teaching Intervention Plan for Administering Desmopressin (DDAVP)

Nursing diagnoses and outcomes

- Deficient knowledge: DDAVP administration

Outcomes:

- The parents and child will understand the need for replacement hormone therapy and long-term follow-up.
- Parents and child will demonstrate how to give DDAVP.
- Parents and child will demonstrate strategies to monitor child's fluid balance.

Teach the child/family

Medication Administration

- Keep DDAVP refrigerated at all times.
- Clear the nostrils before giving medication.
- Insert measured tubing into the bottle of DDAVP.
- Fill the tube to the proper dosage.
- Hold the top of the tube closed.
- Insert the medication-filled end into the nostril.
- Blow the liquid out of the tubing and into the nostril.

Precautions

- Consult the healthcare provider initially to learn how to administer DDAVP.

- Do not repeat doses that have been swallowed or poorly absorbed.
- The medication is poorly absorbed if the child has nasal congestion.
- The dose may need to be repeated if the child sneezes immediately after the administration of the medication.
- Have an extra bottle of medication in case of breakage.
- Have child wear a medical alert bracelet, listing DI and the medications the child is using.

Monitoring of the Child

- Closely monitor fluid balance, including daily weights (same time of day with same amount of clothing), fluid intake and output, measurement of urine specific gravity.
- Look for signs of overdose, such as weight gain, concentrated urine, decreased urine output.
- Look for signs of underdosage, such as polyuria, intense thirst, dilute urine.

Contact the Healthcare Provider if:

- Child has signs of DI, including increased thirst, sudden weight loss, polyuria, urine specific gravity less than 1.005, or altered mental status

headache, nausea and vomiting, irritability, confusion, seizures, and coma.

Specific laboratory diagnostic criteria that define SIADH include the following:

- Hypotonicity: Low serum osmolality (<280 mOsm/kg)
- Elevated urine osmolality (>100 mOsm/kg water)
- Hyponatremia: Low serum sodium levels (<135 mEq/L)
- High urine sodium concentrations (>25 mEq/L)

In addition, diagnostic tests reveal decreased levels of serum urea, creatinine, uric acid, and albumin. Renal, adrenal, and thyroid function tests are generally normal.

Nursing Diagnoses and Outcomes

In addition to the nursing diagnoses presented in Nursing Plan of Care 26–1, the following nursing diagnosis may apply to a child with SIADH:

Disturbed thought processes related to effects of brain cell swelling and increased intracranial pressure as evidenced by confusion, disorientation, memory loss, seizures, and coma

Outcomes: Child's level of consciousness and orientation will remain normal or without further impairment.

Child will remain free from injury during periods of altered level of consciousness.

Interdisciplinary Interventions

Emergency management and long-term interventions for SIADH are tied directly to the cause of the hormone imbalance. Rapid and complete recovery is possible in most cases. Interventions are aimed at maintaining fluid and electrolyte balance, and regulating serum sodium and osmolality. Monitor intake, output, and weight records carefully. Place an indwelling urinary catheter to monitor hourly urine volume and specific gravity. Note any exposure to precipitating factors in the history.

The severity of the SIADH will guide supportive treatment options. For instance, in mild cases, treatment consists of fluid restrictions. Acute treatment is guided by the extent and duration of hyponatremia and the presence of any cerebral dysfunction. Maintaining airway, breathing, and cardiovascular stability is a primary concern and may require the child to be on ventilatory support. As serum sodium levels decrease, treatment consists of reducing the fluid overload and raising the serum sodium level and osmolality. Restricted IV fluids are ordered. Hypertonic saline solution (3% sodium chloride) may be administered

as a sodium replacement. Diuretic agents such as Lasix are prescribed in conjunction with hypertonic or isotonic saline to diurese excess water.

Growth Hormone (GH) Deficiency

Classic GH deficiency is the failure of the pituitary to produce sufficient GH to sustain normal growth in childhood or to produce minimally measurable GH after stimulation with two or more pharmacologic agents. In some cases, the causes of central GH deficiency are idiopathic. Males are twice as likely as females to be referred for idiopathic GH deficiency. Males are referred more often because of the societal expectation for males to be taller. Girls may have as high an incidence of GH deficiency, but may not be referred, because short stature is more acceptable in females.

Beyond idiopathic GH deficiency, other frequently seen causes of GH deficiency include tumors (craniopharyngiomas, optic glioma, adenoma, astrocytoma, and germinoma), septic–optic dysplasia (optic nerve hypoplasia, absence of septum pellucidum, and pituitary hormone deficiencies), long-term sequelae from cranial radiation, head trauma, congenital abnormalities and midline defects, or histiocytosis X.

Pathophysiology

GH stimulates the growth of all organs and tissues in the body, particularly the long bones. The synthesis of insulinlike growth factor 1 (IGF-1) in many tissues, especially the liver, is stimulated by GH. IGF-1, also known as *somatomedin C*, stimulates somatic growth. The child's nutritional state as well as several hormones influence the production of somatomedin C and resulting overall growth (American Association for Clinical Endocrinologists [AACE], 2003).

Prognosis

The child with GH deficiency usually attains an acceptable height with a supportive treatment plan to which they and their family can adhere.

Assessment

The child with GH deficiency may present to the health-care team at any time from birth to adolescence, depending on the causative factor. Conduct a complete evaluation, including family history, the child's birth history including gestational age at delivery, previous and current growth patterns, physical examination, bone age films, and specific endocrine studies.

Determine whether the child has had radiation treatments or a history of a head trauma. Note information about short stature in the family history, as well as the specific heights and weights of both parents and siblings. Obtain these measurements at the time of the initial visit. In the birth history, include any history of maternal illness, infections, tobacco or alcohol use, or malnutrition

that could have affected the weight and height of the growing fetus. Plot birth height, weight, and head circumference for gestational age. Obtain growth charts, because deviation from the normal growth curve is always a cause for concern.

The physical examination is extremely valuable and informative when diagnosing the child with GH deficiency. Physical findings vary somewhat depending on the age of the child. The neonate with idiopathic GH deficiency usually presents with seizures secondary to severe hypoglycemia and may also be cortisol deficient. Prolonged hyperbilirubinemia may also be present. The male can have small testes and micropenis when a gonadotropin deficiency is also present. Infants usually have a cherubic facial appearance, frontal bossing (prominence of the forehead) is common, and the eyes appear prominent. The nasal bridge is not fully developed, the nose is small, and the infant may have micrognathia (abnormal smallness of the jaw). Truncal adiposity (excessive fat over the trunk area of the body) is common, along with small hands and feet. Dentition is often delayed, hair is sparse and thin, and the voice may be high pitched. Growth velocity is decreased, which eventually leads to short stature.

Children who develop GH deficiency beyond the neonatal and infancy period generally experience short stature and growth retardation. Developmental skills are normal, because cognitive development is unaffected. The adolescent with GH deficiency may have a substantial delay of puberty in addition to short stature (Clinical Judgment 26–1).

Emotional difficulties related to small stature are common. The short child is often treated as if younger by teachers and coaches, is teased by peers, and may become shy and withdrawn toward others. Body image is altered, and the child may dress as a younger child.

Diagnostic Tests

The child with GH deficiency usually has normal results of renal and liver function tests as well as normal results of thyroid function tests. The sedimentation rate is normal, indicating the absence of a chronic illness causing the short stature. IGF-1 and IGFBP₃ levels are usually below normal. Bone age, determined by radiograph, is usually interpreted as less than two or more standard deviations from normal. Computed tomography or magnetic resonance imaging of the head will reveal no abnormalities. Overnight sleep studies evaluating GH secretion reveal less than three peaks of GH more than 10 ng/mL. Provocative testing using at least two GH stimulants, such as arginine, clonidine, insulin, glucagon, or levodopa/propranolol, will reveal GH levels less than 10 ng/mL.

Interdisciplinary Interventions

Pharmacologic therapy with GH is the treatment of choice for the child with GH deficiency. Educate the parent and child on the proper way to reconstitute and administer the GH. The parent or the child administers GH by subcutaneous injection usually 3 to 7 days per

CLINICAL JUDGMENT 26–1

The Child With Growth Hormone Deficiency

Ten-year-old Wallace has been diagnosed with GH deficiency. As the nurse at his school, you have been working with Wallace and his family to help them adjust to the diagnosis and follow the treatment plan.

Questions

1. If left untreated, how would this condition manifest itself?
2. What therapy would you anticipate is being provided for Wallace by his primary care provider?
3. Based on Wallace's age and diagnosis, what are some important aspects of nursing care for him?
4. You have noted that other kids at school are teasing Wallace and have nicknamed him "Fly" because he is so little. How should you intervene?
5. How would you evaluate whether Wallace's parents and teachers are responding appropriately to his condition?

Answers

1. Child would continue to appear shorter than others of same chronologic age, with delayed onset of puberty.
2. Intramuscular injections of growth hormone given each week, ranging from one daily to three to four times a week. Treatment is carried out over several years.
3. Recognizing that Wallace may be experiencing threats to his self-esteem and body image, assisting Wallace to cope with these feelings
4. Discuss the situation with Wallace's teachers and ask them to intervene to stop and redirect the kids who are teasing Wallace. If Wallace feels comfortable with the idea, you could give a presentation about GH deficiency to his classmates.
5. Assess if the parents and teachers are interacting with Wallace according to his age rather than to his size.

week (sometimes daily). Discuss the possible side effects of GH with the child and family. These include an increase in blood glucose level, an increased incidence of slipped capital femoral epiphysis, local infection at the injection site, and pseudo-tumor cerebri.

Growth is greatest during the first year of therapy compared with later years; the mechanism for the growth fall-off in subsequent years of treatment is not understood. Currently, GH injections are given until the bone fuses or until the child ceases to respond to treatment with continued growth. Some endocrinologists believe that adults with GH deficiency diagnosed during childhood may need continued treatment (AACE, 2003).

Community Care

For maximal beneficial effects of treatment, emphasize the importance of regular follow-up care and adherence to prescribed medication dose and frequency of administration.

KidKare ■ The child who has needle phobia may need extra attention. The child can help by selecting the injection sites, using an injector pen, and by participating in preparing the equipment. Psychological counseling may be necessary.

Precise heights and weights are obtained every 3 months at follow-up visits, and are precisely plotted on the growth

chart. The child has a bone age study performed at least every year after therapy has been initiated to monitor advancing bone age.

Precocious Puberty

Precocious puberty is development of sexual characteristics before the usual age of puberty. In developed countries, precocious sexual maturation is considered when characteristics such as breast development, growth of pubic hair, and onset of menses occur before age 8 in girls and before 9 years of age in boys (Papadimitriou et al., 2006). The incidence of precocious is about 1 in 5,000 to 1 in 10,000 children in the general population. Girls are more commonly affected by precocious puberty than boys (Antoniazzi & Zamboni, 2004).

Pathophysiology

There are two primary categories of precocious puberty. *Precocious pseudo-puberty* is less common and refers to conditions in which increased production of sex steroids is gonadotropin independent. Gonadotropin-independent precocious puberty does not involve hypothalamic-pituitary gonadal activation. Rather, it is the result of the production of sex hormones by the adrenal gland or gonads and may be secondary to CAH; tumors that secrete human chorionic gonadotropin; tumors of the adrenal gland, ovary, or testis; and exposure to exogenous sex steroid hormones (Antoniazzi & Zamboni, 2004).

Central precocious puberty (CPP) is a gonadotropin dependent form of precocious puberty. This more commonly seen type of precocious puberty is addressed in this section. CPP is initiated by hypothalamic–pituitary gonadal activation and is similar to the mechanism seen in normal puberty. LH-releasing hormone is secreted by the hypothalamus in periodic bursts that stimulate the pituitary to release the gonadotropins LH and FSH. These gonadotropins stimulate the gonads to produce sex hormones, causing sexual maturation. CNS abnormalities associated with CPP include tumors; hypothalamic hamartomas; acquired CNS injury caused by inflammation, surgery, trauma, radiation therapy, or abscess; or congenital anomalies such as hydrocephalus, arachnoid cysts, or suprasellar cysts.

Prognosis

The prognosis for a child with precocious puberty depends on the age at diagnosis and immediate treatment. Appropriate treatment can halt, and sometimes even reverse, sexual development and can stop the rapid growth that results in severe short adult stature caused by premature closure of the epiphysis. Treatment for precocious puberty allows the child to achieve the maximum growth potential possible.

Mental development in children with precocious puberty is normal, and developmental milestones are not affected; however, the behavior may change to that of a typical adolescent. Girls may have episodes of moodiness and irritability, whereas boys may become more aggressive.

Assessment

A comprehensive history, physical examination, and laboratory tests are essential in the diagnosis of precocious puberty.

Obtain and properly graph on the growth charts the current and previous height and weight measurements. Note growth spurts. In the history, include the chronologic timing of pubertal events, such as breast budding, phallic enlargement, body hair, acne, body odor, and deepening of the voice. Ask parents about changes in behavior such as increased moodiness, irritability, or aggressiveness. Elicit an extensive family history, including parental and sibling pubertal history, incidence of precocious puberty, CAH, neurofibromatosis, thyroid disease, and hypothyroidism. Note exposure to exogenous steroids or gonadotropins and any perinatal abnormalities or previous head trauma. Also note signs or symptoms of neurologic involvement, such as headaches, visual disturbances, or motor incoordination.

Note the stage of sexual development according to Tanner classification (see Figs. 3–16 and 3–17). Note testicular, phallic, and breast size, and check breasts for gynecomastia and galactorrhea. Examine the external genitalia for signs of labial fusion, estrogen production, or enlarged clitoris and labia. Examine the skin for café-au-lait spots, which can indicate neurofibromatosis or McCune-Albright syndrome (a genetic disease that

affects the bones and skin and causes hormonal imbalances, also called *polyostotic fibrous dysplasia*), and for the presence of neurofibromas. Neurologic evaluation is essential, with special attention paid to visual fields, optic disks, and signs of increased intracranial pressure.

Diagnostic Tests

Laboratory testing may include different blood tests, depending on the gender of the patient. In boys, the healthcare prescriber may order a serum human chorionic gonadotropin test, which if elevated could indicate a human chorionic gonadotropin-secreting tumor. Suppressed serum LH levels indicate testotoxicosis, in which serum testosterone concentration is high. In girls, an elevated cortisol or ACTH level with no signs of Cushing's syndrome (CS) could be caused by glucocorticoid resistance, evidenced by signs of precocious puberty. Additional laboratory testing may be done to evaluate the function of the adrenal glands and to rule out an adrenal virilizing tumor or hormone deficiencies.

The child will need a bone age determination. A normal bone age is most consistent with premature **adrenarche** (growth of sexual hair), premature **thelarche** (breast development), or ingestion of exogenous sex steroids. An accelerated bone age is more suggestive of CPP, an adrenal or ovarian disorder, McCune-Albright syndrome, or familial male precocious puberty.

Interdisciplinary Interventions

Interventions and treatments vary depending on the cause of the precocious puberty. When a CNS tumor is detected, surgery, radiation, chemotherapy, or a combination of these treatment modalities is recommended.

Pharmacologic Interventions

In the absence of a CNS lesion, several treatment options may be considered. For CPP, long-acting LH-releasing hormone and gonadotropin-releasing hormone (GnRH) agonists provide negative feedback and result in decreased levels of LH and FSH 2 to 4 weeks after initiating treatment. The agonists inhibit the release of LH and FSH, reduce gonadotropins and sex steroids to prepubertal levels, cause regression of secondary sex characteristics, retard sexual maturation, and slow the linear growth velocity and skeletal maturation (see [thePoint](#)). Medications and Administration: Pharmacological Agents Used to Treat Precocious Puberty). The ultimate goal of therapy is to restore normal growth potential while allowing puberty to occur at the normal age with subsequent normal reproductive potential. Medications are administered subcutaneously or intramuscularly on a daily basis, although one LH-releasing hormone agonists (Histrelin) is available in an implant form that is placed in the inner aspect of the upper arm and provides continuous medication release for 12 months. Pharmacologic interventions are usually discontinued when the child reaches the normal age for puberty (approximately age 11 for girls and age 12 for boys).

Supportive Interventions

After treatment is initiated, GnRH testing is performed every 4 to 6 months to assess the effectiveness of the treatment. Normalization of accelerated growth, reduction or no increase in size of breasts, and suppression of gonadotropin levels after a challenge of GnRH indicate effectiveness of the pharmacologic interventions.

In addition to the medical treatment that may be needed, the child with precocious puberty needs psychosocial support. School-aged children with precocious puberty may become very self-conscious about their bodies around their peers and families. The child with precocious puberty may also have adverse psychological effects. The most difficult aspect for the child to endure may be teasing from other children about advanced sexual development. The child may feel isolated and rejected socially. Behavioral changes seen in boys and girls may cause problems in socializing with children in their own age group. Teachers, relatives, and neighbors often expect the child to behave older than the chronologic age because of their physical appearance, causing frustration for the child, who cannot live up to the expectations. Parents need clear and concise explanations concerning the causes of precocious puberty, treatment options, and counseling regarding the emotional and social implications of this condition on their child and the family. Provide the child with explanations in age-appropriate terms about what is happening to his or her body and strategies to cope with the physical changes they are experiencing.

Community Care

Encourage parents, teachers, and friends to interact with the child in an age-appropriate manner, and to promote realistic expectations. Encourage the child to participate in activities with same-age children. Clothing should also be age appropriate, and parents may need assistance concerning how to minimize the appearance of breast development. Remind parents that intellectual, emotional, and social maturation does not keep pace with physical and hormonal changes. The child must be treated according to chronologic age and guarded against sexual abuse from older children or adults. Sexual curiosity is not usually advanced beyond the child's chronologic age. Educate parents and their precocious girls about the potential onset of menarche, if it has not yet occurred. Menstrual hygiene becomes an important concern for the child in elementary school and should be addressed with the teachers and the nurses in the school. Most children who have precocious puberty adjust well, with some assistance; however, some may encounter serious problems adapting to their premature development. Provide counseling for children who experience any signs of substantial psychological effects, such as depression, withdrawal, or aggressive behavior.

Delayed Puberty

Delayed puberty is the failure to develop sexually at an appropriate age or during the normal 3- to 5-year period

at normal age of puberty onset. In girls who have not developed breasts by 13 years of age, or if more than 4½ years have passed between the initiation of breast development and menarche, delayed puberty is considered. Boys are considered to have delayed puberty if secondary sexual development has not started by 14 years of age.

Incidence and Etiology

Delayed puberty is more common in boys than girls and occurs in 2% to 3% of all adolescents. Constitutional growth delay is the most common cause. The serum gonadotropins are typically normal, and the bone age, determined by radiograph, is moderately delayed. The child also has a history of small stature during infancy and early childhood. The two other major categories of delayed puberty are hypogonadotropic hypogonadism and hypergonadotropic hypogonadism. In hypogonadotropic hypogonadism, delayed puberty is associated with low serum gonadotropin levels secondary to abnormalities of the hypothalamus or the pituitary. These abnormalities include craniopharyngiomas, Kallmann's syndrome, idiopathic hypopituitarism, autoimmune disease, fertile eunuch syndrome, isolated FSH deficiency, and hyperprolactinemia. In hypergonadotropic hypogonadism, delayed puberty is associated with elevated serum gonadotropin levels.

Pathophysiology

In girls, the most common abnormality is Turner's syndrome. Girls with Turner's syndrome have delayed puberty, short stature, webbed neck, and cubitus valgus (deformity of the arm in which the forearm deviates laterally). The karyotype in girls with Turner's syndrome is 46XO. In boys, abnormalities include Klinefelter syndrome; bilateral gonadal failure secondary to trauma, autoimmune destruction, infection, or radiation; and congenital anorchia.

Prognosis

Prognosis is dependent on what diagnosis related to delayed puberty is established (e.g., Turner's constitutional delayed puberty). It is hoped that patients undergoing long-term sex steroid replacement will benefit from the maintenance of secondary sexual characteristics, menstruation in females, and maintained sexual drive in the long run as well as positive benefits to bone mineralization and cardiovascular health (Achermann, 2004).

Assessment

Assessing the child with delayed puberty requires a detailed family history as well as the child's history, physical examination, and laboratory studies.

In the family history, include the onset of puberty; the patterns of growth and sexual development of the mother, father, and siblings; a history of consanguinity; and any history of infertility. Obtain growth charts

documenting previous heights and weights. Note the child's history of chronic illness, nutritional disorders, birth trauma, and head trauma that may be indicative of causative factors.

During physical examination of the child with delayed puberty, include an accurate height and weight, the arm span, and the upper-to-lower segment ratio. Document any signs of puberty, noting breast development and presence of axillary hair and/or pubic hair. Measure testicular size and penile length carefully. Assess for the loss of a sense of smell, which would be present in Kallmann's syndrome, one cause of delayed puberty.

Diagnostic Tests

Many laboratory studies are needed. Gonadotropin concentrations (LH and FSH) are usually substantially higher than normal. Electrolytes should be normal. Thyroid levels may indicate hypothyroidism, prolactin levels may be elevated (indicating a pituitary adenoma), and estradiol levels and testosterone levels may be decreased. A bone age, which is usually delayed, is performed along with magnetic resonance imaging and computed tomography (a hypothalamic or pituitary lesion needs to be ruled out).

A GnRH stimulation test can also be performed to distinguish between constitutional delay of growth and hypogonadotropic hypogonadism. A human chorionic gonadotropin stimulation test can also assist in the diagnosis. Some endocrinologists believe that these last two studies are not helpful in making the diagnosis and may be far too expensive to be of any value; thus, the physical examination is sufficient.

Interdisciplinary Interventions

Treating the child with delayed puberty depends on the specific cause of the problem and whether the delay in development will be temporary or permanent. When the diagnosis is constitutional delay of growth, the healthcare team should reassure the child and family that there is no serious problem and that pubertal development will occur with time. Explain to the family that medical intervention will not affect final adult height.

Pharmacologic Interventions

Medical intervention has been used in the boy who is older than age 14 years and whose emotional well-being is adversely affected, as evidenced by a decrease in school performance and a withdrawal from his social circle. A 3- to 6-month course of low-dose testosterone (100–150 mg testosterone enanthate) given intramuscularly every 4 weeks for three doses is recommended, followed by reevaluation for possibility of continued treatment. Larger doses of testosterone were found to cause premature closure of the epiphysis and decrease the final height (Darby & Anawalt, 2005). Spontaneous growth velocity and sexual maturation usually follows, and therapy is no longer needed. Reassurance, close observation, and assistance with clothes selection are usually sufficient for girls with delayed puberty.

The child with hypogonadotropic hypogonadism or hypergonadotropic hypogonadism requires replacement therapy with sex steroids. In boys, testosterone needs to be replaced; and in girls, estrogen and progesterone need to be replaced. Testosterone enanthate is also given intramuscularly every 4 weeks and is started when puberty normally begins in boys. The dose starts at 100 mg and increases by 50 mg every 6 months to a final dose of 200 to 300 mg. Oral therapy or synthetic androgens do not stimulate complete pubertal development and are not an adequate therapy. Oral ethinyl estradiol is the replacement therapy of choice for girls. The usual dose is 0.02 to 0.1 mg/day for the first 21 days of every month. This dose is combined with medroxyprogesterone, 10 mg/day from day 14 to day 21 of each month (Darby & Anawalt, 2005).

Community Care

The child with delayed puberty has some of the same concerns and issues as the child with precocious puberty. Body image concerns may trigger withdrawal from age-appropriate activities and have led to decreased academic performance and altered self-concept. Teasing from peers about their short stature and lack of physical maturation may be especially distressing to the child. Lindfors et al. (2007) examined the relationship between pubertal development and ego development in late-maturing boys. Researchers found that boys with delayed puberty were psychologically more immature than their unaffected peers and that they experienced negative feelings about sexuality. It is believed that lower ego development may be related to the fact that boys with delayed puberty are treated more according to their stature than to their chronologic age. Thus, the child develops in response to how he is treated by others. The adolescent brain undergoes a profound reorganization during puberty, thus psychological immaturity in boys with delayed puberty may also be associated with the lack of brain maturation that would normally occur during puberty. Parental support and professional counseling can assist the youth to develop a healthy sense of self and to focus on personal strengths.

Other Pituitary Disorders

Panhypopituitarism is the lack of all anterior pituitary function, resulting in the deficiency of TSH, GH, ACTH, LH, and FSH. The posterior pituitary may also be affected and ADH may be deficient. The incidence is 1 in 100,000 live births. Causes of panhypopituitarism include tumors, radiation therapy, encephalitis, or head trauma (Marcus & Collins, 2004).

Pituitary gigantism (acromegaly) is an extremely rare disorder resulting from the hypersecretion of GH by the pituitary gland. Few cases of gigantism have been confirmed by appropriate hormonal testing and/or pathologic data. Hypersecretion of GH usually occurs as a result of a pituitary adenoma. Tumors of the hypothalamus may also produce an overabundance of GH. About 20% of the cases of gigantism have been associated with

the McCune-Albright syndrome, which has other features, including café-au-lait pigmentation of the skin and polyostotic fibrous dysplasia. Gigantism has also been associated with acanthosis, hyperinsulinism, obesity, and hyperandrogenism without elevated GH levels.

ALTERATIONS IN THE THYROID GLAND

QUESTION: As you read about alterations of the thyroid decide, which alteration is most similar to diabetes mellitus?

The thyroid gland is responsible for the rate of all metabolic and chemical processes in the body, thereby affecting every cell, tissue, organ, and organ system. The thyroid gland is essential for life, growth, and development. Thyroid hormones affect body temperature and circulation, appetite, energy levels, growth, skeletal development, muscle tone and agility, cardiac rate (force and output), fluid balance, blood sugar levels, CNS function, bowel function, blood fat (cholesterol) levels, and the regulation of fat, carbohydrate, and protein metabolism in all cells.

The thyroid problems are among some of the most common medical conditions, yet because the symptoms appear gradually, the thyroid condition may go undiagnosed for some period of time. Thyroid conditions in children may be congenital, acquired, or secondary. Various congenital defects of the thyroid are caused by developmental malformations. This occurrence is called *thyroid dysgenesis*. The failure of the thyroid to descend to its proper position is manifested by the thyroid developing at the base of the tongue (a lingual thyroid) or in the upper part of the neck (a sublingual thyroid). Disorders may also be acquired, as in the case of Hashimoto's thyroiditis, an autoimmune disease in which the child's own immune system attacks the thyroid gland and interferes with the production of thyroid hormones. Secondary thyroid disorders may result when the pituitary gland fails to secrete enough TSH, which is necessary for normal stimulation of the thyroid.

Hypothyroidism

Hypothyroidism results from deficient production of thyroid hormone or a defect in thyroid hormonal receptor activity. Hypothyroidism in children may be congenital, acquired, or secondary. Acquired hypothyroidism usually refers to thyroid deficiency that becomes evident after a period of apparently normal thyroid function. Acquired hypothyroidism may result from a variety of causes. It may be caused by a congenitally defective thyroid gland that furnishes sufficient amounts of hormone early in life but is inadequate later in childhood. A thyroid gland that is ectopically located at the base of the tongue (lingual thyroid or sublingual thyroid) can also cause acquired hypothyroidism in children. The most common cause of

acquired hypothyroidism in iodine-sufficient regions of the world is lymphocytic thyroiditis (also called *Hashimoto's thyroiditis* or *autoimmune thyroiditis*). Lymphocytic thyroiditis is an autoimmune disorder, and antithyroid antibodies are present. It is often associated with other endocrine disorders, such as diabetes mellitus, and with certain chromosomal disorders, such as Down and Turner's syndromes.

Congenital hypothyroidism is most commonly caused by defective embryonic development of the gland and has a prevalence of 1 in 4,000 newborns (Park & Chatterjee, 2005). The thyroid gland may be ectopic (present in a site higher than the normal position in the neck), aplastic, or hypoplastic. Such defective glands often produce insufficient hormone to meet physiologic requirements. Congenital hypothyroidism may also be caused by maternal ingestion of goitrogens (substances that produce a goiter) such as excessive amounts of iodide or antithyroid drugs.

Pathophysiology

The pathophysiology of hypothyroidism varies, depending on the type of deficiency. Normally, the thyroid gland synthesizes sufficient T_4 and T_3 . These hormones regulate metabolism, increase oxygen consumption, stimulate protein synthesis, affect carbohydrate and lipid metabolism, and promote growth and development. The thyroid also contains parafollicular or C cells. These cells secrete calcitonin, which helps to maintain blood calcium levels. This hormone inhibits skeletal demineralization and promotes calcium deposition in the bone.

Thyroid hormone synthesis is regulated by TSH, which is secreted by the anterior pituitary. The secretion of TSH is under the control of thyrotropin-releasing hormone, which is synthesized in the hypothalamus. When thyroid hormone production decreases, as in primary hypothyroidism, there is a compensatory increase in levels of TSH. Therefore, thyroid hypofunction or hyperfunction may be caused by a defect in the thyroid gland (primary defect) or by a defect in the pituitary or hypothalamus (secondary defect).

Prognosis

Complications of congenital hypothyroidism are severe when treatment is delayed. Without treatment, children may die of respiratory obstruction because of macroglossia. Other severe effects of lack of treatment include dwarfism and severe cognitive challenge; these occurrences are rare in developed countries today. With prompt diagnosis and treatment, children with acquired hypothyroidism will develop completely normally.

Assessment

Assessment of the child with a thyroid disorder includes a comprehensive history, physical examination, laboratory studies, and a scan of the thyroid.

When taking the history, include questions about other family members with thyroid disease, growth and development, level of activity, the integumentary system

(temperature and moistness of skin, texture of hair), gastrointestinal problems (diarrhea or constipation), calorogenesis, feeding problems, and weight gain or loss. During the physical examination, include accurate measurements of height and weight, heart rate, and blood pressure; assessment of skin temperature and moisture; palpation of the neck to assess the size and location of the gland; neurologic evaluation (presence of tremors or hypoactive or hyperactive reflexes); and a developmental assessment.

Congenital hypothyroidism is nearly universally diagnosed within the first few weeks of life as a result of national newborn screening. Screening has allowed early diagnosis and initiation of treatment before symptoms of hypothyroidism occur.

Rarely, the diagnosis is missed or delayed and symptoms occur. Symptoms of congenital hypothyroidism appear in the bottle-fed infant before they appear in the breast-fed baby as a result of the small amounts of thyroid hormone contained in breast milk. Affected infants have a history of feeding difficulties, inactivity, and constipation. They cry little and are often characterized as “good” babies that are quiet and passive.

On physical examination, untreated children may have a characteristic facies that includes a dull appearance, pallor, a flat nasal bridge, puffy eyelids, a thick protuberant tongue, and low hairline (Fig. 26–2). Growth is stunted, and a large posterior fontanel may be palpated. Prolonged jaundice, carotenemia, and anemia are common. The skin is cool, dry, and mottled; the infant may be hypothermic and have a hoarse cry. Cardiovascular manifestations consist of bradycardia and decreased pulse pressure. The muscles are hypotonic, and deep tendon reflexes are abnormal because of delayed relaxation after the reflex response. Congenital hypothyroidism has been associated with speech delay and sensorineural hearing loss if treatment is delayed.

The physical manifestations of acquired hypothyroidism depend on the age of the child. Mental development may be impaired in the very young child, as it is in congenital hypothyroidism. Deceleration of growth rate is

often the first sign of acquired hypothyroidism in children. The child may or may not have an enlarged thyroid (goiter). Children may also present with cold intolerance, constipation, weight gain, and lethargy.

A deficiency of thyroid hormone causes decreased oxygen consumption, metabolic rate, and protein synthesis. A child with congenital hypothyroidism that goes untreated is at grave risk for cognitive challenge. Other children with juvenile or acquired hypothyroidism that is diagnosed later in life may perform well academically, but will express cold intolerance, constipation, and decreased level of energy. Physically, children may demonstrate bradycardia, facial puffiness, and delayed reflexes.

caREminder

Early diagnosis and prompt treatment of congenital hypothyroidism is essential for normal growth and brain development. The greater the delay treating congenital hypothyroidism, the greater the degree of cognitive challenge that results. With early diagnosis and treatment, children with congenital hypothyroidism can develop normally.

Diagnostic Tests

Definitive laboratory findings for congenital or acquired hypothyroidism are low levels of T_3 and T_4 and high levels of TSH. However, in very mild hypothyroidism, T_3 and T_4 levels may be normal, whereas TSH levels are elevated.

Neonatal screening for congenital hypothyroidism is mandatory; the assay usually consists of radioimmunoassay for T_4 on a drop of blood on filter paper. Blood specimens for neonatal screening can be obtained by heel stick at the time screening for phenylketonuria is performed.

Thyroid scans are done to identify thyroid location, size, and function. Positive antithyroid antibodies are diagnostic of autoimmune thyroid disease.

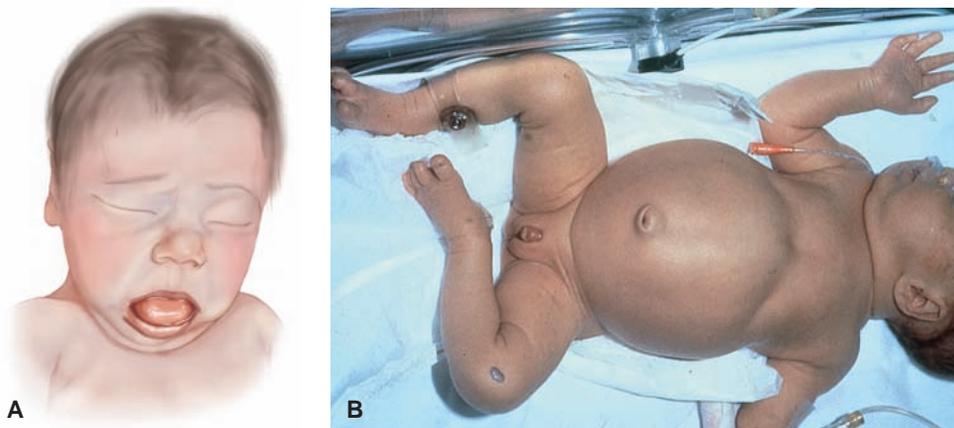

FIGURE 26–2. (A) Congenital hypothyroidism in an infant produces facial puffiness, large tongue, and a dull expression. (B) A newborn with congenital hypothyroidism. Note the short, thick neck and enlarged abdomen.

Nursing Diagnoses and Outcomes

In addition to the nursing diagnoses presented in Nursing Plan of Care 26–1, the following diagnoses may apply to the child with hypothyroidism:

Constipation related to decreased motility of the gastrointestinal tract

Outcome: Child's bowel habits will normalize with thyroid hormone treatment.

Hypothermia related to decreased metabolic rate

Outcome: Child will remain normothermic.

Activity intolerance related to fatigue and decreased strength and endurance

Outcomes: Child's excessive fatigue will resolve with thyroid hormone treatment.

Child will regain physical strength and endurance.

Interdisciplinary Interventions

Treatment of hypothyroidism is pharmacologic and consists of replacement with sodium-L-thyroxine (Synthroid). Serum levels of thyroid hormones and TSH are monitored by the healthcare provider to ensure that the proper dose is administered and that adherence is adequate. After therapy is instituted, growth rate and developmental levels are continually monitored.

Because of the importance of thyroid hormone for normal growth and development, identifying signs of hypothyroidism promptly is essential (Clinical Judgment 26–2). After hypothyroidism is diagnosed, instruct families on the importance of administering thyroid hormone as ordered (Community Care 26–1).

caREminder

Because children and adolescents do not “feel different” if they miss a dose or two of thyroid hormone, they may forget to take the medication. If one dose is missed, it can be taken the next day along with the usual daily dose.

Community Care

Since the advent of thyroid screening, hypothyroidism that occurs early in life remains undiagnosed in very few children, and fewer suffer irreversible developmental delay. If the child demonstrates developmental delays, refer the child to early intervention programs to help him or her achieve maximum potential. In the case of the child with acquired hypothyroidism, the quality of schoolwork may have declined before hypothyroidism was diagnosed and treated. Discuss the diagnosis with the child's teachers to apprise them of the effect of hypothyroidism on learning ability and that treatment with thyroid hormone should return the child to the previous level of ability in school.

ANSWER: Acquired hypothyroidism is similar in onset to type 1 diabetes in that the gland has been functioning normally and then excretes an insufficient amount of hormone.

Hyperthyroidism

Hyperthyroidism occurs less often in children than hypothyroidism. *Graves' disease*, the most common cause of

CLINICAL JUDGMENT 26–2

The Child With Hypothyroidism

Denise is a newborn diagnosed with hypothyroidism. Her parents, Mr. and Mrs. Brown, are very concerned about her disorder and about managing her care at home.

Questions

1. What diagnostic tests are used to assess for hypothyroidism in the newborn?
2. What clinical characteristics would be indicative of hypothyroidism?
3. What would be a major complication if Denise's condition had not been recognized and treated?
4. What steps should be included in the teaching plan for this family?
5. After your teaching is complete, what information would Mr. and Mrs. Brown be able to share with you to validate that they understand Denise's home care needs?

Answers

1. A simple blood test, done via heel stick, to diagnose hypothyroidism is required as part of the newborn screening tests.
2. Feeding difficulties, prolonged physiologic jaundice, lethargy, constipation
3. Mental retardation
4. Teach family how to administer medications. Teach family the importance of lifelong therapy and the need for continual developmental surveillance. Provide family with ongoing education about normal growth and developmental milestones for the child.
5. Importance of administration of sodium-L-thyroxine for life, importance of regular healthcare visits and developmental surveillance to ensure child is meeting developmental norms

COMMUNITY CARE 26–1

Administration of Thyroid Hormone at Home to the Young Child

- No liquid preparation of thyroid hormone exists.
- Thyroid pills must be crushed for very young children. Crush them in a shot glass. Mix with a medicine dropper. Add water to the glass and draw it into the dropper until no residue remains.
- Do not administer by mixing the medication with large amounts of milk or formula.
- Give approximately 30 minutes before a feeding.
- Give the medicine at the same time each day (easier to remember).
- Parents must supervise to ensure that thyroid hormone is taken as ordered.

hyperthyroidism in children, occurs in 1 in 5,000 children between 11 and 15 years of age (LaFranchi, 2004). Hyperthyroidism occurs more often in females, and the peak incidence occurs during adolescence. The incidence is increased in Down syndrome, diabetes mellitus, Addison's disease, and when there is a family history of Graves' disease. Less common causes include functional adenoma (Plummer's disease), polyostotic fibrous dysplasia (McCune-Albright syndrome), thyroid carcinoma, acute suppurative thyroiditis, or pituitary tumor, which secretes excessive TSH.

Pathophysiology

Graves' disease, is characterized by the triad of hypersecretion of thyroid hormone, presence of a goiter, and **exophthalmos** (bulging of the eyeballs). Exophthalmos is less pronounced in children or not usually seen, except in long-standing disease. In this autoimmune disorder, thyroid-stimulating immunoglobulins affect the thyroid gland in much the same fashion as TSH. There is evidence for genetic and immunologic components to Graves' disease.

Prognosis

If the child is **euthyroid** (state of a having a normal size thyroid gland) after 2 to 3 years of therapy, therapy should be discontinued. The likelihood of permanent remission is great. However, if the thyroid is enlarged two times or greater, it is unlikely that remission has occurred. Therapy may be continued, or total thyroidectomy may be performed.

Assessment

The signs and symptoms of hyperthyroidism are manifested in a variety of body systems. The onset is often

insidious, with symptoms developing gradually. The most common early symptoms are related to emotional disturbances and increased motor activity. Ask about symptoms such as mood swings, poor attention span, and insomnia, which can be signs of hyperthyroidism.

caREminder

Hyperthyroid children are emotionally labile and cry easily. They are nervous, have short attention spans, and cannot sit still. Therefore, problems with schoolwork are common.

These children are usually considered to be hyperactive and to have behavior problems. Sleep disturbance is not uncommon. Weight loss, despite **polyphagia** (excessive hunger), is frequent. In addition, increased motility of the gastrointestinal tract may cause diarrhea. Cardiac manifestations include tachycardia with palpitations, increased systolic blood pressure yielding an increased pulse pressure, cardiomegaly, and systolic murmurs. The skin may be flushed, warm, sweaty, and very smooth. Heat intolerance can be mild or severe.

The thyroid gland is usually enlarged by two to four times, making it visible and easily palpable. The gland is most commonly symmetric, and smooth and systolic bruits may be auscultated over it. The most common ocular manifestations are lid retraction with the appearance of staring. Growth rate may be accelerated, and hyperthyroid children are frequently tall, with slightly advanced osseous development. Exophthalmos occurs in only one third of children, although ophthalmic abnormalities are found in most children at diagnosis (Fig. 26–3).

Complications of hyperthyroidism include atrial fibrillation and **thyrotoxicosis** (thyroid “storm,” or crisis). Thyroid crisis is rare in children, but it can be fatal. It is precipitated by stress, such as infection, trauma, and surgical emergencies, or by discontinuation of antithyroid therapy.

Alert! The onset of thyroid storm is abrupt, and the symptoms are severe tachycardia, vomiting, diarrhea, hyperpyrexia, and confusion. If thyroid storm is not treated promptly, death may ensue.

FIGURE 26–3. Children with hyperthyroidism exhibit hypermetabolism and accelerated linear growth. Facial characteristics shown here include “staring eyes” and enlarged thyroid gland (goiter).

Diagnostic Tests

A complete blood count should be done as a baseline, because pharmacologic therapy used to treat hyperthyroidism may cause neutropenia. Blood analysis will demonstrate levels of TSH that are very low because the high levels of thyroid hormone suppress the pituitary. If a thyroid nodule is present, a thyroid scan should be performed to differentiate between a malignant nodule and a thyroid-secreting adenoma. A malignant nodule is usually a “cold” nodule (a lesion with decreased concentration of radioisotope). A thyroid-secreting adenoma is usually “hot” (increased concentration of radioisotope).

Nursing Diagnoses and Outcomes

In addition to the nursing diagnoses presented in Nursing Plan of Care 26–1, the following diagnoses may apply to the child with hyperthyroidism.

Diarrhea related to effects of increased metabolic activity

Outcomes: Child’s bowel habits will normalize.
Child will not experience diarrhea.

Disturbed sleep pattern related to increased metabolic energy production

Outcome: Child’s insomnia and restlessness will resolve.

Risk for decreased cardiac output related to atrial fibrillations

Outcomes: Child will maintain normal cardiac output.
Child will receive prompt treatment for thyroid “storm.”

Interdisciplinary Interventions

Medical treatment for children with hyperthyroidism includes antithyroid drugs to block T₄ synthesis, subtotal thyroidectomy, or radioiodine therapy (Amer, 2005; Glaser et al., 2008).

Pharmacologic Interventions

Medications used to treat hyperthyroidism include propylthiouracil and methimazole (Tapazole). Improvement is usually noticed in 2 weeks, and the child becomes euthyroid in 1 to 3 months. Most side effects of antithyroid medications are mild and include pruritus, rash, and mild leukopenia. Severe leukopenia or agranulocytosis, manifested by sore throat and sudden onset of high fever, is an indication to discontinue the antithyroid medication. Beta-adrenergic blocking agents, such as propranolol, may be used with antithyroid drugs to control tachycardia, tremors, and hyperactivity in the severely toxic patient (Amer, 2005). Treatment may extend over long periods; therefore, adherence with the therapy may become a concern (Glaser et al., 2008). If the medication is ordered three times a day, suggest that the second dose be given as soon as the child returns from school, because that dose is the easiest to forget.

Surgical Management

In children in whom drug therapy is not possible, or in whom medical management has been unsuccessful, subtotal thyroidectomy is indicated (Lee, Grumbach, & Clark, 2007). The child must be euthyroid before surgery

and is therefore treated with antithyroid medication. In addition, approximately 2 weeks before surgery, Lugol solution (potassium iodide), five drops twice a day, is added to the treatment regimen to decrease thyroid vascularity. Complications of thyroid surgery are uncommon but include hemorrhage, vocal cord paralysis, hypoparathyroidism, and hypothyroidism.

Radioiodine Therapy

The outcome of treatment with radioiodine is related to the size of the thyroid gland at diagnosis. Children with a relatively small gland have a more successful treatment course. Some clinicians will recommend surgery if the gland is larger than 100 g, as determined by ultrasonography (Rivkees & Dinauer, 2007). Radioiodine therapy carries less mortality risk than surgery, but the risk of repeat hyperthyroidism or subsequent hypothyroidism must be considered.

Community Care

Although the appropriate dose of antithyroid medication will resolve symptoms, a time lag of a few weeks may occur between the start of therapy and the end of symptoms. During the transition from the start of therapy until the disappearance of symptoms, parents must be educated about the child’s need for small, frequent nutritious meals while polyphagic; lightweight clothing and good ventilation because of increased calorogenesis; and a low-pressure, nonstressful environment. Exophthalmos and a large goiter may cause alterations in body image.

KidKare ■ For children and adolescents, suggest the use of high-necked clothing to mask the goiter. Girls can use scarves to hide the goiter.

Educate teachers that excess thyroid hormone causes hyperactivity and poor attention span. Schoolwork should be structured accordingly until the child reaches a euthyroid state.

ALTERATIONS IN PARATHYROID FUNCTION

Located on the posterior surface of the thyroid gland, the four parathyroid glands secrete parathyroid hormone (PTH), which maintains calcium homeostasis. PTH increases bone resorption, thereby increasing the level of calcium in the serum. In the kidneys, PTH decreases urinary excretion of calcium and increases urinary excretion of phosphate. PTH also increases calcium absorption from the intestine. Parathyroid disorder occurs if the PTH level is too low (hypoparathyroidism) or too high (hyperparathyroidism).

Hypoparathyroidism

Hypoparathyroidism can be congenital or acquired. Familial congenital hypoparathyroidism, transmitted by an

X-linked recessive gene, has been reported only a few times. Sporadic occurrence of aplasia or hypoplasia of the parathyroid glands is a more frequent cause of congenital hypoparathyroidism, yet it is still extremely rare. Absence of the parathyroids is usually coupled with absence of the thymus gland. The absence of these glands is frequently associated with congenital heart defects, especially anomalies of the aortic arch. This constellation of defects, known as the DiGeorge syndrome, is associated with a deletion of the short arm of chromosome 22.

Pathophysiology

The release of PTH depends on the negative feedback relationship between the level of calcium in the serum and the level of PTH. A decreased level of serum calcium stimulates increased secretion of PTH. An elevated serum level of calcium causes decreased secretion of PTH. Low production of PTH in hypoparathyroidism results in hypocalcemia and hyperphosphatemia. Low serum calcium levels cause twitching, cramps, and tingling and, when severe, can induce tetany.

Acquired hypoparathyroidism may be caused by autoimmune destruction of the glands or by inadvertent removal of the parathyroid glands during surgical thyroidectomy. Autoimmune hypoparathyroidism may be associated with Addison's disease, mucocutaneous candidiasis, and alopecia.

Prognosis

The prognosis of hypoparathyroidism depends on the severity of the disorder. Children with mild hypoparathyroidism usually do very well with calcium and vitamin D therapy. However, during periods of illness (e.g., colds, vomiting), the child's calcium requirements may increase and the child may require increased doses of medication. Children with severe hypoparathyroidism require higher doses of medication, and their condition is more precarious. If doses of medication are missed, severe hypocalcemia may ensue.

Assessment

Assessment of the child with hypoparathyroid glands includes a health history, a physical examination, and laboratory studies.

Physical signs of hypoparathyroidism are primarily a result of too little calcium in the blood. These symptoms would include muscle spasm or cramping; tingling, numbness, or burning (especially around the mouth and fingers); headaches; hair loss; dry skin; malformed nails; and a history of yeast infections (candidiasis). Severe hypocalcemia can induce tetany, which is a state of hyperexcitability of the central and peripheral nervous systems. Tetany is manifested by carpopedal spasms, laryngospasms, paresthesias, convulsions, or some combination of these signs. In hypoparathyroidism, teeth may erupt late and be soft. Examination for dentition, skeletal growth, and any skeletal deformities is important. The child may also have mental deficiencies and have had a history of seizures. Diagnosis is based on a posi-

tive history of these signs and, symptoms and on the physical examination. Assess for the presence of positive Chvostek or Trousseau signs, both of which indicate hypocalcemia.

caREminder

To test for the Chvostek sign, tap sharply over the facial nerve below the temple and anteriorly to the ear. The sign is positive when the mouth twitches (contraction of the lateral facial muscles). To check for the Trousseau sign, apply a blood pressure cuff to the patient's upper arm. Inflate the cuff until the blood supply is occluded. If doing so causes carpal spasm (the fingers contract and the patient is unable to open the hand), the Trousseau sign is positive.

Diagnostic Tests

Laboratory studies reveal low serum levels of calcium and PTH, and an elevated serum level of phosphorus. Patients with long-standing hypocalcemia may exhibit calcifications in the basal ganglia, which may be apparent in radiographs of the skull. An electrocardiogram will show a prolonged QT interval, and electroencephalographic tracings usually show widespread, slow activity. Infants with tetany should have radiographs of the chest. DiGeorge syndrome must be part of the differential diagnosis in these infants; visualization of the thymus using chest radiographs will rule out this syndrome.

Diagnostic studies include measuring serum levels of calcium, phosphorus, alkaline phosphatase, magnesium, PTH, and, in some instances, vitamin D. Renal function studies may be necessary to rule out renal insufficiency. Radiographs of the bones, skull, and/or abdomen, an electrocardiogram, and an electroencephalogram may be helpful (Hochberg & Tiosano, 2004).

Nursing Diagnoses and Outcomes

In addition to the nursing diagnoses presented in Nursing Plan of Care 26-1, the following diagnoses are applicable for the child with hypocalcemia:

Risk for injury related to seizures secondary to hypocalcemia

Outcome: Child will be seizure free when treated with calcium supplementation.

Ineffective airway clearance related to laryngospasm secondary to hypocalcemia

Outcome: Child will have no breathing impairment when treated with calcium supplementation.

Impaired skin integrity related to infiltration of calcium infusion

Outcome: Child's skin will not slough during or after calcium infusion.

Ineffective perfusion (cardiopulmonary) related to rapid infusion of calcium

Outcome: Child's heart rate and rhythm will remain normal while the calcium infusion is given.

Interdisciplinary Interventions

Pharmacologic treatment is aimed at correcting hypocalcemia and maintaining a normal serum calcium level (9–11 mg/dL). Hypercalcemia must be avoided. Treatment of hypocalcemia consists of calcium and vitamin D. Calcium replacement therapy in the form of oral calcitriol or calcium glubionate are most commonly used. Oral calcitriol is actually a vitamin D analogue; this medication improves absorption and use of calcium supplements. Calcium glubionate is most commonly used as a calcium supplement in neonates and younger children who require small amounts of supplementation. Other oral forms such as calcium carbonate, citrate, lactate, or gluconate may also be prescribed. For the child with tetany or seizures, give the calcium intravenously, slowly, as calcium gluconate. It can be administered orally later. Vitamin D is also necessary to maintain normocalcemia and serves as a suitable alternative for PTH. Monitor serum levels of calcium and phosphorus frequently, particularly during the early stages of treatment.

Alert! Early identification of the child with hypoparathyroidism is crucial in preventing severe hypocalcemia, which can cause tetany and consequent laryngospasm and death.

Children with severe hypocalcemia may require treatment with intravenous calcium gluconate, which the nurse must administer slowly intravenously over 1 hour while monitoring the heart rate because of the risk that this medication will cause bradycardia and circulatory collapse. Because calcium gluconate is caustic to tissue, and infiltration causes sloughing, administer this drug with extreme caution, making sure that the intravenous line does not become infiltrated. Other forms of intravenous calcium, such as calcium chloride, are given safely only through a central line.

Community Care

The child should be attended by both a pediatric endocrinologist and the primary care provider to monitor growth, development, and electrolyte balances that could indicate a need for medication adjustment or nonadherence to medication schedule. No special diet is needed, although ensure the child's diet does contain adequate calcium and vitamin D intake.

Hyperparathyroidism

Hyperparathyroidism (parathyroid hormone hypersecretion by one or more of the parathyroid glands) may be primary or secondary. Primary hyperparathyroidism may be caused by a defect of the parathyroid gland such as an adenoma or idiopathic hyperplasia of the parathyroid glands. Primary hyperparathyroidism is generally a disease of adults and is rare in children. Mild primary disease is usually identified in an older child or adolescent and is classified as familial hypocalciuric hypercalcemia (FHH). The majority of FHH is caused by

autosomal dominant loss-of-function mutations in the plasma membrane G protein-coupled receptor known as CASR. Secondary hyperparathyroidism is a compensatory increase in PTH in response to hypocalcemia that may be caused by a variety of disorders. Some causes of hypocalcemia that induce compensatory hyperparathyroidism include maternal hypoparathyroidism, vitamin D deficiency, and certain forms of rickets. The most common cause of secondary hyperparathyroidism is chronic renal failure.

Prognosis

The prognosis of hyperparathyroidism and the resultant hypercalcemia depends on the disorder's etiology and severity.

Assessment

Physical manifestations of primary hyperparathyroidism are largely attributable to hypercalcemia. The systems affected in primary hyperparathyroidism are gastrointestinal, CNS, neuromuscular, skeletal, and renal. Ask about gastrointestinal symptoms, including anorexia, nausea, vomiting, pancreatitis, and constipation. Document any CNS disturbances, such as confusion, impaired memory, and an altered level of consciousness. Look for neuromuscular manifestations such as weakness, muscle atrophy, paresthesias of the extremities, bradycardia, and cardiac irregularities. Note any bone pain, fractures, gait disturbance, or compression of the vertebrae. Renal changes related to increased urinary calcium loss are polyuria and polydipsia; in addition, renal calculi, hypertension, and renal colic have been described in children. Calcification in the cornea of the eye (band keratopathy) is an additional sign of hypercalcemia.

Signs and symptoms of secondary hyperparathyroidism depend on the disorder that induces the parathyroids to hypersecrete PTH. Children with secondary hyperparathyroidism usually have some degree of hypocalcemia. Signs and symptoms related to the direct action of excess PTH are bone demineralization (bone pain, fractures), renal damage (hypertension, renal calculi), and pancreatitis.

The major complication of hyperparathyroidism is hypercalcemic crisis, which can adversely affect the cardiac, neurologic, and gastrointestinal systems.

Alert! Signs of hypercalcemic crisis include lethargy, muscle weakness, coma, and oliguria. Their early detection and treatment can help prevent sequelae and possible death.

Diagnostic Tests

In patients with primary hyperparathyroidism, the level of calcium in the serum is elevated (>10.8 mg/dL), the phosphorus level is decreased, and the magnesium level is low. PTH levels are elevated. Radiographs show demineralization of bone, subperiosteal resorption in the phalanges, and granular appearance of the skull. Abdominal films may show renal calculi. In secondary hypoparathyroidism, the

serum level of calcium is decreased, whereas serum levels of phosphorus and PTH are elevated. Additional tests (e.g., renal function studies) must be done to determine the cause of secondary hyperparathyroidism.

Because FHH is primarily associated with mutations in a single gene (*CASR*), genetic testing can assist in the diagnosis of FHH.

Interdisciplinary Interventions

Treatment of hyperparathyroidism depends on whether the disorder is primary or secondary. Treating primary hyperparathyroidism consists of either surgical removal of the parathyroid adenoma, or subtotal or total parathyroidectomy, depending on where the glands are hyperplastic. Treatment for FHH may not be required at the time of diagnosis, unless it occurs in a neonate with severe life-threatening hypercalcemia. Otherwise, there is no treatment for FHH and a parathyroidectomy is unnecessary and ineffective.

In secondary hyperparathyroidism, the underlying cause must be treated. In patients with renal disease, treatment of secondary hyperparathyroidism includes oral administration of vitamin D (i.e., Paricalcitol, a synthetic vitamin D₂), phosphate binders, and calcium (Robinson & Scott, 2005). In addition, a low-phosphorus diet is prescribed. If secondary hyperparathyroidism is severe, parathyroidectomy may be necessary.

caREminder

Hypercalcemia can affect cardiac muscle contractility. Therefore, assess children with hyperparathyroidism for signs of bradycardia or cardiac arrhythmia.

When caring for a child after a parathyroidectomy, watch carefully for signs of postoperative complications, particularly hypoparathyroidism (see the section on care of the child with hypoparathyroidism). Teach parents how to administer vitamin D, phosphate binders, and calcium. Intervention by a nutritionist is required to instruct the family on a low-phosphate diet to decrease hyperphosphatemia. In addition, if hypercalcemia persists, teach parents the importance of giving large amounts of fluids, particularly acidic fluids such as cranberry juice, to help prevent renal calculi.

Community Care

Instruct parents on safety precautions to be taken in the home and at school to prevent bone injury. If the child with hyperparathyroidism has skeletal deformities, the child may have an altered body image. Nurses and school counselors can be very helpful in assisting these children to identify positive, achievable goals for vocation and avocation.

DISORDERS OF THE PANCREAS

Disorders of the pancreas may develop at any age, including the fetal and neonatal periods. Common endocrine

disorders of the pancreas in the pediatric population include diabetes mellitus (type 1 and type 2), hypoglycemia, and hyperinsulinism.

Diabetes Mellitus

Diabetes mellitus is a group of metabolic diseases that are characterized by **hyperglycemia** resulting from defects in insulin action, insulin secretion, or a combination of both (American Diabetes Association [ADA], 2008b). Two major types of diabetes mellitus are recognized in children: type 1 diabetes, also called *immune-mediated diabetes*; and type 2 diabetes, previously referred to as *noninsulin-dependent diabetes*. Type 2 diabetes may still be referred to as *adult-onset diabetes*, despite the increasing incidence in children. Type 2 diabetes involves insulin resistance and usually a relative, but not absolute, insulin deficiency. Both the ADA (2008a, b) and the ACE (2007) have published evidence-based standards for diagnosis and management of diabetes mellitus (see [thePoint](#) Evidence-Based Practice Guidelines).

Type 1 Diabetes

Type 1 diabetes occurs when the pancreas is no longer able to produce insulin. The onset of this disorder may be abrupt in younger children, or over years to months in older adolescents. Type 1 occurs as a result of an autoimmune process that results in destruction of pancreatic beta cells.

Incidence and Etiology

QUESTION: What is an appropriate summary statement for a 6-year-old to explain how he or she “got” diabetes.

The annual incidence of type 1 diabetes in the United States is 13.8 to 16.9 per 100,000 white children and 3.3 to 11.8 per 100,000 black children. Approximately 176,000 children younger than 20 years have type 1 diabetes (ADA, 2008b). The incidence of type 1 diabetes in children increases with age throughout childhood and reaches its peak at puberty.

Type 1 diabetes has no single cause, although certain common characteristics can precede diagnosis, including seasonal variations (midwinter and spring) and a history of illness, emotional stress, or infection immediately preceding diagnosis (Mooney et al., 2004). Many (40%–60%) patients with type 1 diabetes have no prior affected family member. Recent incidence of type 1 diabetes has been cited as 24.3 per 100,000 persons in the birth to 19-year-old age group across all races (SEARCH, The Writing Group for the SEARCH for Diabetes in Youth Study Group, 2007). **Autoimmunity** (a condition in which the immune system attacks the body’s cells), genetics, and environmental factors are all thought to contribute to the destruction of beta cells. Approximately 85% to 90% of newly diagnosed patients with type 1 diabetes have autoantibodies (ADA, 2008b), and autoantibodies to islet

cells, insulin, and certain key enzymes can also be found in relatives of people with type 1 diabetes. The presence of autoantibodies signifies an autoimmune response: The child's immune system is attacking the body and destroying beta cells. However, the mode of inheritance is not fully understood. Research is ongoing to establish a method for predicting relative risk among family members of patients with type 1 diabetes, but a method to prevent progression to type 1 diabetes in these first-degree relatives has not yet been developed (Diabetes Prevention Trial–Type 1 Diabetes Study Group, 2002). In fact, some scientists have theorized that the strongest link to the increasing incidence of type 1 diabetes in children worldwide can be found in the environment (Gale, 2002; Svensson et al., 2002). The major hypothetical environmental factor in the development of type 1 diabetes is a virus that triggers the autoimmune process. Several viruses have been identified as possible triggers, including coxsackievirus B4; retrovirus; cytomegalovirus; and the viruses that cause mumps, hepatitis, and congenital rubella (Kelly, Rayner, Mijovic & Barnett, 2003).

ANSWER: An example of a statement appropriate for Lindsay at age 6 follows. “You have a gland called a pancreas and its job is to make insulin. Insulin makes it so that your body can use the glucose in the blood. Your pancreas stopped making enough insulin and so there is too much glucose in the blood. You did not do anything to make the pancreas stop making enough insulin. We don’t know why, in some kids, their pancreas stops working right. But for your body to use glucose, you will need to get extra insulin.”

Pathophysiology

Insulin deficiency and resistance cause physiologic and metabolic changes throughout the body. Because of the insulin deficiency, glucose derived from dietary sources cannot be used by the cells (specifically muscle and fat cells) and begins to increase in the bloodstream (hyperglycemia). When serum glucose levels approach 180 mg/dL, the renal tubules have difficulty reabsorbing all the glucose, and glucose is spilled into the urine (**glucosuria**). Large amounts of electrolytes (sodium, potassium, calcium, phosphate, and magnesium) are also excreted by the kidneys as hyperglycemia increases, resulting in increased urination (polyuria) and dehydration. Excessive thirst (polydipsia) ensues in an attempt to relieve the dehydration. Polyphagia also results, from the body's attempt to compensate for the calories lost during polyuria. These signs are more dramatic in children with type 1 than with type 2 diabetes, but the three “polys” are present in both types of diabetes nonetheless. Parents will usually report polyuria and polydipsia; in many cases, though, parents have not noticed polyphagia.

Insulin deficiency (and insulin resistance, to a degree) causes increased catabolism of protein, resulting in increased production of amino acids. At the

same time, the liver converts triglycerides (lipolysis) to fatty acids, which in turn change to **ketone bodies**. Ketone bodies, organic acids that are used for energy by the peripheral tissues, are not well used in insulin-deficient states. Excessive ketone bodies accumulate and are excreted by the kidneys (**ketonuria**). Ketone bodies can produce excessive amounts of free hydrogen ions, resulting in metabolic acidosis. Serum pH is lowered because the body cannot compensate. In severe acidosis, the depth and rate of respirations increases and becomes persistent as the body attempts to compensate by excreting excess carbon dioxide; this respiratory pattern mimics a deep panting pattern (Kussmaul respirations).

Insulin deficiency, in association with increased levels of counterregulatory hormones (glucagon, GH, cortisol, catecholamines) and dehydration, is the primary cause of **diabetic ketoacidosis (DKA)**, a life-threatening form of metabolic acidosis that is a frequent complication of diabetes. Counterregulatory hormones, which have an anti-insulin effect, increase during times of stress, and worsen insulin deficiency. Peripheral glucose use decreases, and hepatic gluconeogenesis increases (increased glucose production by the liver). Severe insulin deficiency causing DKA is a medical emergency and is characterized by hyperglycemia (serum glucose >300 mg/dL), hyperketonemia, ketonuria, glucosuria, metabolic acidosis (arterial pH, <7.30; bicarbonate, <15 mEq/L), and severe alterations in electrolyte and fluid balance. The degree of hyperglycemia does not predict the severity of DKA.

Prognosis

Type 1 diabetes can be controlled with proper medical attention, and acute complications are minimized if blood glucose control is maintained within a recommended target range for age. However, long-term complications such as disorders of the eye (diabetic retinopathy), kidney (diabetic nephropathy), circulatory system (heart disease, stroke), and nerve fibers (peripheral neuropathy) are common secondary conditions associated with diabetes. If left untreated, type 1 diabetes can result in death.

Assessment

QUESTION: How typical was Lindsay's presentation of symptoms?

The child with diabetes usually presents with the classic symptoms of polyuria and polydipsia. Enuresis is seen frequently in the young child who was previously toilet trained, and nocturia is seen in all children. Polyphagia is seen early in diabetes, although anorexia is also commonly seen later in the disease when the child feels extremely ill. Compare current and previous weights. Weight loss, which can be as much as 10% to 30% of the original weight, may be substantial before parents even become aware of it, particularly in the older child. Parents may describe a viral illness

preceding the symptoms of polyuria, polydipsia, and polyphagia. Ask about recent illnesses, because fatigue, headache, and malaise, symptoms often seen at the presentation of diabetes, may be attributed to other illnesses or events, such as influenza recent viral illness, urinary tract infection, or summer heat.

 **Alert!** The diagnosis of type 1 diabetes is often delayed in the infant because evaluation by parents of diaper quantity or volume is insufficient; therefore, they do not notice polyuria. Not until diapers are literally “flooded” do parents notice the large amount of urine output.

Consider diabetes as part of the differential diagnosis in the infant presenting with vomiting, diarrhea, or dehydration. Other common but less characteristic symptoms that are more evident in middle childhood or adolescence include personality changes, lethargy, vision changes, altered school performance, headaches, anxiety attacks, intermittent breathlessness, chest pain, nausea, and either diarrhea or constipation.

If insulin deficiency persists and ketone bodies continue to be excreted, the child begins to experience stomach pains, vomiting, and continued weight loss. Dehydration quickly develops as DKA progresses. The degree of dehydration is assessed while the child is weighed and examined. Assessment includes examining the mucous membranes for moistness, the eyeballs for degree of depression, the skin for turgor, and the anterior fontanel (if present) for depression. The child may also show signs of impending shock: tachypnea, decreased output, decreased level of consciousness, slowed capillary refill, and tachycardia. A late sign of shock in children is hypotension.

DKA is most commonly present in new-onset type 1 diabetes or during crises in children with known type 1, but it may also be found in newly diagnosed type 2 diabetes in the adolescent age group. Kussmaul respirations and changes in mental status may ensue. The breath develops a fruity odor in all children with DKA. If the child becomes somnolent and advances into a coma, these are ominous signs of cerebral edema. The child must be treated promptly with medications to reduce the edema in the brain and then be transferred to a pediatric critical care setting.

Identifying DKA is critical to facilitate treatment and the child’s return to good health (Nursing Interventions 26–2). Presenting symptoms of DKA may include altered level of consciousness, dehydration, electrolyte disturbances, dysrhythmias, shock, and complete vascular collapse. These children are seriously ill and require immediate treatment (ADA, 2008a). The condition is best handled by a pediatric critical care team or by skilled pediatric endocrinologists.

 **ANSWER:** For her age, a typical sudden-onset presentation (parents noted two of the three “polys”: polydipsia and polyuria). There was a gradual weight loss and, immediately prior to diagnosis as her blood sugar continued to climb, vomiting.

Diagnostic Tests

Blood glucose levels in type 1 diabetes are usually more than 200 mg/dL, and a urine sample reveals glucosuria and ketonuria, depending on the degree of acidosis. Glucose in the urine alone can be indicative of a low renal threshold for glucose (Silverstein et al., 2005). A glucose tolerance test is not recommended for diagnosing type 1 diabetes in children, because it may delay diagnosis. Blood glucose and urine test results, along with history and physical examination, confirm the diagnosis. The child may appear very healthy or acutely ill, depending on the degree of acidosis.

Nursing Diagnoses and Outcomes

The nursing diagnoses presented in Nursing Plan of Care 26–1 apply to the child with ongoing management of type 1 diabetes (see also [thePoint](#), Care Paths: An Interdisciplinary Plan of Care for the Child With Diabetic Ketoacidosis).

Interdisciplinary Interventions

Diabetes treatment involves medical therapy with insulin and supportive measures to enhance glycemic control. Monitoring and testing of metabolic control is ongoing. Involving a nutritionist experienced in caring for children with diabetes is essential for meal planning and adjustments, and for providing information about exercise and interactions between foods and medications, whether insulin or oral medications. A diabetes educator can also assist the family in fitting diabetes into the child’s lifestyle, as opposed to the older method of fitting the child’s lifestyle into diabetes management. Assure the child and family from the outset that diabetes should not prevent the child from participating in anything.

Pharmacologic Interventions

QUESTION: What are the various modes of insulin administration that Lindsay has mastered between her diagnosis at age 6 to her newest milestone at age 8?

Insulin therapy is required for a child with type 1 diabetes. Without insulin, the child will die. A combination of fast- or rapid-acting insulin and long- or intermediate-acting insulin is used (Tip 26–2). Some children who are newly diagnosed may need insulin twice daily, before breakfast and before dinner, but as beta-cell destruction progresses, they will be required to administer a rapid- or fast-acting insulin injection before each meal or snack, in addition to a long-acting insulin dose once daily or an intermediate-acting insulin twice daily (see [thePoint](#), Medications and Administration: Insulin Types and Actions). These combinations are used to ensure that the peak action of the insulin coincides with the child’s postprandial blood glucose peaks. This injection pattern mimics the basal–bolus pattern an insulin pump could provide. The newest of the long-acting insulins, Lantus, has little if any peak; it serves as the basal, or “background,” insulin. Either Humalog or Novalog may be administered as the rapid-acting insulin

NURSING INTERVENTIONS 26–2

Diabetic Ketoacidosis

Nursing Assessment	Signs and Symptoms	Laboratory Test	Nursing Interventions	Medical Management
Assess for dehydration.	Skin turgor Dry mucous membranes Sunken eyeballs Depressed fontanel Signs of shock: tachypnea, output hypotension, weak pulse	Hemoglobin, hematocrit Blood urea nitrogen, creatinine	Monitor vital signs every hour. Administer 0.9% sodium chloride (NaCl) at rate ordered. Maintain accurate input and output records.	Administer 0.9% NaCl intravenously at a rate of maintenance plus one half of deficit in first 8 hours. Appropriate amount of fluid should be administered to replace losses and to treat any evidence of shock. Fluids should not exceed 4 L/m ² /day.
Assess for potassium depletion.	None	Potassium elevated (or normal if early)	Before administering potassium, ensure <ul style="list-style-type: none"> • Urine flow has been established • Laboratory value has ruled out hyperkalemia Administer potassium as ordered.	Measure electrolytes. Add potassium chloride to intravenous (IV) fluid per prescriber's orders.
Assess for phosphate depletion.	None	Phosphorus elevated (or normal if early)	Monitor blood phosphate levels.	In severe acidosis, IV potassium phosphate may be ordered.
Assess for hyperglycemia.	Polyuria Polydipsia Polyphagia Weight loss	Blood glucose >180 mg/dL Urine glucose positive	Monitor blood glucose every hour. Monitor urine glucose and ketones every void. Prepare IV insulin drip (100 units regular insulin/100 0.9% NaCl) and administer as ordered.	Obtain blood glucose every 1 to 2 hours. Give IV insulin (regular) as ordered: 0.1 U/kg IV push, followed by 0.1 unit/kg/hour. Prime IV tubing with insulin-containing solution to ensure accurate delivery.
Assess for hypoglycemia.	Diaphoresis Tremors Tachycardia Irritability	Blood glucose <60 mg/dL	Suspend insulin drip. Notify physician. Have fast-acting carbohydrate and IV dextrose available.	If child can take oral fluids, offer 2 to 4 oz juice or soda (non-diet). If child cannot take fluids orally, administer 0.5 to 1 g/kg of 50% dextrose (diluted to D25 prior to administration) via IV slow push. Recheck blood glucose in 15 to 20 minutes.

Nursing Assessment	Signs and Symptoms	Laboratory Test	Nursing Interventions	Medical Management
Assess for degree of acidosis.	Kussmaul respirations Acetone odor on breath Change in level of consciousness	Altered pH Altered carbon dioxide Serum bicarbonate Ketone	Monitor vital signs every hour. Measure urine ketones every void. For severely acidotic child, perform neurologic checks every hour and administer bicarbonate as ordered.	Measure serum pH and carbon dioxide every 2 hours. Insulin administration and fluid correction as ordered should correct acidosis except in those patients who are most severely acidotic (pH <7.30).
Assess for factors precipitating DKA.	Signs of infection: fever, otitis media, dysuria, and so on Report of missed or insufficient insulin dose Report of emotional stress	Change in white blood cell count Positive urine culture Positive throat culture	Report signs of infection to physician. Administer antibiotic as ordered. Teach child and family about consequences of insulin errors and sick-day management. Evaluate diabetes plan to determine whether it can be altered to better fit lifestyle. Refer to social service, psychiatrist, school nurse, visiting nurse, as necessary.	Order indicated studies. If infection is bacterial, treat with an antibiotic.

to cover meals and snacks, acting as the “bolus” insulin. Insulin pump therapy is rarely initiated at diagnosis, but it can be started soon thereafter. Pump therapy is also widely used in pediatrics and should be considered if the child and family are capable and interested (Sullivan-Bolyai et al., 2004) (Fig. 26-4).

Insulin dose is calculated using the child’s body weight, pubertal status, and age initially (Silverstein et al., 2005). Time of day for administration can be selected by the parents and child according to their home and school schedules. The rapid (fast-acting, or bolus) insulin, given before meals and snacks, is dosed according to how much carbohydrate the child will consume and what the current blood glucose result is. The parents or child also adjust the dose for any exercise that might be planned. The subcutaneous injections of insulin should be started at mealtimes in the hospital, to mimic the home schedule. The earlier during the course of hospitalization the parents or caregivers start giving injections, the easier it becomes to administer it, and the sooner the child is able to leave the hospital.

Insulin strength is measured in units: 1 mL insulin is equal to 100 units. In the very small child, changing the amount of insulin by 1 or 2 units can represent a 50% or even a 100% increase or decrease, considering that the doses are usually very small. Insulin syringes and insulin

pens that measure in half units are now available and may be helpful in the child’s care. Show the child and the family the best areas for injection (Fig. 26-5).

Hypertrophy (thickening) of the local tissue can occur when insulin is injected into the same location repeatedly. Insulin is not well absorbed into hypertrophied tissue, and its action is unpredictable, making glycemic control more difficult. Therefore, the child and parents should select at least two or three sites (arms, legs, stomach, or buttocks) for injection. Encourage the child and parents to try all the sites while the child is still hospitalized. Children can choose sites and then chart them, so they remember not to overuse sites.

ANSWER: By age 8, Lindsay has mastered three modes of insulin administration. Lindsay gave herself her first insulin injection with a syringe while at diabetes camp when she was 7. She has used the insulin pen at school and now she is managing the insulin pump.

Monitoring Metabolic Control

To ensure that treatment is working, blood glucose and urine ketones must be monitored.

TIP 26–2 A Teaching Intervention Plan for Administering Insulin

Nursing diagnoses and outcomes

- Deficient knowledge: Mixing and administering insulin

Outcomes:

- Child and family will administer the correct kind and doses of insulin to the child.
- Child will demonstrate the highest levels of skill of which he or she is developmentally capable when administering insulin.

Teach the child/family

Insulin Administration

- Remove insulin from the refrigerator. Insulin can also be stored at room temperature for 1 month before being discarded.

- The person preparing and administering insulin should wash his or her hands.
- Wipe the tops of insulin bottles with alcohol.
- Gently roll bottle of intermediate or long-acting insulin to ensure uniform mixture of insulin and to avoid introducing air bubbles.
- Draw up short-acting insulin, removing all air bubbles.
- Draw up intermediate acting insulin. Lantus cannot be mixed in a syringe with any other insulin.
- Pinch the skin being used for injection to separate subcutaneous tissue from muscle.
- Give insulin in the subcutaneous tissue at either a 45- or 90-degree angle.
- Withdraw needle immediately after injection is given. Dispose of the needle in an appropriate needle storage container.

Blood Testing

Capillary blood glucose monitoring is usually done four to eight times a day for type 1 diabetes and two to three times a day for type 2. This test can be performed by the child or a family member. The supplies are easily transportable, and many blood glucose meters are available to fit any patient's lifestyle. Hypoglycemia, normoglycemia,

and hyperglycemia are accurately assessed by capillary testing, and the results are immediate and specific. The disadvantages of blood glucose monitoring are the invasive nature of the procedure and the sometimes excessive cost of the equipment. The child with type 1 diabetes

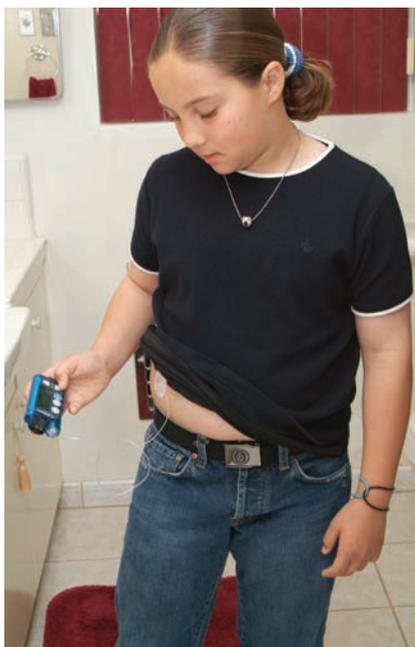

FIGURE 26–4. The patch for the insulin pump can be discreetly placed on the abdomen with the pump placed in the child's pocket.

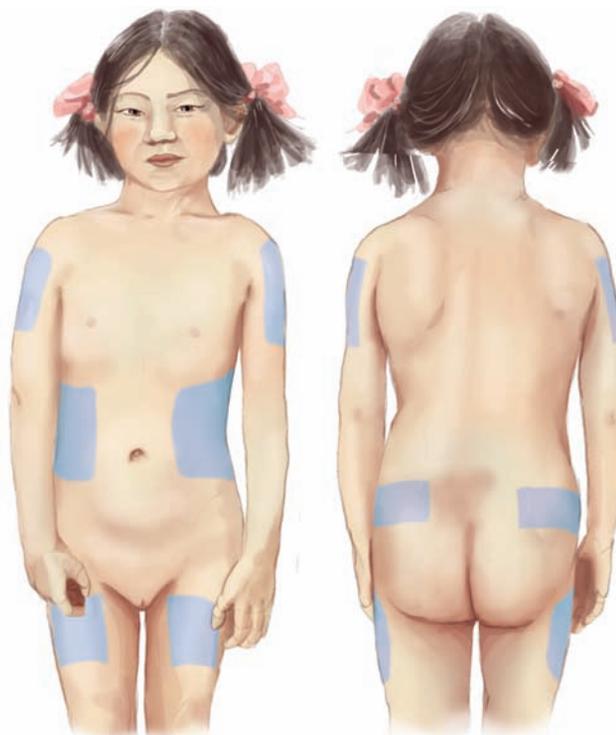

FIGURE 26–5. Sites for insulin injection should be rotated among the areas shown.

FIGURE 26–6. Many children perform blood glucose monitoring at home.

tests blood glucose five to eight times each day: before meals or snacks, before bed, occasionally overnight, and with any signs or symptoms of hypoglycemia or illness (see the section on hypoglycemia in this chapter for more information on managing hypoglycemia). When the child's insulin dose has stabilized, the overnight test can be dropped and only done occasionally, for example with a new sports season, when metabolic demands might change.

Capillary blood glucose monitoring is accomplished by puncturing a finger (or toe in an infant or young child) with a lancet and placing a drop of blood on a blood test strip (Fig. 26–6). The finger should be cleaned with soap and water before testing. The test strip is inserted into a blood glucose meter, and results usually are received in less than 5 seconds. The accuracy of the reading depends on using the test system properly. Quality checks should be completed, using the control solution supplied with the blood glucose meter at purchase, three to four times per year. The hotline number for the meter manufacturer can be found on the back of the meter, so children and families with questions or concerns can access help 24 hours a day.

Test results should be documented and used to regulate the insulin dose. Records should be brought to follow-up appointments and each subsequent healthcare visit. Many meters can download results into a computer program to provide ongoing documentation of the child's status.

Measuring Glycosylated Hemoglobin

QUESTION: Lindsay's A1C has always been less than 8% until she started a growth spurt. Her last A1C was 8.1%. Is this an acceptable measurement or will changes be made in her regimen?

Long-term metabolic control can be evaluated by measuring the glycosylated hemoglobin or hemoglobin A₁C (simplified now to the term *A1C*). Glycosylation is the process by which glucose attaches to hemoglobin nonenzymatically—a slow, mostly irreversible process. The red blood cell, which contains the hemoglobin molecule, lasts in the bloodstream for 90 to 120 days. Increased levels of blood glucose increase the percentage of hemoglobin that is glycosylated and therefore reflect the average glucose concentration for the preceding 3 to 4 months (ADA, 2008a). The A1C level can be helpful in correlating the daily blood glucose results obtained by finger stick with the longer term picture. The daily results really provide only a snapshot of diabetes control, 4 to 8 seconds out of the day, whereas the A1C provides a long-term picture, and should be obtained every 3 months at follow-up visits. The ADA recommends that action be taken when A1C results are more than 8%, but this will vary dependent on patient age. For nonpregnant adults, ADA recommendations consider the diabetes to be under control when the A1C result is less than 7% (ADA, 2008a).

ANSWER: An A1C result of 8.1% is not within the target range for Lindsay's age. The recommendation is for action to be taken. Lindsay's endocrinologist made many changes, including the amount of insulin given per carbohydrate eaten.

Urine Testing

Testing the urine for ketones is an easy and noninvasive monitoring method. However, the test is not considered useful as an effective way to monitor daily insulin doses. Urine ketones indicate fatty acid breakdown and may be present if an illness, insulin deficiency, starvation, or severe hypoglycemic reaction occurs. Teach the child and parents to test the urine for ketones whenever the blood glucose is 240 mg/dL or more, or when the child is ill. The child should increase fluid intake if ketones are present in the urine and should notify the doctor immediately if ketone levels are moderate to high. The family should have a sick-day management chart or handout to guide them in these instances. Extra insulin is essential to “clear” ketones. Initially, the diabetes care provider is needed to determine how much extra insulin the child with type 1 diabetes should administer.

Alert! Urine ketones in association with vomiting may indicate ketoacidosis and should be handled as an emergency. The healthcare provider should be notified immediately, and the child may need to go to the emergency department.

Nutritional Management

QUESTION: Which foods would you tell Lindsay that she cannot eat?

The goals of nutritional therapy in treating diabetes in children (ADA, 2008a; Silverstein et al., 2005) are as follows:

COMMUNITY CARE 26–2

Nutritional Guidelines for Individuals With Diabetes

Protein

- 15% to 20% of daily caloric intake
- Derived from animal or vegetable source

Fat

- 30% or less of the calories from total fat
- Less than 7% of calories from saturated fat
- Up to 10% of calories from polyunsaturated fat
- Minimize intake of trans unsaturated fatty acids

Carbohydrates and Sweeteners

- Carbohydrates and monounsaturated fats: 60% to 70% of energy intake
- Sucrose and sucrose-containing foods: Can substitute for other carbohydrates, but consider nutritional content
- Fructose: May use as a sweetening agent; however, large amounts (>40% of calories) have adverse effects on serum cholesterol and low-density lipoprotein cholesterol

- Sorbitol, mannitol, and xylitol: Produce a lower glycemic response than sucrose and other carbohydrates; however, excessive amounts have a laxative effect
- Saccharin, aspartame, and acesulfame K: Food and Drug Administration approved as nonnutritive sweeteners; can be used by people with diabetes

Fiber

- 20 to 35 g dietary fiber, from varied sources

Alcohol

- Two alcoholic beverages per day for an adult male, one per day for an adult female (1 alcoholic beverage = 12 oz beer, 5 oz wine, or 12 oz distilled spirits) can be ingested with and in addition to the usual meal plan. Children and adolescents should refrain from alcohol use.

Adapted from ADA (American Diabetes Association). (2008). Nutrition principles and recommendations with diabetes. *Diabetes Care*, 21(1), s36–s46.

- Maintaining target blood glucose by balancing food intake with insulin and activity
- Achieving blood glucose goals for age group without excessive hypoglycemia
- Achieving lipid and blood pressure goals
- Providing appropriate calories for normal growth and development in children and adolescents
- Preventing and treating acute complications and preventing long-term complications of type 1 diabetes

For children with type 1 diabetes, integrate insulin injections into usual eating and physical activity habits. Meal plans are based on the child's age, developmental level, preferences, culture, and ethnicity. The nutritionist meets with the child and parents during the hospital stay or early in the outpatient setting. The ADA meal plan is virtually identical to the American Heart Association meal plan: both focus on healthy eating (Community Care 26–2). Children with diabetes should be told that any food they want can be worked into their meal plans. Portion sizes, selection and type of food, and activity are all considered to strike the healthy balance needed.

ANSWER: There is no food that Lindsay is not allowed to eat. Certainly, there are choices that are better than others. But as long as she keeps track of what she eats and programs her insulin pump correctly, there are no forbidden foods.

Community Care

QUESTION: Lindsay plays on a basketball team.

On the days she has a 1-hour basketball practice, her blood sugar will be affected for the next 24 hours. A midnight blood sugar of 150 mg/dL may become a 3:00 AM blood sugar of 50 mg/dL. What strategies can you develop to help stabilize Lindsay's blood glucose on the days when she has basketball practice?

Many children with new-onset type 1 diabetes are never hospitalized, even at diagnosis. Children can receive an initial injection of insulin in the emergency department and then return the next day to begin learning about their condition. Teaching usually is accomplished at large medical centers or communities that have active pediatric diabetes education programs. In smaller outlying communities, hospitalization may still be routinely required for teaching purposes. The degree of acidosis and dehydration, and the family social and support situation, may also drive the need for hospitalization.

Type 1 diabetes, when not managed carefully, can become a life-threatening acute illness. Management requires attention and caring from parents or another supportive person on an ongoing basis, despite the child's perceived ability to manage the physical tasks of care, such as giving insulin injections. Often children who do

CLINICAL JUDGMENT 26–3

A Child With Type 1 Diabetes

Pierre, age 10 years, has type 1 diabetes. He is admitted to the hospital at the time of diagnosis for initial management. In the pediatrician's office, Pierre's blood glucose level is 930 mg/dL.

Questions

1. During your admission assessment, what data would you collect to assist you to teach Pierre about his diagnosis and his management plan?
2. What factors would indicate good metabolic control for the child with type 1 diabetes?
3. On Pierre's fourth morning in the hospital, you note that he is pale and sweaty. Based on his symptoms, what is his problem at this time?
4. When teaching Pierre and his family about insulin administration, what strategies should be used?
5. When the home care nurse visits Pierre 1 week after discharge, what age-appropriate activities should she expect Pierre to be doing in regard to managing his diabetes?

Answers

1. Previous history of any serious or chronic illness, previous hospitalizations, Pierre's exposure to other family members who may have diabetes or another chronic condition.
2. Hemoglobin A1C values less than 7.5%, normal growth and development, and few episodes of hypoglycemia or hyperglycemia.
3. Pierre is hypoglycemic. Rapid treatment would involve giving him 15 g glucose-containing solid, semisolid, or liquid such as orange juice.
4. Plan demonstration, supervision, and practice time with Pierre and his parents to learn injection and site rotation techniques, methods to draw up insulin, and the proper way to store medication and equipment.
5. Pierre is actively involved in testing his blood glucose levels. He gathers all the equipment for insulin administration. With parental assistance, he can draw up the correct dose of insulin. He can administer the injection himself, although sometimes he chooses to have a parent administer the injection, especially in hard-to-reach places. Pierre can discuss appropriate diet choices and restrictions. Pierre can recognize and treat hypoglycemia.

not do well, and thus come to the attention of the acute care system, either have an acute infection that exacerbates the chronic condition or lack parental and social supports, and may be indirectly asking for more adult attention by avoiding proper care of their chronic illness.

Caregivers, teachers, and physical education instructors need to have accurate information concerning the child, and need to know how to identify and treat hypoglycemia (discussed later in this chapter). Inform teachers when a student is diagnosed with type 1 or type 2 diabetes. When the child returns to school, encourage parents to give teachers, school nurses, and coaches instructions for their child, particularly instruction on recognizing and treating hypoglycemia in type 1 diabetes (Clinical Judgment 26–3).

Children, particularly adolescents, may at times record results in their glucose logbooks that are not factual, because high numbers may cause arguments between child and parent that the child wants to avoid. The child may be making up numbers, rather than actually testing for them. The A1C can help to determine whether this is the case, because the A1C and daily log should correlate. If they do not, an explanation for the differences should be sought. High and low results could be occurring at times the child is not testing, or the lack of correlation could be attributable to factitious numbers.

Exercise is a vital component in managing both type 1 and type 2 diabetes in children and offers many benefits. It assists in the use of dietary intake and may decrease the amount of insulin or oral agents that a child requires. Exercise enhances insulin absorption and facilitates weight loss or maintenance. Exercise is also important for the child's normal growth and development. The child should eat a snack before exercising, to prevent hypoglycemia. Exercise lasting less than 1 hour usually requires a small snack consisting of a complex carbohydrate or a protein. More intense exercise or exercise lasting longer than 1 hour may require more frequent snacks throughout the activity and a combination of complex carbohydrates and protein before the activity. An insulin adjustment may also be needed if hypoglycemia occurs frequently with an activity. The family is instructed to check the child's blood glucose level after activity and also before bedtime and overnight to prevent nighttime hypoglycemia events, because exercise can cause delayed hypoglycemia (Community Care 26–3). Healthcare team members, parents, and school support personnel can teach adolescents effective coping skills that may help them deal with day-to-day management of their illness. Long-term care should include annual eye examinations. A fasting lipid panel should also be evaluated in the child within a year after diagnosis. Recommendations for lipid

COMMUNITY CARE 26–3

Living With Newly Diagnosed Type 1 Diabetes

- Liberal bathroom privileges, because hyperglycemia creates polyuria
- Snacks as needed to avoid insulin reaction
- Blood glucose checks as needed, to be performed by younger children in the presence of the school nurse; older children should be allowed to carry meter with them for testing
- Fast-acting glucose in case of hypoglycemia available from teachers, coaches, or school nurses; glucagon available at school
- In emergency, parents notified after 911
- Peer support group recommended for middle childhood and adolescent patients.

goals and management will vary according to the age of the child.

KidKare ■ Hyperglycemia can be exacerbated if the child exercises when the blood glucose level is 240 mg/dL or more and ketones are present in the urine. Therefore, the child should generally avoid exercise if ketones are detected during this time. Guidance from the diabetes team should be sought if ketones are present. Exercise can be reinitiated when the urine is free from ketones.

ANSWER: If Lindsay's midnight blood sugar is less than 150 mg/dL, an effective strategy is to adjust the bedtime snack to include more protein or fat. This should allow Lindsay's 3:00 AM blood sugar not to be too low.

Type 2 Diabetes

QUESTION: What are the ways in which the onset of type 2 diabetes is different from that of type 1 diabetes?

Type 2 diabetes is a condition characterized by insulin resistance. It has a slow and gradual onset, and is most often related to obesity. Type 2 diabetes is not considered an autoimmune disease.

Incidence and Etiology

Based on 2002–2003 data, about 3,700 youth are diagnosed annually with type 2 diabetes (CDC, 2007). Native

Americans, Hispanics, and blacks have a higher incidence than other populations of type 2 diabetes in youth. Obesity (body mass index exceeding the 95th percentile) among American children has increased from 1976 to 2006. For children age 2 to 5 years, prevalence increased from 5.0% to 12.4%; for those age 6 to 11 years, prevalence increased from 6.5% to 17.0%; and for those age 12 to 19 years, prevalence increased from 5.0% to 17.6% (CDC, 2006). Average age of onset for type 2 diabetes is 12 to 14 years, but the diagnosis should not be overlooked even in younger children if risk factors are present.

A strong family history of type 2 is often present, as is a familial tendency toward obesity and a sedentary lifestyle. A child whose mother had gestational diabetes is particularly at risk for diabetes (Bloomgarden, 2004). Although ethnic background and mother's gestational history are not a modifiable risk factor, weight and lifestyle certainly are. The challenge with type 2 diabetes in children is that often the entire family's lifestyle, not just the child's, requires modification.

Pathophysiology

Type 2 diabetes is most often associated with obesity, hypertension, and elevated cholesterol (combined hyperlipidemia). The condition may also be associated with metabolic syndrome. It is also associated with acromegaly, CS, and a number of other endocrinologic disorders, including polycystic ovarian syndrome.

Type 2 diabetes is characterized by peripheral insulin resistance with a defect of insulin secretion (hyperinsulinemia) that varies in severity with the individual. For type 2 diabetes to develop, both defects must be present. Many overweight individuals have insulin resistance, but only those with an inability to increase beta-cell production of insulin develop type 2 diabetes. During the progression from normal glucose tolerance to abnormal glucose tolerance, insulin resistance worsens. Hepatic glucose output increases with increased glycogen production and gluconeogenesis. The failure of the beta cells to hypersecrete insulin underlies the transition from insulin resistance to clinical diabetes as demonstrated by overt fasting hyperglycemia and increased hepatic glucose function (ADA, 2008B). Puberty is believed to play a role in the development of type 2 diabetes. During puberty, resistance to the action of insulin is increased, resulting in hyperinsulinemia. When pancreatic beta-cell functioning is normal, puberty-related insulin resistance is compensated by increased secretion of insulin. Increased GH secretion is believed most likely responsible for the increased insulin resistance. Not surprisingly, the mean age for development of type 2 diabetes in youth is 13½ years (Berry, Urban, & Grey, 2006).

Prognosis

Type 2 diabetes mellitus is one of the leading causes of adult morbidity and mortality in the United States, because of its role in the development of optic, renal, neuropathic, and cardiovascular disease. Children are at risk because type 2 diabetes can go unrecognized and

untreated for many years while the hyperglycemic changes damage vital organs (McKnight-Menci, Sababu, & Kelly, 2005). Advocating for healthy lifestyles in children identified with type 2 diabetes can prevent many of the complications and the long-term economic burden on the individual of managing these complications in adult life.

Assessment

The child with type 2 diabetes usually has glucose in the urine and a high fasting or random blood glucose result. Insulin and C-peptide levels are elevated. A diabetes autoimmune profile will be negative, because type 2 diabetes is not an autoimmune-mediated illness. Acidosis can be present but is usually not as severe as in type 1. The child can have ketones in the urine but does not appear acutely ill.

Look for signs and symptoms similar to those of type 1 diabetes, but much less severe. However, physical examination may reveal **acanthosis nigricans** (discoloration and skin thickening, most commonly found in the axillae, neck folds, and between fingers), which is a clinical sign of insulin resistance. Children with type 2 are usually older at diagnosis than those with type 1, so a history may be easier to elicit. Children are usually older than 12 years of age and obese, but cases certainly do occur in early childhood and the diagnosis should be considered, regardless of age, if the child presents with risk factors. Children and parents may report urinary frequency, increased thirst, and sometimes difficulties in school. Weight loss is rarely a symptom; weight gain is usually the norm. Most children have no physical symptoms, and the diagnosis is discovered by routine urine screening during a school physical or acute visit. Female patients who are suspected of having type 2 diabetes should also be evaluated for signs of polycystic ovarian syndrome as well.

Diagnostic Tests

Children older than 10 years (or earlier if pubertal onset is earlier) should be screened every 2 years for type 2 diabetes if they have certain risk factors: high-risk ethnicity (i.e., Native American, black); family history of type 2 diabetes; signs of insulin resistance (acanthosis nigricans, high blood pressure, polycystic ovarian syndrome, dyslipidemia); and overweight (body mass index >85th percentile for age and gender, weight for height >85th percentile, or weight >120% of ideal for height). A fasting plasma glucose is the preferred test. Random glucose testing can be done if concern exists that the family and child will not return for a fasting study (ADA, 2008a).

Interdisciplinary Interventions

Management of the child with type 2 diabetes focuses on the following four objectives as outlined by the American Academy of Pediatrics (Gahahan & Silverstein, 2003, p. e328):

- Eliminating symptoms of hyperglycemia
- Assisting the child in maintaining a reasonable body weight (weight stabilization)
- Decreasing cardiovascular risk factors: Hypertension, hyperlipidemia, hyperglycemia, microalbuminuria, sedentary lifestyle, and use of tobacco products
- Achieving overall improvement in the child's physical and emotional well-being

Treating Hyperglycemia

Treating type 2 diabetes in children may require insulin at the outset if the child is acidotic and acutely ill. More commonly, the child can be managed initially with oral agents, meal planning, and increasing activity. The only oral agent currently approved for use in children 10 years and older is metformin (McKnight-Menci et al., 2005). Studies are currently exploring the effectiveness of metformin combined with the thiazolidinediones (i.e., Actos) in children with type 2 diabetes; this combination is used very successfully in adults with type 2, but requires study in the pediatric population. Angiotensin-converting enzyme inhibitors (e.g., enalapril) are commonly used in children for their protective effects on the kidneys when microalbuminuria is evident. Additional studies are needed to document optimal dosing for children. Current medication references that focus on dosing and using medication in children should be consulted prior to prescribing.

Blood Testing

Children with type 2 diabetes usually complete blood testing two to three times per day, generally before breakfast and at bedtime; many children test either after school or before dinner as well. Motivating the child to test and understand the importance of testing is as important with type 2 diabetes as it is with type 1. These issues may be more accentuated with type 2, because hypoglycemia is less common in these children; thus, they can become more complacent in their motivation to complete testing.

The child with type 2 diabetes is usually not instructed to have urine ketone strips at home, unless he or she routinely receives insulin as part of care.

KidKare ■ ■ Encouraging the child to self-test can be a challenge. Help the parents to devise different motivating strategies. These strategies must be tailored to the age of the child. For example, parents may have a rule in their house that before a teenager is permitted to take the car keys or get in the driver's seat, a blood glucose test must be performed, regardless of whether the child has type 1 or type 2 diabetes.

Maintaining a Healthy Body Weight

The nutritional therapy goals for the child with type 2 diabetes include maintaining glycemic control and a

healthy body weight. A weight-loss program can be implemented to accommodate the child's lifestyle and cultural preferences. Carbohydrate counting has been found to be an effective method to maintain glycemic control. In addition, a consistent low-carbohydrate meal plan can be effective in reducing caloric intake. The diet should include high-fiber foods. Fiber aids in improving postprandial hyperglycemia, weight loss, and satiety (McKnight-Menci et al., 2005).

Preventing Health Risks and Improving Overall Well-being

Regular physical activity helps to treat type 2 diabetes and prevent cardiovascular complications and other complications from a sedentary lifestyle. Chapter 7 provides an in-depth discussion of physical activity guidelines for adolescents. These guidelines include encouraging adolescents to be physically active daily and engaging in three or more sessions per week of physical activity that last 20 minutes or longer. Following these guidelines will assist the youth to achieve improvement in the child's physical and emotional well-being.

A primary goal of community care is tertiary prevention that targets youth at risk for developing type 2 diabetes. Youth programs are aimed at promoting appropriate nutritional intake and exercise patterns consistent with the child's age and developmental abilities. In addition, education must also focus on encouraging behavioral changes among family members. Mothers do most grocery shopping and make most decisions about the child's eating patterns at home. Parents should role-model making healthy nutritional choices and participating in physical activities that promote cardiovascular health (Berry et al., 2006). Tip 26–3 summarizes the components of the teaching plan to be used with children and their families. The teaching plan includes discussing home care issues such as nutrition, exercise, and medication administration.

ANSWER: Although type 1 diabetes usually has a sudden onset, type 2 may have a very slow progression of symptoms and may remain undetected for a long time. Children who develop type 2 diabetes are usually obese and those with type 1 are not. There are more often other members of the family who are also diabetic and a greater chance that the mother experienced gestational diabetes during her pregnancy when a child develops type 2 diabetes.

Hypoglycemia

Hypoglycemia (usually defined as blood glucose level <60 mg/dL) is a common complication for children with type 1 diabetes. It often occurs if a meal is missed or late, if the insulin dose is too high or drawn up incorrectly, or in the case of strenuous physical activity without an added snack. Alcohol ingestion, gastroenteritis, or extra insulin administration can also precipitate

hypoglycemia. Alcohol intensifies insulin action and may inhibit gluconeogenesis, causing delayed hypoglycemia.

KidKare ■ The child and parents need to know that hypoglycemia can occur not only during or immediately after a strenuous activity, but also several hours after the activity, when the child is resting quietly.

Assessment

Signs of hypoglycemia include diaphoresis, tremulousness, tachycardia, hunger, weakness, pallor, and dizziness. CNS symptoms consist of headache, irritability, poor coordination, combativeness, double vision, and confusion. Signs of severe CNS depression from hypoglycemia include unconsciousness and seizures.

KidKare ■ Infants cannot describe their symptoms and usually do not demonstrate many of the symptoms of hypoglycemia. Teach parents to rely on blood glucose monitoring and to administer glucose in the form of juice or tubes of decorative cake gel (not the larger tubes of icing) squirted inside the cheek pouch. In the case of an emergency, the parent administers glucagon either intramuscularly or subcutaneously.

Interdisciplinary Interventions

Hypoglycemia is treated based on the severity of the symptoms. In the case of mild or moderate hypoglycemia, simple carbohydrates are the treatment of choice; 15 grams of carbohydrates is the recommended dosage for an older child, followed by a snack containing protein if a meal will not be eaten in the next 1 to 2 hours. Instruct the older child to ingest 4 to 6 oz of juice or regular soda, two to three glucose tablets, commercially available glucose gel, or a small tube of commercially available decorative cake gel. Children in the infant and early childhood age groups can be treated with 2 oz of juice, or two thirds of a tube of decorative cake gel, to equal 10 g fast-acting carbohydrate. Many parents of these young patients find that milk flavored with a small amount of syrup that contains sugar enables the child to consume a fast-acting carbohydrate and a protein together and is easier for the child to consume (Silverstein et al., 2005). The amount of carbohydrate should be adjusted according to the severity of the hypoglycemia and the blood glucose result. Mild to moderate hypoglycemia can occur in children with both type 1 and type 2 diabetes. It is common in children with type 1 diabetes, from the action of insulin. It is less common in children with type 2 diabetes and may depend on their treatment plan, and whether it includes insulin or oral agents that carry hypoglycemia as a side effect.

TIP 26–3 A Teaching Intervention Plan for the Child With Type 2 Diabetes

Nursing diagnoses and outcomes

- Imbalanced nutrition: More than body requirements related to intake in excess of activity and metabolic expenditure, lack of knowledge and/or ineffective coping

Outcomes:

- Child will maintain adequate caloric intake, as evidenced by achieving desired weight parameters.
- Child will maintain blood glucose and lipid levels within target parameters.
- Child will be able to make daily meal and snack choices that incorporate desired weight management goals and physical activity schedule.
- Risk for noncompliance related to challenges required in changing one's lifestyle and maintaining these changes as child grows and develops

Outcomes:

- Child and family will understand management plan and be able to incorporate dietary, physical activity, and medication administration changes into family lifestyle.
- Child or adolescent will make personal choices that are consistent with daily management plan for diabetes.

Teach the child/family

Managing the Child's Condition

Prevention

- Evaluate family lifestyle modifications that can be made to reduce risk of diabetes.

Stay at a Healthy Weight

- Establish goals for weight loss, blood glucose, and lipid values.
- Restrict carbohydrate intake to 45 g at each of the three main meals of the day.
- Eat smaller portions.
- Take your time to eat. A good rule of thumb is to take 45 minutes to eat each meal.

Eat Healthy Foods

- Identify eating patterns that need changing.
- Read food labels to learn about the food and how much you should eat.
- Refer to registered dietitian for individualized diet plan.

- Eat meals and snacks about the same time each day; try not to skip any meals.
- If you eat too many carbohydrates at one time, your blood glucose may go too high. Choose high-fiber carbohydrates and foods low in saturated fats and high in monounsaturated fats.
- Drink water instead of juice and soda.

Be Active

- Determine frequency of exercise and type of moderate-intensity physical activity to be completed.
- Be physically active for at least 60 minutes every day.
- Discuss methods to maintain hydration and avoid hypoglycemia during exercise activities.

Medication Administration

Oral Agents

- Take oral medications for diabetes (i.e., Metformin) as directed if needed to assist in control of diabetes.
- Side effects include nausea, cramping, diarrhea, and lactic acidosis.

Insulin

- May need to be used depending on severity of acidosis and hyperglycemia.
- Side effects include hypoglycemia and possible weight gain.

Monitoring

- Height and weight.
- Signs of diabetic ketoacidosis.
- Signs of hypoglycemia

Contact the Healthcare Provider if:

- Child has signs of hyperglycemia (polyphagia, polyuria, or polydipsia) or signs of hypoglycemia (hunger, nervousness and shakiness, perspiration, dizziness or light-headedness, sleepiness, confusion, difficulty speaking, feeling anxious or weak).
- Child experiences fatigue, malaise, or vomiting and the child is taking Metformin, stop the medication and notify healthcare provider immediately, because these symptoms may indicate life-threatening lactic acidosis.

Severe hypoglycemia results in loss of consciousness or seizures and must be treated with glucagon. Glucagon is a counterregulatory hormone that stimulates the liver to produce enough glucose to increase the blood glucose

level by about 80 mg/dL. Instruct the parents how to administer glucagon properly. The child may be combative and thrashing, so administration can be difficult. Children younger than 6 years of age receive 0.5 mL (0.5 mg)

glucagon subcutaneously or intramuscularly, and children 7 years and older receive 1 mL (1 mg) subcutaneously or intramuscularly. The child should respond within 10 to 15 minutes after the injection. The injection may be given right through clothing, because trying to undress the child to give the injection wastes unnecessary time and may be impossible with a thrashing child. Teach parents to obtain a blood glucose level before giving the glucagon or immediately after the injection has been given to document hypoglycemia. When glucagon is administered, the child is very likely to vomit while in a semiconscious state. Prepare the parents for this possibility and instruct them to keep the child on his or her side after glucagon administration. The parent should take the child to the nearest emergency department or notify the rescue squad if the child does not respond within 15 minutes. If the child recovers at home, instruct the parents to call their primary care provider or endocrinologist to report the severe hypoglycemic episode and discuss any insulin adjustment that may be required within the next 24 hours. Severe hypoglycemia would be a very rare event for a child with type 2 diabetes, but any parent with a child with type 1 diabetes should be prepared, with glucagon on hand at all times.

Community Care

Teach the parents and children the causes, symptoms, and treatment of hypoglycemia. Advise the child to wear an identification tag or MedicAlert bracelet, especially when away from home. Many types of emergency alert tags are available through mail-order houses, Internet sites, and jewelry stores. A bracelet or tag that the child finds appealing greatly increases the possibility that the child will wear it routinely. Adolescents, in particular, need to be educated concerning the effects of drugs and alcohol on diabetes. Judgment-altering substances or appetite suppressants affect the daily routine and create an imbalance among food, insulin, and exercise. Alcohol intensifies the glucose-lowering effects of insulin and also causes hypoglycemia (Silverstein et al., 2005).

Explore the topic of alcohol ingestion routinely with children during follow-up visits for diabetes. As the children enter middle childhood and adolescence, ask parents to step out of the room for some topics, such as alcohol and drug use, and sexual activity. Girls with poorly controlled diabetes may have difficulty conceiving, leading them to a false belief that they cannot become pregnant. Sexual activity must be discussed with these patients.

The risk-taking behaviors common among adolescents predispose this age group to frequent episodes of DKA. Groups that teach coping skills assist adolescents to prepare for situations (such as peer pressure to drink alcohol or use illicit drugs) and are an effective way to prevent health- and life-threatening behaviors (Silverstein et al., 2005). For medical and nursing management of DKA, see Focused Physical Assessment 26–2 and [thePoint](#). Care Paths: An Interdisciplinary Plan of Care for the Child With Diabetic Ketoacidosis.

Hyperinsulinemia

Hyperinsulinemia is an overabundance of insulin, which results in rapid depletion of exogenous and endogenous glucose and causes hypoglycemia. Hyperinsulinemia may present as a transient disease during the neonatal period, occurring almost exclusively among infants of mothers with diabetes. The most common cause of persistent hyperinsulinemia after the neonatal period is a combination of four genetic mutations on chromosome 11, a condition called *persistent hyperinsulinemic hypoglycemia of infancy* (PHHI). The incidence of PHHI in northern Europe is 1 in 50,000 live births, but it is higher in countries where the occurrence of consanguinity is high (as in Saudi Arabia, where the incidence is 1 in 2,675 live births) (Snehag & Haymond, 2004). Hyperinsulinism seen in the older child is usually associated with a pancreatic adenoma, although this association is rare in the pediatric population.

Pathophysiology

In infants of diabetic mothers in whom excellent blood glucose control (euglycemia) has not been achieved during pregnancy, second and third trimester hyperglycemia may result in metabolic complications. When blood glucose levels are elevated in the pregnant mother, the fetus then receives larger than required amounts of glucose, amino acids, and fatty fuels during growth and development. This supply far exceeds the growing fetus' demands and requires an increased supply of insulin from both mother and fetus. The immature beta cells in the fetal pancreas respond by proliferating more than is normally needed, producing excess insulin. After the infant is delivered, the pancreas continues to produce excessive amounts of insulin that may result in neonatal hypoglycemia. Peak incidence of neonatal hyperinsulinemia and subsequent hypoglycemia is 6 to 12 hours after birth, but in severe cases it can persist for several days after birth. In PHHI, the normal relationship of insulin release in response to glucose levels is disrupted; the pancreas and beta cells secrete excessive amounts of insulin in response to glucose levels (Snehag & Haymond, 2004).

Prognosis

Hyperinsulinism may cause hypoglycemic brain damage. Injury to brain tissue can cause cognitive challenge, cerebral palsy, seizure disorder, microcephaly, spasticity, and ataxia (Steinkrauss et al., 2005). When infants with hypoglycemia caused by hyperinsulinemia are identified early and oral feedings are initiated promptly, the prognosis is quite good. The neonatal form is transient and will dissipate as the infant adjusts to exogenous sources of glucose and develops an appropriate beta-cell response. Because the hypoglycemia of PHHI is more long-lasting than hypoglycemia in infants of diabetic mothers, infants with PHHI are at greater risk for the neurologic sequelae of repeated hypoglycemic events. PHHI must be identified and appropriately treated over

the long term for the best prognosis; otherwise, neurologic damage may occur.

Assessment

The infant with hyperinsulinemia is often macrosomic, or large for gestational age, at birth. Blood glucose levels in the term neonate may be less than 35 mg/dL. The infant may be lethargic, irritable, tachypneic, tremulous, diaphoretic, hypothermia, display episodic cyanosis, and have a high-pitched cry. Criteria for diagnosing hyperinsulinism include

- Plasma insulin concentrations $>5\text{--}10\ \mu\text{U/mL}$ at time of documented hypoglycemia
- Insulin: Glucose ratio is 0.4 or higher
- Low plasma ketones
- Low free fatty acid levels
- Rapid development of fasting hypoglycemia
- High exogenous glucose infusion rates needed to maintain euglycemia
- Absence of ketonemia or ketonuria
- Elevated C-peptide
- Increased plasma glucose after glucagon administration at time of hypoglycemia

Serum glucose and insulin levels are obtained every 2 hours. Every void should be checked for ketone bodies, although ketone levels are usually low or absent.

Interdisciplinary Interventions

Whether the underlying etiology is transient neonatal hyperinsulinemia or PPHI, the child with hyperinsulinemia initially may be given infusions of glucose and glucagon, administered by the nurse. If the hypoglycemia does not resolve during the neonatal period, care at home will include providing frequent feedings throughout the day, awakening the infant for nighttime feedings, and initiating oral diazoxide.

Oral diazoxide suppresses the secretion of insulin by the beta cells without lowering the blood pressure (Steinkrauss et al., 2005). The initial dose is usually 5 to 20 mg/kg/day, divided into three doses. A common acute side effect of diazoxide is the retention of salt and water. Water retention can be reduced by administering hydrochlorothiazide, which may also further decrease insulin secretion. Life-threatening complications such as nonketotic hyperosmolar coma, congestive heart failure, and ketoacidosis can be avoided by diligently monitoring fluid balance, electrolytes, and urine ketone levels.

Surgery for subtotal pancreatectomy or removal of focal lesions is indicated in infants who are unable to maintain euglycemia with pharmacologic treatment or who cannot be removed from intravenous therapy. A 95% to 99% subtotal pancreatectomy is performed by a pediatric surgeon. The spleen is left in place. Results of surgery can vary. Many children require insulin administration for weeks or months to control hyperglycemia while their bodies adapt, whereas other children have

recurrent hypoglycemia shortly after surgery. In these cases, reexploration with a near-total pancreatectomy may be indicated. Any child who requires surgical intervention is considered at much greater risk to develop diabetes later in life.

Community Care

Provide parents clear and concise explanations for the cause of the hyperinsulinemia, after it has been established, and the specific therapy recommended. Teach parents the techniques to monitor blood glucose at home and to recognize the signs and symptoms of hypoglycemia. Instruct parents on the medical therapy and its possible side effects. Frequent feedings are required for nearly all these infants. If the infant must receive nighttime nasogastric feedings at home, teach the parents how to place a nasogastric feeding tube properly and refer them to a home care company to obtain supplies, feeding pump, or formulas.

Preoperative preparation and psychological support are essential if surgery is recommended. Infants with hyperinsulinemia, whether transient neonatal or PPHI, usually improve rapidly with medical or surgical therapy.

ALTERATIONS IN FUNCTION OF THE ADRENAL GLANDS

The adrenal glands have two distinct portions: the adrenal medulla and the adrenal cortex. The two tissues have different embryonic origins, secrete different hormones, and have different regulatory mechanisms. The adrenal medulla secretes the catecholamines epinephrine (adrenaline) and norepinephrine (noradrenaline). Because these hormones are also produced by the sympathetic nervous system, the absence of a medullary adrenal supply is not life threatening. The adrenal cortex secretes steroid hormones that are essential to life (see Table 26–1). The three major groups of steroids are the mineralocorticoids, the glucocorticoids, and the sex steroids. The adrenal gland depends on pituitary secretion of ACTH. Therefore a lack of adrenal steroids may be caused by inadequate ACTH production from the pituitary to stimulate the adrenal gland or a defect in the adrenal gland itself (Geller & Miller, 2004).

The conditions discussed in this section include adrenocortical insufficiency, CAH, CS, and premature adrenarche (see also [thePoint](#) Supplemental Information for a discussion of pheochromocytoma).

Adrenocortical Insufficiency

Acquired or chronic adrenocortical insufficiency results when the adrenal gland is absent or damaged. *Acquired adrenocortical insufficiency* is a relatively rare phenomenon in childhood. Common causes include traumatic, hemorrhagic, and neoplastic insults to the hypothalamic-pituitary

axis (Root & Shulman, 2004). Trauma and hemorrhage may occur during the neonatal period as a consequence of prolonged labor. Treatment for illnesses such as neoplasms, nephrotic syndrome, severe respiratory distress, or rheumatoid arthritis with glucocorticoids can lead to suppression of the hypothalamic–pituitary function and secondary, usually temporary, loss of adrenocortical activity.

Abrupt withdrawal of corticosteroids in patients who have been given large doses for a long time or failure to give increased doses of corticosteroids during stressful situations such as surgery or severe infections may precipitate acute *adrenal crisis*. This type of acquired adrenocortical insufficiency may be characterized by hypoglycemia without an associated illness (such as diabetes), failure of linear growth, or unexplained weight gain. Acute infections, such as meningococemia, can lead to adrenal hemorrhage and shock (Waterhouse-Friderichsen syndrome). Other causes of adrenocortical insufficiency include metastatic cancer, familial glucocorticoid deficiency, defects of steroid biosynthesis (adrenal hyperplasia, discussed later in this chapter), isolated aldosterone deficiency, adrenalectomy for CS, and certain drugs.

Chronic adrenocortical insufficiency (Addison's disease) is commonly caused by autoimmune destruction of the adrenal cortex, which results in dysfunction of steroidogenesis. The condition usually occurs during early adolescence. Addison's disease has become more common in children through its association with type 1 diabetes. Patients with type 1 diabetes are at increased risk for Addison's disease: Approximately 1% of patients with this type of diabetes have the autoantibodies associated with Addison's disease (Barker, Fain, & Eisenbarth, 2005). Addison's disease is rare in the general population, affecting approximately 1 per 10,000 people. By contrast, it occurs in approximately 1 per 200 patients with type 1 diabetes (Park et al., 2002).

It has been hypothesized that an environmental trigger initiates the autoimmune process that ultimately results in progressive dysfunction of the adrenal gland and the subsequent adrenal insufficiency of Addison's disease, but no such trigger has yet been defined. Risk for adrenal autoimmunity is considered genetic. Many relatives of individuals with Addison's disease have other autoimmune diseases such as type 1 diabetes or autoimmune thyroid disease (Barker, Fain, & Eisenbarth, 2005).

Pathophysiology

Aldosterone is the most potent mineralocorticoid, and its principal action is in maintaining electrolyte balance and blood pressure. Aldosterone secretion is regulated by activation of the renin–angiotensin system, so adequate levels can be maintained even in the absence of ACTH. The predominant glucocorticoid is cortisol. It also maintains homeostasis of electrolytes, blood pressure, and blood glucose by its influence on the metabolism of most tissues. Without prompt treatment, acquired deficiency in the production of corti-

sol, and to a lesser degree aldosterone, may lead to life-threatening electrolyte and fluid imbalance. These imbalances must be treated, and the deficient steroid (cortisol and/or aldosterone) must also be replaced. After the acute manifestations of adrenal insufficiency are under control, its underlying causes must be investigated.

In chronic deficiency, the slow and progressive nature of the condition means that substantial damage occurs in the adrenal cortex before symptoms become evident. When there is enough damage to the adrenal cortex, insufficient amounts of cortisol (glucocorticoid) and aldosterone (mineralocorticoid) are released.

Prognosis

If acute adrenocortical insufficiency is recognized and treated promptly, prognosis is good. Similarly, as long as the child with chronic adrenal insufficiency maintains appropriate daily hormone replacement therapy and increases doses during stress, the prognosis is good. Insufficient replacement therapy places the child at risk for adrenal shock during times of illness or stress.

Assessment

The age at onset and the clinical manifestations depend on the underlying cause of acquired adrenal insufficiency. For example, those symptoms that are usually seen after birth, such as in adrenal hypoplasia, are characteristic of salt loss and include lethargy, nausea and vomiting, dehydration, fever, irritability, and pallor.

The onset of symptoms of chronic insufficiency is gradual, except in those patients with undiagnosed deficiency who show signs of acquired adrenal insufficiency after a minor illness or trauma. Chronic symptoms include weakness, headache, irritability, anorexia, weight loss, nausea and vomiting, diarrhea, and signs of dehydration. Diminishing amounts of aldosterone from the adrenal cortex causes fluid and electrolyte imbalances and a subsequent decrease in blood pressure. These children usually crave salty foods, because of their sodium deficit. Another characteristic finding is in the pigment of the skin. Children with Addison's disease usually appear suntanned, but without suntan lines, because of excessive secretion of corticotropin and melanocyte-stimulating hormone. Hyperpigmentation is most noticeable on the face, hands, elbows, and knees, as well as the groin, genitalia, areolae, and gums. Pubertal females may show less pubic hair because of diminished androgen production.

Diagnostic Tests

Laboratory data for both types of insufficiency reveal hyponatremia, hypoglycemia, and hyperkalemia. Serum cortisol, ACTH, electrolytes, and renin and aldosterone levels should be measured during the early waking hours, around 8:00 AM. The most definitive test for adrenal insufficiency is to measure plasma cortisol levels before and after administering exogenous ACTH, but this test is

usually not necessary. Basal levels can establish the diagnosis without additional testing. In adrenal insufficiency, the baseline cortisol level is low, and no increase occurs after ACTH administration.

In chronic insufficiency with an autoimmune cause, high antibody titers to the adrenal gland are seen. Ultrasound images, computed tomographic scans, and abdominal radiographs are useful in visualizing the integrity of the adrenal glands. Because some of the conditions resulting in adrenocortical insufficiency have a genetic basis, the siblings of the patient should also be evaluated (Root & Shulman, 2004).

Interdisciplinary Interventions

The child with adrenal insufficiency may or may not require hospitalization, depending on the severity of the symptoms. Those children with severe electrolyte imbalance require immediate intervention. Intravenous solutions are administered to restore electrolyte balance and intravascular volume. At the same time, parenteral cortisol is administered at 100 mg/m² every 6 to 8 hours. Dosing is based on measurement of body surface area in square meters that is calculated by the child's height and weight. If intravenous access is not immediately available, the hydrocortisone should be given intramuscularly. After 24 hours, these higher doses may be reduced, and oral doses of corticosteroids may be given.

Teach the patient and family how to administer the replacement steroids cortisol (hydrocortisone) and mineralocorticoids (aldosterone). Some children can be treated with hydrocortisone only if they maintain a liberal intake of salt in their diet. Hydrocortisone is usually given three times a day, and aldosterone medication (fludrocortisone) can be given as a single daily dose. Fludrocortisone does not need to be increased during times of stress. The parents need to demonstrate proper mixing and intramuscular administration of hydrocortisone in the event of an emergency or excessive vomiting. Administration three times daily can be a barrier for some families, so twice-daily dosing can be attempted with close monitoring of clinical effects and laboratory studies such as ACTH levels. Give parents written guidelines regarding when and how much to increase maintenance doses during times of illness, trauma, or other periods of physical or emotional stress. If surgery is needed, the anesthesiologist must be told of the child's cortisol dependency. The family should feel comfortable with contacting their pediatric endocrinology team whenever there is a question about adjusting medication.

KidKare ■ All children with adrenal insufficiency should wear some form of medical identification alerting medical personnel that the child has adrenal insufficiency and is steroid dependent.

Parents need to be aware of potential side effects of the medications. Ensure that the family understands that the dosage of steroids used to treat adrenal insufficiency is meant to replace the deficit created by the condition. Much of the negative publicity about steroids is about glucocorticoids and androgens taken in excessive doses; side effects of this type of steroid use include poor growth, weight gain, poor wound healing, increased susceptibility to infection, and excessive bruising. A possible side effect with replacement doses of cortisol is gastric irritation, which can be minimized by taking cortisol with food or with an antacid. Manifestations of excessive fludrocortisone ingestion include generalized edema from water retention, hypertension, headaches, and signs of hypokalemia.

Alert! Families must maintain an adequate stock of medication and never allow the prescription to run out; acute withdrawal of cortisol can lead to adrenal crisis.

Community Care

Parents may need help in finding a balance between protecting their child from potential life-threatening situations and the need to participate in age-appropriate activities necessary for physical, social, and emotional growth. Children's school and play activities should not be restricted. School and daycare personnel should be made aware of the need to notify the parents promptly if their child becomes ill or injured and to preplan cooperation with medication administration if a dose needs to be given during school hours.

Congenital Adrenal Hyperplasia (CAH)

CAH is an autosomal recessive condition caused by an inborn deficiency of one of the enzymes needed to synthesize cortisol. Ninety percent to 95% of children born with CAH have a deficiency of 21-hydroxylase. The incidence of CAH is 1 in 15,000 births (Trakakis, Loghis & Kassanos, 2009). Because the 21-hydroxylase enzyme is involved in cortisol and aldosterone synthesis, most children (75%) present with the more severe, salt-losing forms of CAH.

Pathophysiology

Hormone synthesis by the adrenal cortex is controlled by the hypothalamic-pituitary-adrenal feedback system. Any condition that alters circulating blood levels of any adrenal hormone results in an imbalance in hormone production or inhibition. In CAH, blood levels of cortisol are inadequate. As a result, secretion of ACTH by the pituitary is increased in an effort to improve cortisol production. This prolonged hypersecretion results in adrenal gland hyperplasia and sex steroid overproduction. In

females, this condition causes masculinization or virilization of the clitoris. In males, it may cause precocious puberty (Trakakis, Loghis & Kassanos, 2009). Children with CAH who cannot maintain a sodium balance (salt-losing form of CAH), if they are not diagnosed and treated promptly, are at increased risk for severe hyponatremic dehydration, seizures, shock, and death from this electrolyte imbalance.

Prognosis

Prognosis depends on the type and severity of CAH the child has inherited. If left untreated, the child with classic 21-hydroxylase deficiency, the salt-losing form, could die from severe hyponatremia. Children with partial deficiency have enough aldosterone to maintain sodium levels. If appropriately treated, children born with CAH enjoy a normal life expectancy. Cognitive and perceptual abilities in children with CAH are no different than among those without CAH.

For children with only the virilizing form of CAH, lack of treatment results in precocious puberty and adult short stature. In females born with CAH, the internal sex organs (uterus, ovaries, and fallopian tubes) are normal. With appropriate treatment, fertility should not be impaired. Menses should occur at the appropriate age if the girl's CAH is well controlled (Speiser, 2004; Speiser & White, 2003).

Assessment

In the United States, newborn screening for CAH is required. Thus, most infants are generally diagnosed at, or shortly after, birth. Female newborns with CAH almost always present with ambiguous genitalia, a condition also known as *pseudohermaphroditism* (Fig. 26–7). Steroid synthesis occurs early during fetal life, so a lack of cortisol response within the pituitary–adrenal pathway results in excess ACTH production and, in turn, hypersecretion of the adrenal androgens and virilization. The external genitalia of females reveals an enlarged clitoris that resembles a penis. Urethral displacement onto the ventral shaft of the clitoris can be mistaken for hypospadias. The labia are fused and can take on the appearance of a scrotallike sac without testes. This condition may be misdiagnosed as cryptorchidism. The vaginal orifice may be incomplete. In general, more extreme virilization reflects greater severity of the enzyme defect.

Male newborns with CAH do not necessarily show abnormalities of the internal or external genitalia. The penis may be enlarged, and pigmentation of the scrotum may be darker than normal. Because CAH may have no obvious physical findings, male newborns generally are not diagnosed until they present with signs of adrenal insufficiency. In both sexes, recurrent vomiting and irritability may be mistaken for reflux, pyloric stenosis, or colic. The symptoms progress and include lethargy, pallor, dehydration, hypoglycemia, hyponatremia, and hyperkalemia. Children with partial enzyme deficiency may not be diagnosed until childhood, when severe illness,

FIGURE 26–7. Genitalia of a female newborn with congenital adrenal hyperplasia shows pseudohermaphroditism. CAH may cause clitoral enlargement.

surgery, or precocious puberty makes signs of adrenal crisis evident.

Diagnostic Tests

Early prenatal diagnosis is possible through chorionic vilus sampling, molecular techniques of DNA analysis, and amniocentesis.

Laboratory studies to confirm the diagnosis of CAH of the infant include serum levels of 17-hydroxyprogesterone, a cortisol precursor. Markedly elevated levels indicate CAH. ACTH, testosterone, dehydroepiandrosterone (DHEA), and androstenedione levels may also be obtained. Children with salt-losing CAH have low serum levels of sodium and chloride, and elevated potassium and plasma renin activity. Chromosomal testing needs urgent attention to determine appropriate sex identification. Radiographic studies include pelvic ultrasonography to determine the presence of internal reproductive organs as well as the integrity of the adrenal glands (Trakakis, Loghis & Kassanos, 2009).

Nursing Diagnoses and Outcomes

In addition to the nursing diagnoses and outcomes presented in Nursing Plan of Care 26–1, the following diagnoses and outcomes apply to the child with CAH:

Risk for impaired parent/infant/child attachment related to reaction to sexual ambiguity of child

Outcomes: Parents will express concerns about sexuality issues to the healthcare team.

Parents will initiate and maintain positive interactions with the infant.

Risk for sexual dysfunction in females related to virilization of the genitalia

Outcome: Child will receive appropriate information regarding treatment for virilization.

Interdisciplinary Interventions

The care for children born with CAH varies; however, the goal for all children includes providing lifelong replacement doses of deficient steroids, preventing excessive androgen production, and maintaining adequate growth. Dietary salt supplements may also be required for the salt-wasting form of the disease. Treatment includes appropriate care for these children and adults during periods of major illness, trauma, or surgery.

Pharmacologic Interventions

Neonates or children presenting in adrenal crisis require immediate intervention. This medical emergency includes providing appropriate intravenous solutions to correct fluid and electrolyte imbalances and hypoglycemia. Also, a parenteral form of hydrocortisone must be administered intravenously at double or triple the maintenance dose; it can also be given intramuscularly if intravenous access is not immediately available.

For children diagnosed in the absence of adrenal crisis, administering glucocorticoids inhibits the excessive production of androgens. Hydrocortisone (cortisol) is the treatment of choice for children and is considered a long-term therapy.

Children who are classified as having the salt-wasting form of the disease and also display diminished aldosterone production require a replacement mineralocorticoid called *fludrocortisone*, and sodium chloride supplements. Doses for both replacement steroids are individualized throughout life by measuring renin and 17-hydroxyprogesterone levels (Speiser & White, 2003).

KidKare ■ ■ Fludrocortisone (Florinef) is not available in liquid form. The pill can be finely crushed and added to a small amount of formula or breast milk. These infants and children also require added salt in their formula or food.

caREminder

Be sure to teach children with CAH and their families about the need for increased doses of cortisol (not fludrocortisone) during times of increased physical stress and illness. Without increased doses, inadequate corticosteroid supply could lead to adrenal crisis, which is life-threatening.

Surgical Management

Female infants with ambiguous genitalia require reconstructive surgery to ensure a normal appearance of the genitalia and adequate sexual functioning. For that reason, the clitoris is not removed but is reduced in size and repositioned below the pubis, preserving the glans and all its blood and nerve components so that complete sexual

gratification, including orgasm, can be achieved. The labia also must be separated (labioplasty) and a vaginal orifice (vaginoplasty) must be created; the ideal time for this elective surgery is between 6 and 12 months of age. Vaginal dilation may be required when the girl reaches puberty or becomes sexually active.

Genetic Counseling

Given the genetic nature of CAH, the parents benefit from genetic counseling. A family history or genogram can identify previous infant deaths or sudden, unexplained deaths possibly caused by adrenal crises in infants, children, and adults with undiagnosed CAH. Parents need to understand that CAH is an autosomal recessive disorder, which means that both of them are carriers. Therefore, there is a 25% chance with *each* pregnancy of having a child with CAH. Prenatal testing for the 21-hydroxylase deficiency is available for parents who already have an affected child. For subsequent pregnancies, these mothers can be given high doses of cortisol, in the form of dexamethasone, during the first trimester to inhibit ACTH overproduction and to prevent or minimize virilization in the developing fetus.

Community Care

Teach parents about cortisol and aldosterone replacement and the need to increase doses, including those of intramuscular hydrocortisone, when the child is faced with stress, illness, and trauma (including extensive dental work). Review the potential side effects of the medications and discuss their concerns about having a child on steroid therapy. Remind the family that the child is only taking a replacement dose of the steroid that his or her body cannot produce. School and daycare personnel must promptly notify parents in the event of illness or injury.

KidKare ■ ■ Children with CAH need to wear some form of medical identification at all times. The parent or older child should carry an emergency hydrocortisone injection kit with him or her.

Cushing's Syndrome (CS)

CS is a characteristic cluster of signs and symptoms resulting from excessive levels of circulating cortisol. In infants and young children, CS is often caused endogenously by an adrenocortical tumor, usually a malignant carcinoma, and occasionally by a benign adenoma. In older children, the cause is more likely of pituitary origin, such as a pituitary tumor that produces excessive ACTH. This condition is known as *ectopic ACTH syndrome*. The more common cause of CS in children is side effects of prolonged or excessive treatment with

exogenous corticosteroids for a medical condition such as asthma, lupus, or inflammatory bowel disease. Most of these side effects can be reversed after the corticosteroid treatment is reduced or the doses are gradually tapered.

Pathophysiology

Excess cortisol produces diverse side effects seen throughout the body. The most noticeable side effect is obesity or rapid weight gain with arrest in linear growth. Hypercortisolism retards linear growth by suppressing the release of GH (Root & Shulman, 2004). Alterations in the normal processes of carbohydrate, protein, and fat metabolism lead to increased protein catabolism, loss of muscle mass, and altered fat distribution. Fat distribution tends to be centrally located, with the child showing a characteristic rounded or moon face with flushed cheeks, a supraclavicular fat pad (known as a buffalo hump), and truncal obesity with red abdominal striae (Fig. 26–8). The thinned muscles of the extremities resulting from muscle wasting may be masked by generalized obesity.

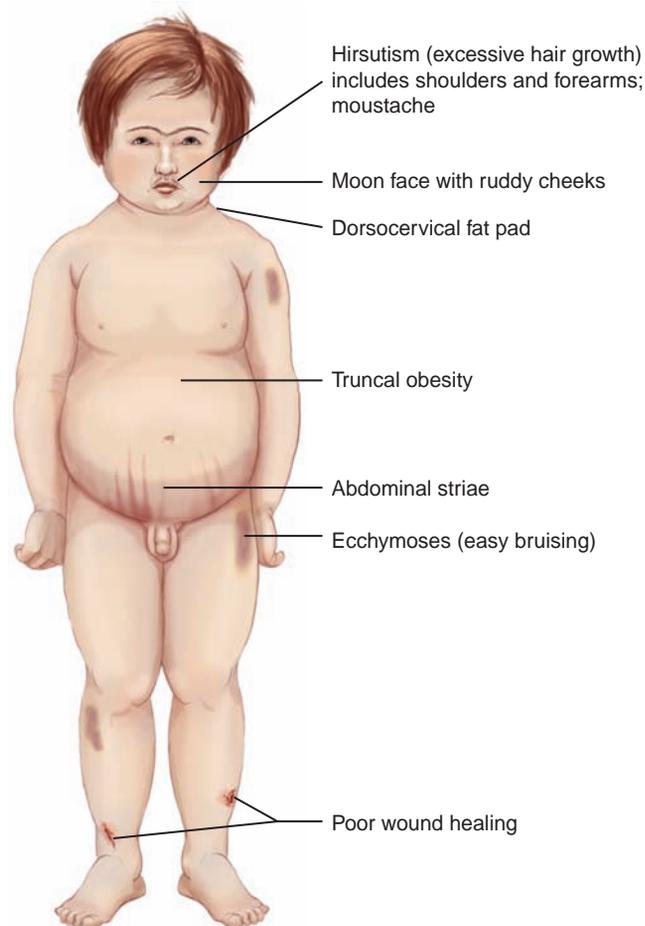

FIGURE 26–8. Typical clinical manifestations of Cushing's syndrome.

Other physiologic consequences of excessive cortisol include poor wound healing, increased susceptibility to infections, and decreased inflammatory response. Excessive bruising, thin skin, and osteoporosis are also seen; hypertension, headaches, and mood disorders are less common. Production of androgens usually is excessive, which can cause virilization, characterized by increased body hair (hypertrichosis) on the face and trunk, pubic hair, acne, and deepening of the voice.

Prognosis

Prognosis for these children depends on the underlying etiology. For children with the endogenous form of CS caused by a neoplasm, symptoms usually disappear within 1 year of pituitary surgery. Primary adrenal tumors carry a poorer prognosis, because the primary cancer often metastasizes to the lymph system, lung, liver, or bone before being diagnosed. Children experiencing symptoms of CS from an exogenous cause, such as increased doses or length of therapy with glucocorticoids, will do quite well if the medications can be tapered enough to eliminate the physiologic sequelae. However, in some diseases, such as severe forms of lupus, dose reduction may be difficult, because high doses of glucocorticoids are needed to treat the primary condition.

Assessment

Assessment focuses on evaluating the child for the characteristic physical signs of CS, such as a full round face, truncal obesity, purple-red striae, and ecchymoses. Hypertension, hirsutism, acne, delayed puberty, or menstrual irregularities are also commonly found, although these symptoms are prevalent in varying degrees in the general population. A very careful family history may reveal others with CS or endocrine neoplasias.

Diagnostic evaluation of CS is a challenge, because the performance characteristics of the tests depend on the degree of severity of CS. In severe, overt CS, all diagnostic tests demonstrate high sensitivity and specificity to confirm the diagnosis. However, in subclinical or mild CS, test results may overlap with normal ranges defined for patients without CS (Liu & Crapo, 2005). Laboratory studies include a complete blood cell count and blood and chemistry studies. Plasma cortisol levels are elevated, and the levels do not fluctuate throughout the day as they typically do. Urinary excretion of cortisol as measured by 24-hour collection is elevated. Computed tomography and magnetic resonance imaging may locate pituitary or adrenal lesions. A low-dose (1 mg or 0.3 mg/m²) dexamethasone suppression test can be performed as an outpatient procedure. Parents administer dexamethasone orally during the evening and then bring the child in to measure the cortisol level the following morning. False-positive results may occur but are more common in adults. This test can also be performed with a high dose of dexamethasone (8 mg or 120 μg/kg); some clinicians believe that this test is more specific than the low dose. Recently, tests such as salivary cortisol and

combination corticotrophin-releasing hormone–dexamethasone testing have been advocated to assist diagnosis (Liu & Crapo, 2005).

Nursing Diagnoses and Outcomes

In addition to the nursing diagnoses presented in Nursing Plan of Care 26–1, the following diagnosis applies to the child with CS:

Risk for injury related to delayed wound healing, decreased inflammatory response, osteoporosis, and muscle weakness

Outcomes: Child will be protected from potential infections by practicing good health habits and avoiding exposure to pathogens.

Child will remain free from injury.

Interdisciplinary Interventions

Treatment for CS depends on the specific reason for excess cortisol and may include surgery, radiation, chemotherapy, or the use of cortisol-inhibiting drugs. Surgery is the primary intervention of CH caused by adrenal or pituitary tumors. Microsurgery to excise only the tumor avoids the consequences of panhypopituitarism, and prognosis is quite good if metastasis has not occurred. In the event of adrenalectomy, appropriate stress and replacement doses of glucocorticoids are planned preoperatively to avoid adrenal crisis. Radiation and/or chemotherapy may also be used if the cause of the CS is ectopic ACTH syndrome. Cancerous tissue can be eliminated using surgery, radiation, and chemotherapy, thus curing the overproduction of cortisol caused by ectopic ACTH syndrome.

CS caused by exogenous steroid preparations requires a fine balance between continuing to use steroids to treat the underlying condition and avoiding their unpleasant side effects. If possible, the medication should be given early during the day to mimic the normal diurnal pattern of cortisol secretion. Alternate-day scheduling could also lessen stress on the hypothalamic–pituitary–adrenal pathway.

Various drugs have been used to manage CS, many with only limited effectiveness, depending on the underlying etiology of the hypercortisolism. Medications with potential efficacy at the hypothalamic–pituitary level (e.g., thiazolidinedione compounds and retinoic acid) are under investigation. A pharmacologic approach to the syndrome cannot be standardized, because the pathophysiology of the syndrome varies from patient to patient (Sonino, Boscaro, & Fallo, 2005).

Community Care

Healthcare personnel treating children with long-term corticosteroid use should advise the child and family of the potential side effects before initiating treatment. Provide anticipatory guidance about diet, involvement in contact sports, injury prevention, and methods of avoiding exposure to infections.

Premature Adrenarche

Adrenarche is the development of pubic hair, axillary hair, acne, and adult body odor that occurs when adrenal androgen secretion in the adrenal cortex matures. Premature adrenarche is the development of pubic hair that may be accompanied by axillary hair before age 8 years in girls and 9 years in boys. This condition occurs more often in girls. In most cases it is considered a normal variant in sexual development, especially if no other signs of pubertal development have occurred. However premature adrenarche is gaining more attention from healthcare providers because it has been noted that girls with premature adrenarche are prone to have hyperinsulinemia, dyslipidemia, and hypertension, which may lead to atherosclerosis and metabolic syndrome later in life (Utrainen et al., 2008).

An investigation may be required to determine whether premature adrenarche is of central (hypothalamic–pituitary) origin (see earlier section on precocious puberty) if other signs of advancing puberty are evident, such as clitoral enlargement, or advanced bone age. Baseline dehydroepiandrosterone and testosterone levels may be obtained. ACTH testing is usually unnecessary because CAH is not the cause for isolated premature adrenarche. However, some healthcare providers prefer to screen for some of the nonclassic forms of CAH.

Treatment consists of reassuring the child and family of the benign nature of this condition. The child may develop a body image disturbance related to premature adrenarche. Attempt to help the child and family verbalize concerns about body image. Current literature reflects a concern that females with a history of premature adrenarche, intrauterine growth retardation, family history of type 2 diabetes, hypertension, and ovarian hyperandrogenism may represent a group at high risk for cardiovascular disease and type 2 diabetes. Given the association between premature adrenarche, hyperinsulinemia, dyslipidemia, and cardiovascular disease, long-term monitoring should be considered in such cases. Screening for type 2 diabetes with fasting plasma glucose, and for cardiovascular risk with lipid panels, may be warranted (Lee & Kerrigan, 2004).

GONADAL DISORDERS

The genetic gender of an embryo is determined at the time of fertilization by the X- or Y-bearing sperm that penetrates the ovum; however, sex differentiation does not occur until the seventh week of gestation. At that time, the future ovaries or testes begin to take on their specific characteristics. The presence of the Y chromosome influences testicular development; its absence results in the creation of ovaries. By the 12th week, the external genitalia become distinctly masculine or feminine. The male gonads (testes) and female gonads (ovaries) have different functions (see Table 26–1). Both gonads are controlled by LH and FSH secreted by the anterior pituitary. Adequate treatment of children with

disorders of sexual differentiation requires considering not only the external genitalia and appearance, but also the complex effect of androgens during the prenatal and postnatal periods of life.

Ambiguous Genitalia

The term *ambiguous genitalia* refers to any condition in which the male or female external genitalia appear abnormal. External genitalia include the clitoris, vagina, labia, and urethral meatus of the female and the penis, scrotum, testes, and urethral meatus of the male (see Fig. 26–9). *Hermaphroditism* is a discrepancy between the gonads (ovaries or testes) and the external genitalia. In true hermaphroditism, which is a rare condition, the child is genetically male or female but has both testicular and ovarian tissue; most frequently an ovotestis is found. Pseudohermaphroditism in the female reveals normal XX genotype and normal gonads, but the external genitalia are virilized. The male pseudohermaphrodite has normal XY genotype and testes, but the external genitalia are ambiguous or incompletely virilized.

Pathophysiology

Any interruption or abnormality in fetal sexual determination or differentiation results in ambiguous genitalia. Ambiguous genitalia may be caused by hormone imbalance or chromosomal aberrations. The most common cause of female pseudohermaphroditism is CAH. In CAH, androgen exposure on the developing female fetus creates virilization (see the discussion of pathophysiology in the section on CAH). Male pseudohermaphroditism could be caused by defects in testicular differentiation, such as in gonadal dysgenesis or in defective testicular or androgen hormone synthesis or action. Some males are insensitive to the effect of androgens and are classified as having a partial androgen insensitivity syndrome, which also results in genitalia (micropenis) that are not as devel-

FIGURE 26–9. Male with ambiguous genitalia.

oped as those of a male who is sensitive to the effects of androgens.

Prognosis

With the exception of CAH, none of the conditions resulting in ambiguous genitalia is life threatening. Children with ambiguous genitalia may not be biologically capable of conceiving children, depending on the extent of their hormone deficiency and the alteration of internal and external reproductive organs. Males with a micropenis can engage in heterosexual activities and father children through testosterone treatment to increase penile size.

Assessment

Ambiguous genitalia in genetic females (two X chromosomes) usually have some or all of the following clinical features:

- An enlarged clitoris that resembles a small penis
- A urethral opening (where urine comes out) anywhere along, above, or below the surface of the clitoris
- Fused labia that resemble a scrotum. Sometimes a lump of tissue is felt within the fused labia, further making them look like a scrotum with testicles

An infant with these features may be thought to be a male with undescended testicles.

Ambiguous genitalia in genetic males (one X and one Y chromosome) typically include some or all of the following features:

- A small penis (less than 2–3 cm or 0.8–1.2 in) that resembles an enlarged clitoris
- A urethral opening anywhere along, above, or below the penis; it can be placed as low as on the peritoneum, further making the infant appear to be female
- A small scrotum with any degree of separation, resembling labia
- Undescended testicles commonly accompany ambiguous genitalia

For any child with delayed puberty or suspicious genitalia, hormone levels must be assessed to determine the integrity of the hypothalamus, anterior pituitary, and gonads (see earlier sections on precocious puberty and delayed puberty). Genetic testing is also completed to determine whether the child is a genetic male or female. Endoscopy, abdominal radiograph, and abdominal or pelvic ultrasound may be needed to determine the presence or absence of internal genital structures (such as undescended testes). In some cases, laparoscopy, exploratory laparotomy, or biopsy of the gonads may be necessary to confirm disorders associated with ambiguous genitalia.

Interdisciplinary Interventions

Ambiguous genitalia in the newborn creates anxiety for many. The parents have many questions and need

assistance regarding what to tell inquisitive family members about the gender of the newborn. If there is any question about the external genitalia, a swift investigation must be undertaken to determine genetic sexual identification. Until the sex assignment has been determined, the healthcare team should refer to the newborn as “the baby” rather than “he” or “she.” The name card placed in the newborn’s bassinet should be white instead of pink or blue. Discourage the parents from giving the child an ambiguous name, because it could serve as a reminder of the events surrounding the sexual ambiguity at birth. In addition, it would be wise to postpone sending birth announcements until the sex assignment is completed.

The first goal in treating ambiguous genitalia is to determine gender through chromosomal analysis. Unfortunately, this test can be time-consuming, and gender assignment is delayed. Healthcare providers must be honest and forthright with parents when gender identification is unclear, because erroneous sex assignment can cause major lifelong social and emotional problems for the child and family.

If CAH is suspected, appropriate steroid replacement therapy is initiated and reconstructive surgery for the virilized female is planned. Genetic counseling is indicated, given the autosomal recessive nature of CAH (see the section on CAH for details).

Most children born as hermaphrodites are best reared as female; the testicular tissue is removed, and reconstructive surgery is done to create suitable female external genitalia, because creating an adequately functional male phallus is much more difficult.

In some children, ambiguous genitalia are not obvious at birth. They are diagnosed at the time of adolescence or young adulthood when stunted growth, delayed puberty, or infertility raises the question of a broader chromosomal or hormonal abnormality. With this diagnosis also comes the developing awareness of possible permanent infertility or sexual dysfunction and a sense of loss.

With any genetic condition, a genetic counselor can give accurate information and prognoses. Issues for the child include differences from their peers in relation to sexual development, body image, and reproductive capabilities. Options are presented for alternative forms of raising a family through adoption as well as awareness that childless couples can also lead a very fulfilling life. Future advances in reproductive science may include the possibility of reproduction through donor gametes and hormonal support. Education and support groups for most syndromes are available to parents and families through newsletters and from the local and national chapter for specific disorders (see Resources on the Student Resource CD).

Gynecomastia

Gynecomastia is a condition in boys, usually occurring during early or mid puberty, that involves unilateral or

bilateral breast enlargement. This common, transient occurrence usually lasts a few months to a year (Nordt & DiVasta, 2008). Gynecomastia is usually secondary to the normal hormonal imbalances between testosterone and estrogen that commonly occur during puberty. Hormone levels for FSH, LH, prolactin, testosterone, and estradiol are normal, but the ratio of testosterone to estradiol may be decreased. In younger children with gynecomastia who also show increased pigmentation of the nipple and areola, suspect exogenous estrogens in the form of creams, pills, or inhaled medications. The antifungal drug ketoconazole can also cause gynecomastia. Drugs of abuse such as alcohol, amphetamines, and marijuana can also cause gynecomastia in adolescent and adult males. Use of anabolic steroids and GH may also stimulate breast development, but adolescents abusing these medications tend to be athletes, so the gynecomastia may not be clinically evident because of increased muscle mass. Breast enlargement may also be a sign of other conditions, such as Klinefelter’s syndrome or other rare endocrine disorders.

The boy may develop body image disturbance related to gynecomastia. Therefore, encourage him and his family to verbalize concerns about body image. Treatment usually consists of reassurance to the boy and his family of the benign and transient nature of this condition. Surgical intervention is rarely indicated and should be considered only if the gynecomastia persists after the child completes puberty. Although several hormone therapies have been investigated for treatment of gynecomastia, none have been approved by the Food and Drug Administration for use in adolescents (Nordt & DiVasta, 2008).

Premature Thelarche

In girls, premature breast development is known as *premature thelarche*. It is a benign condition that may appear during the first 2 years of life. Breast development may be unilateral or bilateral, and regression usually occurs after a few years. These girls do not show maturation of the genitalia or presence of pubic hair, and menarche occurs at the expected age. Growth usually occurs at the normal rate and rarely is accelerated. This condition is thought to occur from an imbalance in the LH–FSH ratio within the hypothalamic–pituitary–gonadal pathway.

A girl with early breast development should be screened for true precocious puberty, especially if the age at onset is older than 2 years. Obtain plasma levels of LH, FSH, and estradiol. This condition may be caused by exogenous exposure to estrogens. As with gynecomastia in boys, treatment includes reassuring the girl and family that this condition is benign and transient, and that the other aspects of female pubertal progression should occur in normal sequence.

See [thePoint](#) for a summary of Key Concepts.

The Child With an Inborn Error of Metabolism

Case History

Remember the Rollins family? Joellen and her husband Chris were expecting their third child. They also have two other children, Selena, age 5, and James, age 2½. Joellen went into labor at 38 weeks' gestation and gave birth vaginally to their son, Sean, weighing 6 lb 10 oz and 20 inches in length. Joellen progressed through labor without complications and received epidural anesthesia during labor for pain management. Joellen has chosen to breast-feed her son.

Sean's 1-minute and 5-minute Apgar scores were 7 and 9, respectively. His initial physical examination revealed slight molding of the head with firm, flat fontanels. Head circumference was 34.5 cm; chest circumference was 32.5 cm. Skin was reddish pink with acrocyanosis. Vital signs were as follows: temperature, 99 °F (37.2 C); apical pulse, 140 beats/minute; respiration, 56 breaths/minute. Some mucus was noted in his nose and mouth, which was removed with a bulb syringe. New-

born reflexes were intact. Sean continued to adapt well

to extrauterine life and was discharged from the hospital after 24 hours.

Joellen brings Sean to the clinic for a checkup. He is now 4 months old. Joellen mentions that she's noticed that Sean seems to be vomiting more often during the past 2 to 3 weeks. "It's not the usual baby spit up either. It seems more forceful and it's much larger amounts." Assessment reveals some hyperactivity, with fine hand tremors. Sean's skin appears dry with some scaly patches noted. His cheeks are reddened with two dime-sized crusted areas bilaterally. Several areas on Sean's upper extremities appear erythematous with oozing vesicles. His wet diaper has a musty odor. Developmental assessment reveals that Sean is somewhat behind in achieving his milestones. Joellen reports she missed the follow-up appointment for testing after Sean's discharge from the hospital because she developed mastitis.

CHAPTER OBJECTIVES

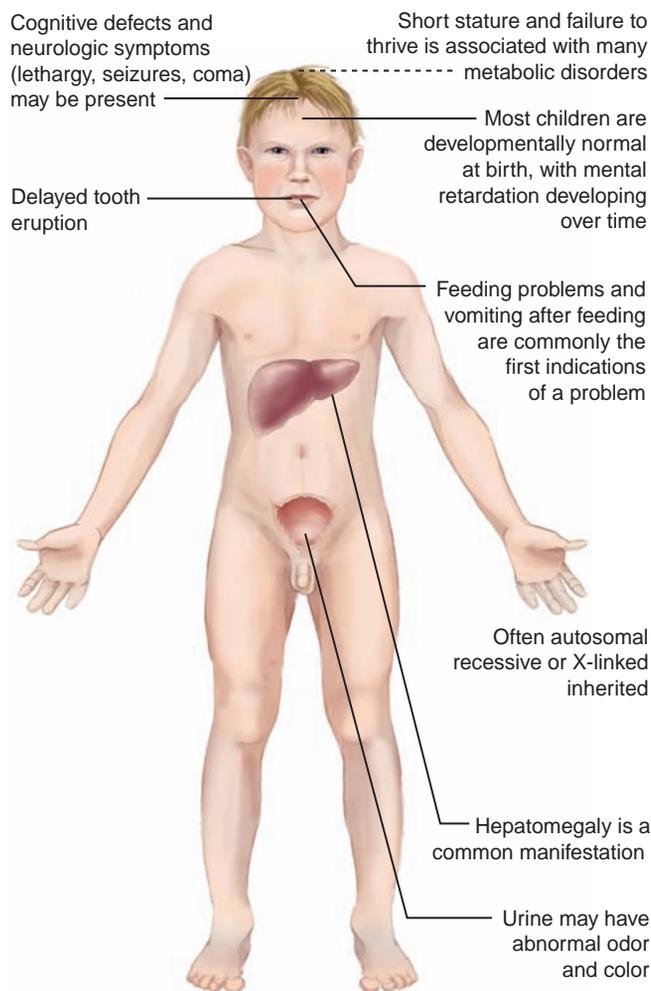

1. Differentiate between inborn errors of metabolism that manifest at birth or in the immediate neonatal period (i.e., maple syrup disease) and those with later childhood onset (i.e., Wilson disease).
2. Describe key assessment factors that can assist in early identification of metabolic disorders in children.
3. Describe interventions performed by the healthcare team that are related to early identification of selected inborn errors of metabolism.
4. State the dietary management specific to each metabolic disorder that can prevent disease symptoms or decrease their severity.
5. Identify nursing interventions that assist the family and community to provide optimal care to the child with an inborn error of metabolism.

See [thePoint](#) for a list of Key Terms.

The body builds and maintains itself by *metabolizing* the food and fluid it ingests. The metabolic pathways used during this process may have inborn errors that cause an untoward reaction or lead to the creation of toxic substances. The mutation of single genes either results in a structurally altered enzyme that is not capable of normal catalytic activity or causes an inhibition of enzyme synthesis. Reduced enzymatic function produces a block in the metabolic pathway at a specific point. This block leads to an abnormal accumulation of substrate, or building block in the metabolic pathway, causing a block or “log jam” in the pathway. The accumulated substrate appears in the blood, urine, and tissues and can affect the body in many ways. The presenting symptoms are correlated with the potential effects of inborn errors during the intrauterine period of growth. For example, inborn errors of metabolism can cause defective development of the brain in utero. After birth, the infant’s developing neurotransmitter system continues to be especially vulnerable to the abnormal biosynthesis of enzymes. Most inborn errors of metabolism are transmitted through autosomal recessive or X-linked inheritance. Type 1 diabetes, described in Chapter 26, is one of the most common errors of metabolism in children.

DEVELOPMENTAL AND BIOLOGIC VARIANCES

Inborn errors of metabolism can produce genetic changes that may vary from child to child, depending on the degree of alteration and the system affected (Fig. 27–1). For some children, the clinical manifestations of these changes are inconsequential and are merely noted as some of the characteristics that make one person different from another. Other metabolic conditions produce symptoms that become apparent only under specific conditions that the child may or may not encounter during

Most inborn errors of metabolism present in the childhood years and, if untreated, result in early death

FIGURE 27–1. Developmental and biologic variances: inborn errors of metabolism.

life. Still other conditions produce disease states that vary from mild to fatal. Most inborn errors of metabolism become clinically evident during the neonatal period, although some may not manifest themselves until later (Developmental Considerations 27–1). Presentation in the adult years is not common, except with mitochondrial disorders, and is more likely to represent a metabolic disorder that has been activated or triggered by the presence of another disease state.

Be aware that certain ethnic and geographic origins confer risk for metabolic disorders. When these variances are known, carrier testing, genetic counseling, prenatal diagnosis, and neonatal screening are initiated to help decrease the incidence of the disease and to enhance early identification of affected infants.

WORLDVIEW: Certain metabolic disorders are known to be more prevalent in specific ethnic groups and in those from specific geographic locations. For instance, the tyrosine defect tyrosinemia type I has a higher prevalence in patients with a French-Canadian ancestry. In the French-Canadian population of Quebec, the incidence of this condition is 1 in 1,846 newborn infants. The classic form of maple syrup urine

disease (MSUD) is more common among members of Mennonite and Amish sects. Hyperglycemia is more common in Finland than in other parts of the world. Phenylketonuria (PKU) is most common among Jews of Yemenite origin and in the populations of northern Europe, particularly Ireland, Scotland, Belgium, and western Germany. Tay-Sachs disease, Gaucher's disease, and Niemann-Pick disease occur more frequently among individuals of Ashkenazi Jewish descent. Although Tay-Sachs disease occurs 1 in 3,500 to 4,000 births, the carrier rate among Ashkenazi Jews is 1 in 30 (Kliegman, Behrman, Jenson & Stanton, 2007).

ASSESSMENT OF THE CHILD WITH AN INBORN ERROR OF METABOLISM

QUESTION: What might be the impact of Sean not having had diagnostic testing as scheduled after his discharge from the hospital?

ANSWER: The lack of diagnostic testing as scheduled after birth may have significant effects on Sean's health should he be diagnosed with an inborn error of metabolism. Early recognition is essential so that treatment can be initiated as soon as possible to prevent possible complications associated with the disease.

DEVELOPMENTAL CONSIDERATIONS 27-1

Developmental Age and Appearance of Selected Inborn Errors of Metabolism

Neonatal

- Galactosemia
- Hyperammonemia
- Hyperglycemia
- Isovaleric acidemia
- Maple syrup disease
- Menkes disease
- Phenylketonuria
- Sulfite oxidase deficiency
- Tyrosinemia type I (acute form)

Infancy

- Fructosuria
- Hurler's syndrome
- Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency
- Medium-chain acyl-CoA dehydrogenase deficiency
- X-linked hypophosphatemic rickets

Early Childhood

- Homocystinuria
- Hunter's syndrome
- Hurler's syndrome
- Hyperammonemia
- Tyrosinemia type I (chronic form)

Middle Childhood and Adolescence

- Wilson's disease

Although the incidence of most inborn errors of metabolism is low, these biochemical disorders must be recognized and treated immediately, because, for many children, early intervention can alter long-term outcome. Without interventions, many disorders result in progressive loss of neurologic function, developmental disabilities, psychomotor retardation, growth abnormalities, seizures, and other severe symptoms that profoundly affect quality of life for the child and the family. Early recognition is, therefore, the primary goal in diagnostic evaluation for inborn errors of metabolism. The sooner a metabolic disorder is detected, the sooner treatment can be initiated in an attempt to avert the negative consequences of the disease process.

Focused Health History

Information obtained from a genetic history is important, because genetic counseling provides guidance for families as they make decisions about childbearing. Understanding their genetic risks can help parents to make informed decisions about continuing pregnancy. In utero diagnosis early during pregnancy is already possible for many of the inherited metabolic disorders, and techniques for detecting others are being researched. **Newborn screening** programs provide early diagnosis for many of the more common metabolic disorders (see Treatment Modalities for more information on newborn screening). Diagnosis enables timely intervention to prevent symptoms or to decrease their severity.

A detailed history of the child's health status and developmental progress can provide many clues to the existence of a metabolic disorder. Common to most metabolic problems is a history of poor feeding, including rejection or dislike of protein foods, vomiting, listlessness, failure to thrive, delayed development, and increasing weakness (Focused Health History 27-1). As the child grows, delays in reaching psychomotor developmental milestones or a regression in developmental achievements is noted. The child may have a history of an apparent life-threatening event (e.g., near-miss sudden infant death).

The pattern of heredity for many of the metabolic conditions is recessive, with neither parent presenting with clinically abnormal signs or symptoms. However, the health history of older and younger siblings may reveal symptoms similar to those of the child being assessed. Alternately, siblings or other close relatives may have a variant form of the disorder, with different or sporadic symptoms.

FOCUSED HEALTH HISTORY 27–1

Inborn Errors of Metabolism*

Current history	<p>Clinical deterioration in a previously normal neonate, infant, or child</p> <p>Neurologic abnormalities such as lethargy, hypotonia or hypertonia, seizures, migrainelike headaches, coma not responsive to intravenous glucose or calcium</p> <p>Apparent sepsis</p> <p>Respiratory insufficiency manifested by apneic episodes, or tachypnea</p> <p>Cardiac failure, myopathy, pericardial effusion, arrhythmias</p> <p>Metabolic instability manifested as acidosis, ketosis, hyperammonemia, or hypoglycemia</p> <p>Gastrointestinal problems such as abdominal pain, poor feeding, vomiting, diarrhea, constipation, weight loss, hepatomegaly</p>
Past medical history	<p>Birth History</p> <p>Was newborn screening completed? What were the results?</p> <p>Any episodes of temperature instability</p> <p>Feeding difficulties</p> <p>Any history of apparent life-threatening event or prolonged apnea spells, inconsolable irritability, involuntary movements, or seizures during neonatal period</p> <p>Presence of dysmorphic features</p> <p>Previous Health Challenges</p> <p>Unexplained cognitive deficits, developmental delay, motor deficits, or seizures</p> <p>Unusual odor of urine or sweat, particularly during acute illnesses</p> <p>Intermittent episodes of unexplained vomiting, acidosis</p> <p>History of renal stones</p> <p>Cataracts, corneal clouding, or other ophthalmologic abnormalities</p> <p>Hematologic abnormalities (e.g., thrombocytopenia, neutropenia, anemia) in presence of normal bone marrow findings</p> <p>Exaggerated response to minor stress or infection resulting in neurologic signs, acidosis, hypoglycemia</p>
Nutritional assessment	<p>Growth (head circumference, weight, length) plotted on growth chart, recent weight loss or gain, failure to thrive</p> <p>Poor feeding, persistent vomiting</p> <p>Food likes and dislikes (e.g., salt craving, protein avoidance, lactose intolerance)</p>
Family medical history	<p>Any family history of miscarriages, stillbirths, or unexplained deaths during neonatal period or infancy</p> <p>Family history of consanguinity (birth as the result of a sexual relationship between blood relatives)</p> <p>Any parents, siblings, or cousins with symptoms similar to those presented by the patient</p> <p>Any family members with developmental delays, low intellectual functioning, or cognitive challenges</p>
Social history	<p>Family eating patterns and health beliefs related to food</p>
Growth and development	<p>Inability to meet growth and developmental norms, delay in the onset of puberty</p> <p>Failure to thrive</p> <p>Loss of previously acquired developmental milestones</p> <p>Decreased level of activity</p>

*This history is focused on the metabolic system. See Chapter 8 for a comprehensive format.

caREminder

If one child in the family has suspicious symptoms, counsel the family to have all other siblings evaluated, even if their symptoms are not exactly the same.

The family history may reveal unexplained deaths (i.e., sudden infant death syndrome) during the neonatal period, possibly indicating an undiagnosed, untreated metabolic disorder. The ill child and family members with suspicious symptoms should be questioned about the correlation

between their symptoms and the presence of other common illnesses. Some variant forms of the metabolic disorders appear symptomatic only when exacerbated by a cold, vomiting, diarrhea, or other concurrent illnesses.

Ask parents whether newborn screening was completed and, if so, whether they were informed about the results.

WORLDVIEW: In the United States, the disorders that neonatal screening programs test for vary from state to state. Tests for PKU and galactosemia are commonly mandated by state law. Children born in other countries may not have been screened as neonates for metabolic disorders, because other countries, especially the developing nations, do not have rigorous enforcement of or control over screening programs. Investigate the neonatal screening requirements for the child's state or country of origin; determine whether the child underwent screening and what these clinical assessments showed.

Responses to the questions asked during a health history can possibly indicate a metabolic problem but must be considered in the context of the physical examination and laboratory findings before a diagnosis can be reached.

Focused Physical Assessment

QUESTION: Which assessment findings would lead you to suspect that Sean may have a metabolic disorder?

More than 300 metabolic diseases have been described in the medical literature to date. Most of these disorders are clinically recognized during the newborn period or the first year of life. Unfortunately, many of the early signs of metabolic problems in children are vague. Presenting symptoms vary with age (see Focused Health History 27–1). The astute nurse recognizes that these symptoms are indices of many serious problems, including metabolic disorders, and motivates the interdisciplinary team to look more closely for underlying causes.

A crisis can develop rapidly in the presence of metabolic disturbance and cause irreversible symptoms or death. Identifying the cause of symptoms accurately and quickly is essential. A thorough physical assessment should be completed by the physician or advanced practice registered nurse. Any member of the healthcare team may note some of the changes, particularly in urine and body odors, which are specific to certain metabolic disorders (Table 27–1).

The nervous system is most consistently affected. The physical examination should focus on evaluating neurodevelopmental functions. Abnormalities commonly revealed include impaired states of alertness and arousal, tremors, posturing, clonic jerking, tonic spasms, or seizures. Symptoms such as **opisthotonos** (extreme spasmic extension of the body resulting in arching of the back at severe angle) and disturbances of ocular movement may be noted. Limb movements are diminished or absent as neuromuscular function declines. Other neurologic responses that are affected include thermoregulation causing hypothermia or **poikilothermia** (inability to

TABLE 27–1

Unusual Odors Associated With Metabolic Disorders

Urine and Body Odors	Disorder
Maple syrup or burnt sugar	Maple syrup urine disease
Musty, mousey	PKU or tyrosinemia type I
Boiled cabbage, rancid butter, or rotting fish	Hypermethioninemia or tyrosinemia type I
Cat urine	Multiple carboxylase deficiency
Sweaty feet	Glutaricaciduria (type II) or isovalericacidemia
Swimming pool	Hawkinsinuria
Rotting fish	Trimethylaminuria

maintain a consistent core body temperature) and cardiac and respiratory function. Irregular respirations, bradycardia, circulatory difficulties, and poor color may all be present (Focused Physical Assessment 27–1).

Nearly all metabolic disorders negatively affect growth and development. Therefore, assessment of the child's growth should be accurate and ongoing, and developmental status should be monitored with developmental screening tools (see Chapter 3 for a discussion of developmental screening tools). During infancy and early childhood, loss of previously attained milestones often occurs as disease symptoms progress. Metabolic diseases that first manifest during late childhood and adolescence are usually less severe and progress less rapidly; however, they may still affect behavior, thinking, and emotions. Children with metabolic disease who are diagnosed and treated at a young age require continuing assessment to evaluate the effectiveness of therapy. If dietary or pharmacologic management regimens are failing, effects on the child's physical and cognitive functions can be noted.

ANSWER: Several assessment findings may suggest a metabolic disorder. Important findings would include no diagnostic testing for screening, evidence of tremors, reports of forceful vomiting, and appearance of skin lesions. Additionally, the lagging behind on achievement of developmental milestones is a crucial indicator that would provide further evidence of a problem.

Diagnostic Criteria for Evaluating Inborn Errors of Metabolism

Neonatal screening programs have made early diagnosis of more than 30 inborn metabolic errors possible. Every state screens for PKU; galactosemia and maple syrup disease are also included in most newborn screening tests (Tradition or Science 27–1).

FOCUSED PHYSICAL ASSESSMENT, HUNTER'S DISEASE 27-1

Metabolic System

Assessment Parameter	Alterations/Clinical Significance
General appearance	General appearance of clinical deterioration in previously normal child may indicate metabolic disorder Failure to thrive Impaired states of alertness and arousal Poor temperature control
Integumentary system (skin, hair, nails)	Coarse, sparse, or brittle hair as seen in Menkes disease Unexplained jaundice from hepatic involvement Hypothermia or poikilothermia (inability to maintain a constant core temperature) Sagging skin related to weight loss Tooth eruption delayed, abnormal shape, presence of many tooth abscesses as seen with X-linked hypophosphatemic rickets
Head and neck	Dysmorphic features such as microcephaly, abnormal facial features (e.g., gargoylike facial features seen in Hurler's syndrome)
Eyes	Dislocated lenses, cataracts (galactosemia, Menkes disease, and Wilson's disease) Disturbances of ocular movement, deterioration in vision including blindness (MSUD, Mitochondrial disorders) Abnormal corneal pigmentation, Kayser-Fleischer ring seen in Wilson's disease
Ears	Deafness (Hurler's syndrome, Hunter's disease)
Thorax and lungs	Irregular respirations, tachypnea, apnea related to metabolic acidosis (associated with many metabolic disorders) Pectus excavatum seen in Menkes disease
Cardiovascular system	Bradycardia, arrhythmias, circulatory difficulties related to hypoglycemia Advanced cardiac involvement such as hypertrophic or dilated cardiomyopathy, pericardial effusion
Gastrointestinal system	Hepatomegaly, splenomegaly associated with Wilson's disease and hepatic dysfunction Jaundice from hepatic involvement (Tyrosinemia type I, Wilson's disease, galactosemia) Intermittent, unexplained recurrent episodes of vomiting related to protein imbalance, metabolic acidosis, or hyperammonemia
Genitourinary system	Unusual urine and body odors, particularly during acute illnesses, related to ketones and other metabolic substrates in urine Presence of renal stones (hyperparathyroidism)
Musculoskeletal system	Skeletal deformities (e.g., abnormal bone growth and formation) seen in Wilson's disease, Hurler's syndrome, and lysosomal storage diseases Involuntary, diminished, or absent limb or motor function (e.g., waddling gait, hypotonia, hypertonia) seen in Menkes disease, galactosemia, Tay-Sachs disease
Neurologic system	Neurologic deterioration, ataxia, tremors, clonic jerking, tonic spasms, and seizures; coma, encephalopathy related to effects of accumulating metabolites on the CNS

Although screening is available for numerous metabolic disorders, the cost-to-benefit ratio of such screening, in both economic and ethical terms, must be considered for each disorder. For the rarer metabolic disorders, the expense associated with testing all newborns may be perceived as unjustified. Therefore, specific criteria must be met before a metabolic disorder is included in a neonatal screening program. Generally, disorders included in screening programs are those with

- Relatively high prevalence
- Clinical symptoms that are not present until irreversible damage occurs
- Clinical manifestations severe enough to affect society
- Treatments that are known and facilities are available to provide treatment
- Diagnostic evaluation possible through a simple method of collection
- Follow-up available if test results are abnormal (includes retesting, because all screening tests have false-positive and false-negative results)

If results of neonatal screening are positive, or if the child presents with clinical manifestations consistent with a metabolic disorder, laboratory studies can differentiate the cause of the child's illness. High-pressure gas-liquid chromatography, ion-exchange chromatography, mass spectroscopy, and electron microscopy are used to analyze blood, plasma,

TRADITION OR SCIENCE 27–1

Do infants in all parts of the United States have equal access to newborn screening and its potential to prevent morbidity and mortality?

EVIDENCE-BASED PRACTICE

Variations exist among state newborn screening systems, and a national model for the structure and function of newborn screening systems has not yet been embraced. In addition, no uniform guidelines exist to direct periodic assessment for the conditions for which screening is performed. A national Task Force on Newborn Screening (2000), convened by the AAP, has identified a need for the nation to address unequal access to comprehensive newborn screening programs. National standards are needed to make newborn screening programs more comparable and address inequities in the provision of healthcare services. When completing a health assessment, note the state in which the child was born and determine whether further screening is needed, because some tests may not have been completed during the neonatal screening process in the state where the child was born.

urine, or cerebrospinal fluid to detect metabolic disorders (Tests and Procedures 27–1). The enzymatic defect that is interrupting the metabolic pathway results in either a deficiency of an essential substrate or the accumulation of a harmful metabolite. These deficiencies or elevations in the substrates can be detected in the body fluids. In some cases, when the presence of an inborn error of metabolism has been determined, further diagnostic testing may be done to determine the extent of organ involvement.

TREATMENT MODALITIES

QUESTION: Why are newborn screening tests so important for newborns, such as Sean?

Advances in diagnosing and treating inborn errors of metabolism have greatly improved the prognosis for many children. Many of the treatable errors of metabolism require lifelong management, usually in the form of dietary restriction. Other metabolic diseases are fatal or result in severe mental retardation, and no successful intervention has been developed.

The management of children and families affected by inborn errors of metabolism is approached by the healthcare team in three ways: prevention, early diagnosis, and prompt treatment.

Prevention

Prevention, when it is possible, is the first intervention. For some diseases such as Tay-Sachs disease, mild hyperphenylalaninemia, and Gaucher's disease, **carrier testing** (heterozygote screening) is possible. Carrier testing is war-

ranted for people who may have elevated risk because of their ethnic or national origin. The nurse has an important role in providing genetic counseling to families who are suspected or known carriers of a metabolic disorder. This preventive intervention can serve as a way to provide full disclosure to couples regarding their risk of the disease, the burden of the disease, and their reproductive options before they make decisions regarding childbearing.

Early Diagnosis

Early diagnosis is the second focus of the healthcare team. In many cases, a diagnosis can be made in utero. Amniocentesis and chorionic villus sampling can detect many of the metabolic disorders. If a diagnosis is confirmed, a member of the healthcare team with genetic counseling experience and preparation can provide the family with information regarding the severity of the illness, the child's long-term prognosis, and the range of options available for maintaining or terminating the pregnancy. The family may experience turmoil and grief as they come to terms with the diagnosis for their unborn child. Providing emotional support to the family is an important aspect of care at this time. Chapter 13 provides an in-depth description of the interventions that can be implemented to support the family during the grieving process.

Neonatal screening is also an aspect of early diagnosis (Nursing Interventions 27–1). When the neonate has been tested, results may be sent back to the physician in as few as 2 weeks. Positive results may be the first and only indicator of disease in an otherwise asymptomatic newborn. Further blood and urine testing is then initiated to confirm the diagnosis.

Another, later aspect of early diagnosis is early recognition of symptoms during the neonatal period. Because children with inborn errors of metabolism may present with one or more of a large variety of symptoms (see Focused Physical Assessment 27–1), differentiating the condition from other childhood disorders may be difficult. Infants may present with lethargy, poor feeding, tachypnea or apnea, and recurrent vomiting. Because the clinical symptoms are usually nonspecific and may appear similar to those present with any number of generalized infections that can affect infants (Rezvani, 2007), opportunities to diagnose inborn errors may be missed. Thus, a primary intervention of the healthcare team is to consider and suspect a metabolic disorder when a neonate becomes severely ill, when developmental milestones are not met, or when developmental regression begins to appear in the previously healthy child.

Prompt Treatment

Prompt treatment is the third essential intervention. Treatment interventions may include

- Decreasing substrates preceding the enzymatic block (e.g., avoiding a particular amino acid or carbohydrate)
- Administering a supplement of the deficient product that should have been produced
- Providing an enzymatic cofactor

Tests and Procedures 27–1 Evaluating Inborn Errors of Metabolism

Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Responsibilities
Blood Tests			
Neonatal screening	Early diagnosis of inborn errors of metabolism. Specific diseases assessed vary based on state regulations.	Identifies presence of disorders such as phenylketonuria, galactosemia, hypothyroidism, and maple syrup disease.	Screening must be completed before discharge from the acute care facility (see Nursing Interventions 27–1).
Complete blood cell count, glucose, electrolytes, arterial blood gas, anion gap, plasma ammonium level	Used to rule out or confirm metabolic disorder.	Alterations in glucose, ketones, blood pH and bicarbonate, blood lactate all indicate metabolic disorder.	Note child's diet before the test, the ingestion of food or formula may impact lab results if a metabolic disorder is present.
Plasma amino acids, plasma carnitine	Detects changes in amino acid patterns, thus detecting abnormalities of amino acid transport or metabolism.	Defects related to metabolism of amino acids result in increased levels in the blood.	Note time of collection in relation to feeding. Fasting usually required prior to test. Verify length of fasting period needed with laboratory.
BUN, creatinine	Evaluates renal function.	Elevations indicate renal involvement as seen in conditions such as Wilson's disease.	Sample may be obtained at same time as completing other blood specimens.
Ammonia, lactic acid	Evaluates metabolism. Ammonia is an end product of protein metabolism and lactate is an end product of carbohydrate metabolism.	Lactate elevated in disorders of carbohydrate and energy metabolism. Ammonia is markedly elevated in urea cycle defects. Obtain if child has altered level of consciousness or recurrent vomiting, or if metabolic acidosis with increased anion gap is present.	Ammonia and lactate must be drawn without the use of a tourniquet. Blood should be free flowing or result can be falsely elevated. Arterial sample is preferred for this reason. Blood sample is placed on ice and should be analyzed immediately.
Liver function panel or hepatic panel (should include bilirubin, transaminase, partial thromboplastin time, prothrombin time)	Evaluation of hepatic function.	Hepatic involvement seen in conditions such as Menkes disease and Wilson's disease.	Sample may be obtained at same time as completing other blood specimens.
Urine Tests			
Ketones	Helpful in differentiating causes and types of metabolic disorders.	Ketones are elevated in many metabolic disorders and low in others.	Urine kept at room temperature for 1 hour or more before testing may produce a false-negative result.
Urine analysis, urine-reducing substances, assessment of urine odor	Deviation from normal ranges helpful in determining presence of metabolic disorder or in determining whether another causative factor exists for child's clinical presentation.	Accumulated substrates from faulty metabolic pathways will be present in the urine. Certain metabolic disorders have distinctive odors (e.g., maple syrup urine smells like burned sugar or maple syrup).	Note type of formula or food intake before the test. If 24-hour urine collection is needed, ensure that all urine is collected. Assist family to help young children who may be forgetful. For infants, drain the 24-hour collection bag frequently to help maintain stability of bag adhering to the child.

(Continued)

Tests and Procedures 27–1 Evaluating Inborn Errors of Metabolism (Continued)

Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Responsibilities
			Penicillin administration may cause a false positive for reducing substances.
Urine amino acids and organic acids	Detects changes in amino acid patterns, thus detecting abnormalities of amino acid transport or metabolism.	Defects related to metabolism of amino acids result in increased levels in the urine.	No food or fluid restriction before test. Collect a clean random urine specimen. A 24-hour urine specimen may be requested.
Other Tests			
Mitochondrial DNA analysis	Determines presence of abnormal genes involved in inborn errors of metabolism.	May identify primary genetic abnormality.	Parental consent is required. Genetic counseling should be provided. Samples are obtained from a variety body fluids and tissues. Tests results may take weeks or months.
Liver biopsy	Determines extent of hepatic involvement.	Hepatic involvement seen in Menkes disease and Wilson's disease.	Parental consent must be obtained. Monitor biopsy site, noting any bleeding and intervening if it occurs.
Skin biopsy, muscle biopsy	Evaluates skin and muscle fibroblasts, and evaluates for presence of mitochondrial disease.	Mitochondrial disease will show alterations in muscle tissue.	Because these tests are more invasive, they would usually be performed only when index of suspicion for metabolic disease is high. Blood and urine tests should have been obtained prior to biopsies.

NURSING INTERVENTIONS 27–1

Guidelines for Completing Neonatal Screening

- All newborns complete newborn screening before discharge from the newborn nursery, preferably between 24 and 72 hours of age, and in no case later than 7 days of life.
- Screening of premature or sick infants is completed as close as possible to the time of discharge from the nursery or at or near the seventh day of age, regardless of feeding status.
- If the initial specimen for newborn screening is collected before 12 hours of age, a second specimen should be collected at 1 to 2 weeks of age.
- Complete screening before transfusion or dialysis, if the child's condition permits. If the infant requires a blood transfusion or dialysis before the specimen is collected, complete newborn screening 24 hours after the blood transfusion/dialysis is completed.

- Using medications to remove accumulated substrates
- Replacing deficient enzymes through intravenous administration
- Undergoing liver or bone marrow transplantation to eliminate all deficient enzymes
- Providing somatic gene therapy (future option)

Dietary Management

The goal of dietary restriction, the primary treatment modality for inborn errors of metabolism, is to control the substrate accumulation by reducing or eliminating carbohydrates, proteins, or both. Special diet restrictions and synthetic **medical foods** are the two most successful methods of controlling the enzyme deficiencies. Medical foods are prescribed by a physician to manage a disease or health condition in a child with special nutrient needs; use of these foods requires ongoing evaluation by the healthcare team. The label on the product must clearly state that the product is intended to be used to manage a specific medical disorder or condition. Provide nutritional counseling for children on special diets and their families (see Nursing Plan of Care 29–1). Strategies to assist the family include

- Assisting the caregivers to obtain specialized infant formulas or medical foods
- Assisting the child and/or caregiver to incorporate individual and ethnic food preferences into the diet of the older child
- Instructing the caregiver and/or child on how to read labels and how to select appropriate food
- Observing the child and/or caregiver's selection of foods appropriate to the prescribed diet
- Assisting the caregiver in substituting ingredients to conform favorite recipes to the diet
- Providing written meal plans
- Teaching the child and/or caregiver how to keep a food diary and how to use it as a method for evaluating the child's compliance with the dietary restrictions
- Providing the child and/or caregiver with scenarios to preplan food selection at events such as parties, fast-food restaurants, and meals at other people's homes
- Providing written instructions for daycare, preschool, and school officials regarding dietary restrictions

Dietary management changes as the child grows, moving from a formula-based diet to solid foods. The primary care physician, the nurse, and the nutritionist can work together to provide the family with a nutritional plan. The diet must incorporate the restrictions mandated by the particular metabolic disorder, while considering the child's personal tastes and ethnic preferences. Ensuring that dietary restrictions are maintained outside the child's home environment is often difficult. Providing dietary instructions to daycare and school personnel is a key intervention. When the child attends a social event at which food is served, parents should either inquire beforehand whether appropriate foods will be served or take food items with them that are on the child's diet.

Pharmacologic Management

Pharmacologic dosages of vitamins and medications may be given in some instances. These products are used to supplement any deficient products or to assist in removing accumulated substrates. Work with the child and family to be certain they understand the importance of continuing pharmacologic therapy for an extended period. In most cases, the treatment is lifelong. The agreeable young child who easily adheres to the treatment regimen may become an independent adolescent who rejects being told what to do. Assisting the maturing child to be actively involved in his or her care and providing the child with a solid understanding of the importance of the pharmacologic and dietary regimen are aspects of the nurse's work with the family.

Other Therapies

Enzyme therapy is another treatment modality currently being used for some conditions (e.g., Cerezyme, currently in use for Gaucher's disease) and researched for others. Enzyme activity can be delivered to such organs as the liver and spleen to treat noncentral nervous system

manifestations such as anemia, bone disease, and hepatosplenomegaly.

Liver and bone marrow transplantations have demonstrated some success in halting or slowing the progression of peripheral complications in conditions such as Hurler's syndrome and Gaucher's disease.

Advances in *gene therapy* bring new hope that metabolic disorders can be managed and perhaps cured. In gene therapy, normal genetic information is introduced into defective cells to compensate for genetic defects and correct disease phenotypes. Replacing the defective gene itself (*somatic gene therapy*) is currently being evaluated as a treatment alternative. Ethical issues concerning the harvesting of genetic material and the ability to construct or alter human tissue have kept gene therapy primarily in the research laboratory. However, as these ethical issues are resolved and the technical and medical problems of gene therapy are mastered, this management option is an increasingly attainable goal.

Advances in biochemistry continue to reveal previously unknown metabolic diseases and clarify the basic pathophysiology of known disorders, giving rise to hope for new treatments and improved outcomes for these children and their families. Provide counseling to the child and the family to ensure that they understand the risks, uncertain outcomes, and hardships that are associated with the initiation of therapies that have not yet proved their long-term effectiveness.

ANSWER: Newborn screening tests are important for all newborns, including Sean, because they allow for early diagnosis of inborn metabolic errors. Additionally, these tests provide a baseline for helping to differentiate the wide variety of signs and symptoms of an inborn error disorder from other childhood disorders. Advances in diagnosing and treating these disorders have greatly improved the prognosis for many children. Moreover, positive results of screening tests may be the first and only indicator of a metabolic disorder in an otherwise asymptomatic newborn.

NURSING PLAN OF CARE FOR THE CHILD WITH INBORN ERRORS OF METABOLISM

Although inborn errors of metabolism can be attributed to a variety of changes occurring in the metabolic pathway, the diseases present many common healthcare needs for the child and the family. Nursing diagnoses that can be applied to the child with a metabolic disorder reflect the need for long-term management and a focus on supportive care for the family of a child with a chronic, potentially fatal condition. The nursing plan of care correlates with the three primary interdisciplinary interventions of prevention, early diagnosis, and prompt treatment (Nursing Plan of Care 27-1). Several other chapters in this text contain care plans that

NURSING PLAN OF CARE 27–1 FOR THE CHILD WITH A METABOLIC DISORDER

Nursing Diagnosis: Risk for disproportionate growth and development related to accumulation of metabolites affecting body system development (e.g., neurotoxic levels of metabolites may cause brain damage)

Interventions/Rationale

- Assess growth and development on diagnosis; reassess periodically using developmental screening tools (e.g., Denver II; see Tests and Procedures 3–1).

Provides baseline and ongoing data to determine whether developmental delay, physical disability, or mental retardation is present. Changes in assessment findings may indicate progression of child's condition or need to reassess child's health status and alter treatment plan.

- Assess parent's knowledge of developmental tasks. Encourage parents to expect age-appropriate behavior and set realistic limits for their child.

Promotes realistic expectation of age-appropriate norms. Restricting activities may decrease environmental stimuli and contribute to developmental delays. Unrealistic expectations may affect child's self-esteem and place child at risk for injury.

- Emphasize the importance of treating the child normally to avoid overdependency; model this behavior for parents.

Ineffective or inconsistent discipline places the child at risk for inappropriate behaviors and social acting out. Role modeling enables the parents to see the expectation in a nonthreatening way.

- As the child matures, provide opportunities for the child to exert some degree of control over management of care (e.g., making meal choices). Include the child in planning the daily routine.

Participating in care and decision making is a developmental task, and it encourages independence.

- Ensure that the child completes health supervision and screening activities recommended for developmental age (i.e., immunizations and well check-ups; see Chapter 8 and Appendix G).

Provides opportunity for developmental surveillance and ensures that health promotion and prevention activities are completed.

Expected Outcomes

- Parents will provide developmental enhancement measures as needed to support and maximize the child's potential.
- Child will achieve developmental skills and perform self-care activities typical for age and to the extent allowed by the child's condition.
- Child's physical growth will remain and progress within normal limits for age and condition.

- Developmental delays will be identified by parents.

Nursing Diagnosis: Imbalanced nutrition: More or less than body requirements related to ingesting withholding nutrients that activate biochemical reactions to build up a metabolic substrate or prohibit formation of enzymes in a particular metabolic pathway

Interventions/Rationale

- Assess the child's nutritional status, including growth parameters, nutritional intake, appetite, bowel and bladder functioning, and presence of nausea or vomiting.

Growth parameters provide trends in weight loss and gains. Nutritional status necessary to determine whether caloric needs, fluid balance, and adequacy of fluid volume replacement goals are being accomplished. Appetite can be encouraged with preferred and tolerable foods. Disease process and medication can impair gastrointestinal function, causing nausea and vomiting.

- Complete a physical assessment to determine the extent of physical manifestations of the child's metabolic condition (see Focused Physical Assessment 27–1). Assess vital signs, skin turgor, and mucous membranes for signs of dehydration.

Physical findings assist in confirming diagnosis. Baseline data are needed to evaluate effectiveness of dietary regimen. Dehydration may be present if child has history of vomiting after eating.

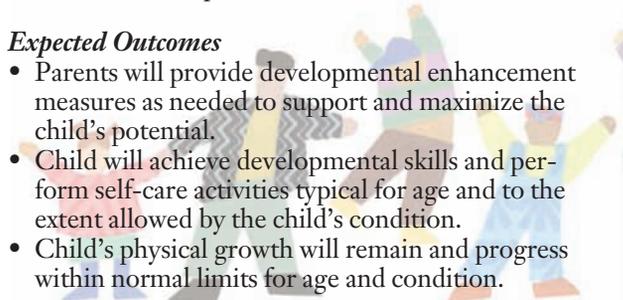

- Assess laboratory values (e.g., phenylalanine, blood lactate, amino acids) at time of diagnosis and periodically thereafter.

Lab values indicate presence of metabolic condition and provide ongoing data about fluid status, metabolic activity, and response to therapeutic regimen.

- Teach parents and child and other caregivers (grandparents, daycare providers) the dietary plan to enhance metabolic stability. Plan may include dietary restrictions (e.g., eliminating protein), dietary additions (e.g., adding foods high in calcium and phosphorus), and the use of dietary supplements or medical foods as ordered (see also Treatment Modalities in this chapter).

Dietary additions or restrictions are defined by the characteristics of the metabolic condition and are used either to decrease the substrate preceding the enzymatic block or to supplement the deficient product that should have been produced.

- Assist the family to incorporate the child's diet into family lifestyle. Demonstrate strategies to promote normal family activities (e.g., dining out, outdoor cooking, and meals at extracurricular activities).

Enhances adherence to child's diet. Provides strategies for successful adaptation of diet in settings outside the home.

- Assess parent's and child's adherence to dietary regimen on long-term basis. Reinforce dietary information as needed.

Evaluates adherence to nutritional plan to determine whether plan needs to be altered to fit family lifestyle and child's changing developmental needs.

Expected Outcomes

- Family and child will have knowledge sufficient to manage the child's diet and meet the health goals of the growing child.
- Child's dietary patterns will adhere to the nutritional regimen needed to prevent accumulation of metabolic substrates in the body.
- Signs and symptoms of the metabolic disorder will be controlled, and the child will achieve stable health status, as indicated by stable growth pattern on growth chart, appropriate weight gain, satisfactory blood values, and attainment of age-appropriate developmental milestones.

Nursing Diagnosis: Disturbed body image related to perception of skeletal deformities

See Nursing Plan of Care 12–1.

Expected Outcome

- The child and parents will maintain positive conscious and unconscious perceptions and attitudes about the child's appearance.

Nursing Diagnosis: Risk for ineffective management of family therapeutic regimen related to complexity of home care required and family resources

Interventions/Rationale

- Support family with reassurance, realism, and repetition, as family members come to grips with the reality of the child's illness and treatment.

Enables family to understand information and enhance retention. Expression of emotion must often precede problem solving.

- Help family develop strategies to adjust to the crisis of chronic illness.

Assists the family to explore new resources for coping with child's condition and its effect on family life.

- Refer to community services to provide additional family support.

Enhances the overall adaptation to the chronic illness. Emotional support can be provided by referral to a support group.

- Coordinate services and help family and health-care team to effectively communicate with one another.

Decreases stress and improves communication between professionals and parents.

- Evaluate child's and family's ability to implement desired regimen in home and at school and other community venues (e.g., daycare, summer camp). Upon family's request, provide information to community settings about child's condition and measures to ensure adherence to healthcare plan.

Provides information about family's ability to translate plan of care to home setting. Family may request that healthcare team serve as advocates to ensure that schools and daycare facilities understand child's health-care needs.

- Based on family assessment, provide family with information and resources to tailor the child's therapy to the family's lifestyle (e.g., explore ways to simplify the regimen; provide easy access to healthcare resources; and help family secure medical food, medications, and other supplies as needed).

Working within the family lifestyle may improve adherence.

Expected Outcomes

- Family actions and activities will support dietary and pharmacologic regimens necessary for the developing child with a chronic condition.
- Maturing child will accept increased responsibility for managing the condition and making modifications as necessary in the presence of maturational changes, illness, and stress.

also apply to children with metabolic disorders. Children with metabolic conditions have chronic conditions that will affect their diets and activities for the rest of their lives, and changes in family roles and lifestyles may be necessary to adapt to these children's needs. Chapter 12 presents the plan of care for the child with a chronic condition and specifically addresses the nursing care concerns related to the family's adaptation to managing the child's chronic condition. Some meta-

bolic disorders cannot be managed effectively, and these children have poor prognoses for survival. Families experience anticipatory grief and loss. Chapter 13 covers palliative care and provides a nursing plan of care for the grieving family. Last, many metabolic conditions are diagnosed during the neonatal period; therefore, the nursing plan of care in Chapter 14 will be applicable to managing neonates with an altered health state.

ALTERATIONS IN METABOLIC STATUS

Alterations in metabolic status encompass disorders of amino acid, mineral, carbohydrate, and mucopolysaccharide metabolism as well as disorders of mitochondrial function and fatty acid oxidation.

AMINO ACID DISORDERS

Amino acids are the primary building blocks of proteins, which are key factors in many metabolic cycles and may function as neurotransmitters. Even in utero, amino acids are essential to life. Inherited errors of amino acid metabolism occur primarily in catabolic pathways. Most of the associated disorders can result in severe central nervous system dysfunction. However, early diagnosis, removal of toxic metabolites, promotion of anabolism, and adherence to dietary restrictions can prevent catastrophic outcomes. This section covers two of the most common amino acid disorders: PKU and maple syrup disease. Table 27–2 provides a summary of important features of additional amino acid disorders.

Phenylketonuria

Phenylketonuria, more commonly known as PKU, is the most frequently occurring aminoaciduria. PKU was first recognized in 1934 and was associated with an excess of phenylpyruvic acid in the urine.

Incidence and Etiology

QUESTION: You suspect that Sean has PKU. You explain to Joellen that this is an inherited metabolic problem. She asks you, “Then why don’t my other two children have the problem?” How would you respond?

The incidence of PKU in North America is approximately 1 in 16,000 live births (Harding, 2008). The highest incidence is found in Ireland and Turkey, at a rate of 1 in 4,500 births. Ethnic variability occurs; the incidence is highest among whites and Native Americans and lower among blacks, Hispanics, and Asians (Gambol, 2007).

PKU is an autosomal recessive genetic defect in which an enzyme deficiency renders the body unable to metabolize phenylalanine efficiently (see Fig. 3–3). Phenylalanine and its metabolites accumulate in the blood and the urine and exert deleterious effects on brain development, especially during the periods of active myelination. A very small subset of patients with PKU do not develop cognitive deficits, however, even without treatment. This fact strongly suggests that modifier genes are responsible for this clinical variation, but none have yet been identified.

The recessive gene that transmits PKU is found on chromosome 12. The defect in the gene for phenylalanine hydrolase is responsible for more than 400 mutations that

allow for more than 10,000 genotype combinations (Gambol, 2007). To have PKU, the child must receive the defective gene from both parents. Thus, the chance of a PKU birth when both parents are carriers is one in four. An estimated 1 person out of 50 is an asymptomatic heterozygous carrier of the PKU gene.

ANSWER: You would need to explain to Joellen that PKU is an autosomal recessive genetic defect. For Sean to have the disorder, both parents must carry the recessive gene. However, even in this case, when both parents each carry the defective gene, the chance of a child having PKU is one in four.

Pathophysiology

The exact pathogenic mechanisms of PKU have not been determined. Phenylalanine is an essential amino acid found in all protein foods. During a child’s early growth period, approximately 50% of the phenylalanine in the normal daily intake is used for protein synthesis. As growth slows, the amount of phenylalanine needed by the body diminishes. Normally, excess phenylalanine is converted in the liver, pancreas, and kidneys to tyrosine (Rezvani, 2007). In the most severe (classic) form of PKU, the hepatic enzyme phenylalanine hydroxylase is completely inactive. This lack of enzymatic activity results in a buildup of phenylalanine and its metabolites, which affects numerous areas of metabolism, including the conversion of phenylalanine to tyrosine. Tyrosine plays an important role in the development of the central nervous system. It is the precursor of dopamine and norepinephrine. Tyrosine is also a substrate in the synthesis of thyroxine and melanin, which affect growth and pigmentation of the skin, hair, and eyes.

Prognosis

If untreated, PKU almost always leads to severe, irreparable damage to the central nervous system. With adequate dietary treatment, however, the prognosis is good. The success of childhood treatment for PKU has led to increasing prevalence of maternal PKU. Childbearing women who have PKU are at risk for having infants with psychomotor retardation (92%), intrauterine growth retardation (40%), microcephaly (73%), or congenital heart defects (10%) (American Academy of Pediatrics [AAP], Committee on Genetics, 2008). High maternal phenylalanine levels have a teratogenic effect on the fetus, and defects are directly associated with degree to which maternal phenylalanine levels are elevated. Dietary management throughout pregnancy must be extremely rigid for optimal neonatal outcomes to occur. Infants may or may not be born with PKU themselves, although the incidence of hyperphenylalaninemia is higher among infants born to PKU mothers. Approximately 1 in 120 infants born to a mother with PKU will inherit an abnormal gene from both parents and be affected by PKU (AAP, Committee on Genetics, 2008).

TABLE 27-2
Selected Amino Acid Disorders

Disorder and Inheritance	Pathophysiology	Significant Clinical Features	Laboratory Findings	Management	Prognosis
Hemocystinuria Autosomal recessive (chromosome 21)	Deficient cystathionine beta-synthase Prevents interaction of the intermediate product of the amino acid methionine with serine to form cystathionine	Dislocation of the lens Mental retardation Convulsions Osteoporosis Arterial and venous vascular thrombosis Limb overgrowth Fair hair and skin Connective tissue deficit, leading to scoliosis	Plasma homocystine 0.02 to 0.025 mmol/L Plasma methionine up to 2 mmol/L Plasma cystine low Increased homocystine in urine	High doses of pyridoxine (vitamin B ₆), 200 to 500 mg per 24 hours Low-methionine, high-cystine diet Use of low-methionine formulas	Progress of the disease may not be stemmed.
Isovaleric academia Autosomal recessive (chromosome 15)	Deficient isovaleryl-CoA dehydrogenase	Mental retardation Acidosis Vomiting Lethargy Coma Urine odor of sweaty feet	Isovaleric acid in blood and urine	Low-protein, specific low-leucine diet	Near-normal intelligence if compliant with diet.
Methylmalonic-aciduria Autosomal recessive (chromosome 6)	Possible defect in the B ₁₂ coenzyme	Low blood pH Lethargy Vomiting Ketoacidosis Failure to thrive Mental retardation	Methylmalonic acid in blood and urine	B ₁₂ unresponsive: low-protein diet B ₁₂ responsive: B ₁₂ in large doses	B ₁₂ unresponsive: death usually in infancy. B ₁₂ responsive: normal growth and development.
Tyrosinemia type I Autosomal recessive	Defect in which an enzyme is missing to break down the amino acid tyrosine	Poor appetite and failure to grow normally Vomiting Diarrhea, bloody stools A cabbage-like odor Jaundice (yellow skin and whites of eyes) Swollen liver Irritability Lethargy (overwhelming tiredness) Liver cirrhosis Kidney problems	Succinylacetone present in urine Abnormal liver function tests	Restriction of the amount of tyrosine and another amino acid, phenylalanine, in the baby's food Administration of Nitisinone (Orfadin) to reduce toxic effects of tyrosine in the body. Liver transplantation may be needed.	May cause death from liver failure.

Assessment

QUESTION: Sean was scheduled for testing after his discharge from the hospital. Why wasn't the testing done in the hospital before discharge?

Infants with PKU appear normal for about the first 3 to 6 months of life. Vomiting, sometimes mimicking the presentation seen in pyloric stenosis, may be severe and may lead to misdiagnosis. Be alert to this potential for misdiagnosis. After this time, an untreated child begins to excrete phenylacetic acid in the urine and perspiration, and to manifest symptoms of the tyrosine deficiency. These symptoms include severe psychomotor retardation, microcephaly, seizures, and hyperactivity. The child may develop a clumsy gait, fine tremors of the hands, poor coordination, odd posturing, or repetitious digital mannerisms. The inability to produce melanin causes hypopigmentation of the hair, eyes, and skin; children with PKU are very blond and fair skinned compared with their parents. Eczema occurs in 25% of untreated children. A musty or mousey odor from the child's urine and sweat is a classic sign of PKU but may not be noticed by parents because they are around the child daily. The nurse may note this odor during a routine physical examination or during the initial assessment of a child being evaluated for developmental delay. Clinical manifestations of PKU are rarely seen in countries where neonatal screening programs are mandated and followed (Rezvani, 2007).

Diagnostic Tests

Plasma phenylalanine levels of >20 mg/dL are indicative of PKU. At birth, an infant with PKU has normal phenylalanine levels because of the rapid placental exchange of amino acids that has been occurring in utero. However, these levels increase sharply after the baby has been fed, because most formulas and breast milk contain phenylalanine. Screening for PKU is mandated in all 50 states in the United States. Three screening methods are available: the Guthrie Bacterial Inhibition Assay, automated fluorometric assay, and tandem mass spectrometry (U.S. Preventive Services Task Force, 2008). The Guthrie Bacterial Inhibition Assay remains the most commonly used test to detect phenylalanine in blood. In this test, a drop of blood is obtained with a heel stick and is collected on special filter paper (Fig. 27–2). This test is performed routinely by nurses in the nursery, home setting, or pediatrician's office. The screening is performed after 24 hours of life but before the infant is 7 days old. Infants treated within the first 24 hours after birth should receive a repeat screening test within 2 weeks. Premature infants and those with illnesses are tested at or near 7 days of age (U.S. Preventive Services Task Force, 2008).

caREminder

Ensure that the first drop of blood is large enough to fill the imprinted space on the filter paper. Squeezing out more

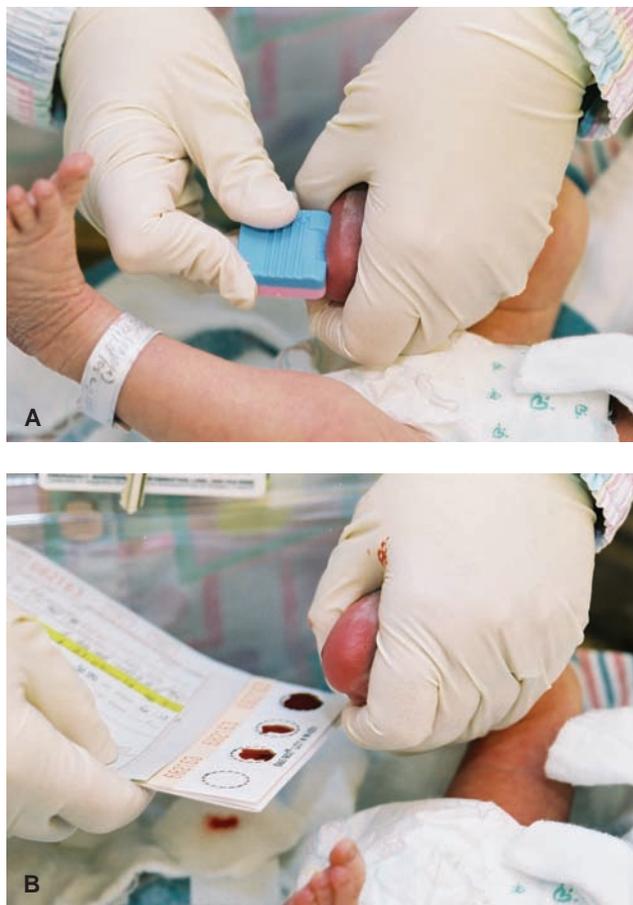

FIGURE 27–2. Screening for PKU. (A) Performing a heel stick. (B) Applying blood specimen to the card for screening.

blood onto the paper creates a layering effect that can produce a false-positive test result.

Other diagnostic laboratory findings include a normal plasma tyrosine level, and elevated urine metabolites such as phenylpyruvic acid, phenylacetic acid, and phenyl acetyl glutamine.

ANSWER: At birth, an infant with PKU has normal phenylalanine levels because of the rapid placental exchange of amino acids that has been occurring in utero. However, these levels increase sharply after the baby has been fed, because most formulas and breast milk contain phenylalanine. To ensure the accuracy of the testing results, testing should occur 48 to 72 hours after birth to make sure that the infant has had an adequate intake of breast milk or formula. Sean was discharged when he was 24 hours old. Therefore, testing was scheduled to occur after he was discharged.

Nursing Diagnoses and Outcomes

Management of the child with PKU focuses on early detection and intervention to avert the deleterious effects

of the disease process. See Nursing Plan of Care 27–1 and [thePoint](#) Care Path: An Interdisciplinary Plan of Care for the Infant With PKU for examples of the nursing diagnoses and interdisciplinary care that can be instituted for the newly diagnosed child and his or her family.

Interdisciplinary Interventions

QUESTION: Sean is diagnosed with PKU. Joellen is scheduled to speak to a nutritionist about Sean's diet, and Sean is scheduled for follow-up blood testing to evaluate serum phenylalanine levels. What type of diet would you expect to be prescribed, how often would you expect Sean to have his serum levels checked, and what serum levels would indicate effectiveness of therapy?

Dietary treatment remains the safest option for optimal growth and development. Newer cell-directed therapies are also being investigated, including cell transplantation and gene therapy (Harding, 2008). Management of children with PKU focuses on preventing excessive accumulation of phenylalanine by restricting protein intake. The goal of dietary management is to maintain serum phenylalanine levels for children 12 years of age or younger between 2 to 6 mg/dL and for children older than 12 years between 2 to 10 mg/dL (National Institutes of Health Consensus Development Panel, 2000). The amount of phenylalanine allowed is based on ongoing assessment of the child's blood and urine phenylalanine levels. Dietary allowances of phenylalanine change depending on hunger, growth, development, and serum phenylalanine levels. Monitoring serum phenylalanine levels regularly is the primary way to ensure that blood levels remain within the therapeutic range. During infancy, blood levels are commonly measured weekly for the first 6 months and then every other week until 1 year of age. At 1 year and thereafter, monitoring usually occurs at the time of routine health surveillance visits (see Chapter 8 and Appendix G).

Dietary Management During Infancy

Begin dietary intervention within the first weeks of life. Typically, the infant and family are instructed by a nutritionist experienced with dietary restrictions for children with metabolic disorders. At each contact throughout the child's life, reinforce this teaching and assess adherence to dietary restrictions. Either the nutritionist or the nurse will assist the family in obtaining the formula for home use. A referral to social services is appropriate and will be a long-term need for the family to ensure that they have a reimbursement mechanism to purchase formula.

Infants diagnosed with PKU may continue to breast-feed. When a diagnosis has been made, the child's phenylalanine level needs to be reduced as quickly as possible. This is achieved through the use of a PKU medical food product. However, a small amount of natural protein is needed in the infant's diet and can be provided

through breast milk. The phenylalanine content of breast milk varies from mother to mother. It is highest in the colostrum and declines with the duration of lactation. The phenylalanine content of the breast milk is counted toward the child's needs. Generally, the number of breast-feedings to be allowed in a 24-hour period is specified (two to four feedings), with phenylalanine-free formula given at the other times. Infants who are not breast-fed are given a different medical food that contains some phenylalanine necessary for growth and development. Work with the mother to develop a system to keep track of the number of times she is breast-feeding each day.

Medical foods, sold in powder form, are a chief source of nutrition for infants and children with PKU. These foods are low in phenylalanine and contain vitamins, minerals, and, in some cases, carbohydrates and fats (e.g., Lofenalac, Phenyl-Free 2). Medical foods are reconstituted as formulas for infants and as milk substitutes for older children. The proteins in the medical foods have a characteristic flavor and, in some cases, aroma that are different from those of regular formula.

KidKare When the medical food is introduced within the first few months of life, infants usually grow accustomed to the flavor and readily accept the formula. If PKU is diagnosed late, the older infant or child is likely to find the taste of the medical food unacceptable. If parents encounter this problem, recommend that they try preflavored medical foods, which may be better accepted. Older children can flavor their drink with Quik, Tang, or Kool-Aid to make it more appealing.

The particular type and brand of medical food used are based on the child's age, dietary likes and dislikes, and variations in dietary needs, and on the cost and availability to the family. The cost of all formulas and many foods are covered by insurance or public health programs, but not all families and states have the same level of coverage.

caREminder

If the family is having difficulty adhering to the nutritional recommendations, financial hardship might be the reason. If the family is not already in contact with social services, ensure that they are referred.

Dietary Management Beyond Infancy

As solid foods are added to the diet, high-protein foods such as meat, fish, poultry, cheese, eggs, milk, nuts, beans, peas, and flour require the most severe limitations. Legumes, grains, and potatoes also have a relatively high phenylalanine content. The PKU diet is based on a food exchange list. The phenylalanine-free formula continues to be the key element of the child's diet, particularly during infancy, providing 90% of the child's protein calories,

vitamins, and minerals. In addition, the food exchange lists include vegetables, fruits, breads, cereals, fats, miscellaneous, and “free” foods that are allowed on the diet.

Alert! Advise parents not to use products sweetened with aspartame, including those marked with the brand name NutraSweet, because they contain phenylalanine. Products sweetened with sucralose, marketed as Splenda, are allowable in the diet of a child with PKU.

Assist the parents and the older child to become adept at reading labels on packaged foods and beverages. Even in many foods not considered protein sources, phenylalanine may appear in the form of NutraSweet (Fig. 27–3).

Current recommendations are that all affected adults and children should be kept on a phenylalanine-restricted diet for life. Discontinuing dietary restrictions can cause deterioration of IQ and cognitive performance (Rezvani, 2007). Dietary counseling and monitoring of phenylalanine levels are recommended for all girls and women of childbearing age (AAP, Committee on Genetics, 2008).

Alert! Elevated maternal phenylalanine concentrations during pregnancy can lead to adverse fetal outcomes such as microcephaly, mental retardation, and fetal anomalies. Provide genetic counseling and nutritional counseling to pregnant girls and women with PKU before (if possible) and after conception.

Protein catabolism occurs during infection and may cause serum phenylalanine levels to become elevated.

Illnesses that involve decreased appetite or vomiting may also affect the child’s phenylalanine levels. In these cases, serum levels should be monitored, the medical food should be continued, and fluid intake must be increased. Tea, gelatin, and carbonated beverages are appropriate to offer.

Alert! Overtreatment for PKU can cause a phenylalanine deficiency. The child with PKU does not synthesize phenylalanine. Teach parents the signs of phenylalanine deficiency: loss of appetite, vomiting, lethargy, failure to thrive, and malaise. Parents can readily reverse these symptoms by feeding the child small volumes of milk.

ANSWER: Typically, a child with PKU receives a protein-restricted diet. For Sean, who is an infant, breast milk or medical food, sold in powder form, is the chief source of nutrition. Medical foods are reconstituted as formulas for infants, and then as milk substitutes for older children. It is important to remember that phenylalanine is an essential amino acid necessary for growth and development. During infancy, the child obtains phenylalanine as a part of the medical formula or through breast milk. Diet is based on the child’s blood and urine phenylalanine levels in conjunction with the child’s hunger, and growth and development. Follow-up testing of serum levels would be scheduled weekly for the first 6 months and then every other week until 1 year of age. Then it is checked during routine health visits, unless more frequent monitoring is warranted. Therapy is considered effective when Sean’s serum phenylalanine levels are maintained between 2 to 6 mg/dL through the age of 12 years.

FIGURE 27–3. When buying food for the child with PKU, parents must examine product labels to check for aspartame or NutraSweet, which must be avoided. Products containing sucralose, marketed as Splenda, are acceptable.

Community Care

The nurse's ongoing role in managing the care of the child with PKU centers on educating the family, the child, other caregivers, and school personnel. Teaching that reinforces the dietary regimen is critical to managing PKU successfully. Growth and developmental changes necessitate adaptation of the dietary plan. As the child matures, she or he must learn to manage the diet and take more responsibility for dietary choices. Parents may seek advice and intervention to cope with the child who challenges the treatment plan (Developmental Considerations 27–2). Studies have shown that family cohesion and adherence to the restricted diet correlate positively with higher IQ levels. Thus, assessing family dynamics and implementing interventions to support the family under stress are important nursing interventions to enhance the long-term outcomes of these children and their families. Family counseling and participation in support groups can improve the family's coping abilities and strengthen the child's ability to manage the diet independently as the child becomes older.

Assist the family by providing information to all family caregivers, daycare providers, and school officials regarding the child's dietary restrictions. After the child enters the school setting, most school lunches can be adapted to fit the child's prescribed diet. These community care providers also need information regarding symptoms that indicate that appropriate phenylalanine levels are not being maintained.

Routine analysis of serum phenylalanine is a part of the continuing care of the child with PKU. Family members can be taught how to do routine blood collection, but at times may need assistance in collecting the samples, especially if the child becomes combative and resistant to sampling.

Maple Syrup Urine Disease

MSUD is an inherited autosomal recessive disorder of branched-chain amino acid catabolism—specifically, a deficiency of branched-chain 2-oxoacid dehydrogenase (see Fig. 3–3). The name comes from the sweet odor of

DEVELOPMENTAL CONSIDERATIONS 27–2

When the Child Does Not Want to Follow the PKU Treatment Plan

Age	Reasons	Interventions
Infancy	Dislike taste of medical formula Dislike smell of formula when switching from bottle to the cup	Purchase formulas that can be easily served in a bottle to hide the smell. When foods are being introduced, begin with a paste of the medical food and water.
Early childhood	Assertion of autonomy Dislike taste Desire to explore tastes of “forbidden” foods	Encourage the introduction of the cup and self-feeding skills. Use flavorings to alter the taste of the medical food. Encourage parents not to be overly protective.
Middle childhood	Embarrassment or being self-conscious at school because they are eating something “different” from others Desire to have more control Eating lunch away from home, which makes it easy to disregard the diet	Be sure the child understands the condition. Give the child responsibility for the diet. Let the child choose and prepare his or her own medical food. Let the child select at what times the medical food is eaten. Let the child answer others' questions about the diet.
Adolescence	Rejection of authority Desire to have more control Poor eating habits of adolescence associated with busy schedule Development of physical and sexual identity	Allow the intake of free foods such as soda and candy, while still assisting the adolescent to maintain his or her weight. Have the adolescent explain the diet to friends as a vegetarian diet with a special formula. Provide genetic counseling and information regarding the risks and requirements of a PKU pregnancy.

maple syrup found in body fluids, particularly the cerumen (ear wax) and urine of infants with this condition.

Incidence and Etiology

The incidence of MSUD is not known; it varies between 1 in 185,000 to 1 in 225,000 live births in the United States, depending on the geographic area (Strauss et al., 2006a). The incidence is as high as 1 in 200 live births in selected Mennonite settlements in Pennsylvania, Kentucky, New York, Indiana, Wisconsin, Michigan, Iowa, and Missouri.

Pathophysiology

QUESTION: You know that Sean has been diagnosed with PKU. How are Sean's signs and symptoms similar to and different from those associated with maple syrup disease?

In MSUD, the inborn error of metabolism results in deficient oxidative decarboxylation of the alpha-keto acids of the branched-chain amino acids: leucine, isoleucine, and valine. Accumulation of these amino acids, particularly leucine, causes severe neurologic symptoms. Variant forms of the disease, in which some residual activity of branched-chain oxoacid dehydrogenase occurs, have a more insidious onset and less severe course. The three variant forms are intermittent MSUD, mild or intermediate MSUD, and thiamine-responsive MSUD. This chapter covers only the more prevalent, classic form of MSUD. The classic form produces severe mental retardation unless intervention begins immediately after birth.

Infants appear normal at birth, but within the first week of life, acid-base, gastrointestinal, and neurologic problems appear. Initial signs of MSUD include poor feeding, a maple syrup odor in cerumen, ketonuria, and vomiting, which occur within 48 hours of delivery. Subsequent to the first 2 days of life, infants develop deepening encephalopathy characterized by intermittent hypertonicity, lethargy, opisthotonos, and respiratory irregularities. Hypoglycemia is common, but infants do not clinically improve when glucose is administered intravenously as might be anticipated. Without intervention, symptoms progress to dehydration, convulsions, severe ketoacidosis, acute pancreatitis, coma, and death within 7 to 10 days. The three common causes of injury to the brain in MSUD are hyponatremia and cerebral edema, acute and chronic essential amino acid deficiencies, and inadequate follow-up care during recurrent and acute illnesses.

ANSWER: With PKU and MSUD, both inborn errors of metabolism, infants appear normal at birth. Vomiting also occurs, however, with MSUD, the vomiting occurs within 48 hours of birth. Sean did not experience vomiting until a couple of weeks ago. Additionally, neurologic symptoms are usually severe and symptoms progress rapidly with MSUD,

such that death may occur in 2 to 4 weeks. Sean's symptoms seem to have progressed slowly and the only neurologic-type findings noted were lagging developmental milestones, hyperactivity, and fine hand tremors.

Prognosis

Untreated, the child with MSUD will die as early as 7 days of life. Early diagnosis and management substantially influence the prognosis for children with MSUD. Generally, the more severely the metabolic pathway is disturbed and the longer the resulting high levels of leucine remain, the poorer the child's prognosis. Injury to the child's brain from encephalopathy is the most common cause of developmental delays. Relatively normal intellectual outcomes are possible with early intervention, appropriate sick-day management under the guidance of a clinician, and consistent dietary management.

Assessment

The key goal in assessment is early diagnosis. Newborn screening assists in early diagnosis. The nurse may be the first to recognize MSUD, typically by noting the characteristic maple syrup smell of the infant's urine when changing his or her diapers, but this observation may not occur until 3 to 7 days after birth. Report any odd odor of the urine (often characterized as smelling like maple syrup or burned sugar) immediately to the physician or nurse practitioner. The maple syrup odor in cerumen (ear wax) is evident within 24 hours of birth and should be assessed if any suspicion or risk factors for MSUD exists (Strauss, Puffenberger & Morton, 2006b).

Diagnostic Tests

All states require newborn screening for MSUD. Tandem mass spectroscopy is the most reliable method of testing. The Guthrie test (a bacterial inhibition assay also used to evaluate for PKU), once standard for this purpose, is still in use, but antibiotic use in the ill neonate can cause false-positive results; thus, it is not considered a reliable method for screening for MSUD. Also, the Guthrie test is slow. By the time Guthrie results are available, MSUD could already have been detected through other methods and clinical examination. If a suspicion of MSUD exists, testing routinely done includes plasma amino acids and urine organic acids. Ketonuria as detected by use of standard urine strip tests is present in MSUD. Additional laboratory findings that indicate MSUD are increased levels of leucine, isoleucine, valine, keto acids, and alloisoleucine in both plasma and urine.

As an autosomal recessive condition, 50% of children born to affected parents may be unaffected and a carrier. Molecular genetic testing of healthy children and prenatal testing is available if the condition has been detected in a family member.

Nursing Diagnoses and Outcomes

A nursing plan of care for the child with a metabolic disease is presented in Nursing Plan of Care 27–1. The Nursing Plan of Care in Chapter 14 is an additional resource for care planning for the neonate with altered health status. In addition, the following nursing diagnoses and outcomes apply to the child with MSUD during the neonatal period:

Ineffective infant feeding pattern related to neurologic deterioration

Outcome: Parents will demonstrate appropriate feeding techniques to ensure that the child is receiving adequate nutrition.

Risk for deficient fluid volume related to initiation of therapies to remove toxic metabolites (peritoneal dialysis, hemodialysis, hemofiltration)

Outcome: Child will not experience vascular, cellular, or intracellular dehydration as a result of therapies to remove the toxic metabolites.

Interdisciplinary Interventions

The management goals for MSUD are to establish an early diagnosis, to remove the toxic metabolites, and to prevent tissue catabolism. Long-term treatment includes dietary leucine restriction, high-calorie, branched-chain amino acid-free formulas, and frequent monitoring. Liver transplantation is a reasonable treatment option for classic MSUD (Strauss, Puffenberger, & Morton, 2006b).

Medical Management

Management of the child with suspected or confirmed MSUD in an intensive care setting is required. The complications from encephalopathy and metabolic decompensation necessitate frequent healthcare monitoring and interventions. Careful monitoring of the child's hydration and electrolyte status, and treatment to adjust amino acid and electrolyte levels, have been found to be effective for even the most extreme elevations of plasma leucine (Strauss, Puffenberger & Morton, 2006b). In MSUD, nutritional management alone does not decrease leucine levels quickly enough to reduce the risk of brain damage, as it can in some metabolic disorders. Therefore, for the neonate, the initial treatment includes frequent adjustments in intravenous fluids and formulas with additives to control brain edema, minimize water retention, prevent catabolism, and maintain clinical stability while allowing weight gain and growth.

Debate exists about whether peritoneal dialysis, hemodialysis, or hemofiltration are required to remove the high levels of the branched-chain amino acids and their metabolites. These procedures involve a risk of infection and increased catabolism.

Parents may feel intimidated and frightened by the sudden changes in their child's condition and the need to have the child in the intensive care unit. Work with the social worker and child life specialist to provide support and teaching to assist the family through the crisis associated with the initial diagnosis and rigorous treatment methods.

Nutritional Management

After the toxic metabolites have been removed, or their levels decreased, dietary management is the primary component of ongoing treatment of MSUD. The required diet is high in calories but restricted in leucine, isoleucine, and valine. The diet should be started immediately after diagnosis and at least by the fifth day of life. Several proprietary formulas free of branched-chain amino acids are available. If the child demonstrates feeding difficulties, nasogastric feedings may be needed to ensure that the child's nutritional health is maintained. As the child gains strength, and neurologic symptoms resolve, feeding problems may resolve and the infant can be bottle-fed once again.

Plasma levels are monitored every 1 to 2 weeks during the rapid growth phase of infancy and frequently throughout the child's life. Plasma leucine concentration should range from 150 to 300 $\mu\text{mol/L}$ with an age-appropriate intake.

Ongoing management with restricted intake of the branched-chain amino acids leucine, isoleucine, and valine must be adjusted according to plasma levels. Dietary management for the asymptomatic infant or young child includes

- Isoleucine and valine each: neonates 10 to 40 mg/kg/day
- Glutamine and alanine each: 50 to 100 mg/kg/day
- Omega-3 polyunsaturated fatty acids as alpha-linolenic acid: 100 to 150 mg/kg/day (flaxseed oil is 50% alpha-linolenate by weight)
- Iodized sodium chloride in formula (17 mEq sodium/g): 3.5 to 5.0 mEq/kg/day
- Age-appropriate intake for vitamins, minerals, and micronutrients (Strauss, Puffenberger, & Morton, 2006b)

caREminder

Attention to the potential presence of catabolic states, even during minor illnesses, must continue throughout life. Instruct the family to contact the metabolic healthcare team to provide guidance during acute illnesses that may cause a catabolic state.

Community Care

When the child is ill, protein intake should be reduced, and caloric intake should be increased from 80 to 120 kcal/kg/day to 120 to 140 kcal/kg/day by encouraging consumption of carbohydrate- and fat-containing foods (Strauss, Puffenberger, & Morton, 2006b). Teach the parents how to perform tests for urinary ketones, keto acids, or both at home if they note any changes in their child's behavior, if the child has an illness that could cause a metabolic imbalance, or if the child is having difficulty with adhering to prescribed dietary restrictions. Early treatment of dehydration and acidosis may prevent death. When the affected child has surgery for any reason, postoperative management must focus on the

accelerated breakdown of body proteins that occurs post-operatively, which results in high metabolite levels.

Family education goals should focus on reinforcing the need for the prescribed dietary regimen, the importance of follow-up appointments, and sick-day management. As the child grows, the frequency and severity of crisis events decrease, although lifelong dietary management is required. Genetic counseling should be provided to family members, and identification of carriers of this metabolic condition is possible.

MINERAL DISORDERS

Mineral disorders are inherited defects characterized by alterations in metabolic pathways for the essential body metals iron, copper, zinc, magnesium, molybdenum, and manganese. The defects can affect absorption, transport, cellular use, storage, or excretion of a mineral needed to perform certain body functions and thereby produce a variety of sequelae. Three of these disorders—Menkes disease, X-linked hypophosphatemic rickets, and Wilson's disease—are covered in this chapter. Table 27–3 highlights other selected mineral disorders.

Menkes Disease

Menkes disease is also called *Menkes syndrome* or *trichophiodystrophy*. An X-linked recessive gene causes Menkes disease. This rare disorder, most typically affecting males, is sometimes called kinky hair or steely hair syndrome because it causes a unique kinky conformation of the hair strands. Its hallmark is an extreme copper deficiency.

Pathophysiology

The primary defect in Menkes disease is caused by mutations of ATP7A, an X-chromosomal gene that leads to an abnormal cellular copper transport and reduced activities of numerous copper-dependent enzymes (Godwin et al., 2006). The available amount of the copper proenzymes dopamine hydroxylase and cytochrome-*c* oxidase is reduced, and levels of **ceruloplasmin** (a glycoprotein to which most of the copper in the blood is attached) are low. As a result, the brain's content of unsaturated fatty acids is decreased. Tissues such as the brain, liver, and muscle are subject to increased lipofuscin and degenerative changes. Malformation of connective tissue results in vascular, skeletal, dermal, and urogenital defects. Because copper does not cross the placenta, copper may be reduced in the liver and brain of affected individuals at birth.

Prognosis

Infants with Menkes disease have a life expectancy of 4 months to 17 years. Certain mutations of the syndrome are receptive to treatment, but children with other mutations derive no benefit and progress to death by 3 years of age despite early treatment. Death is usually attributable to intracranial hemorrhages, uncontrolled convulsions, severe failure to thrive, infection, or some

combination of these factors. In some variants of the disease with milder expression of the phenotype, survival into early adult years is possible with early treatment.

Assessment

The mutated gene causing Menkes disease has been identified, making carrier testing possible. A detailed family history and genetic assessment can determine females at risk for producing affected offspring. Antenatal diagnosis in at-risk pregnancies can be made for males by measuring the uptake and retention of copper in vitro using cultured amniotic fibroblasts. Potential termination of pregnancy may be considered. Genetic testing may also identify family members with variants of the disease.

Most children with Menkes disease begin to exhibit symptoms by the age of 2 to 3 months. Some initial, non-specific signs include poor feeding, failure to thrive, hypotonia, and hypothermia. Psychomotor developmental arrest, loss of developmental milestones, and general myoclonic seizures may occur if the disease continues undetected. Some affected children present later in childhood and show slowed growth, intellectual impairment, and neurologic deficits.

These signs should alert the nurse to perform a thorough physical assessment. Children with Menkes disease have several characteristic features. Scalp hair is classically short, twisted, coarse, sparse, and very brittle or kinky; the same hair is often noted on the eyebrows. The infant's face is "jowly," with sagging skin at the cheeks, and the ears appear large for the face. The palate tends to be high arched, and tooth eruption is often delayed. Pectus excavatum (a midline narrowing of the thoracic cavity, also described as *funnel chest*) is a common thoracic finding. Cognitive difficulties can also be noted. These children often have dysphagia, hypotonia, apnea, and spasticity with hyperreflexia. Ophthalmologic findings such as retinal degeneration, aberrant lashes with a texture similar to that of the rest of the hair, optic atrophy, cataracts, iris hypoplasia, and peripheral iris transillumination are usually present.

Diagnostic Tests

When the healthcare team's suspicions are aroused by the physical examination, laboratory values and genetic testing can confirm the diagnosis. Laboratory findings indicative of Menkes disease include hypocupremia (serum copper $<11 \mu\text{mol/L}$ or $<70 \mu\text{g/dL}$), hypoceruloplasminemia (ceruloplasmin $<200 \text{ mg/L}$), and low hepatic copper concentrations ($<50 \mu\text{g/g}$ dry weight). The radiographic findings show abnormalities of bone formation in the skull (particularly of the wormian bones), metaphyseal spurring (primarily of the femur or other long bones), and anterior flaring or multiple fractures of the ribs. Magnetic resonance imaging often reveals tortuosity and elongation of cerebral and systemic arteries, with occlusion of some vessels, diffuse atrophy with ventriculomegaly, and white matter abnormalities that reflect impaired myelination.

T A B L E 27-3

Selected Mineral Disorders

Disorder and Inheritance	Pathophysiology	Significant Clinical Features	Laboratory Findings	Management	Prognosis
Primary hypomagnesemia Autosomal recessive (chromosome unknown)	Intestinal malabsorption of magnesium	Small for gestational age Sleeping and feeding difficulties during infancy Progressive neurologic dysfunction (hyperactivity, tetany, convulsions) Renal tubular acidosis	Hypomagnesemia, <0.7 mmol/L Hypocalcemia	Parenteral or intramuscular magnesium for acute symptoms, followed by oral supplements Calcium supplements	Well controlled if management maintained.
Acrodermatitis enteropathica Autosomal recessive (chromosome unknown)	Systemic zinc deficiency	Neuropsychiatric disorders Dermatitis Alopecia Ophthalmologic problems Frequent, loose stools Failure to thrive Recurrent infections Swollen, painful fingers and toes	Plasma zinc concentrations <9 μmol/L	Zinc supplements of 35 to 100 mg/day	Progressive deterioration without treatment. In less severe cases, only growth retardation and delayed development are evident.
Hereditary hemochromatosis Autosomal recessive (chromosome 6)	Excessive accumulation of iron causing extensive tissue damage	Lassitude Pigmentation of skin, mucous membranes, conjunctiva, scars, and external genitalia Loss of body hair Dermal atrophy Hepatosplenomegaly Weight loss Chondrocalcinosis Diabetes mellitus Pituitary damage Testicular atrophy Gynecomastia Cardiac failure	Serum iron >25 μmol/L Liver iron content by biopsy >1,000 μg/100 mg dry weight	Phlebotomy to reduce iron	Organ damage can be prevented with treatment.

Interdisciplinary Interventions

Therapy for Menkes disease is both palliative and supportive.

Medical Management

Current treatment for classic Menkes disease consists of administering copper histidine (copper salts). Copper histidine is a copper replacement that is injected directly into the body to avoid absorption by the gastrointestinal system. Parenteral administration of copper histidine can correct the serum and hepatic copper deficiencies, deliver copper to brain cells, and make copper available for use by enzymes. In some variants of the disease, early treatment may be effective. However, copper histidine treatments will not reverse any of the child's presenting neurologic symptoms. A small subgroup of children benefit from these treatments if begun within days after birth. Pharmacologic management of seizures and infection should be initiated, as these sequelae occur throughout the child's life span.

Supportive Care

Beyond daily copper medications, other treatments are primarily symptomatic and supportive. Radiant heat using an infant warmer may be required to correct hypothermia, especially during the neonatal period. Vigilant monitoring of the child for early signs of infection (e.g., elevated temperature, vomiting, fussiness) enables specific workup and management. Observing for focal or generalized seizures permits early anticonvulsant therapy. Gentle handling of the child and padding of the crib sides help to minimize the risk of fracture and should also be carried out at home. Provide a high-calorie diet, with careful monitoring of the child's weight gain. If vomiting caused by gastroesophageal reflux occurs, positioning and possibly nasogastric feedings may be necessary.

Assist the infant or child thrive to his or her greatest potential while supporting the family in the care techniques to achieve this goal. The families of children with Menkes disease are most likely to display grief as they cope with their child's terminal prognosis (see Chapter 13). Further stress is added because of the implications for future pregnancies. Groups of parents whose children have the same or similar problem are frequently helpful, as are groups focusing on palliative care support. Provide the family with contact information for these groups. The possibility of frequent hospitalizations for complications may require financial counseling. The coordination of acute care, home care agencies, and possibly a hospice service should be established by either social services or a nurse case manager as needs arise.

X-Linked Hypophosphatemic Rickets

X-linked hypophosphatemic rickets is a hereditary, X-linked dominant, renal phosphate wasting disorder (see Fig. 3–3). Spontaneous genetic mutations are also thought to occur, because both autosomal recessive and autosomal dominant variants have been described. Prevalence in the United States is not known.

Pathophysiology

The defects associated with X-linked hypophosphatemic rickets are caused by mutations in the phosphate-regulating endopeptidase (*PHEX*) gene (Nabbout, Salti, & Choucair, 2009). The condition is characterized by defective renal tubular reabsorption of phosphate, leading to phosphaturia (excess of phosphates in the urine) and hypophosphatemia (deficiency of phosphates in the blood). Poor reabsorption of phosphate leads to abnormalities in bone and dental formation.

Prognosis

Early, adequate management of phosphorus and calcium levels usually results in normal bone development. In some patients, the phosphorus deficiency resolves spontaneously. Lack of or inadequate treatment may result in the need for corrective orthopedic surgery for leg lengthening and straightening procedures.

Assessment

Full-term infants appear normal at birth. The disease becomes clinically detectable about the first year of life, when a mild to moderate linear growth deficiency can be noted. Frontal bossing develops during early childhood. As the child begins to walk, the femur and tibia bow (genu valgum, or bowlegs) as a result of weight bearing (Fig. 27–4). This malformation, combined with a developing tibial torsion (see Chapter 20), gives the child an

FIGURE 27–4. X-linked hypophosphatemic rickets affects skeletal development of the femur and tibia.

unstable, waddling gait. Fractures, signs of swelling, and pain, especially in the extremities, indicate a need for further assessment in any infant or young child. Muscle weakness and decreased energy levels may also be noted. Teeth may erupt late, but will be normal in appearance. A tendency toward dental decay and dental abscesses may be noted during the second decade of life. Thus, include a dental history and documentation of preventive dental activities in the assessment information gathered.

Diagnostic Tests

Significant laboratory findings include serum phosphorus less than 4 mg (although this constituent may remain normal up to age 9 months despite disease), alkaline phosphatase more than 200 IU/L (in preterm infants, >300–400 IU/L), and reduced transfer maximum for phosphate per unit volume of glomerular filtration rate in the presence of normal renal tubular function. Radiographic findings are most apparent in the lower body and include fractures of the long bones and ribs (which may be noted in the premature infant by 10 weeks of age); fraying, widening, and cupping of the metaphyses (especially of the tibia, femur, ulna, and radius); thickened cortices of long bone shafts with dense trabecular bone (first seen during late childhood); and calcification of tendons, ligament insertions, and joint capsules (seen in adolescence and later).

Nursing Diagnoses and Outcomes

The deficiency of phosphorus in children with X-linked hypophosphatemic rickets places the children at risk for orthopedic and dental problems. Therefore, in addition to the nursing plan of care presented in Nursing Plan of Care 27–1, the following nursing diagnoses and outcomes may apply to this patient population:

Risk for activity intolerance related to potential for fractures, bone pain, and skeletal deformities

Outcomes: Child will participate in activities appropriate to his or her ability level that do not pose a threat of injury.

School teachers and parents will assist the child in pursuing activities that are safe and will build the child's self-confidence.

Impaired oral mucous membrane related to higher incidence of dental abscesses

Outcome: Child will be recognized early and treated promptly for dental decay and abscesses.

Impaired verbal communication related to high number of dental extractions

Outcome: Child will be free from speech impairments.

Interdisciplinary Interventions

Management of X-linked hypophosphatemic rickets is designed to promote normal bone strength and growth.

Medical Management

Interdisciplinary interventions begin with the prescription of a phosphate supplement, coupled with Calcitrol

or another vitamin D analogue. Calcitrol is classified as a vitamin D analogue and a fat-soluble vitamin. Calcitrol's mechanism of action is to promote absorption of calcium in the kidneys and gastrointestinal tract to increase the serum levels of calcium. Calcitrol also decreases the serum phosphatase level and decreases bone reabsorption, enabling healthy bone to grow. Treatment is geared toward stabilizing the phosphorous level in the blood. Weight, calcium, parathyroid hormone, urinary calcium excretion, and alkaline phosphatase levels determine dosage levels. Frequent adjustment in dosages of the phosphate supplement and vitamin D analogue helps to prevent hyperparathyroidism or hypercalcuria. Observe children for signs of hypercalcemia. These signs include weakness, fatigue, lassitude, headache, nausea, vomiting, and diarrhea. Serum and urine calcium levels should be monitored at least quarterly after the condition is stabilized, and the kidneys should be annually evaluated by ultrasonography.

As children reach adulthood, continued treatment with Calcitrol alone may be sufficient for those who remain asymptomatic. Treatment with growth hormone for **rachitic** children (those affected by rickets) who do not achieve normal linear growth may be initiated. Research on ways of correcting the basic metabolic error through genetic therapy is in progress. Treatment with thiazides may also be instituted to assist in counteracting the tendency for bone calcium loss.

caREminder

Consider the family's ability to adhere to medication dosing schedules when determining dosing for Calcitrol and phosphate supplementation. Multiple daily doses may not be the best frequency.

Nutritional Management

Special nutritional consideration is needed for the premature infant. Preterm breast milk contains adequate quantities of all the essential nutrients *except* calcium and phosphorus. Commercial preterm formula contains the necessary additional calcium and phosphorus, but premature infants must receive total parenteral nutrition until they are able to take and tolerate adequate amounts of formula. Counsel parents to avoid soy formulas, which have a phytase binding quality that inhibits the intestinal absorption of phosphorus.

Community Care

Oral medications are required for years. Teach parents to give both medications together at set times of the day, which will help them remember to give medication regularly. This practice also establishes a routine pattern for children to use as they become more independent in taking responsibility for their medications.

Dental problems are a continuing challenge for the child with rickets because of the tendency to abscess. Primary teeth are usually extracted if abscessed. Depending on the site and number of extractions, speech could be adversely affected, and the child may need speech

therapy. Root canals or other endodontic procedures are usually necessary for abscesses of the secondary teeth. Work with the child and the family to communicate the importance of good dental hygiene and regular visits to the dentist. Children should be encouraged to brush after every meal. The school nurse can support these actions by offering a place for children to store their cleaning materials and by encouraging them to brush their teeth.

Gentle handling of premature infants and any child with rickets is critical to prevent fractures. Family members need to be taught the importance of this concept as well. The nurse or social worker can discuss nonphysical forms of discipline with the parents. In addition, parents, daycare providers, and school officials require guidance in selecting safe, soft toys for the child and in providing activities that safeguard against physical harm. For instance, contact sports and gymnastics are not recommended. The child's musical, science, or computer interests should be encouraged, because these are safe activities that can enhance self-esteem and minimize physical injury. Self-image and esteem are important concepts to build. If growth has been slowed, the child may be sensitive about being shorter than peers. Depending on the child's clinical status, the risk of fractures will probably limit the child's involvement in physical education, sports, and rough games. This, too, sets the child apart from others, and the child may become the focus of teasing. Family counseling and support groups can help prepare the child to cope with teasing and identify areas where he or she can excel to gain peer recognition.

The family may need financial support to manage the child's care properly. The cost of years of medications, laboratory tests, and follow-up visits, with the possible additional expenses of orthopedic surgery and dental care, is considerable (see Chapter 2 for a discussion of financial support options for the family).

Wilson's Disease

Wilson's disease is an autosomal recessive disorder of copper metabolism characterized by cirrhosis of the liver and degenerative changes in the brain. Occurring in 1 in 30,000 children, Wilson's disease results from a defective gene located on chromosome 13 (Ala et al., 2007; Roberts, Schilsky & American Association for the Study of Liver Diseases [AASLD], 2008). Although the symptoms are primarily hepatic, multisystem toxicity does occur. The disease is fatal unless recognized and treated early.

Pathophysiology

The metabolic defect in Wilson's disease impairs normal hepatic excretion of dietary copper. As a result, soon after birth, copper begins to accumulate in the liver, causing progressive hepatic damage. Copper then escapes the liver and begins to accumulate in other major organs, such as the brain and the kidneys, and in the corneas. Fatty changes, inflammation, necrosis, and hepatic injury that can be virtually indistinguishable from chronic hepatitis become evident, and the brain and spinal column can be severely damaged.

Prognosis

Although the disorder is invariably fatal if not treated, administration of chelating agents or liver transplantation when the disease is identified may lead to a positive prognosis. Lifelong treatment with chelating agents is usually sufficient to reach a clinical remission in most cases. Management is aimed at minimizing liver and neurologic damage, and at controlling the effects of copper toxicity on other body systems.

Assessment

The diagnosis of Wilson's disease should be considered in anyone between the ages of 5 and 30 with liver abnormalities of uncertain cause (Roberts, Schilsky & AASLD, 2008). The diagnosis can easily be missed because of the natural tendency to interpret the severe liver or neurologic manifestations as conditions of other disorders.

Note whether a sibling or first cousin has been previously diagnosed with the disease or has demonstrated symptoms similar to those of the child currently being evaluated. In addition, all patients with hemolysis or recurrent jaundice should be investigated for Wilson's disease.

The physical manifestations of Wilson's disease appear in multiple body systems. All affected children have hepatic involvement. However, only about 40% of children have hepatic symptoms such as chronic or active hepatitis, cirrhosis, or hepatic insufficiency. Neurologic symptoms occur in 35% to 40% of affected children and include encephalopathy, ataxia, fine tremor, dysarthria, dysphagia, dystonia, and epilepsy. Hematologic effects include acute hemolysis and coagulopathies. Ophthalmic signs include the characteristic **Kayser-Fleischer rings** (corneal copper deposits that appear as a rust-brown ring around the iris), visible on slit-lamp ophthalmologic examination. Cataracts, strabismus, and impaired visual acuity may also be noted. Renal involvement is characterized by renal tubular acidosis, aminoaciduria, acute renal failure, and hematuria. Skeletal involvement includes osteoporosis and osteoarthritis. Amenorrhea and an increased incidence of spontaneous abortions are noted in affected adolescents. Other symptoms include abdominal pain, bacterial peritonitis, and blue lunules of the fingernails. About 12% of affected children exhibit neuropsychiatric disorders such as sudden onset of socially inappropriate behavior; depression; deterioration in school performance; or obsessive, bipolar, or schizophrenic behaviors (Langner & Denk, 2004).

Diagnostic Tests

Diagnostic tests of the blood reveal low serum ceruloplasmin levels (<20 mg/dL). Basal 24-hour urinary excretion of copper is obtained and is significant if more than 40 μg . A penicillamine challenge study may be performed to further confirm diagnosis. During this test, 500 mg D-penicillamine is administered, and urine is collected and tested at 12 hours and 24 hours after administration.

The agent acts as a chelating agent to help with the excretion of copper. Thus, a child with Wilson's disease will have more copper excreted in their urine after taking this agent (Roberts, Schilsky, & AASLD, 2008).

Interdisciplinary Interventions

Chelating agents and a low-copper diet are the primary treatments for Wilson's disease.

Medical Management

D-penicillamine (the drug of choice) and trientine may be given to promote urinary excretion of copper and to detoxify excess copper remaining in the liver. These medications are given orally in two to four divided doses, 30 minutes before or 2 hours after meals. Because D-penicillamine causes antipyridoxine activity, a daily pyridoxine supplement is added to the patient's diet. Oral zinc gluconate and other zinc salts may also be prescribed. The zinc products have proved effective in arresting liver damage, although they cannot reverse existing hepatic cirrhosis, portal hypertension, or neurologic symptoms.

Emphasize to the child and family that the medications must be taken at all times and continued throughout the child's life. During the first month of treatment with D-penicillamine, the parents need to be alert for the development of fever and rash, sometimes accompanied by enlarged lymph nodes, which indicate hypersensitivity to the medication. Leukopenia or thrombocytopenia may also develop. If these adverse effects occur, the drug is discontinued until they subside, then is gradually reintroduced. If the adverse effects persist, D-penicillamine may be discontinued and trientine given instead. Proteinuria, a possible late adverse reaction, requires changing the chelating agent from D-penicillamine to trientine.

Nutritional Management

Treatment for Wilson's disease commonly involves a low-copper diet in conjunction with chelation therapy (see Treatment Modalities). Chart 27-1 lists foods with high and low copper content. The nutritionist can serve as an expert consultant to the healthcare team and the family. Working with the family, the nutritionist evaluates the child's urinary copper level and adjusts the child's

CHART 27-1 DIETARY CONSIDERATIONS FOR WILSON'S DISEASE

Foods Low in Copper (<0.1 mg/portion)

Meat

- Beef, eggs, turkey, and chicken (white meat only), cold cuts containing no pork, organ meats, or dark meat

Vegetables

- Most included

Fruits

- Most fruits

Starches/Breads/Grains

- Breads and pastas from refined flour, oatmeal

Fats/Oils

- Butter, cream, mayonnaise, nondairy creamer, sour cream, oils, salad dressing

Milk/Milk Products

- Most milk products

Sweets/Desserts

- Jams, jellies, candies with allowable ingredients, flavoring extracts

Beverages/Miscellaneous

- Coffee, tea, fruit juices, lemonade, fruit-flavored drinks, soups with allowable ingredients

Foods High in Copper

Meat

- Lamb, pork, duck, goose, squid, salmon, organ meats, shellfish, soy protein meat substitutes, tofu, nuts, and seeds

Vegetables

- Vegetable juice cocktail, mushrooms

Fruits

- Nectarines, commercially dried fruits (e.g., raisins, dates, prunes), avocados

Starches/Breads/Grains

- Dried beans (e.g., lima, pinto, garbanzo, soy), lentils, millet, barley, wheat germ, bran breads and cereals, soy flour, soy grits, fresh sweet potatoes

Fats/Oils

- No restrictions

Milk/Milk Products

- Chocolate milk, soy milk, cocoa

Sweets/Desserts

- Candy with nuts, chocolate, or cocoa; desserts with ingredients rich in copper

Beverages/Miscellaneous

- Instant breakfast drinks, mineral water, soy-based beverages, brewer's yeast, multivitamins with copper

diet accordingly. Foods rich in copper can be eaten in moderation as long as drug treatment is maintained. Drinking water should be analyzed to ensure it does not contain more than 100 μg copper/L. Bottled demineralized water may be used, and should contain only 1 μg copper/L. Alcohol should be avoided because it may harm the liver, which is already compromised as a result of Wilson's disease. Use of copper cooking utensils is avoided.

Surgical Management

A child with fulminant hepatitis or hepatic failure related to Wilson's disease may be a candidate for liver transplantation. The transplant cures the genetic defect and restores normal copper balance. Further neurologic deterioration is halted, although no clear evidence exists that neurologic symptoms can be reversed. The family of a liver transplantation candidate needs assistance in becoming part of the organ transplant network. Social services can serve as liaisons between the family and the transplant agencies. During the evaluation and waiting period before transplantation surgery, the family needs intensive emotional support. The social worker and nurse can help the family to prepare for the transplantation and to get in touch with families of children who have already undergone the procedure.

Community Care

Through the phases of Wilson's disease, including diagnosis, ongoing management, monitoring of its effects, and the liver transplantation process, numerous invasive procedures are required. Play therapy with child life specialists helps to alleviate the fear of these procedures. Children may experience symptoms that keep them from attending school. If this occurs, homeschooling should be arranged early.

The nurse plays an important role in the ongoing monitoring and management of the child with Wilson's disease. Responses to drug and dietary regimes are evaluated at frequent intervals during the first year of therapy and on a routine basis thereafter. Blood and urine analyses are the primary modes of evaluation, so ensure that patient and family education stresses the importance of blood and urine collection.

KidKare ■ Twenty-four-hour urine specimens are difficult to collect from children, who may forget to save their urine. Instruct parents to ensure that the child is at home during the entire collection process. They should encourage the child to void in only one bathroom, ensure that a collection device is always in place, and offer a reward for each successful collection of urine.

Also help parents determine whether the child's symptoms are improving or worsening when treatment has begun. Because overt signs of the disease may vary among children, review with the family the particular signs that their child has demonstrated and explain which of these signs are expected to diminish with treatment. Dimin-

ished cerebral and hepatic signs and symptoms and fading Kayser-Fleischer rings are the best indicators of successful therapy.

As the child matures, work with the nutritionist, the child, and the family to expand the child's diet and personal responsibility for making dietary selections. Siblings should be screened for presymptomatic Wilson's disease; if the metabolic defect is found, expression of the disease can be prevented by initiating the chelating agents promptly. In addition, genetic screening should be provided to all family members to detect asymptomatic homozygote carriers. Discuss with the family the results of the screening examinations and the implications for future pregnancies, prenatal diagnosis, and cessation of pregnancy if necessary.

CARBOHYDRATE DISORDERS

Carbohydrates include starch, sucrose, and lactose. Various disorders related to interruptions in the pathway of carbohydrate metabolism result from specific genetic defects. Their classifications include galactose disorders, glycogen storage disorders, and fructose disorders. Galactosemia is discussed in this chapter. Table 27-4 highlights other selected carbohydrate disorders.

Galactosemia

Galactosemia is a rare, inherited metabolic disorder in which the body is unable to metabolize galactose, which reaches high levels in the body, damaging the liver, central nervous system, and various other body systems. Estimates of the incidence of classic galactosemia occurs about 1 in every 30,000 live births in the United States (Barbouth et al., 2007). As an inherited autosomal recessive trait, galactosemia occurs in one of seven different forms, depending on the degree to which the metabolic pathway is blocked. Genotyping is required to determine the specific classification. Affected tissues include the lens, liver, brain, kidney, and ovaries.

Pathophysiology

The classic, and most common form of galactosemia involves a defect in the enzyme galactose-1-phosphate uridylyltransferase (GALT). This defect disrupts the conversion of galactose-1-phosphate to galactose uridine diphosphate. Consequently, galactose, a monosaccharide, is not converted to glucose. The accumulation of galactose-1-phosphate results in injury to the kidneys, liver, and brain.

Prognosis

Severe, untreated cases of galactosemia are invariably fatal. Patients affected less severely have retarded psychomotor development, visual impairment, and residual cirrhosis. If chronic errors in metabolism persist, other complications appear despite treatment. Such complications may include speech abnormalities, ovarian failure, cognitive deficits, poor growth, and impaired motor function and balance. Among parents who have a child affected by galactosemia, each pregnancy carries a

TABLE 27-4

Selected Carbohydrate Disorders

Disorder	Pathophysiology	Significant Clinical Features	Key Diagnostic Findings	Management	Prognosis
Fructose 1-phosphate aldolase (aldolase B) deficiency Autosomal recessive	Defect in fructose 1-phosphate aldolase B enzyme; fructose not converted to glucose	Infants: anorexia, vomiting, failure to thrive, hypoglycemic convulsions, liver and kidney dysfunction Older children: spontaneous hypoglycemia and vomiting after ingestion of fructose	Increased serum and urine fructose	Diet free of fructose and sucrose	Good if diet followed
Pyruvate dehydrogenase deficiency X-linked or autosomal recessive	Defect in the multi-enzyme complex responsible for the generation of acetyl CoA from pyruvate for the Krebs cycle	Lactic acidosis CNS malformations and other postnatal changes (e.g., cystic lesions of the cerebral cortex, brain stem, and basal ganglia; ataxia; and psychomotor retardation)	Elevation of pyruvate and thus elevation of lactic acid levels	No clearly effective treatment Low-carbohydrate or ketogenic diet and dietary thiamin supplementation may be beneficial for some	CNS deterioration over time

one-in-four chance that they will have another child with galactosemia (see Fig. 3-3). Prenatal testing by amniocentesis or chorionic villus sampling is available and should be offered for subsequent pregnancies.

Assessment

Infants with galactosemia appear normal at birth. Manifestation of symptoms can be noted within the first days of life after the infant has begun ingesting formula that contains lactose. The infant may exhibit anorexia, vomiting, diarrhea, hypotonia, jaundice, liver dysfunction or hepatomegaly, and cataracts (sometimes during the first week of life) if dietary management is not instituted. Neonates may become septic; the mortality rate from sepsis caused by *Escherichia coli* in particular is very high among infants with galactosemia (Anadiotis & Berry, 2003). Other common signs in untreated infants include drowsiness, inattention, decreased vigor of neonatal reflexes, bulging fontanel, and bleeding from coagulopathies. An accumulation of galactitol in the lens leads to cataract development, which sometimes is evident during the first few days of life. Physical and cognitive challenges become evident over time.

Diagnostic Tests

Early identification of galactosemia is possible through the blood assay completed for state-mandated newborn screening. The Beutler method, which measures GALT in dried blood on filter paper, is used. Some states use

total galactose quantization testing. Other laboratory findings indicative of galactosemia include elevated blood galactose level, low glucose level, galactosuria (urinary total reducing substances should be tested with a Clinistest tablet, rather than a routine urine dipstick for glucose; test results usually yield a positive result, which is abnormal), positive Benedict's test of urine, deficiency of galactose-1-phosphate in red and white blood cells and liver cells, and elevated Serum glutamic pyruvic transaminase (SGPT), serum glutamic-oxaloacetic transaminase (SGOT) and bilirubin. In acute illness, hypocalcemia and aminoaciduria are also present.

Nursing Diagnoses and Outcomes

The nursing plan of care to support the dietary management of galactosemia is consistent with the diagnoses associated with other metabolic conditions (see Nursing Plan of Care 27-1). The child with galactosemia is at risk for dehydration, speech problems, and the development of cataracts. Thus, the following nursing diagnoses and outcomes may apply:

Deficient fluid volume related to vomiting and diarrhea related to ingestion of lactose

Outcomes: Child's vomiting and diarrhea will be corrected through a galactose-restricted diet.

Child will maintain a balanced fluid and electrolyte status.

Disturbed sensory perception: Visual related to manifestations of disease process

Outcomes: Child will be evaluated on a regular basis for the presence of cataracts.

Child's visual acuity will be optimized by maintaining a galactose-free diet.

Impaired verbal communication related to speech disorder and delayed development

Outcomes: Child's communication will be correctly interpreted.

Child will receive from others communication that is directed at the child's appropriate developmental level.

Interdisciplinary Interventions

Dietary management is the primary intervention for galactosemia, with appropriate pharmacologic intervention as needed for infection, dehydration, and ovarian dysfunction.

Nutritional Management

The primary nutritional goal is to provide dietary intervention that will prevent manifestation of the condition. A galactose-restricted diet rapidly resolves and prevents most acute symptoms. Galactose is derived from the hydrolysis of lactose into glucose and galactose. The diet is

therefore milk free, with *all* sources of lactose restricted (Chart 27–2). A soy protein isolate formula with added methionine and carnitine can provide all necessary nutrients for the infant. As processed foods are added to the child's diet, instruct parents to check labels for milk or milk products such as dry milk solids, lactose, curds, and whey. Casein (sodium caseinate, calcium caseinate), a milk protein sometimes called *hydrolyzed protein*, must also be avoided. Parents can be advised that kosher foods are usually lactose free. These products can be a source of dietary options for the child. Reinforce the importance of this prescribed diet with each family contact. Collaborate with the nutritionist to ensure that the child is receiving adequate calories, protein, vitamins, and minerals such as calcium. Calcium supplementation may be necessary given the numerous restrictions of dairy items in the child's diet. Recipes that use galactose-free milk substitutes can be provided to the family (Clinical Judgment 27–1).

The restricted diet is generally recommended for life. Parents must understand that the child does not develop an increased tolerance for milk products as he or she grows older. In addition to dietary restrictions, parents must be aware of the many medications, particularly antibiotics, that use lactose as fillers. Examples include cephalosporins, erythromycin, lactulose syrup, and Neo-Calglucon. Be sure that the pharmacy from which the parents obtain any prescriptions is aware of the child's diagnosis of galactosemia.

CHART 27–2 THE GALACTOSE-FREE DIET

Restricted Foods	Foods Allowed
Bread	Soy-based formula (Nutramigen or Alimentum), soy milk, and soy cheese
Cheese, all types	Unfermented soy sauce
Drug preparations that contain lactose as a filler	Cereals
Dried beans and peas	Vegetables
Ice cream, sherbet	Fruit
Margarine	Meats
Milk (nonfat milk, nonfat dry milk, milk solids and derivatives, milk chocolate, buttermilk, butter)	Kosher foods
Monosodium glutamates (MSGs) that contain lactose extenders	
Organ meats (brains, liver, kidney, heart, sweetbreads)	
Prepared foods containing galactose, lactose, whey, tragacanth gum, calcium caseinate (e.g., baked goods, confections, and frozen foods)	
Pudding	
Yogurt, sour cream	

Medical Management

Infections, most commonly with gram-negative organisms, are treated with the appropriate antibiotic. If jaundice related to the galactosemia is present in the newborn, treatment may be required. Other supportive therapies include resolving any dehydration and electrolyte imbalances that have occurred as a result of the vomiting, anorexia, and diarrhea. Females who manifest symptoms of ovarian dysfunction later in life, including irregular menses and decreased fertility, may require hormonal therapy.

Evaluate all children diagnosed with galactosemia for cataracts. In many cases, introducing the galactose-free diet leads to spontaneous resolution of cataracts. Yearly evaluation of the child by an ophthalmologist is highly recommended. Children who do not adhere well to the diet are at risk for developing cataracts, as are those who were not diagnosed and treated for the metabolic condition at an early age.

Community Care

Children with galactosemia, even those whose condition is controlled, may experience learning difficulties. In one study, more than half the children had delayed vocabularies and speech difficulties, and 15% to 20% had problems with coordination, gait, and balance, and demonstrated fine motor tremors despite adherence to the galactose-free diet (Webb et al., 2003). Family conferences with schoolteachers or daycare workers help school personnel understand the need for specialized classes and teaching techniques that enhance the child's developmental abilities. In addition, work with school officials to

CLINICAL JUDGMENT 27–1

Nutritional Counseling

Nikki was born 2 months ago, normal for gestational age and without any postnatal complications. The results of Nikki's neonatal screening test were positive for galactosemia. The parents, Melissa and Tom, both 17, were called and Nikki was brought back to the clinic for a repeated blood test. The diagnosis is confirmed. You have been asked to provide teaching regarding the child's diet and home management. As you enter the room, Nikki's mother is clutching her baby and crying. Nikki's father has stepped out of the room to smoke a cigarette.

Questions

1. Before your teaching, what assessment data would it be helpful to collect about the family?
2. Although the child is not eating solid foods, why do you want to know more about the family's diet?
3. What factors about the parents would influence your teaching?
4. What topics should your nutritional counseling cover?
5. How could you evaluate the effectiveness of your teaching?

Answers

1. Family dietary patterns and dietary preferences related to ethnic or religious influences; whether healthcare insurance will cover the cost of medical food; primary caregiver of infant, including day-care providers
2. The child needs a lactose-free diet. Milk products are contained in a variety of products. Family members need to start learning which of those products they should not introduce to the child after feeding has begun.
3. Parents' level of understanding of the metabolic condition itself; parents' ability to accept the diagnosis realistically and take responsibility for the child's care
4. Name of diet, why the diet will help the child, formula that Nikki may drink, how to obtain formula, signs and symptoms of worsening condition, management of the child during childhood illnesses, how the diet will change as the child grows
5. Use "scenarios" to have parents select appropriate formula. Parents should relate the signs and symptoms of formula intolerance. Call parents in 1 week and again in 2 weeks for follow-up.

emphasize the need to monitor the child's diet when away from home and find ways to offer dietary alternatives when special class functions include food.

MUCOPOLYSACCHARIDE DISORDERS

This group of lysosomal storage disorders involves abnormal storage of lipids in the neurons and of polysaccharides in the connective tissues. This abnormal storage results in multiple neurologic and skeletal abnormalities. Specific mucopolysaccharide disorders include Hurler's syndrome, Hunter's syndrome, Tay-Sachs disease, Neimann-Pick disease, Gaucher's disease, Fabry's disease, Sanfilippo disease, Morquio's syndrome, Shafe's disease, and Maroteaux-Lamy disease. Most are autosomal recessive defects, although a few such as Hunter's syndrome are X-linked. This section covers Hurler's syndrome; an overview of the important factors of other selected lysosomal storage disorders is provided in Table 27–5.

Hurler's Syndrome

Hurler's syndrome, or mucopolysaccharidosis I, is the classic and most severe form of mucopolysaccharidosis type I. Hurler's syndrome occurs in approximately 1 in

76,000 births and is inherited as an autosomal recessive trait (Hingston et al., 2006). The disease is sometimes known as *gargoylism*, because infants have distinctive gargoylike facial features.

Pathophysiology

A defect in the lysosomal enzyme α -L-iduronidase prevents the degradation of acid mucopolysaccharides, also known as *glucosaminoglycans*. As a result, dermatan sulfate and heparin sulfates (polyglycosaminoglycans) accumulate in the tissues, producing the symptoms of Hurler's syndrome. Because this metabolic pathway is part of cellular metabolism in many body organs, the defect results in damage to the brain, spinal cord, heart, viscera, bone, and connective tissue.

Prognosis

In the past, children with Hurler's syndrome deteriorated progressively, and death usually occurred by age 10 from respiratory or cardiac failure resulting from organ damage. Bone marrow or cord blood transplantation has increased the lifespan of a child with Hurler's syndrome by arresting its progress and reversing some of the most severe sequelae. Transplantation can also greatly decrease

TABLE 27-5

Selected Mucopolysaccharide Disorders

Disorder and Inheritance	Pathophysiology	Significant Clinical Features	Laboratory Findings	Management	Prognosis
Tay-Sachs disease Autosomal recessive	Deficient hexosaminidase A	Onset, 4 to 6 months of age Cherry-red macula Optic atrophy Hypotonia Seizures, late onset Dementia, early onset Almost all of Jewish ethnicity	Sphingolipidoses	No treatment	Death by age 2 to 3 years
Niemann-Pick disease Autosomal recessive	Deficient sphingomyelinase	Hepatosplenomegaly Enlarged lymph nodes Onset younger than age 6 months Cherry-red macula Optic atrophy 50% Jewish ethnicity Spastic paresis Dementia, early onset	Elevated serum lipids Serum glutamic-oxaloacetic transaminase Vacuolated lymphocytes Foam cells in bone marrow	No treatment	Death by age 3 years
Gaucher's disease Autosomal recessive	Deficient beta-glucosidase	Onset younger than 6 months of age Hepatosplenomegaly Dementia Strabismus Bulbar palsy Spastic paralysis	Elevated acid phosphatase Lipid-laden Gaucher's cells found in bone marrow	Enzyme replacement therapy Splenectomy (rarely used)	Death by age 2 years
Fabry's disease Sex-linked recessive	Deficit of alpha-galactosidase	Episodic, incapacitating pain, initially of fingers and toes Mild mental retardation Seizures Peripheral red or purple macules or papules Renal disease Diabetes insipidus	Abnormal renal function	Management of pain crises Renal transplantation for renal failure	Death related to renal complications or stroke Renal treatment reverses symptoms

Selected Mucopolysaccharide Disorders (Continued)

Disorder and Inheritance	Pathophysiology	Significant Clinical Features	Laboratory Findings	Management	Prognosis
Hunter's disease Sex-linked recessive	Deficient iduronate sulfatase	Plethoric facies Hepatosplenomegaly Hydrocephalus Kyphosis without gibbus Claw-hand deformity Hypertrichosis Dwarfism Deafness Mental retardation	Excessive dermatan sulfate and heparan sulfate	Success of bone marrow transplantation being evaluated	Late onset: live to age 40 to 70 years Some with average intelligence Juvenile type: death during adolescence
Sanfilippo disease Autosomal recessive	Deficit of heparan sulfatase (Type A disease); N-acetyl-alpha-D-glucosaminidase (NAG) (Type B disease); acetyl CoA: acetylglucosamine N acetyltransferase (Type C disease); or N acetylglucosamine 6-sulphate sulphatase (Type D disease).	Severe retardation Mild shortness of stature Mild coarsening of facial features Hepatosplenomegaly Mild hirsutism	Heparin sulfate in urine	Bone marrow transplantation being evaluated	Severe retardation May live 40 to 50 years

the degree of cognitive damage associated with Hurler's syndrome.

Assessment

Although Hurler's syndrome produces distinctive clinical manifestations, diagnosis is not often reached during the neonatal period. Manifestations develop over time. Initial reasons to screen a patient for Hurler's syndrome include rather common symptoms such as a swollen abdomen or a hernia. The growth of these children is usually within the normal range for the first year but falls below the third percentile thereafter. Physical examination will reveal hepatosplenomegaly, kyphosis, persistent nasal discharge, and noisy breathing. Neurologic development appears normal at first, but the child typically has delays in sitting, walking, and toilet training.

The skeletal deformities of Hurler's syndrome are easily visible during a nursing assessment and include "gargoyle" facies (prominent supraorbital ridges with bushy brows, thickened lips, low nasal bridge, mild hypertelorism); large head with synostosis of the longitudinal suture; dwarfism; bone dysplasia, kyphosis, and gibbus, which produce a "catlike" posturing; broad hands with short, stubby fingers and clawlike deformities; flexion contractures of knees and elbows; and bilateral hip dislocation.

Neurologic manifestations include cystic areas in the white matter of the brain, severe mental retardation, communicating hydrocephalus with possible increased intracranial pressure, and corticospinal signs. Other prominent symptoms include hepatosplenomegaly, protuberant abdomen, inguinal and umbilical hernias, conductive deafness, valvular heart disease, chronic rhinitis and respiratory infections related to a narrow pharynx and enlarged tongue, corneal opacities, and hirsutism.

As with other metabolic disorders, diagnosis relies heavily upon blood, urine, and other radiographic tests. The nurse's role remains one of developmental surveillance. Changes in development, or inability of the child to meet developmental milestones, should serve as triggers to warrant referral to the primary healthcare provider for further investigation of the underlying cause of abnormalities in the physical and developmental assessments performed by the nurse.

Diagnostic Tests

The diagnosis is suggested by clinical examination and radiographic findings. Laboratory findings indicative of Hurler's syndrome include dermatan and heparin sulfates in the urine. Definitive diagnosis requires detection of α -L-iduronidase deficiency in cultured skin fibroblasts, serum, or white blood cells.

Nursing Diagnoses and Outcomes

A plan of care for the child with Hurler's syndrome can be implemented using diagnoses and interventions from Nursing Plan of Care 27-1. In addition, the skeletal deformities and oral-facial deformities characteristic in

children with Hurler's syndrome may prompt the following nursing diagnosis:

Ineffective infant feeding pattern related to oral-facial deformities

Outcome: Parents will demonstrate appropriate feeding techniques to prevent aspiration and ensure that the child is receiving adequate nutrition.

Interdisciplinary Interventions

Early diagnosis and supportive care (e.g., medications, respiratory treatments) focused on the respiratory and cardiac complications are the most common goals of management. Clinical progression can occur rapidly after the third year of life because of buildup of the storage material (mucopolysaccharides). Early diagnosis provides opportunities to get the missing enzyme into the body. Enzyme replacement therapy using laronidase has been shown to be effective in improving the respiratory, bone, and cardiac complications. It has no effect on the progressive mental retardation.

Allogenic bone marrow transplantation, cord blood transplantation with stem cells, and gene therapy hold promise to correct the metabolic defect and diminish symptoms. In gene therapy, researchers use a virus to place the gene that produces alpha-L-iduronidase into the patient's cells. Using transplantation, healthy marrow or stem cells replace genetically damaged or absent blood cells and enable genetically normal blood cells to deliver normal protein to the host tissue. Marrow transplantation has corrected hepatosplenomegaly, cleared corneal opacities, improved heart failure, and normalized the facies and nasal sinus. The child can stand erect and walk, but may require fusion of the lumbar vertebra. The clawlike hands straighten, and fine, skilled movements can be performed. Neurodegeneration has stabilized in some recipients (Hingston et al., 2006)

Community Care

Families of children with a lysosomal storage disease require a great deal of emotional and social support. They are caring for a child whose physical and mental health deteriorates over a period of years, often resulting in severe neurologic impairment and death. Nursing personnel play a pivotal role in managing home care needs. Arrangements for medical equipment in the home, such as a wheelchair, are necessary. Depending on the family's situation, home healthcare assistance, respite care, or long-term care placement may be necessary. Coordination with transplant centers is indicated for the advanced practice nurse if the child is a candidate for bone marrow or cord blood stem cell transplantation.

Teach families that their child may not progress in motor activities, including walking and toilet training. Assistive devices to allow the child to sit comfortably, move about, and attain some use of the hands can be obtained by nursing personnel through occupational therapy and physical therapy consultations. The child

may also experience behavioral problems such as emotional outbursts, excessive crying, and sleep disturbances in response to the neurologic deterioration. In these cases, sedatives may be administered to help manage the child.

The infant's large, protuberant tongue and narrowed nasopharynx cause difficulty in sucking and feeding. Teach the family feeding techniques to use that prevent aspiration and assist the child to swallow (Nursing Interventions 27–2). Breast-feeding can certainly be tried, but may not be successful. Bottles with a small-holed, soft nipple allow formula to flow slowly and may prevent choking. Nasal or deep suctioning may be required if aspiration does occur, so the family should be taught these techniques for home care.

As the disease progresses, the family has some difficult decisions to make regarding the child's care and the extent of medical interventions to be used to continue to support the child's physical health. Provide the family with anticipatory guidance regarding measures to prolong the child's life. Parents may elect not to subject their child to certain interventions. Serve as an advocate for the child and the family, ensuring that all members of the healthcare team respect the family's wishes.

MITOCHONDRIAL DISORDERS

Mitochondrial disease is thought to be a predominantly inherited disorder, but in some cases a random mutation or an environmental toxin is thought to have contributed. All mitochondria are inherited from the mother, so the mutation in the DNA of the mitochondria will be passed on to all the children. However, only daughters will be able to pass that mutation onto their progeny. Because mitochondria serve as an energy center, converting the food we eat into sources of energy, the effects of mito-

chondrial disease can be broad reaching, and its effects on the individual child vary considerably. Mitochondrial disease affects every organ in the body, presents with many disease manifestations, and becomes evident at any age, from infancy through late adulthood. In a child affected by mitochondrial disease, always think: any organ, any disease, anytime—that is how far reaching the effects of this disease can be on children throughout their lives.

Pathophysiology

The mitochondria serve as the energy powerhouse of the human body. Within the mitochondria, the chemical energy from food is harvested. This process results in the production of adenosine triphosphate, better known as ATP. ATP is the predominant power source for all processes within the body. In addition to energy production, mitochondria carry out several other vital functions. These powerhouses are also involved in producing steroid hormones, manufacturing building blocks of DNA, and playing a role in eliminating ammonia from the liver. Thus, the effects of a mitochondrial disorder on the overall functioning of the human body can be devastating. The more common mitochondrial disorders include mitochondrial myopathy, encephalopathy, lactic acidosis, and strokelike episodes (or MELAS); Leigh syndrome; Wolfram syndrome; mitochondrial respiratory chain disorders; and many other inborn errors of metabolism, such as fatty acid oxidation disorders and carbohydrate sensitivities.

Mitochondrial disorders can also be acquired through some drug treatment regimes, such as the use of ifosfamide in cancer treatment, or zidovudine (AZT) in the treatment of HIV infection. Whether these drugs unmask a previously, genetically determined mitochondrial disorder or actually cause the damage to the mitochondria themselves is not fully understood.

Prognosis

Mitochondrial disease has been identified in adults as well as children. Disease in adults are often related defects of mitochondrial functioning related to aging (e.g. Parkinson's disease, stroke, Alzheimer's disease). Most children with mitochondrial disorders appear normal at birth. Children most often present with developmental delays, failure to thrive, or neurologic disorders, some mild, some so severe at presentation that they require an intensive care admission. Some mitochondrial disorders, such as Leigh syndrome, have a rapid downhill course and are fatal in a year's time, whereas others appear milder. Prognosis, therefore, is extremely difficult to estimate; it depends on which organ systems are affected and how severely. Generally, the more systems affected, the poorer the prognosis.

Assessment

A precise family history is essential when beginning any assessment of a child suspected of having an inborn error

NURSING INTERVENTIONS 27–2

Feeding the Child With an Enlarged Tongue

- Hold the child in an upright position with the head slightly tilted back to encourage the tongue to fall back.
- If bottle-feeding, initiate sucking by putting pressure on the tongue with the nipple and placing the nipple in a downward and posterior direction.
- When bottle-feeding, give cheek support so that the tongue curls around the nipple.
- If feeding with a spoon, place downward pressure on the tongue with the spoon to encourage swallowing and to displace the tongue.

of metabolism. Mitochondrial disorders have a wide variety of symptoms that vary from person to person. Developmental and neurologic symptoms include poor growth, developmental delays, learning disabilities, mental retardation, neurologic problems, confusion, memory loss, seizures, and dementia. Sensory impairments may include hearing loss, eye muscle paralysis, and progressive loss of vision. Loss of muscle coordination, muscle weakness, muscle cramping, muscle pain, and exercise intolerance affect motor development and skills. Organ involvement may include thyroid dysfunction and heart, liver, or kidney disease. Gastrointestinal disorders, severe constipation, respiratory disorders, diabetes mellitus, and pancreatic failure may also occur in children with a mitochondrial disorder.

Two people with the exact same defect in their mitochondrial DNA may not show the same symptoms. For this reason, family members who have all inherited a mitochondrial defect from their mother will not all show the same symptoms or show them to the same degree. Some disorders are not evident until adulthood, and some never cause symptoms. Some cause the child to fall increasingly further behind in development. The symptoms of the specific mitochondrial disorder determine treatment.

Diagnostic Tests

Many of the laboratory tests recommended for mitochondrial disease diagnosis are either extremely invasive or available only at a very few centers. Muscle biopsies, for example, require an invasive procedure that parents may be hesitant to have their child undergo unless they are assured that a firm answer will result. Often, the results of biopsy are inconclusive, however, and parents should be aware of this fact before their consent is obtained. Other laboratory testing, such as testing on skin fibroblasts, can be extremely expensive because the samples must be packed and shipped to distant centers that can perform the tests. This expense is added to the expense required just to complete the testing in the referral laboratory. Insurance companies may hesitate to pay for such testing or may require such exhaustive supporting data from the physicians and families that testing may not be done.

Laboratory studies should include mitochondrial DNA analysis, complete blood analysis including assessment of serum amino acids, lactic acid, carnitine, and ammonia, and urine analysis including assessment of carnitine and organic acids. Other testing that may be ordered, depending on the child's history and symptoms, include brain magnetic resonance imaging, muscle biopsy or skin biopsy, electroencephalogram, electromyogram, and electrocardiogram. These lists are by no means exhaustive. Clearly, diagnosis of this disease can entail great expense, and the family may have to seek the expertise of many clinical specialist.

Nursing Diagnoses and Outcomes

Nursing diagnoses and outcomes for the child with metabolic disease are presented in Nursing Plan of Care 27–1.

In addition, the following nursing diagnoses apply to the child with mitochondrial disease:

Risk for injury related to seizure activity

Outcomes: Child and family will manage the environment to protect the child from injury if seizures occur.

Child's medication regimen will be monitored and maintained so as to prevent seizures, accounting for changing demands related to illness and growth.

Ineffective infant feeding pattern related to neurologic deterioration

Outcome: Parents will demonstrate appropriate feeding techniques to ensure that the child is receiving adequate nutrition.

Interdisciplinary Interventions

After a mitochondrial disorder has been identified, management is primarily nutritional and supportive.

Medical and Nursing Management

The initial management goal of mitochondrial disease is to confirm that the patient has a mitochondrial disorder. Definitive diagnosis will assist in planning treatment and, more important, in counseling the family about what to expect if the disease progresses. Nursing personnel assist in the diagnostic process by ensuring that ordered tests and procedures are completed. Providing information to the parents on an ongoing basis will help reduce anxiety during this period of uncertainty about the diagnosis.

Treatment for mitochondrial disorders has been cited as inadequate, and the evidence-based practice recommendations available are insufficient. Treatments have been palliative and unproved, because many parents do not pursue muscle or skin biopsies, and children are often treated empirically with vitamins and mixtures of vitamins, cofactors, and oxygen-radical scavengers mixed in a so-called "vitamin cocktail" (DiMauro & Schon, 2003). Some families have reported improvement, most frequently in strength, stamina, and attention span, after administering the cocktail. Yet other families, using precisely the same "cocktail," notice no difference.

Investigational studies into other treatments such as bone marrow transplant and pharmacologic interventions continue, but many drug treatments have carried far too many side effects for patients to tolerate. Bone marrow transplant has shown promise for improving clinical manifestations of the disease and improving long-term survival. For many children with mitochondrial disorders, the best treatments are aimed not at the mitochondrial disorder itself, but at the diseases that the mitochondrial disorder causes in the organs of the body. For example, many children require antiepileptic medications for seizures, thyroid medication for thyroid disorders, or insulin for diabetes.

Supportive therapies such as physical therapy, occupational therapy, speech therapy, and adjustments to the educational plan in the school setting are essential. Act as coordinator and advocate for the child and family.

Families require ongoing emotional support and any respite care that can be arranged, because the child's needs can become more intense and demanding as time goes on.

Nutritional Management

The goal of nutritional therapy is to promote optimal growth and development by meeting the child's nutritional needs for energy, protein, fluids, calories, vitamins, and minerals. Maintaining adequate nutrition will also assist in promoting as healthy an immune response as possible. Refer the family for a visit with a nutritionist experienced with metabolic disease to discuss ways to maximize the child's caloric intake, especially when muscle weakness and ataxia may make it difficult for children to feed, or to simply have the energy to take in adequate calories.

Dietary interventions differ according to the suspected underlying etiology of the mitochondrial disorder. Dietary restrictions or additions will be different for a child with a fatty acid oxidation disorder than for a child with a carbohydrate sensitivity. The nutritionist will also collaborate with the primary care physician to determine whether any nutrients such as thiamin, riboflavin, coenzyme Q10, or ascorbic acid should be added at pharmacologic doses rather than the over-the-counter strengths normally available.

Community Care

Refer families to a support organization such as the United Mitochondrial Disease Foundation (see [thePoint](#), Organizations). Many parents have sought a diagnosis for years and are greatly relieved to learn that an international association, with education and support, is available. Informing the school nurse, who likely will not have had experience with a child with a mitochondrial disorder, is crucial. Often adjusting the child's school day to incorporate frequent rest periods and snacks enables them to participate more fully in academics and activities. Encourage families to use spiritual support if doing so has been helpful to them in the past.

Parents of children with mitochondrial disease are often much more knowledgeable about their child's disease than many of the healthcare professionals they encounter. This knowledge imbalance can lead to frustration on the parents' part. Ask them to share information. Acknowledging what we do not know as healthcare providers is an important step in establishing a supportive relationship with the child and family. Parents also need assistance from their healthcare team to obtain insurance coverage for many medications, needed therapies, and home care assistance.

Fatty Acid Oxidation Disorders

Fatty acid oxidation disorders are inherited mitochondrial conditions that affect the way the body can break down particular fats (fatty acids). Medium-chain-acyl-CoA dehydrogenase deficiency (MCADD) is the most common of the fatty acid oxidation disorders with an

incidence of 1 in 15,000 to 1 in 20,000 live births (Grosse et al., 2006). Many (but not all) states assess for this disorder during newborn screening.

Pathophysiology

A child affected by a fatty acid oxidation disorder cannot break down stored fat for energy. After the food that is eaten is used up in the gastrointestinal tract, the child will begin to experience problems such as hypoglycemia, vomiting, acidemia, lethargy, and difficulty breathing. Fatty acid oxidation becomes important when the body must switch from using carbohydrates as the predominant fuel source to using fat as its major fuel. For a child, in times of illness or prolonged fasting (which could be just an overnight fast from 8 PM to 8 AM, normal sleeping hours for some younger children), fatty acids are essential. During these times, free fatty acids are released from adipose tissue and are used directly by skeletal muscle, the heart, brain, skin, gut, and other body tissues as an energy source. In the liver, the end product of fatty acid oxidation is ketone bodies, which are exported to be used as an important source of fuel in peripheral organs, particularly in the brain.

For MCADD, the most common presentation is an acute life-threatening episode of hypoglycemia (a state in which plasma and urine ketone concentrations are inappropriately low), often preceded by a prolonged fast or illness. Because of the absence of ketones, little or no acidemia occurs. Liver function tests are abnormal. Cardiomyopathy may be another manifestation at presentation.

Prognosis

Prognosis for children with fatty acid oxidation disorders is good if the diagnosis is made prior to acute clinical presentation and metabolic decompensation. However, if the diagnosis is made after acute decompensation, and substantial organic failure has occurred, the prognosis can be very poor. For example, as many as 25% of children treated for MCADD die during their first acute presentation, whether it is brought on by illness or a prolonged fast (Grosse et al., 2006). As many as 50% of children who are not treated die from MCADD.

Assessment

Many states include screening for fatty acid oxidation disorders in their newborn screening program. A debate continues about the cost-effectiveness of adding these tests (Leonard & Dezateux, 2009).

Infants appear normal at birth and continue to develop normally until they reach a stage when they no longer need to feed overnight and begin normal prolonged overnight fasting, or they experience an intercurrent illness accompanied by vomiting and diarrhea that requires the body to mobilize energy sources from adipose tissue.

Parents may describe going in to wake the child from a nap and being unable to awaken them. Other children are brought in to the emergency room with seizurelike

activity or coma, unexplained lethargy, vomiting, or other signs of encephalopathy. Attacks of this illness may be misdiagnosed as Reye syndrome, severe dehydration, sudden infant death, or a seizure disorder. The clinical history of a child with no previous problems who has a sudden onset of severe clinical decompensation accompanied by any aspect of this clinical picture should have fatty acid oxidation disorder considered in the differential diagnosis.

Diagnostic Tests

Tandem mass spectrometry testing can be used to test for MCADD during newborn screening. This is the same heel stick blood sampling test used for screening phenylalanine. For the child not diagnosed during the newborn period, the following laboratory studies should be considered: basic metabolic panel that includes blood glucose, complete blood count with differential, blood gas, plasma ammonia, urine for reducing substances, urine ketones, quantitative plasma and urine amino acids, urine organic acids, and plasma lactate.

Alert! Draw the lactate sample when the child is as calm as possible and without using a tourniquet. Using a tourniquet, or drawing blood from a struggling child, will yield falsely elevated serum lactate levels.

Interdisciplinary Interventions

The immediate management goals for a child with acute metabolic decompensation is to suppress lipolysis as quickly as possible. Suppression is accomplished by administering 10% dextrose intravenously. Supplying an energy source is essential, because the child is not able to access stored energy sources, and acidosis will continue to worsen and possibly kill the child. After the initial crisis is past, management is primarily nutritional.

The infant or child with a fatty acid oxidation disorder needs to have frequent feedings, must incorporate sustained-release carbohydrate into the diet, and should minimize lipids. The primary goal of nutritional management is to prevent long-term fasting. Any fast longer than 10 hours can present an enormous stress to the child with any of these disorders. Children with MCADD usually increase in fasting tolerance as they age and experience less decompensation with acute illnesses. Children may incorporate a sustained release carbohydrate, such as uncooked cornstarch mixed into pudding, into their diet with a bedtime snack to prevent negative effects of prolonged fasts during sleep hours.

Community Care

Providing family education regarding the interaction between diet, fasting, and symptom onset is an important nursing intervention. Teach the family the importance of monitoring blood sugar and urine ketones during acute illnesses (e.g., colds, gastrointestinal problems, chicken pox). Collaborate with the healthcare team to help

parents develop a “rescue protocol” that will direct emergency care personnel on the immediate needs of the child if ill, such as the need for a high-concentrate glucose infusion and any necessary laboratory studies that should be monitored during a crisis. For infants and young children in daycare, the importance of adhering to the meal and snack schedule the parent has set up with the physician must be strictly reinforced. Educate the family in meal and snack planning and advise them that even apparently unaffected siblings may have the disorder. Testing siblings and parents will help to determine whether the disease is present.

The Child With Altered Sensory Status

Case History

Gabriella is now 1 month old or 32 weeks' gestation. Today the ophthalmologist is coming to the neonatal intensive care unit to examine Gabriella's eyes. The nurse swaddles Gabriella and gives her a pacifier coated with sucrose in an attempt to provide comfort and address any pain that Gabriella may experience from the examination. The nurse also assists during the examination by holding her still while the ophthalmologist uses light and a special lens to see the retinal vasculature of the eye. The ophthalmologist determines that Gabriella does have an overgrowth of vasculature in her eye, or retinopathy of prematurity (ROP) stage II. At this time there is no specific treatment and her condition will be followed, but Abby and Ben Goldman, her parents, have lots of questions.

During a team conference, Abby and Ben are also told that Gabriella will be tested before discharge by an audiologist for hearing loss because premature infants are at risk for sensorineural hearing loss. Gabriella has several specific risk factors that increase her risk for hearing loss: her increased serum bilirubin level, the use of furosemide (Lasix) to treat pulmonary edema, the use of indomethacin to close her patent ductus arteriosus and the use of aminoglycosides to treat infection. Again, there is no precise answer—only the knowledge that there is the possibility of sensorineural hearing loss.

The week of Gabriella's discharge from the hospital arrives, and Gabriella has her auditory brain stem response (ABR) hearing screening test. She fails.

CHAPTER OBJECTIVES

1. Identify deviations from normal developmental patterns that indicate a visual, hearing, or communication disorder.
2. Describe assessment techniques commonly used to identify vision, hearing, and communication disorders in infants and children.
3. Identify the nursing interventions necessary to prepare children and their families for tests of sensory function.
4. Describe the etiology of common vision, hearing, and communication disorders of infants and children.
5. Discuss the pathophysiology related to common disorders of vision, hearing, and communication in infancy and childhood.
6. Identify the roles of the interdisciplinary team members in identifying and managing sensory disorders in children.
7. Develop a plan of care for an infant or child with an alteration in vision, hearing, or communication.
8. Summarize parent and child education to prevent injuries and illness resulting in alterations in sensory function.

See [thePoint](#) for a list of Key Terms.

Infants and children depend on sensory input from the external world to assist them in their cognitive, social, and emotional growth. Sensory input comes in the form of visual and auditory stimulation, and through the senses of touch, smell, and taste. To benefit fully from sensory stimulation to grow and develop, children must possess intact peripheral nerve pathways to receive the stimuli (sensory reception), and they must have brain development capable of recognizing and attaching meaning to the sensations received (sensory perception).

Communication is the child's ability to interact with the outside world in response to the sensations received. This exchange of ideas, messages, and information involves both receptive and expressive abilities. The child who has intact sensory systems receives sensory input, to which he or she cognitively and emotionally attaches significance. A child reacts to the environment by expressing behavioral and vocal responses. These responses complete the process of communication. Alterations in either receiving or sending that make the child unable to share needs, desires, or ideas with others deeply affect the developmental process.

Children with altered sensory status, whether congenital or acquired, permanent or temporary, need interventions from other persons in the environment to facilitate their development. Nurses are uniquely positioned within the healthcare team to help prevent, screen, and identify deviations from normal and intervene in assisting the family in either seeking a solution or adapting to the alteration to promote optimal development. The nurse's role in this process includes (1) promoting early identification and treatment of sensory alterations, (2) assisting and teaching parents and children how to prevent or

minimize trauma that could affect sensory abilities, (3) developing and implementing a care plan for the child with altered sensory function, and (4) helping parents to find ways to promote the development of the permanently impaired child. To this end, the nurse collaborates with a variety of specialists in sensory and communication disorders, such as ophthalmologists and optometrists for visual problems; audiologists, otolaryngologists, and otologists for hearing disorders; and speech language pathologists and speech therapists for communication difficulties.

DEVELOPMENTAL AND BIOLOGIC VARIANCES

Development of sensory abilities are incomplete at birth. As the infant grows and develops, maturation of visual, auditory, and communication capabilities will occur, providing greater opportunities for children to engage with their environment and to grow emotionally, socially, and intellectually.

Vision

Early development of vision begins between the second and fourth weeks of fetal life, along with development of the fetal brain. By the 16th week of fetal development, the eye has acquired its human appearance and rudimentary internal structures are forming (Graven, 2004).

At birth, the optic nerve (cranial nerve II) is functional and peripheral vision is fully developed (Fig. 28–1). However, development of visual acuity at birth is incomplete, and is estimated to be 20/400 (Olitsky, Hug & Smith, 2007). The *macula*, the portion of the retina that receives the image focused on it through the lens, has yet to develop; and the *fovea*, the central portion of the macula, is unable to transmit an image to the brain. **Central vision**, which occurs as the fovea and macula mature, develops during the first few weeks and months of extrauterine life, when ocular structures that are stimulated by normal sights of the infant's world repeatedly have images focused on them. Subsequently, the brain learns to merge the images from the two eyes.

If a defect or injury prevents images from reaching the retina, the macula and fovea are deprived of stimulation and do not develop the ability to transmit images. For example, congenital cataracts and ptosis of the eyelids are conditions that prevent visual development. If not treated early, the eye loses its ability to continue to develop, and **amblyopia** (loss of functional vision in an otherwise normal eye) develops.

As visual acuity is developing, **accommodation**—the eye's ability to focus clearly—also improves. At birth, the infant can fix visually on near objects, depending primarily on sounds to recognize the approaching parent. The newborn's eyes are able to focus clearly only on objects within very close range. During the next 4 months, the

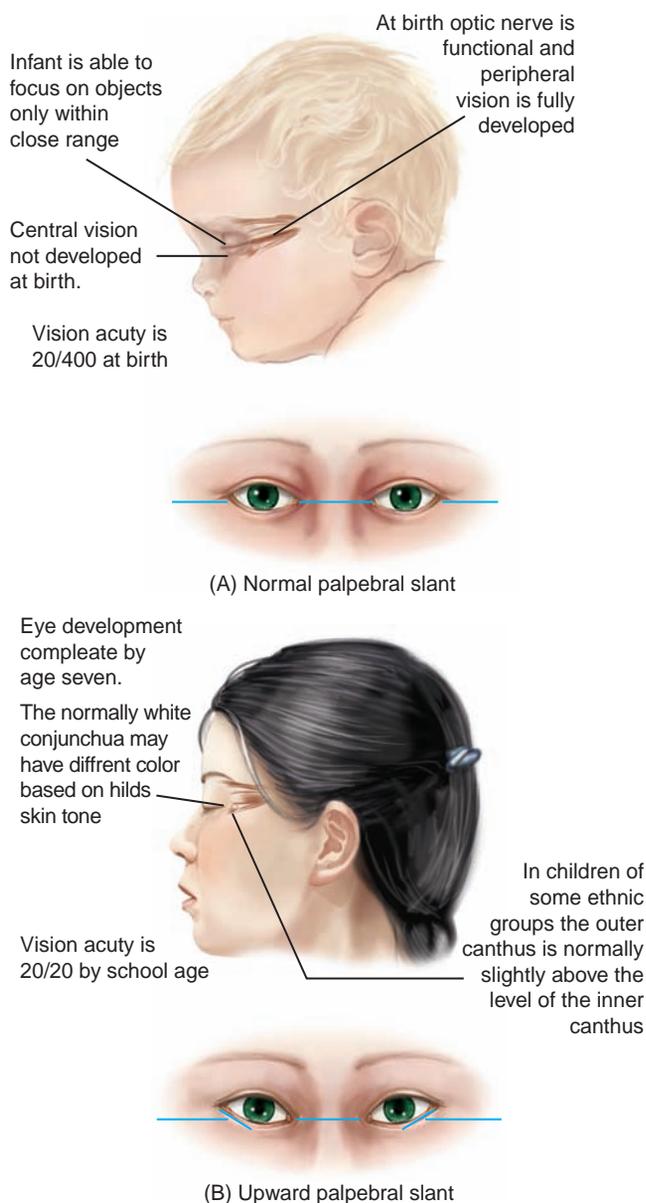

FIGURE 28-1. Developmental and biologic variances: vision.

infant's eyes develop the ability to change shape (accommodate), allowing close and distant images to be focused on the retina. By age 5 to 7 years, eye development is complete (Rozhkova, Podugolnikova & Vasijeva, 2005). Developmental Considerations 3-1 presents the pattern of visual development in children.

WORLDVIEW: Biologic variations are seen in different cultural groups and in children with different amounts of melanin in their skin. In children of Asian descent, the outer canthus of each eye may be located slightly above the imaginary line drawn from the inner canthus

to the top of the ear. This slight upward slant is a normal biologic variation. Children with dark skin may have flecks of brown in the conjunctiva and have an orange-brown hue to the retina, rather than the bright yellow-orange present in persons with less melanin in the skin. Children of Hispanic descent may have brown flecks even if their skin color is light.

Hearing

Hearing is fully developed at birth; however, the neural pathways that enable the child to assign meaning to sounds in the environment are still being developed. Newborn infants quiet more quickly to a parent's voice than to the voice of a stranger. Music that the mother listened to before the birth of an infant has been shown to quiet the infant much more readily than unfamiliar music. These findings seem to indicate not only that the infant's hearing is fully developed at birth, but also that it is fully developed well before birth. Developmental Considerations 3-2 presents the progression of hearing from birth to 15 months of age.

Communication

Children's speech and language development begins at birth, with the differentiated cries that infants make to indicate discomfort, hunger, or loneliness. As the infant develops, syllables are differentiated, vowel sounds are articulated, and, finally, syllables are joined to make words and sentences. As the infant's cognitive skills grow, application of words to concrete objects progresses to the use of word symbols for abstract applications. Developmental Considerations 3-3 presents the progression of language acquisition in children.

Biologic variations account for very little variation from the norms. Boys tend to begin to speak later than girls, and girls develop greater fluency at an earlier age, but the established "normal" ranges have been developed to include both sexes. Teaching prelingual infants to sign to communicate common needs has been found to be quite effective. As soon as infants can control their fingers, they can be taught to sign.

Developmental variations occur in the presence of hearing impairment or lack of stimulation. Infants and small children in bilingual families may take slightly longer than other children to develop full language skills, because they are learning two language vocabularies and two language structures at the same time. The bilingual child's comprehension of abstract concepts is not delayed, however. Lack of stimulation is sometimes the reason children with visual impairment take longer to comprehend abstract concepts, but with assistance, they can learn these concepts also.

ASSESSMENT

Vision is assessed at birth and regularly throughout infancy and childhood. During the early childhood,

screening is imperative to detect eye disease that must be treated within a specific time frame so that children have optimal vision as they begin formal schooling (AAO, 2007; American Academy of Pediatrics [AAP], 2003; Kerr & Arnold, 2004). Even though an infant's eyes seem normal, the growth process can cause subtle changes in the shape and function of the eye. Abnormalities must be identified as soon as possible to enable normal development.

Hearing also must be assessed at birth and frequently thereafter during the first 36 months of life, particularly if the child is at risk for hearing impairment. The AAP endorses universal hearing screening for all newborns and infants as well as periodic screening for every child through adolescence (AAP, 2007; Cunningham & Cox, 2003) (see Appendix G for the schedule of preventative healthcare visits for infants and children).

Keep in mind that not all hearing impairments manifest themselves at birth. Both late-onset genetic factors and factors within the child's medical history can contribute to the development of hearing impairment at any time during childhood.

Hearing and language development are intertwined and so, too, is assessment. The ability of a young child with hearing impairment to learn language and speech is closely related to the time when remediation is begun; therefore, early identification and intervention are key (Cunningham & Cox, 2003).

Assessment of vision, hearing, and communication in infants and children begins with a focused health history followed by a physical examination. As children grow older and increasingly able to cooperate, the physical examination becomes more comprehensive (see Chapter 8). Depending on his or her expertise, the nurse may perform some or all of this examination. Nurse practitioners may provide the entire examination. For example, screening tests of visual acuity are often done in the school setting and may be completed by the school nurse and assistants.

Remind parents that sensory screening is a valuable part of health assessment and that it should be done at regular intervals during childhood when the child visits their primary healthcare provider or during routine school-based assessments (see Appendix G). A child's inability to cooperate, perhaps because the child does not speak the dominant language or is developmentally delayed, must not prevent accurate sensory screening. Children with special needs may be tested differently, but they should not be allowed to skip routine screening.

Focused Health History

Health history data concerning vision, hearing, and communication elicited from the parent or child, if old enough, enables the nurse to make inferences about possible deviations from normal sensory abilities. Suggested topics useful for eliciting this information are pro-

vided in Focused Health History 28–1. Additional data collected depends largely on the age of the child.

caREminder

Always pay attention to parents' observations, because they are usually the first to detect abnormal signs or symptoms.

QUESTION: Using Focused Health History 28–1, what are some risk factors that apply to Gabriella?

Visual History

Begin the visual history by questioning the parents about any concerns they might have related to their child's vision. Also question the child about any complaints. Be aware that a young child may have difficulty answering questions about the quality of sight. Assess the child's visual acuity indirectly by asking whether the child enjoys looking at picture books and "reading." A child who seems to be frustrated by books or dislikes fine motor tasks that require close vision may truly have difficulty seeing the book or object (Fig. 28–2). For the child in school, ask whether the child can see the blackboard easily without squinting or closing one eye. At this age, the child could also report blurring or double vision.

Hearing History

An infant's ability to attend to environmental sounds and parental voice is critical. Parents' observations concerning the child's responsiveness to their voices, and of the child's general behavior, are important. Parents are often the ones who first notice a problem with the child's ability to hear well. When parents raise such a question, the child should be tested in the office, referred to the audiologist, or both.

Carefully assess vocalization and language development as measures of hearing ability; also use them as measures of language, cognitive, and expressive development. The child who cannot hear sounds cannot imitate them and is less likely to make the developmentally appropriate vocalizations during infancy and early childhood.

caREminder

A child who does not hear directions, parental requests, or environmental sounds may not be able to respond appropriately. Although this behavior may be interpreted as uncooperative or unusual, it should be noted as potentially indicating hearing impairment. Ensure that the child's hearing is assessed.

FOCUSED HEALTH HISTORY 28–1

The Child With Sensory Alterations*

Current history

General Information

- Parental concerns related to vision, hearing, or communication
- Completion of any vision, hearing, or communication testing

Eye-Related Concerns

- Poor school performance; child complains of difficulty seeing writing on black board at school or reading book, street signs
- Squinting of both eyes
- Headaches or complaints of pain in the eyes
- Unexplained crying
- Rubbing the eyes, tearing, redness, discharge, eyelid swelling
- Rocking head side to side, abnormal head position
- Complaints of blurred vision while reading, holding things close
- Current medications related to treatment of eye disorder or medications or solutions used for contact lens wear

Ear-Related Concerns

- Complaints of ears “popping,” feeling plugged or full, or difficulty in hearing
- Inattention to environmental sounds or human voice
- Pulling and tugging at ears

Communication-Related Concerns

- Languages spoken and languages understood
- Parents’ perception of child’s communication abilities

Past medical history

General

- Congenital anomalies
- Trauma to eyes, ears, or head
- Eye or ear infections
- Previous referral for vision or hearing testing
- Immunization status
- Syndromes associated with vision or hearing loss

Prenatal/Neonatal History

- Problems during delivery or perinatal period
- Prematurity or low birth weight
- Mechanical ventilation
- Hyperbilirubinemia; use of phototherapy
- Perinatal or congenital infections (rubella, chlamydia, gonorrhea, cytomegalovirus, syphilis)

Health Challenges, Illness, or Injury Related to the Eye

- Glaucoma, cataracts
- Discharge from eyes
- Periorbital cellulitis
- Unexplained crying, blurred vision, double vision
- Strabismus
- Amblyopia
- Allergies, including those that may cause orbital redness or eye irritation

Health Challenges, Illness, or Injury Related to the Ear

- Bacterial meningitis, encephalitis
- Infectious diseases associated with hearing loss (mumps, measles, Epstein-Barr virus)
- Ototoxic drugs or radiation therapy
- Neurodegenerative disorder known to be associated with hearing loss
- History of otitis media

Family medical history

Health Challenges, Illness, or Injury Related to Communication

- Tonsillitis or enlarged adenoids
- Cleft lip or cleft palate
- Chronic otitis media
- Difficulty in chewing or swallowing
- Mental retardation, cerebral palsy
- Trauma or strictures of trachea

Vision Related

- Visual disorders, such as glaucoma, cataracts
- Blindness
- Metabolic or genetic disorders affecting vision (e.g., Marfan syndrome, Down syndrome)

Hearing Related

- Congenital or childhood-onset hearing loss

Communication Related

- Family members with speech or language disorders

Social and environmental history

Age-appropriate interactions with others

Decline in academic grades or generally doing poorly in school

Vision Related

- Child's response to visual cues, ability to track objects, ability to see objects in the environment clearly (TV, pages in a book, puzzles)
- Exposure to irritant environmental agents (e.g., smog, prolonged exposure to bright sunlight, frequent swimming)

Hearing Related

- Exposure to loud noises (music, lawnmowers, fireworks)
- Parental complaints that child "doesn't listen" or is "uncooperative"

Communication Related

- Bilingual family setting

Growth and development

Dates and results of previous vision and hearing testing

Age-appropriate gross and fine motor skill development; delays

Distance (near or far) child sits to watch television

Speech or Language Acquisition

- Age words first spoken
- Progress of language acquisition; current level of language acquisition
- Age-appropriate demonstration of expected knowledge (e.g., knows colors, body parts, points to named objects)
- Use of visual communication (e.g., waves bye-bye, points, finger counts)
- Methods used for expression of wants and needs

Speech

- Percentage of speech intelligible to parents? To others?
- Response of others to child's speech patterns
- Child's perception of his or her speech patterns
- Presence of stuttering

*This history is focused on vision. See Chapter 8 for a comprehensive format.

Pay attention to other behavioral observations made by parents that may be helpful in identifying a hearing deficit. For instance, suspect a hearing deficit in children who turn the television or radio volume up loud, or who consistently turn their heads as if to catch the sound of the spoken word more easily. Also suspect a hearing deficit in middle childhood if the child suddenly begins to do less well in school, who miss directions, or who fail to answer questions correctly. Children may be doing their best and may be unaware that they are not hearing all information

provided in class. The inability to hear directions may cause them to do poorly in school, which in turn can negatively affect the child's psychosocial development, especially if the child is punished or admonished to work harder because of failure to achieve in school.

Alert! Infants and children in whom otitis media (OM) develops are particularly prone to development of either temporary or permanent hearing impairment.

FIGURE 28–2. A child who stands close to the TV might do so because he or she has difficulty seeing.

The child may use behavior in an attempt to cover up the problem. Silliness, using excuses, or joking may be attempts to distract peers, teachers, and parents from the fact that the youngster did not clearly hear directions. Indeed, the youngster may not know that he or she did not hear all the directions. The child only knows that he or she did not perform as desired by the parent or teacher, or as expected by peers.

Prenatal, environmental, and disease-related factors may affect development of the auditory systems and/or the ability to hear. Refer to Focused Health History 28–1 for examples of variables that can may lead to hearing losses.

Alert! Medications such as gentamicin or dihydrostreptomycin may be ototoxic (damaging to the cochlear mechanism of the inner ear) when given in high doses or under certain conditions. Space doses equally around the clock and measure peak/trough levels to avoid serum levels in the toxic range. Monitor renal function and hydration to ensure that they are within normal limits.

ANSWER: Prematurity, hyperbilirubinemia, mechanical ventilation, and exposure to ototoxic medications are risk factors for impaired hearing and all are present in Gabriella’s health history.

Communication and Language Development History

The critical period for learning language is the first 36 months of life. Children who are unable to hear during

that time are unable to learn the language necessary for normal verbal communication unless hearing intervention is provided. This deficit can affect learning, social development, and eventual vocational and economic potential. Learning the vocabulary and skills needed for communication is much harder after those first critical months have passed. Hearing deficit that begins after 36 months of age also diminishes the ability to profit from spoken words and sounds, but not to the same extent as a hearing deficit that begins prelingually.

Begin the health history with an assessment of articulation and language usage appropriate to the age of the child (see Focused Health History 28–1 and Developmental Considerations 3–3). If deviations from normal are found in the parent’s report, describe the characteristics of the child’s speech and language ability with respect to articulation, fluency, voice quality, and word usage both by parent report and by observation. Note psychosocial stressors or issues that could affect communication, such as bilingual environment.

Focused Physical Assessment

QUESTION: The Goldman’s first questions are, “How will you check her vision?” and “When will you know if her vision is impaired?” What explanation would you give to Abby and Ben?

Examination of the Eyes

Physical assessment of vision begins in infancy, when the eye and sight are undergoing great change in a short period of time. Abnormalities identified and treated at this early age can prevent permanent loss of vision. Infants and young children are less able to understand directions and cooperate with the examiner, making assessment a challenge. However, children who are younger than 5 years of age should not forgo assessment because of development challenges; rather they should be screened for vision problems such as amblyopia, strabismus, and near- and farsightedness (Agency for Healthcare Research and Quality, 2004; American Academy of Ophthalmology [AAO], 2007). As children grow older, their cooperation makes physical assessment much easier and more accurate (Focused Physical Assessment 28–1). Chapter 8 provides an in-depth description of the physical assessment of the eyes.

During middle childhood, vision should be assessed every year. During the teenage years, eye examinations should be completed at least every 2 years, and the teenager should be encouraged to report unclear vision, close or distant. Concerns raised by parents or teachers should prompt appropriate eye examinations, particularly because eye changes occur as physical growth progresses. The teenager’s ability to succeed and to reach his or her maximum potential in school and on the job could be jeopardized by the inability to see clearly.

FOCUSED PHYSICAL ASSESSMENT 28-1

The Child With Sensory Alterations

Assessment Parameter	Alterations/Clinical Significance	
General appearance	<p><i>Eyes</i></p> <ul style="list-style-type: none"> • Asymmetric placement and wide or close-set spacing of eyes may indicate congenital malformation. • Ptosis (drooping eye lids) and sunset eyes (appearance of upper portion of the sclera) may indicate neurologic conditions. • Slanted palpebral fissures are seen in children of Asian descent and in children with chromosomal abnormalities. • Discolored eyelids may indicate erythema, hematoma. • Swelling, tenderness, or lesions of the eyelid and surrounding tissue seen with blocked sebaceous gland, periorbital cellulitis. • Excessive tearing or discharge can indicate infection or trauma. <p><i>Ears</i></p> <ul style="list-style-type: none"> • Presence of lop ears, skin tags, dimples, sinus tracts, and developmental anomalies (e.g., cleft lip or palate, abnormality of the pinna) may indicate congenital malformation • Low-set or asymmetric placement may indicate congenital malformation or other congenital condition (e.g., chromosomal disorders, genitourinary disorders). • Excessive cerumen or discharge (yellow or greenish) from ear canal may indicate infection or presence of foreign body. • Structural abnormalities of head and neck may indicate congenital defect. • Presence of piercings and any signs of infection at piercing sites <p><i>Oral Cavity</i></p> <ul style="list-style-type: none"> • Symmetry, facial expression may indicate cranial nerve defect or congenital defects. • Structural abnormalities such as cleft lip or palate, mandibular hypoplasia indicate congenital malformation • Presence or absence of teeth may affect speech (e.g., young child who has recently lost front teeth). • Lesions or excoriations of the mouth may make speaking painful. 	
	Structures	<p><i>Eyes</i></p> <ul style="list-style-type: none"> • Color changes of the sclera (yellow tint may be the result of jaundice; bluish tint, osteogenesis imperfecta) • Pupils unequal in size, shape, movement, or reaction to light may indicate trauma, accommodation disorders, strabismus, nystagmus. • Black-and-white spots on the iris (Brushfield spots) are noted both in children with trisomy 21 and in normal children. <p><i>Ears</i></p> <ul style="list-style-type: none"> • Inflammation of ear canal or tympanic membrane may indicate infection. • Pain with movement of the tragus may indicate otitis externa. • Inability to visualize landmarks of middle ear, a pearly gray tympanic membrane, or other changes in the tympanic membrane (e.g., bulging, red, lack of mobility) may indicate inflammation, presence of a foreign body, or perforation. • Presence of fluid or bubbles behind tympanic membrane indicates otitis media. • Tympanic membrane that is scarred or an ashen gray color indicates previous perforations. <p><i>Oral Cavity</i></p> <ul style="list-style-type: none"> • Presence of a tight frenulum as indicated by the child's inability to touch the tongue to the roof of the mouth • Lack of gag reflex may indicate damage to the glossopharyngeal nerve or vagus nerve • Enlarged tonsils or increased redness or tonsillar exudate indicates infection.

 **ANSWER:** An example of the explanation the nurse might give to Abby and Ben is, "Right now, the ophthalmologists will examine the blood vessels of her retina weekly. It is also possible that the blood vessels will

stop spreading and growing, and no intervention will be needed. If the proliferation of retinal blood vessels increases dramatically, there are procedures that can be done to stop them, such as laser surgery or cryotherapy.

There are also rare complications of ROP, such as a detached retina, that would immediately indicate her vision would be significantly impaired. Most of the time, we just don't know exactly how well she can see until she is older."

Eye photography (or photoscreening) is a vision screening technique used to detect eye muscle and ocular disorders such as strabismus, media opacities, and significant refractive errors (AAP, 2002). Children who have difficulty holding still or undergoing examination with the ophthalmoscope or other equipment may be able to look at a particular object long enough for a photograph to obtain images of the pupillary reflexes (inflections) and the red reflex (Bruckner test). The ophthalmologist can review the screened images and the computer analysis to detect any positive findings. This graphic record also enables comparison with future photographs as a child with a detected disorder progresses in their therapy. Children who do not pass the assessment should receive a more complete eye examination.

Examination of the Ears

Assessment continues with evaluation of the anatomic structures associated with hearing. Chapter 8 provides an in-depth description of the physical assessment of the head, neck, and ears. Inspecting the child's head and neck for structural anomalies or congenital defects is particularly important. Some facial structures arise from the same fetal tissue or are subject to the same genetic influences that affect the ears; thus, an abnormality in one should alert the healthcare practitioner to the possibility of other defects. Assessment of the ear includes evaluation of external structures, the ear canal, and otoscopic examination of the internal structures of the middle ear (see Focused Physical Assessment 28–1). Several assessment techniques can be used to further assess hearing. These include techniques for hearing acuity, and the Weber and Rinne tests.

When the assessment, performed by the nurse or other primary care practitioner, indicates that a hearing deficit could or does exist, then the child is referred to an audiologist. Criteria for referral includes the following:

- Evidence of one or more risk factors
- Reported observations by parents or teachers of concern
- Questionable results with Rinne, Weber, or other screening test
- Decline in child's school performance
- Child complaints of inability to hear as well as before

QUESTION: Abby and Ben ask, "How will Gabriella's hearing be tested? When will we know for sure if she does have a hearing loss?" How will you answer them?

Hearing Acuity

Behavioral assessment of hearing acuity is ideally done in a quiet room without external noise—a difficult task in the typical office or clinic. The whisper test, which is part of the basic physical assessment protocol used in many offices and clinics, requires the examiner to whisper a selected word while out of the line of vision of the child. The child's ability to hear the word is recorded as normal if the infant turns toward the examiner or exhibits pupillary response or blink reflex, or if the older child is able to repeat the word. In the case of preverbal children, a change in behavior is considered an indication of hearing. Because of the variability in infant behavior, lack of consistency between examiners, and inability to control for either volume of the whisper or external noise, the whisper test is, at best, a gross measure of hearing acuity that should not be depended on to indicate normal hearing, particularly in high-risk infants and children.

Hearing in infants and young children may also be assessed in the home or office by making noise using a bell, a noisemaker toy, or a jangling set of keys out of the child's line of vision. A behavioral change, quieting behavior, or searching behavior is expected if the child hears the sound. These tests also are, at best, rough estimates of the child's hearing ability and should not be depended on if other indicators of hearing deficit, such as delayed speech, occur.

Rinne and Weber tests

The Rinne and Weber tests can be used to assess hearing when the child reaches middle childhood. However, these tests may not yield accurate results until the child is 8 or 9 years of age, because of behavioral factors and the child's desire to give the examiner the "correct" answer. A child who is at risk for or suspected of having a hearing deficit should be examined with tests that have been shown to be more accurate for the younger age groups. The Rinne and Weber tests are described here in case they are selected for use with older children.

The Rinne test evaluates for conductive and sensorineural hearing loss. A tuning fork is struck against the examiner's hand and then the base is held against the mastoid bone. The child is asked to indicate when the sound is no longer heard. At that time, the tuning fork is held near the ear. The child with normal hearing again hears the sound through air conduction. Normal finding is air conduction (AC) greater than bone conduction (BC) and is recorded as $AC > BC$.

The Weber test is done by striking the tuning fork on the hand, causing it to vibrate, and then placing the base in the midline on the client's forehead. The child is asked to indicate whether the sound is heard better on one side than on the other. Normally, the sound is heard equally on both sides. If the sound is heard better on one side than the other, a hearing impairment exists. If the sound *lateralizes* to (is heard better in) the impaired ear, the middle-ear apparatus is at fault; if the sound is heard better in the normal ear, the hearing deficit is caused by impaired sensorineural apparatus.

Evaluation of Communication

All children are assessed for developmental delays in communication on a regular basis during well-child examinations. A variety of language and cognitive screening tools exist, although none are designed specifically for primary care settings. Any tool used should rely on both parent report and observations of the evaluator. The purpose of screening is not to differentiate one type of disorder from another; rather, screening distinguishes between those who have delays or disorders and those who do not (Scheffler et al., 2007). Any infant or child who is suspected of having a communication disorder should receive a full assessment done by a certified speech–language pathologist. If hearing ability is in question, the child’s hearing should be assessed by an audiologist. When assessment results are obtained, the speech–language pathologist is equipped to recommend speech therapy if necessary.

Alterations in hearing often affect speech and language development; therefore, including speech and language in an evaluation of hearing is essential. Assessing the infant’s vocalization, early syllable formation, and eventual verbalization, and comparing the assessment with developmental norms provides additional clues to hearing impairment. An infant who fails to vocalize within the expected age range or who fails to form syllables may be unable to hear the vocalizations of other people. The nonhearing infant makes normal infant sounds; however, these sounds do not progress to syllabic babbling. Any infant or child with delayed speech should receive a full hearing assessment from an audiologist as soon as possible. Any child who fails to repeat new words in their entirety requires further assessment. A child who omits initial sounds or final sounds may not be hearing the sounds in a particular decibel range. For example, the final “ing” or “p” or “b” may simply be lost to the hearing of the child with residual fluid in the middle ear.

Diagnostic Criteria

In addition to the previously described elements of the physical examination, more complex technologic methods using sophisticated equipment are sometimes used to identify specific aspects of sensory impairment and to monitor progress as a child undergoes treatment (Tests and Procedures 28–1). Parents and family members need to be kept fully informed concerning the purpose of each test and how it is done. None of the tests are invasive or painful.

Audiometry

Audiometry measures two characteristics of sound: intensity and pitch. The *intensity* of sounds that are heard by the human ear is measured in **decibels (dB)**. The least sound that the normal ear can hear is said to be 0 dB. A normal speaking voice is between 40 and 50 dB, and the sound of a train traveling rapidly on a nearby track measures approximately 90 dB. A normal conversation is about 60 dB. Chain saws, hammer drills, and bulldozers ring in at more than 100 dB. The *pitch* of a sound is its tonal quality, the speed at which the sound waves vibrate.

High tones are caused by rapid vibration of sound waves, whereas the vibrations of low tones are slower. Both intensity and pitch are important to the ability to hear and comprehend verbal communication. Audiometric testing assesses the infant’s or child’s ability to hear sounds of various intensities as well as of various pitches.

The accuracy of hearing screening has improved with use of otoacoustic emission tests and automated auditory brain stem response (ABR) testing (see Tests and Procedures 28–1). Otoacoustic emissions can be recorded from the ears of normal-hearing people, but not from the ears of those with more than mild hearing loss (Holte, 2003). Otoacoustic emission tests are quick, noninvasive, and inexpensive, and thus many states have adopted them to evaluate the hearing of all newborns prior to discharge. ABR is a electrophysiologic measurement of activity in the auditory nerve and brain stem pathways (ASHA, 2004; Cunningham & Cox, 2003). Although more expensive, it is known to yield fewer false-positive results (ASHA, 2004; Elden & Potsic, 2002).

Legislation in many states requires that all newborns undergo more objective screening via measurement of automated ABR. The Joint Commission on Infant Hearing (2007) recommends that infants admitted to the neonatal intensive care unit for more than 5 days should have ABR testing completed to screen for neural loss. Infants who do not pass this screening are referred to an audiologist for rescreening and more comprehensive testing as indicated. It is also recommended that infants readmitted to the hospital in the first month of life for should have a repeat hearing screening before discharge when the child has conditions associated with potential hearing loss (e.g., hyperbilirubinemia requiring exchange transfusion or culture-positive sepsis). Last, all children younger than 3 years of age should have at least one ABR test as part of a complete audiology diagnostic evaluation for detection and confirmation of permanent hearing loss.

ANSWER: Gabriella will be tested at discharge for hearing loss with the ABR. The test uses click stimuli to evaluate the cochlear and brain stem response of the infant. The ABR does not specifically test what frequencies Gabriella can hear. It is possible for her to fail the ABR, have some hearing loss, but still be able to hear and understand conversation. On the other hand, and more rarely, she may pass the ABR and later be diagnosed with hearing loss in specific frequencies.

TREATMENT MODALITIES

The treatments for sensory alterations include measures to fully correct or reverse the underlying condition as well as those measures to optimize vision, hearing and communication to the greatest extent possible given the child’s condition.

QUESTION: Ben and Abby also ask, “If Gabriella does have retinopathy of prematurity, how will it be treated?”

Tests and Procedures 28–1 Evaluating Sensory Alterations

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
Vision			
Visual acuity: Snellen E Kindergarten Test Chart Tumbling E chart Handheld Tumbling E or picture chart HOTV system (visual chart of letters H–O–T–V in various sizes) LEA Symbols Titmus Vision Screening	Tests visual acuity.	Acuity should be normal for age in each eye. To achieve credit for a line on the Snellen chart, the child must identify four out of six symbols on the line. For tests with larger letters/symbols where there are fewer per line, child must identify one more than half the letters/symbols on the line to pass. <i>Abnormal scores:</i> For ages 5 and younger, anything worse than 20/40 or a 2 line difference between eyes needs referring For ages 6 through adult, anything worse than 20/30 or a 2 line difference between eyes needs referring	Cover one eye at a time; test the other eye. Child should avoid putting pressure on the eyeball that is covered. Any child who refuses to complete the test on one eye or the other is presumed to be unable to see well using that eye. If age 3, retest in 6 months; if age 4 years or older, retest in 1 month. If child refuses again, refer to the ophthalmologist. Children with deviations from normal should see the eye care specialist. Remind parent that visual acuity changes as the child grows in height and in maturity.
Blackbird Vision Screening System	Screens for visual acuity in young children who have short attention spans, are preverbal, and are preliterate.	Normal acuity is indicated when the child is able to accurately tell position and direction of the bird in the story.	Child puts on a pair of cardboard “glasses” that allows first one, then the other eye to be occluded as the child listens to the story and watches the bird in the examiner’s book fly to different positions and shows the examiner which way the bird is flying. The “glasses,” which the child takes home, contain a message to the parent indicating that the child has participated in vision screening on that day.
Red reflex assessment	Screens for abnormalities of the back of the eye (posterior segment) and opacities in the visual axis, such as a cataract or corneal opacity.	Both red reflexes should be of similar pink color, of same hue with no opacities or white spots. Presence of white reflex or any white or dark spots is considered abnormal.	Ophthalmoscope is held close to the examiner’s eye at 12 to 18 in from the child’s eyes. If color differs, or one is white and the other pink, report this to the primary care physician for referral to the eye care professional.
Funduscopy examination	Identifies characteristics of internal ocular structures using an ophthalmoscope.	Any abnormal findings in structure or appearance	Abnormal findings should be evaluated by the eye care specialist.
Eye photography (photoscreening)	Obtains a graphic record of appearance of the cornea and lens for current	Abnormal appearance of cornea and lens	Have the child rest his or her chin on the machine’s chin rest and look at a spot in the center of the camera. Chil-

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
	assessment and future comparison.		<p>Children submit more easily to having photo taken than to a full ophthalmic examination. Valuable for use with children who may be less cooperative during a complete eye examination (e.g., infancy, early childhood, and children with developmental delays). Tests can be completed by anyone trained to use the equipment. Photos can be taken at school, or in any location, and evaluated later by an eye care professional.</p> <p>Abnormal appearance requires further ophthalmologic testing using other technologies.</p>
Vision field tests	<p>Determines vision loss in any area of the visual field.</p> <p>Screens for eye diseases, such as macular degeneration and glaucoma, which cause gaps in the visual field.</p> <p>Completed as part of a neurologic examination after a stroke, head injury, or other condition that causes reduced blood flow to the brain.</p>	<p>The complete visual field is seen by both eyes at the same time, and it includes the central visual field—which detects the highest degree of detail—and the side (peripheral) visual fields.</p> <p>Abnormal findings: visual cues in all visual fields are not accurately identified by the patient. May indicate presence of eye disease or nervous system disorder (e.g., tumor).</p>	<p>Difficult for young children to follow instructions and to complete this examination in an accurate fashion.</p> <p>Noninvasive tests</p>
Color vision tests (e.g. Ishihara color plates)	<p>Assesses ability to distinguish color.</p> <p>Used to screen for color blindness in people with suspected retinal or optic nerve disease, or who have a family history of color blindness.</p>	<p>People who have normal color vision are able to distinguish the colored numbers, symbols, or paths from the background of colored dots.</p> <p>Color vision tests merely detect a problem; further testing is needed to identify what is causing the problem.</p>	<p>Tests can be completed in a few minutes and are noninvasive. Refer for further testing if indicated.</p> <p>Color vision is usually tested only once, usually around age 5 as children are entering their school years.</p>
Refraction tests	<p>Determines the correct prescription for eyeglasses or contact lenses.</p>	<p>The result of a refraction test determines the prescription eyeglass or contact lens strength.</p> <p>Refraction is done as a routine part of an eye examination for people who already wear glasses or contact lenses, but it will also be done if the results of the other visual acuity tests show that eyesight is not normal and can be corrected by glasses.</p>	<p>Usually done after a visual acuity test. Optometrist or ophthalmologist tests eyes with different lenses until the lens that corrects vision the best (sometimes better than 20/20 or 6/6) is found.</p> <p>Child may have difficulty describing the effects of looking at an eye chart through various corrective lenses.</p> <p>This noninvasive test takes about 10 to 30 minutes to complete.</p>

(Continued)

Tests and Procedures 28–1 Evaluating Sensory Alterations (Continued)

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
<i>Hearing</i>			
Auditory brain stem response (ABR)	<p>Detects brain activity and quantifies the characteristics of the response when sounds are presented. May be used as part of newborn screening program.</p> <p>Earphones are placed on the child for introduction of clicking sounds. Electrodes are placed on the child's head to detect brain activity when sounds are heard. A computer averages these responses and displays waveforms. The child must remain quiet throughout the 15-minute test. If the child is older than 4 months of age, sedation may be necessary.</p>	<p>There are characteristic waveforms for normal hearing in portions of the speech range. If brain activity is identified, test result is "Pass." A normal ABR can predict fairly well that a child's hearing is normal in that part of the range. Characteristics of the response are measured and quantified by the audiologist.</p> <p>An abnormal ABR may be the result of hearing loss, but it may also be the result of some medical problems or measurement difficulties.</p>	<p>Discuss purpose of the test with parents. If not yet done, discuss family history for possible identification of risk factors for the infant.</p> <p>Ask parents to feed the infant immediately before the test is scheduled so the infant is quiet and calm.</p> <p>If the child is a very young age, the test may be performed under natural sleep; otherwise, the test is performed when the child is sedated.</p> <p>Provide parents with the results (pass/fail) and further information about follow-up if necessary.</p>
<p>Otoacoustic emissions (OAE)</p> <p>Includes transient evoked OAE (TEOAE) and distortion product OAE (DPOAE)</p>	<p>Screens for middle and inner ear abnormalities contributing to diminished hearing.</p> <p>Measures acoustic emissions generated in the cochlea in response to sounds. These emissions are picked up by sensitive microphones placed in the outer ear canal. This test identifies cochlear activity in each ear separately.</p>	<p>Probes are placed in each ear canal, signals are delivered, and otoacoustic response (presence, absence, intensity) is recorded. The test does not measure transmission of sounds to the brain.</p> <p>Residual vernix in the ear or mild middle ear effusion can interfere with the recording of the otoacoustic emissions, creating a false-positive result.</p>	<p>Test is performed by technicians trained in the use of the measurement device.</p> <p>Infant should be quiet during the test.</p>
Tympanometry	<p>Assesses the status of the middle ear conduction system—that is, the tympanic membrane and the mobility of the bones of the middle ear.</p> <p>A tone is introduced into the ear canal and the amount of sound reflected back from</p>	<p>The resulting graph should show a clear peak in the center as the mobile tympanic membrane moves in response to the sound.</p> <p>An ear with effusion (fluid behind the membrane) will show little if any mobility of the tympanic membrane.</p>	<p>Administered to children of all ages, although special equipment is needed to test infants younger than 4 months because of the small size of the external auditory canal.</p> <p>Inform parent and child of the purpose of the test and findings. If abnormality is found, show parent the graph indicating that effusion is present</p>

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
	the tympanic membrane is measured as the pressure changes during the test.		and the child is probably not hearing well at this time.
Play audiometry	Evaluates hearing in each ear separately and evaluates behavioral responses to the sounds. After training and practice, earphones are placed on the child and sounds of specific frequencies and decibels are introduced. Child's behavior in response to sounds is recorded.	No response to sounds or inconsistent responds to sounds indicates hearing loss.	Used with children who cooperate sufficiently to put a peg in a board or drop a block in a box in response to sounds. Test is usually conducted in a specialized quiet location by a trained technician. Teach the child to perform an activity each time a sound is heard (e.g. putting a block in a box, placing pegs in a hole). Teach the child to wait, listen, and respond. Ideally earphones are placed on the child's head so that independent information can be obtained for each ear. If the child refuses earphone placement or earphone placement is otherwise not possible, sounds are presented through speakers inside a sound booth. However, sound field screening does not give ear specific information, thus hearing loss in only one ear may be missed.
Pure tone audiometry	Allows office screening for hearing loss for children 4 years and older. In a quiet room, child is asked to indicate when a sound is heard. Various tones are presented by the instrument.	Success of the test depends the child's cooperation and ability to focus on the sounds being presented. If hearing loss is identified, the primary care physician assesses the child's physical status and may refer the child to the audiologist if indicated.	Any healthcare provider may learn to use the equipment and to administer the screening test. The test is best done in a quiet room. Gain the child's cooperation and practice using midrange, louder sounds. Administer the test and record findings on the test report provided.

TREATMENTS FOR VISUAL PROBLEMS

Treatments for altered vision include corrective lenses, occlusion therapy, medication, and surgical intervention.

Corrective Lenses

Corrective lenses can be prescribed for children of any age to correct refractive errors (e.g., myopia, anisometropia, strabismus), or to protect a nonamblyopic eye. For instance, if a child has an unrecoverable loss of vision in

one eye, polycarbonate protective lenses are highly recommended to protect the normal eye. Contact lenses may be substituted for eyeglasses when children are old enough to take responsibility for their care, insertion, removal, and cleaning (Tradition or Science 28–1).

The rate of visual development is rapid during infancy and early childhood; thus, a young child who has corrective lenses prescribed should wear them all the time. All adults who work with the child should be encouraged to find ways to assist the child to keep the glasses on. The young child needs to see the ophthalmologist

TRADITION OR SCIENCE 28–1

At what age can children start wearing contact lenses?

EVIDENCE-BASED PRACTICE

For older children who really do not want to wear glasses, contact lenses are a good option. However, younger children aren't thought to be responsible enough to put lenses in, take them out, or clean and disinfect them without parental help. Walline, Long, and Zadnik (2004) conducted a study to determine whether 8- to 11-year-old myopic children were able to wear, and successfully manage the use of, daily disposable contact lenses. The study demonstrated that these children were able to independently care for daily disposable lenses and wear them successfully. The disposable lenses eliminated the need for cleaning and disinfecting, which improved adherence to procedures required to avoid eye infections and eye injury. The researchers concluded that these lenses should be strongly considered as an option for younger children.

at regular, short intervals for possible changes in the prescription.

The majority of glasses for children are quite sturdy and have unbreakable lenses that are capable of withstanding much but not all of the wear and tear given to them by children. Breakage, loss, and physical injury to the face and eyes from falls can occur.

KidKare ■ Protect Active children from losing or breaking eyeglasses by using sports elastic to prevent loss during games such as basketball and soccer and encourage children not to remove the eyeglasses during extracurricular activities.

Occlusion Therapy

Occlusion therapy is used to treat eye muscle weakness (see Strabismus). The stronger eye is covered with an eye patch. Alternatively, one lens of the child's eyeglasses is clouded or covered. Covering enables the weaker eye to work alone for all or part of every day, thus becoming stronger. However, covering one lens of the eyeglasses loses its therapeutic value, if the child learns to peek around the covered or fogged lens. In that case, the eye patch is the treatment of choice (Fig. 28–3).

During occlusion therapy, the ophthalmologist examines the child at frequent intervals to evaluate the progress made by the weaker eye and to detect any possible loss of vision in the patched good eye. The duration of treatment is determined by the ophthalmologist. Nursing responsibilities include working with the family to find

FIGURE 28–3. In occlusion therapy, the child keeps one eye patched to strengthen the other eye.

ways to help the child accept the patching routine and thus strengthen the weaker eye. Gaining and keeping the child's cooperation is often a major challenge.

Medications

Antibiotics are used to treat bacterial infections of the eye and are administered topically as drops or ointment (Fig. 28–4) or systemically. Some infections, such as bacterial conjunctivitis may require treatment by both topical and systemic antibiotics. Corticosteroids, used topically or systemically, may be used to treat children's eye conditions when inflammation is present. Because steroid use (including ocular steroids) is associated with numerous side effects and complications, ensure that the child receiving this type of medication is seen by the ophthalmologist at regular 2- to 3-month intervals to check for side effects if long-term use of these medications is necessary. Decongestants, antihistamines, or a combination may be used topically or systemically to treat various

FIGURE 28–4. The nurse administers antibiotic eye ointment.

ophthalmologic conditions such as allergic conjunctivitis. These medications may be prescribed to reduce ocular congestion, irritation, and itching (Burns, Dunn, Brady et al., 2009).

In all cases, emphasize to parents the importance of using the medication according to directions, administering all doses each day, and finishing the prescription even if symptoms improve (see **thePoint**, Procedures/Interventions: Medication Administration: Ophthalmic). Warn older children and teenagers who may be self-administering the medication about the effects of using the medication more frequently than ordered. Additional information about administering ophthalmic medications is presented in Chapter 9.

Surgical Interventions

Surgical intervention may be necessary when the condition cannot be effectively treated with medical methods alone. Surgical alignment of the eyes may be considered for strabismus. Congenital cataracts are removed surgically, and laser surgery may be the treatment of choice for ROP, described later in this chapter.

Laser surgery, such as photorefractive keratometry and laser in situ keratomileusis, has been used in adults to correct refractory errors, but these procedures are considered experimental and are not approved by the Food and Drug Administration for children and adolescents younger than the age of 18. The procedures are difficult to perform in children because they must remain still and cooperative during the procedures. In addition, the eyes of children are still developing, and the refractive error remains in a state of change. The long-term effects of these procedures on a young child's eyes are unknown, so this mode of treatment is not generally recommended.

Preoperative and postoperative teaching is essential for the child and family. Ensure that the child and family understand what will be done and what to expect after surgery. Teach the child using age-appropriate terms. For example, toddlers may need to know that one eye (or both eyes) “will be covered up so it [they] can get better after the doctor fixes it [them].” In some cases, elbow restraints may be necessary postoperatively for a young child to prevent him or her from bringing the hands to the eyes, and visual therapy may be started very soon after the surgical procedure. Teaching for the family may include instructions for changing an eye patch or administering eye medications, or information about danger signs and symptoms to report to the healthcare provider.

ANSWER: In response to Abby and Ben's question regarding treatment, you might provide the following explanation: “In most cases of ROP, the child's vision can be improved by wearing glasses. In situations when the growth of vessels warrants aggressive intervention, laser surgery might be performed.”

TREATMENTS FOR HEARING PROBLEMS

QUESTION: If Gabriella is found to have a sensorineural hearing loss, is there treatment for this problem?

The most important “treatment” for hearing loss is prevention. With the increased use of MP3 players, iPods, and other audio technology, children and adolescents have become at increase risk for noise-induced hearing loss. Healthcare providers and parents can partner to teach children to curtail hearing loss.

When children are born with or incur hearing impairment, treatment focuses on securing care and therapy for the child to maximize use of the residual hearing. The healthcare team works with the family to enhance communication and facilitate the child's developing independence and self-sufficiency.

Other treatment measures for disorders that may alter hearing include medication administration, use of hearing aids, and surgery. Surgery may be indicated for reconstruction or cosmetic alteration of anatomic or structural defects. Surgical interventions may also be indicated to treat severe infections, and surgery is necessary when implanting certain types of hearing devices.

Prevention of Hearing Loss

A primary intervention of the healthcare team is to teach the family ways of preventing or minimizing injury to the ear or hearing loss. Routine health visits provide an excellent opportunity to discuss ear care with children and their parents (Nursing Interventions Classification [NIC] 28–1).

Review how to best clean the ear without causing damage to the sensitive tissues of the external canal. Urge parents and older children never to insert anything into the external canal. Advise them to clean the outer portion with a moist washcloth, leaving the cerumen in the external auditory canal to help maintain skin integrity inside the canal. Older children and adolescents may learn how to avoid infection at insertion sites on pierced ears by cleansing with soap and water if needed (see TIP 7–1 for more information about care of piercings). For the child who has excessive cerumen buildup, use of an over-the-counter (OTC) product may be recommended. This treatment may include drops followed by gentle washing with warm water and a bulb syringe.

In a survey conducted by ASHA (2006), more than half of the surveyed adolescents reported at least one symptom of hearing loss. Teach the child and parents about risk factors associated with hearing loss and how to minimize them, including preventing prolonged exposure to sound levels more than 85 dB. Inner ear cells are sensitive to vibrations, but excessive exposure to loud noise can damage the hairs in the cochlea (inner ear) and lead to hearing loss. This type of hearing loss often is reversible (except in some cases of sudden, very loud noise, such as an explosion). However, repeated exposure to loud noise

NIC 28–1 Nursing Interventions Classification: Ear Care

Definition: Prevention or minimization of threats to ear or hearing

Activities:

Position infant so ears remain flat to head
 Monitor for drainage from ears, as appropriate
 Irrigate the ear, as appropriate
 Avoid placing sharp objects in the ear
 Administer eardrops, as appropriate
 Instruct parents how to cleanse infant's ears
 Instruct parents to monitor child with nasal congestion for ear infections
 Explain the relationship between balance and the inner ear, as appropriate
 Monitor for episodes of dizziness associated with ear problems, as appropriate
 Instruct parents how to observe for ear infections in infant
 Instruct parents about importance of completing antibiotic regimen
 Instruct parents to hold baby upright when bottle feeding to avoid reflux into eustachian tubes
 Determine if cerumen in the ear canal is causing pain or hearing loss
 Instill mineral oil in the ear to soften impacted cerumen before irrigation
 Irrigate the ear canal with a Water-Pik on a low setting (or similar device) using warm water (80 to 90 °F), as appropriate

Demonstrate proper technique for ear irrigation to parents/caregiver, as appropriate
 Monitor frequency of ear infections
 Instruct parents about tubes as a medical treatment, as appropriate
 Instruct parents to avoid immersing child's ears in water with tubes present
 Instruct parents how to administer eardrops, as appropriate
 Instruct parents about the importance of routine hearing testing
 Instruct children not to put foreign objects in ears
 Instruct how to monitor and regulate high-volume noise exposure
 Instruct patient to wear hearing protection for exposure to high-intensity noise
 Instruct teenager concerning the potential danger of exposure to high-volume music, especially with headphones
 Instruct patient with pierced ears how to avoid infection at the insertion site
 Encourage use of ear plugs for swimming, if patient is susceptible to ear infections

From Bulechek, G., Butcher, H., & Dochterman, J. (Eds.). (2008). *Nursing interventions classification (NIC)*. St. Louis, MO: Mosby. Reprinted with permission.

can cause permanent damage and hearing loss, a condition known as *noise-induced hearing loss*. If the ears are damaged, they still record ringing or buzzing, even when there is no sound. Ringing in the ears, hissing, clicking, or buzzing sounds are all types of *tinnitus*, a common side effect of noise-induced hearing loss. A Web survey completed by 9,363 adolescents and young adults indicated, by Likert scale, that hearing loss was considered a “very big problem” by only 8% of the respondents. However, most respondents had experienced tinnitus or hearing impairment after attending concerts (61%) and clubs (43%). Only 14% of survey participants had used earplugs. A large number (66%) indicated they could be motivated to wear ear protection if they were aware of the potential for permanent hearing loss. The research indicates that poor use of ear protection among young people could be improved if the rationale for protection was explained (Chung, et al 2005).

Repeated OM infections also contribute to hearing loss. Reducing the incidence of respiratory tract infections in children, implementing breast-feeding for at least the first 6 months of life, avoiding supine bottle-feeding, and eliminating passive exposure to tobacco smoke have all been identified as effective in reducing the incidence

of acute otitis media (American Academy of Family Physicians [AAFP], American Academy of Otolaryngology–Head and Neck Surgery [AAO-HNS], & AAP, 2004).

Medications

Anti-infective drugs may be used topically in otic solution administered as eardrops when infections are present in the external auditory canal. Antibiotics may be given orally in liquid, chewable, or tablet form when the infection is located in the middle ear. Stress to the family that prescriptions must be given for the length of time prescribed or the child runs the risk of recurrence or complications resulting from incomplete eradication of the organism. It is not unusual, however, for the child to require more than one treatment period to recover completely from an ear infection even when the medication is given according to directions. Chapter 9 describes the technique for administering otic medications (see [thePoint](#), Procedures/Interventions for procedure on Medication Administration: Otic).

Antipyretics and analgesics are useful in treating fever and pain associated with ear infections. Cerumenolytics are medications used to soften cerumen impacted in the external auditory canal for removal. Acidic eardrops help to prevent growth of bacteria or fungi in the external ear, particularly in children who swim frequently during the summer months. Parents may choose to use an OTC product, placed in the child's external auditory canal after swimming, to prevent swimmer's ear or may use equal parts rubbing alcohol and white vinegar (Bluestone, Caselbrant, & Dohar, 2003).

Hearing Aids

Hearing aids are devices used to amplify sounds to assist a person with a hearing loss. They are distinguished by where they are worn: in the ear, completely in the canal, in the canal, behind the ear, body hearing aid, and cochlear implants (Chart 28–1). Except for cochlear implants, which enhance hearing for those with sensorineural hearing loss by directly stimulating any functioning auditory nerves inside the cochlea with electrical impulses, hearing aids provide amplification in the decibel range where the individual child has a deficiency. The hearing aid does not differentiate between voices and background noises. The child using the hearing aid learns to recognize sounds as they are received, which may be quite different from the sounds received by persons without hearing impairment (Fig. 28–5). The child may need to use lip-reading in addition to the amplification device. TIP 28–1 summarizes the instructions for a family with a child using a hearing aid. Cochlear implants are covered later in the chapter.

Surgery

Surgical intervention, to correct hearing impairments or enhance auditory functioning, may be a component of the treatment plan. Ear surgery is also performed to treat diseases, injuries, or deformities of the ear's auditory tube, middle ear, inner ear, and auditory and vestibular systems. Ear surgery is commonly performed to treat conductive

FIGURE 28–5. The child with a hearing aid.

CHART 28–1 TYPES OF HEARING AIDS

BTE (Behind the Ear)

- Suitable for all types of hearing losses, from mild to profound.
- Electronics housed in a case that fits behind the ear; tubing and a custom made earmold direct the sound to the ear canal.
- Most often recommended for children, exceptionally sturdy; not limited by the size of the child's ear.
- Made in several colors to match hair and skin tones.

ITE (In the Ear)

- Used for a wide range of hearing losses.
- Custom-made to fit the individual user's ear.
- Worn inside the ear; usually recommended for mild to moderate, or sometimes even severe, hearing loss.
- Available in several sizes; not usually recommended for young children (outer ears and ear canals are too small; still growing).
- Typically wear beginning about the age of 8 to 10 years and older.

CIC (Completely in the Canal)

- Smallest hearing aid style available, almost invisible in the ear.
- All components housed in a small case that fits deep into the ear canal.
- Takes advantage of the ear's own natural sound-collecting design; makes telephone use convenient.
- Suitable for mild to moderate hearing loss; not suitable for severe hearing loss.
- Most children's ear canals not large enough to use CIC devices; possibly appropriate for older adolescents.

ITC (In the Canal)

- A little bigger than the CIC; also fits deep into the ear canal.
- Uses a slightly larger battery than CIC devices.
- Used for mild to moderate hearing losses.
- Not suitable for young children because their ear canals are too small; possibly appropriate for older adolescents.

Body Hearing Aid

- Microphone, amplifier, and battery are housed in a small unit worn on the body. Ear mold is connected to a receiver connected by a cord to the hearing aid.
- Capable of providing powerful amplification.

Cochlear Implant

- Small electronic device surgically placed under the skin behind the ear.
- Restores partial hearing for person who is profoundly deaf or severely hard of hearing.

(Continued)

CHART 28–1 CONTINUED

- Unlike a hearing aid, does not make sound louder or clearer. Instead, the device bypasses damaged parts of the auditory system and directly stimulates the nerves of hearing, allowing individuals who are profoundly hearing impaired to receive sound.

hearing impairment, persistent ear infections, unhealed perforated eardrums, congenital ear defects, and tumors.

Surgery may be the primary mode of treatment, or it may be used when more conservative medical treatments have failed. Common types of ear surgery include stapedectomy, tympanoplasty, myringotomy, removal of tumors, and insertion of cochlear implants.

Ear surgery may also be performed for cosmetic purposes, to set disproportionately large or prominent ears closer to the head. This corrective surgery, called *otoplasty*, should be considered for ears that protrude more than four fifths of an inch (2 cm) from the back of the head. It can be performed at any age, but most commonly at 5 or 6 years of age, after the ears have reached full size. Having the surgery at a young age has two benefits: the cartilage is more pliable, making it easier to reshape, and the child will experience the psychological benefits of the cosmetic improvement.

Most ear surgery is performed with an operating microscope (microsurgery) to enable the surgeon to view the very small structures of the ear. The popularity of minimally invasive laser surgery for middle ear procedures is growing because it reduces the amount of trauma caused by vibration, enhances coagulation, and enables surgeons to access hard-to-reach places in the middle ear. Laser surgery can be safely performed in an outpatient operating suite.

TIP 28–1: A Teaching Intervention Plan for Care of the Child With a Hearing Aid**Nursing diagnoses and outcomes**

- **Disturbed sensory perception (auditory) related to hearing impairment**

Outcome

- Child will adapt to use of hearing aid to enhance communication ability.
- **Deficient knowledge: Care and management of hearing aid**

Outcome

- Child will learn to care for own hearing aid.

Teach Child/Family**General Information About Hearing Aids**

- Information concerning children's hearing aid (amplification devices) styles and selection (see Chart 28–1).
- Characteristics of children's hearing aid such as
 - Are not easily broken
 - Do not require resizing as the child grows
 - Has sufficient power to meet the needs of the individual child

Adjusting to a hearing Aid

- Both family and child need a period of time to adjust to the use and care of the hearing aid.
- At first, the amplification device may frighten the infant or confuse the older child.
- Some children may have physiologic responses, such as dizziness, when the amplification device is first used.

- An infant or child may require up to 30 days to adjust to wearing the hearing aid and attending to sounds.
- During and after the adjustment period, the infant or child must learn to assign meaning to sounds. Parents can help by making specific sounds to accompany pleasurable experiences.

Keeping the hearing aid working properly

- Examine the hearing aid daily, clean the ear mold, and test the battery.

Care of the Hearing Aid as the Child Matures

- By the age of 5 years, the child should be able to take on responsibilities for the care and maintenance of the hearing aid, which include:
 - Inserting and removing the ear mold and hearing aid
 - Notifying the parent or teacher when a battery change is needed or the unit is malfunctioning
 - Adjusting the volume in different acoustic environments
- When manual dexterity is present, taking on full responsibility for cleaning and testing the unit and for changing batteries

Contact Healthcare Provider if:

- Unit is not providing amplification as expected
- Ear mold is causing pain in the ear
- Child refuses to wear the hearing aid for any reason
- Ear mold or battery pack is broken

ANSWER: There is not a single treatment for sensorineural hearing loss. Amplification devices may be of some assistance. The primary focus of the intervention is to prevent the hearing loss from altering communication and the child's development of clear language.

Treatments for Communication and Language Problems

Treatment modalities designed to assist the child to overcome a communication disorder must necessarily involve a number of persons with whom the child comes into contact. This could include, in addition to the family, the primary care physician, nurse, audiologist, speech pathologist, speech therapist, daycare teacher or schoolteacher, school nurse, and social worker.

The primary roles of the nurse and the physician include identifying problems, providing encouragement and support to the child and family, and maintaining the child's general health. In the primary care setting in the office, clinic, or school, the nurse may participate in case finding as a part of well-child examinations or screening programs, may make independent observations, or may be responding to a parent's concern. Guidelines for referral when a child is found to have a communication impairment are found in Community Care 28–1.

The nurse may also be responsible for encouraging follow-up visits or for encouraging the parent, family, and child to adhere to the recommendations of the speech pathologist or audiologist.

In cases of communication disorder, the audiologist acts as a consultant to rule out or manage a hearing disorder. The audiologist can identify hearing disability and recommend the use of an amplification device (hearing aid) as needed.

The speech pathologist may provide a detailed description of the child's disability and plan a program of therapy to improve the child's communication ability. The speech pathologist may also provide the therapy or may delegate the daily or weekly therapy to a speech therapist.

Speech therapy may be provided in a private practice setting or in the school. Children assessed and identified with communication disorders and in need of speech therapy are provided services free of charge through their public school system. An individualized education program may be used to specify the child's learning needs and accommodations to enhance the child's classroom abilities. The school speech therapist will meet with the child during school hours, taking the child out of the classroom to work with them. Thus, the child's teacher and the school nurse are integral parts of the therapeutic team and should be kept fully informed of the program in progress. In addition the teacher will want to ensure that the child has opportunity to review and make up any class activities missed while the child was attending their speech therapy session. Chapters 2 and 12 provide further discussion about individualized education programs.

COMMUNITY CARE 28–1

Guidelines for Referral If Communication Impairment Is Suspected

Infancy

- Responsiveness to environmental sounds limited or absent
- Responsiveness to parental voice limited or absent
- Infant quieted by touch but not by voice
- Responsive vocalization limited or absent

Early Childhood

- Limited responsiveness to environmental sounds
- Does not seem to hear parental requests for their attention
- Does not use syllables or words
- Speech difficult to understand by 3 years of age
- Responds to visual cues but fails to respond to verbal cues
- Fails to follow directions when given verbally
- Inappropriate word usage for the age (e.g., vocabulary does not seem to grow with the child)
- Fails to use correct word endings (e.g., omits “ed,” “ing,” “s”)
- Fails to form sentences correctly
- Stuttering or tonal dysfluency

Middle Childhood

- Any of the previous concerns identified in early childhood
- Consistent failure to follow directions presented verbally
- Failure to use appropriate voice quality or tone of voice (e.g., too loud, too soft, abnormally high or low pitch)
- Inability to construct complete and accurate sentences
- Consistent errors in pronunciation of specific sounds
- Inability to respond with verbally appropriate terms in social and play situations

NURSING PLAN OF CARE FOR THE CHILD WITH SENSORY ALTERATIONS

QUESTION: Review Nursing Plan of Care 28–1. Which of the nursing diagnoses is most appropriate for the Goldman family at this time?

The nursing plan of care for a child with sensory alterations reflects the three-pronged scope of care in this area.

First, the healthcare team should perform developmental surveillance to monitor the normal and healthy development of a child's vision, hearing, and communication. Second, they should provide education to prevent illness and injury that could impair sensory function. Third, they should select a plan of care that reflects the individual needs of the child with a diagnosed vision, hearing, or communication disorder (Nursing Plan of Care 28–1).

Family adaptation to alterations in the child's sensory status will vary, based on the extent of the impairment and the healthcare resources available to the family. For instance, corrective lenses may appear to be a small and easy adjustment for the child and family to make to improve a child's vision. However, if that child is homeless, and the family lacks the resources to acquire corrective lenses and maintain annual visits to manage changes in vision, care management for the child can become more complex. The nursing plan must also always address the related physiologic, psychosocial, and educational factors. The attitudes of child and family toward the child's condition (i.e., psychosocial and emotional factors) greatly influence the child's ability to make the greatest use of his or her skills and abilities. Nursing Plan of Care 12–1 provides additional information to guide interventions when the child's sensory condition is identified as a lifelong chronic condition.

ANSWER: The most appropriate nursing diagnosis for Gabriella is compromised individual/family coping related to multiple adjustments secondary to child's diagnosis of vision, hearing, or communication impairments. At this time, the parents are the focus of intervention to enhance understanding, coping, and strategies to ameliorate the consequences of hearing loss.

ALTERATIONS IN VISION

Vision is one of the most important senses a child uses as he or she develops. Sight enables infants to bond with parents, explore their surroundings, move about, read, and interact with the world. Without the sense of sight, a child requires different approaches to and assistance in accomplishing developmental milestones. Children experience alterations in vision as a result of many conditions, including injury, refractive errors, eye muscle disorders, ROP, cataracts, glaucoma, and conjunctivitis. Refractive errors, conjunctivitis, and traumatic injury to the eyes are among the most common problems.

Refractive Errors

Visual images pass as light rays through the lens of the eye, bending so that the image focuses on the retina. The ability of the eye to focus an image clearly on the retina involves both accommodation and convergence. *Accommodation* is the eye's ability to change the shape of the lens so that the image, whether near or distant, is clearly focused on the retina. The ciliary muscles in the eye contract or

relax to change the bending (refractive) angle of the lens. *Convergence* is the movement of the eyes toward the midline and occurs as objects are brought closer. Convergence occurs simultaneously with accommodation to enable the visual images in the two eyes to be focused at the same position on the retina of each eye, allowing **binocular vision** (fusion of the images from the two eyes) to occur.

During childhood, the child's eyes grow physically. As the child grows and the globe or lens changes shape, the eye muscles may be unable to compensate for the change in shape. As a result the visual image focuses improperly in the retina, causing a refractive error that results in blurred near vision, distant vision, or both. The four types of refractive errors include *myopia*, *hyperopia*, *astigmatism*, and *anisometropia* (Table 28–1). Regardless of the type of refractive error, corrective lenses are used.

Strabismus

Each eye is controlled by six small muscles that move it into the six cardinal fields of gaze. These muscles must move with coordination and balanced strength so that both eyes can focus on the same location or object (binocular vision). Cranial nerves III, IV, and VI innervate these muscles.

Alert! Eye muscle disorders should not be ignored; ensure the child is assessed and treated as soon as concerns are identified, preferably before visual maturity at age 7 years.

Disorders of eye movement may be a result of damage to one of the innervating cranial nerves or to one of the eye muscles. If any of the muscles that control eye movement are stronger or weaker than the opposing muscle in the same eye, that eye deviates from the line of vision, and the child develops strabismus. Strabismus, also called *lazy eye*, is a common eye problem in children (Fig. 28–6). If the eye turns inward toward the nose, the child has **esotropia**; if the eye turns outward, **exotropia**. Mild or transient strabismus is frequently found in infants younger than 3 months old and resolves spontaneously as the child develops and the eye strengthens (Olitsky, Hug & Smith, 2007; Rubin, 2001).

Strabismus affects approximately 4% of children younger than age 6 years. As many as 30% to 50% of children with strabismus suffer permanent visual loss (Olitsky, Hug & Smith, 2007).

Pathophysiology

At birth, the development of the infant eye is incomplete. During the first 4 months of life, binocularity (both eyes working together) is not consistent, thus intermittent esotropia or exotropia may normally occur. Beginning at about age 4 months, as the eyes work together more consistently, divergence decreases, and binocularity increases. Eventually, the child sees a single, clear image. If the infant

NURSING PLAN OF CARE 28–1 FOR THE CHILD WITH SENSORY ALTERATIONS

Nursing Diagnosis: Disturbed sensory perception (visual, auditory) related to effects of altered sensory reception, transmission, or integration from visual or hearing impairment, or loss of vision or hearing

Interventions/Rationale

- Introduce self to child and family, acknowledging child's sensory impairment.
Orients child and helps reduce fears of being in unfamiliar environment.
- Assess vision/hearing/communication to determine child's functional capability. In-depth evaluation must be conducted by an optometrist, ophthalmologist, or otolaryngologist.
Vision and hearing loss may occur gradually or abruptly (e.g., an accident) and may not affect both eyes or ears to the same extent. Evaluation provides baseline data regarding the extent of the child's visual loss.
- Review with the child and parents the extent of the child's sensory impairment and management strategies the family has implemented to optimize the child's sensory perception.
Ensures that home interventions to enhance the child's sensory perception are maintained during hospital or clinic visits. Communicate this information on the plan of care to ensure that, even when parents are not present with the child, adaptive measures are implemented.
- Ensure that adaptive devices (e.g., glasses, contact lenses, magnifying glass, large-type books, and hearing aids) are accessible to the child and being used to optimize the child's vision and related visual activities.
Use of adaptive devices may be essential for the child's optimal visual and auditory functioning. Ensuring that these devices are available and used provides optimum sensory perception for the child.
- When implementing new visual adaptive devices, demonstrate proper use and allow for return demonstration by child and parent.
Ensures child and family will be able to use assistive devices at home and school.

Expected Outcomes

- Child will maintain sensory functioning at his or her highest level possible.
- Child will maintain optimal functioning within parameters of visual or hearing impairment, as evidenced by ability to care for self; navigate the environment safely; and participate in school, play, and family activities.
- Child will compensate for visual or hearing loss by using adaptive devices.
- Child and family will identify and use alternative methods to facilitate communication.

Nursing Diagnosis: Risk for delayed development related to lack of stimulation secondary to visual, auditory, or communication impairment

Interventions/Rationale

- Perform baseline assessment of child's achievement of developmental milestones. Reassess on routine basis following developmental surveillance guidelines (e.g., Bright Future Guidelines).
Baseline assessments provide an index upon which to determine whether child meets age-appropriate developmental norms. Reassessment provides ongoing information about child's ongoing development and improvements when interventions have been used.
- Modify approach to child based on sensory deficits (e.g., approach from unaffected side of visual impairment, use touch, and talk to child).
Interactions and interventions should be individualized to child according to abilities and not age.
- Increase/decrease stimuli and activities as appropriate to correct sensory deprivation/overload.
Sensory deprivation and overload may both be detrimental. Sensory deprivation does not allow the child to have experiences that may be critical for stimulating new learning and behaviors; sensory overload may cause the child to "shut down" to protect self and maintain control.
- Collaborate with the interdisciplinary team (social worker, physician, school nurse, and so on) to develop a plan for the child to participate in family, school, play, and social activities to maximum capability.
Provides additional support system for the family to ensure child's successful adaptation at home and school.

Expected Outcomes

- Child will attain age-appropriate developmental milestones within limits of functional abilities.
- Child will participate in family, school, and social activities using strategies that maximize child's sensory capabilities.
- Child's social development will progress according to developmental level.

Nursing Diagnosis: Risk for injury related to diminished sensory capabilities (vision, auditory, communication)

Interventions/Rationale

- Assess the environment to determine factors that may place child at risk for injury. Elicit parental feedback regarding ways to ensure a safe environment for the child.
Modifying the environment may enhance the child's sensory perception and maintain the child's safety. Examples of such modifications include increasing room

NURSING PLAN OF CARE 28–1 FOR THE CHILD WITH SENSORY ALTERATIONS (CONTINUED)

lighting, ensuring that the bed is located in a low position with unobstructed access to the bathroom, ensuring that the floor is free of debris, and increasing the ring tone volume on a nearby phone.

- Assess for dizziness or disequilibrium.
Disorders of the ear may be accompanied by dizziness because of the relationship between the inner ear and maintenance of equilibrium.

- Remove environmental barriers that may impede safe movement of child.

Child's ability to see environmental obstacles may be impaired because of sensory deficit.

- Modify approach to and interventions for child according to deficits and specific sensory deficit.
The child's ability to interpret the environment may be impaired by sensory deficits. Adaptations by parents (describing actions, writing in large print, speaking slowly) ensure that the child is not frightened by people and movement in the environment, and can manage and interact appropriately with his or her environment.

Expected Outcomes

- Child's safety will be maintained.
- Child will be able to participate in activities while maintaining freedom from injury.

Nursing Diagnosis: Risk for impaired verbal communication related to diminished visual cues, auditory cues, or communication disorder (e.g., language delays, articulation or fluency disorder)

Interventions/Rationale

- Assess child's primary and preferred method of communication (e.g., sign language, written); ability to understand spoken word, written word, pictures, and gestures; and ability to convey information. Assess conditions or situations (e.g., tracheostomy, intubation) that may impair verbal communication.

Communication may be impaired for a variety of reasons. Baseline assessment assists to determine the interventions that will have to be used to enhance communication with the child.

- Assess family's understanding of speech development and age-appropriate verbal milestones.
Lack of understanding of age-appropriate norms for verbal communication may create unrealistically high expectations for the child's communication patterns or an inability to recognize that a speech problem exists and intervention is necessary.
- Use measures to enhance child's ability to understand communications from others:
 - Verbalize what you are doing.

- Pause and wait for child to respond.
- Provide stimuli to optimize functioning of other senses (e.g., tactile, auditory, kinesthetic).
- Face child in good light, keeping hands away from your mouth.
- Speak close to child.
- Speak slowly and distinctly.
- Reduce environmental noise.
- Speak at normal volume unless requested to speak louder.
- Use short sentences and ask one question at a time.
- Avoid finishing sentences for the child.

Taking time to communicate with child will assist child to feel valued and less fearful of the healthcare provider and healthcare setting.

- Refer child and family to community services to provide corrective therapy for speech disorders.
Speech evaluation and therapy is available for all children age 3 and older from their local public school districts. Speech therapists provide in-depth evaluation of a speech impediment and use techniques to promote age-appropriate development of speech.

Expected Outcomes

- Child's ability to communicate will develop according to expectations for age.
- Child will produce understandable speech and communicate needs.
- Family members will demonstrate an understanding of verbal development in children and of alternative communication techniques.

Nursing Diagnosis: Ineffective coping or compromised family coping related to multiple adjustments secondary to child's diagnosis of vision, hearing, or communication impairments

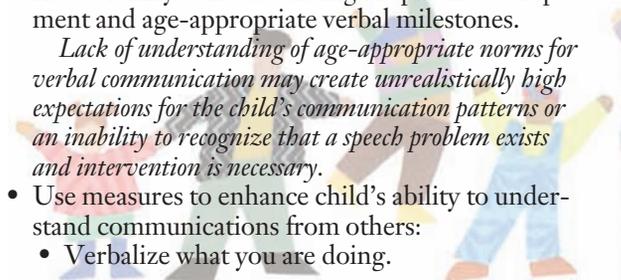

Interventions/Rationale

- Assess child's and family's understanding of child's condition, and anticipated short- and long-term outcomes.

Establishes family knowledge base and expectations of outcomes. Provides data upon which to engage family in teaching (as needed) and goal setting.

- Determine child's and family's psychological response to visual, hearing, or communication disorder.

Responses may vary from acceptance to anger, withdrawal, and depression. Self-esteem may be negatively affected, especially if child is teased by peers about eye-wear and visual limitations, wearing a hearing aid, or "talking funny."

- Explain tests and procedures, frequent assessments, and treatments in simple, concrete terms; repeat as necessary.

Knowing what to expect may help reduce anxiety, distress, and feelings of uncertainty.

- Keep family informed about child's progress.
Family is an integral part of child's care team. Regular updates on child's status assist parents in decision-making process.
- Use other healthcare personnel (e.g., child life specialist, clinical nurse specialist, social service worker) to assist child and family to cope with child's condition.

Child and family may need additional support services to effectively cope with the child's condition and to learn to manage home care.

Expected Outcomes

- Child will demonstrate appropriate use of coping mechanisms.
- Child will request help as needed and function independently when possible.
- Child and parents will effectively adapt to actual or potential altered abilities.
- Family will modify communication patterns to include new measures to communicate with the child.
- Family will use available support systems and coping mechanisms to adjust to their child's diagnosis.
- Child will demonstrate ability to communicate needs.
- Child will express decrease in frustration with regard to communicating with others.

is unable to achieve central fusion of the visual image, or if an eye muscle weakness or imbalance occurs possibly as a result of a congenital defect, systemic infection early in life, or intracranial injury, the eyes are unable to work together. The infant sees two images that cannot be merged (diplopia). The developing brain suppresses one image, and the infant develops amblyopia—functional blindness—in that eye. In many cases, however, appropriate therapy for strabismus can prevent this type of amblyopia.

Assessment

The assessment and diagnosis of strabismus is done during the routine eye examination (see Chapter 8, and Focused Physical Assessment earlier in this chapter). Suspect strabismus if

- The corneal light reflex is not symmetric
- Eye muscle movement is not smooth and consistent
- The cover–uncover tests demonstrate abnormal eye movement

FIGURE 28–6. Strabismus in an infant.

WORLDVIEW: Among certain ethnic groups, the bridge of the nose in infants and young children is broad. Some children may have asymmetric epicanthal tissue that may give the appearance of convergence (deviation toward the midline) of one eye. These children have an “extra” fold of tissue at the inner canthus of one eye. If they do not have a symmetric fold on the other side, one eye appears to be closer to the bridge of the nose. This variation may cause the examiner to suspect an eye muscle imbalance; however, if the corneal light reflex is symmetric, the eyes are properly aligned and the condition is called *pseudoesotropia* or *pseudostrabismus* and requires no treatment.

All deviations in eye muscle movement must be reassessed at each visit. If any deviations are accompanied by other symptoms that are new, such as ptosis of the eyelid or evidence of neurologic involvement, the child should be referred *immediately* to the eye care professional.

Nursing Diagnoses and Outcomes

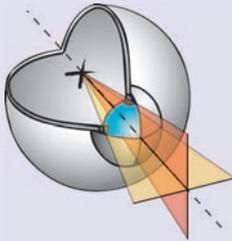

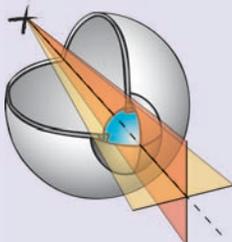

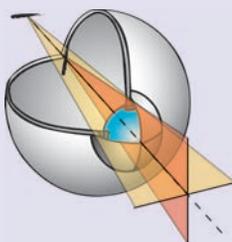

Nursing diagnoses that are useful in planning the care of children with strabismus focus on supporting the family in their decision to seek medical attention for the child, and in their efforts to adhere to any treatment protocol prescribed by the ophthalmologist. Assisting the family to adhere to treatment protocols may involve teaching them how to gain the child's cooperation by using principles of normal development.

KidKare ■ Make adherence into a game, in which the child gains rewards for wearing the patch or cooperating with the treatment protocol.

In addition to those listed in Nursing Plan of Care 28–, the following nursing diagnosis and outcomes may apply:

TABLE 28-1

Comparing Refractive Errors

Refractive Error	Description/Pathophysiology	Common Assessment Findings
Myopia	Nearsightedness Light rays focused in front of retina Development especially during preteen and early teenage years hereditary	No difficulty reading Inability to see distant objects clearly (such as blackboard) If severe, child holding printed page very close to eyes
		
Hyperopia	Farsightedness Short axial length (shorter than normal distance from lens to retina) or decreased lens curvature Image focused behind the retina Possible overcoming of hyperopia if child's eye able to change shape via accommodation	Ability to see clearly Eyestrain with close work such as reading Fatigue when reading or lack of interest in reading Squinting, rubbing eyes, tightly opening and closing eyes periodically Red, swollen eyelids
		
Astigmatism	Asymmetric shape and curvature of cornea	Eyestrain Blurring or distortion of images
		
Anisometropia	Refractive errors in both eyes that are considerably different; the two eyes unable to work together	Possible development of amblyopia if severe

Noncompliance related to inconvenience of care and age of the child

Outcomes: Child and family will adhere to treatment protocol as recommended by the ophthalmologist.

Child will experience no permanent visual impairment resulting from nonadherence to treatment protocol.

Interdisciplinary Interventions

Some cases of strabismus are obvious; others are detected by primary healthcare providers during routine examination. All should be referred immediately to an ophthalmologist for treatment. The earlier that treatment is initiated, the greater the likelihood of good visual outcome.

Occlusion Therapy

The most common treatment for strabismus is occlusion therapy (see Treatment Modalities, discussed previously). Vision in the stronger eye is occluded, continuously or intermittently, to improve the muscles of the weaker eye (see Fig. 28–3). Adherence depends on striking an acceptable balance between occlusion and nonocclusion time, which may have to be explained carefully to and negotiated with the child.

Surgery

Surgical correction of strabismus may be necessary depending on the child's condition and the success of occlusion therapy. It involves an eye muscle procedure designed to realign the eyes and enable binocularity to develop. Forbes and Khazaeni (2003) suggest that surgery is most successful if done between 4 and 24 months of age. See Chapter 11 regarding preoperative and postoperative care of the child.

An eye patch may be needed during the first day or few days after surgery to remind the child not to rub or put pressure on the eye. If the child is young, elbow restraints may need to be provided to the family to place on the child to prevent the child's hands from contacting the eye. Pain is seldom a problem; however, acetaminophen or ibuprofen may be given as needed.

Botulinum Toxin Injections

An alternative treatment being tested with some types of strabismus is injection with botulinum toxin to temporarily weaken the stronger muscle, allowing the weaker muscle to strengthen (Marsh, 2003). With this treatment, some children achieve **orthotropia** (alignment of the eyes) in 2 to 4 weeks. The effects of the treatment persist for 5 to 8 weeks, and it may have to be repeated before orthotropia is permanently achieved (Forbes & Khazaeni, 2003).

The injections are performed under local or general anesthesia, with general anesthesia preferable for children. Complications can occur if, when injected, the solution diffuses into the orbit, affecting other extraocular muscles, leading to ptosis or secondary vertical strabismus. To minimize side effects, the child should be positioned vertically during and after injections (Chatzistefanou & Mills, 2000). An expected side effect is soreness in the area that was injected. Ask parents to notify the healthcare provider if they notice any adverse side effects after the injections.

Community Care

When a child who is undergoing occlusion therapy is in daycare or in school, patching is monitored by teachers, volunteers, and the school nurse. Each of these adults needs to be knowledgeable about the purpose for eye patching and informed of the plan for the individual child. The school administrators need to be fully informed and have a written copy of the treatment plan in the school file.

The purpose of patching is to stimulate visual development in the nonoccluded eye, not to treat some malady of the patched eye, as some would believe. The child should be able to maintain consistent progress in school during treatment. If, however, wearing the eye patch during school hours prevents the progress of the child's education, the treatment plan needs to be reevaluated by the ophthalmologist.

The teacher and daycare providers may need to discourage teasing and educate the other children concerning the reason that the child wears the eye patch. Other children can learn to be a help rather than a hindrance in the treatment program and in the continued social development of the individual child.

The teacher or school nurse may need to replace the patch during the school day. A conference between teacher and parent (and school nurse, if possible) can ensure that supplies (which the parent can provide) are available and that school protocols are in place for the child to have the patch changed. The patch is put on loosely, but not so loosely that the child can peek around it. It is secured with nonirritating tape and may be decorated with drawings, stickers, or sequins. Channels of communication must be clarified with the school so that changes in the treatment plan can be implemented promptly and accurately, and so that nonadherence is reported to the parent without delay. Nonadherence could result in reevaluation of the treatment protocol, or it may simply be discussed with the child to establish the reason for it. Children may need rewards for adherence. If wearing the patch is a game, or it can be decorated or regarded as part of the child's clothing, adherence will be much easier.

Amblyopia

Amblyopia is diminished effective vision in one or both eyes, even with use of proper optical correction. Amblyopia results from altered or abnormal visual development despite apparently normal retinal and optic nerve anatomy (Rubin, 2001). The incidence of amblyopia may be higher than usual among some groups of children, such as those born prematurely, children of drug-dependent mothers, and children with other neurologic impairments.

Amblyopia is often preventable, yet many children with the condition are not identified until permanent damage has already occurred. Amblyopia is difficult to identify in infants; it is much more easily identified when children are old enough to follow directions and to make simple choices. However, waiting for the child to grow

old enough to cooperate can jeopardize vision in the affected eye.

Because amblyopia is usually asymptomatic, a complete ophthalmologic examination is necessary to confirm the diagnosis. Examination reveals reduced visual acuity but fails to identify any organic abnormality.

caREminder

If vision is obstructed for an extended time (e.g. due to cataracts), amblyopia and loss of vision can develop in any infant or child younger than age 7 years. For this reason, obstructions to vision should be resolved as soon as possible.

Pathophysiology

The critical period for visual center development in the brain is birth to age 6 or 7 years. During the first 6 months of life, the neurologic pathways between the eyes and the visual centers of the brain mature, and binocular vision is achieved; the brain merges the images from the two eyes, allowing a single image to be perceived. Normally, these images are focused on the macular portion of the developing retina. If images are not focused on similar locations on the retina of each eye, the brain perceives a blurred image and reacts by suppressing vision in one eye. As a result, the portion of the brain associated with that eye is not stimulated and does not develop, leading to functional blindness in that eye. Similarly, if a congenital cataract prevents the image being transmitted to the brain from one eye, amblyopia can result. The longer visual suppression continues, the less reversible it becomes.

Amblyopia does not develop after the critical period for visual development is over, so it does not develop in an older child or adult who sustains an injury that causes eye muscle imbalance. Amblyopia can be subdivided according to its primary cause: deprivation, strabismic, or refractive. In each case, the visual image from the weaker eye is ignored by the visual center of the brain.

Assessment

Early identification of amblyopia is essential. Assessment of vision should begin with the first contact between health professional and family, and should continue regularly throughout childhood (Developmental Considerations 28–1). Photoscreening has been suggested as a technique for screening children with risk factors associated with amblyopia who are difficult to assess because of their age and inability to cooperate with visual testing (e.g., infants, young children, and children with developmental delays) (AAP, 2002; Kerr & Arnold, 2004).

When diagnosed, testing of visual acuity assesses the effectiveness of treatment. As the amblyopia improves, visual acuity improves in the affected eye.

Interdisciplinary Interventions

The goal of treatment for amblyopia is to stimulate normal visual development. The earlier the condition is

identified and treatment is begun, the greater the likelihood of a positive outcome. Treatment of the child with amblyopia should address its underlying cause and includes occlusion therapy (see Treatment Modalities earlier in this chapter) and surgical correction of any related problem, such as strabismus, ptosis, cataract, or other anomaly. Occlusion therapy is usually the treatment of choice.

Because development at young ages is more rapid, improvement may occur more quickly if the child is quite young when treatment begins. Although the best time to treat children with amblyopia is when they are younger than 7 years, Mohan et al. (2004) found significant improvement in visual acuity among children 11 to 15 years of age who had amblyopia caused by strabismus, anisometropia, or both and who adhered to full-time occlusion. This type of research provides hope for children who are well beyond the age at which it was thought that no further improvement could occur.

Community Care

Intervention for the child with amblyopia must always be a cooperative effort among all persons who come into daily contact with the child. This group may include not only parents and healthcare professionals, such as the pediatrician, family physician, ophthalmologist, optician, and nurse or nurse practitioner in the office, clinic, or school, but also schoolteachers or daycare providers, all of whom need to know the treatment protocol being used and their responsibility in assisting the child and family to comply with it.

Conjunctivitis

QUESTION: Gabriella received a ribbon of erythromycin ointment in each eye at birth. Newborn eye prophylaxis is a state requirement. What organisms cause conjunctivitis and why do all babies receive treatment instead of just the infected ones?

Conjunctivitis is an inflammation in and around the eye. It may be of bacterial, viral, allergic, or irritative origin. It occurs in a child of any age. The younger the child, the greater the likelihood for severe damage resulting from an eye infection. Conjunctivitis is usually less severe in older infants and children than it is in neonates. Table 28-2 summarizes the major types of conjunctivitis.

Neonatal conjunctivitis, also called *ophthalmia neonatorum*, is a broad term applied to the ocular reaction of newborn infants in response either to a viral (such as herpesvirus, cytomegalovirus) or bacterial invasion (most commonly *Chlamydia trachomatis* or *Neisseria gonorrhoeae*), or to the chemical substance instilled at birth to prevent the bacterial invasion. The chemical substances currently in use worldwide to prevent bacterial invasion include silver nitrate 1% drops and erythromycin

DEVELOPMENTAL CONSIDERATIONS 28–1

Screening for Amblyopia

Birth to Age 4 Months

History: Pay close attention to parents' concerns about the infant's vision.

Inspection: Face and eyes should appear structurally normal:

- Eyes symmetric
- Lids open and close completely
- Color of pupil is variable
- Sclera white (without blue tinge)
- No drainage; no excessive blinking or tearing

With ophthalmoscope or penlight

- Identify red reflex
- Infant should “fix” vision on light source and briefly follow the light as it is moved

Age 4 to 12 Months

History: Continue to seek parental reports of observations, which may indicate abnormal vision.

Inspect eyes for symmetry and normal appearance, including color of sclera and absence of drainage or excessive tearing.

Observe for symmetric corneal light reflection.

Identify red reflex again.

Do funduscopic examination if possible.

Between Age 6 Months and 3 to 4 Years

Begin to attempt further eye examination.

Observe behavior during cover–uncover testing.

Greater agitation when one eye is covered could indicate that the child does not see equally well with both eyes.

Attempt to get the child to fix vision on an object with each eye separately and to follow its movement.

By Age 4 Years

The child will probably be able to cooperate with the examiner who performs standard measures of ocular movement and visual acuity.

Testing should include measures of visual acuity in each eye separately as well as in both eyes together.

Middle Childhood

Vision should be checked annually. As physical growth and development occur, ocular changes may occur as well. Visual acuity significantly affects school performance and social adjustment.

School-aged children are anxious to please the examiner. Be particularly alert for “peeking” around the occluder card or other means of “cheating,” such as memorizing the chart in use by watching other children taking the test.

0.5% or tetracycline 1% drops or ointment (Simon, 2003; Teoh & Reynolds, 2003). Erythromycin and tetracycline drops or ointment may also cause a mild reaction, although such reactions are rare. Povidone–iodine 2.5% drops are used in developing countries because they are inexpensive and easy to store. They turn the conjunctiva brown for a short time but cause less ocular reaction than other prophylactic agents (Isenberg, 2002). Although effective against bacterial conjunctivitis, povidone–iodine 2.5% drops seem to increase the risk of acquiring chlamydial conjunctivitis. Thus, additional measures would need to be used to prevent mother-to-fetus transmission of chlamydial infection (Ramirez-Ortiz, Rodriquez-Alvarez, Ochoa-DiazLopez, et al., 2007). Ophthalmia neonatorum presents as an inflammation of the conjunctiva with redness, swelling, and purulent discharge (Fig. 28–7). Symptoms vary from mild to severe. The severity of the symptoms is not an indication of the causative organism.

Alert! Gonorrheal conjunctivitis is a medical emergency. Any newborn with eye drainage should be referred immediately to a pediatric ophthalmologist.

Conjunctivitis in older infants and children is usually either infectious (bacterial or viral) or allergic in origin. Eye drainage cultures and sensitivity studies are used to identify the organism (Clinical Judgment 28–1). Allergic conjunctivitis may be a reaction to allergens carried by air currents or carried to the eyes by soiled hands, or a reaction to substances placed in the eye for other purposes.

Conjunctivitis in infants and children must be identified and treated without delay. Consider any eye drainage that is yellow and sticky as contagious because this could indicate an infection. To clean the eye, instruct parents to wash their hands carefully with soap and water before

TABLE 28-2

Types of Conjunctivitis

Type	Description/Etiology	Assessment	Interventions
Neonatal conjunctivitis (ophthalmia neonatorum)	<p>Ocular reaction of newborn infants in response to viral or bacterial invasion or to the chemical substance instilled at birth to prevent bacterial invasion</p> <p><i>Chemical:</i> silver nitrate 1%, erythromycin 0.5%, or tetracycline 1%</p> <p><i>Bacterial:</i> <i>Chlamydia trachomatis</i> (most common), <i>Neisseria gonorrhoeae</i></p> <p><i>Viral:</i> herpesvirus, cytomegalovirus, other viruses</p>	<p>Variable symptoms ranging from mild to severe</p> <p>Maternal history related to prenatal care and exposure to sexually transmitted infections and treatment</p> <p>Generalized response: elevated or subnormal temperature, lack of interest in feeding, increased irritability</p> <p><i>Chemical:</i> usually within 24 hours after eye prophylaxis; redness, irritation, negative cultures of drainage</p> <p><i>Gonorrhoea:</i> conjunctival inflammation and purulent discharge within 3 to 5 days of birth; fussiness, crying, especially when cleaning or examining eyes; possible progression to corneal ulcerations and destruction of ocular structures leading to scarring and blindness if left untreated</p> <p><i>Chlamydia:</i> mild to moderate erythematous conjunctiva, moderate to large amounts of discharge within 5 to 14 days of birth; positive cultures (as early as 1–3 days after birth); fast spreading to other body organs such as lungs and gastrointestinal tract, leading to otitis media, pneumonia, rhinitis; possible isolation of organism in newborn's feces</p> <p><i>Herpesvirus:</i> discharge, inflammation usually appearing during second and third weeks of life; mouth or skin lesions</p>	<p>Frequent cleansing of eye with normal saline</p> <p>Administration of topical agent (drops or ointment)</p> <p>Referral to ophthalmologist</p> <p>Infection control measures to prevent transmission</p> <p>If large amount of drainage present, hospitalization, intravenous or intramuscular aqueous penicillin or other antibiotic; hourly eye irrigation with normal saline until drainage subsides</p> <p>Ceftriaxone to newborn and mother if culture positive for <i>N. gonorrhoeae</i></p> <p>Parental education about medication administration, eye cleaning, and follow up appointments</p>

		<p>licular hyperplasia (in older children); other signs of viral illness or gastrointestinal symptoms</p>	<p>hands away from eyes and no rubbing, cleaning infected eye), administration of eye drops or ointment, comfort measures</p> <p><i>Bacterial:</i> broad-spectrum topical agent until organism identified; possible oral antibiotic; parenteral antibiotics if other routes unsuccessful or treatment adherence is questionable; aqueous penicillin given parenterally as drug of choice for gonococcal conjunctivitis</p> <p>Child considered contagious until he or she treated for 24 hours; usually kept out of school until cleared</p> <p><i>Viral:</i> usually self-limiting; possible topical antibiotic to prevent superinfection; cool, moist compresses for comfort</p>
Allergic conjunctivitis	<p>Seasonal, induced by airborne antigens such as ragweed or pollen; year-round resulting from animal dander, dust mites, or other ever-present allergen</p> <p>Sole manifestation of child’s allergy or possibly accompanied by respiratory or dermatologic responses.</p> <p>Irritation from contact lenses or use of makeup that causes an allergic reaction</p>	<p>History of allergy to foods, medicines, environmental triggers, rhinitis</p> <p>Bilateral</p> <p>Eyelid swelling</p> <p>Watery or clear stringy, mucous discharge</p> <p>Inflamed conjunctiva</p> <p>Itching</p> <p>Rhinitis and related nose and throat symptoms</p> <p>Culture of drainage positive for eosinophils</p>	<p>Medications to treat symptoms and prophylaxis: topical, systemic, or both</p> <p>Vasoconstrictor eye drops (used sparingly and no longer than 3 days)</p> <p>Antihistamine and mast cell stabilizer eyedrops; oral antihistamines</p> <p>Artificial tears to soothe and cool the eye</p> <p>Education related to elimination or avoidance of pollen related allergies; measures to reduce exposure to triggers such as cleaning procedures for removal of dust mites or animal dander, restriction of pets</p> <p>Removal of contacts until redness and irritation has ceased</p>

and after wiping the baby’s eyes. Wipe away the drainage with a clean tissue, working from the nose toward the temple. Use a clean spot on the tissue for each motion across the eye. Use a new tissue to wipe the other eye.

For most conjunctival conditions, a topical agent (drops or ointment) is prescribed. Ointments are preferred for bacterial conjunctivitis, because treatment requires fewer

doses over a shorter period. In addition, prescription ointments do not sting or burn and are not absorbed systematically to the extent that drops are. If the conjunctivitis is related to an allergic response, artificial tears can be used to soothe and cool the eye and possibly decrease the amount of allergen in the eye (Rosenthal, 2004b).

FIGURE 28–7. Neonatal conjunctivitis. A purulent, yellow discharge is noted draining from the conjunctiva.

caREminder

The family must learn how to instill the eye ointment so that a maximum amount is spread across the conjunctiva. Teach them to keep the tube at room temperature and to help the child to hold the eye open while a thin line of ointment is spread along the lower conjunctival sac. The child should be encouraged to blink several times to spread the ointment, then to hold the eyes lightly closed for a short time.

Emphasize that it is critical that good handwashing techniques are used with this procedure, before and after instilling the medication.

Teach parents to prevent other children from coming into contact with the infected child or eye drainage until an infection has been ruled out or an antibiotic has been given for 24 hours.

ANSWER: Several sexually transmitted infections cause conjunctivitis and may cause subsequent blindness, including gonorrhea and chlamydia. The presence of these organisms is not always known at the time of delivery. Most states have therefore legislated the mandatory but fairly benign treatment of all babies to protect a few from blindness.

Eye Injuries

Eye injuries include those caused by accident, abuse, sports participation, fire, chemicals, or ordinary everyday play. In addition, chemical ingestion (e.g., antifreeze) or disease processes (e.g., hydrocephalus with shunt failure) may cause injury to structures of vision. Healthcare providers and adults alike need to be alert to the potential for

CLINICAL JUDGMENT 28–1

The Child With Eye Drainage

Cindy is a nurse practitioner who provides healthcare services to a number of daycare facilities. She receives a call from a daycare director regarding Daniel, age 4, who awoke from his nap and was unable to open his eyes because of the presence of crusty exudate. After Daniel's eyes were cleansed with a wet, warm cloth, Cindy was called. Cindy goes to the daycare center to see Daniel.

Questions

1. What other questions regarding Daniel's status should Cindy ask the daycare director at this time?
2. What actions should Cindy recommend be taken with Daniel?
3. What is Daniel's diagnosis?
4. What treatment measures should be instituted at this time for Daniel and the other children at the daycare center?
5. How would Cindy determine that Daniel's condition has improved?

Answers

1. Does he have a fever? Does he have any known allergies? Has any drainage been observed before

this event? What color is the eye drainage? Has Daniel been rubbing his eyes frequently? Is he receiving treatment at home for this condition or for any other health problem? Do any family members or other children or workers at the daycare center have an infection?

2. Cindy should complete a physical assessment of the eye noting signs of redness, and the amount, color, and consistency of eye drainage. Recommend to the parents that a culture of the eye drainage be completed.
3. Conjunctivitis of unknown etiology until culture results are returned. Yellow, purulent eye drainage indicates a likely bacterial cause. A watery discharge would indicate a viral conjunctivitis.
4. Antibiotic therapy should be ordered for a bacterial infection. The child should not return to daycare until treatment has been initiated for 2 days. Towels, clothing, or pillows that have contacted the child's eyes should be washed. Viral conjunctivitis is usually self-limiting. A warm compress may also help decrease pain and discomfort.
5. Absence of eye drainage and fever.

ocular and visual damage in each of these situations and to do everything possible to prevent visual loss by preventing accidents and injury.

According to the AAP Committee on Sports Medicine and Fitness (2004), of the 42,000 sports- and recreation-related eye injuries during the year 2000, 43% occurred in persons younger than 15 years of age. A U.S. emergency room treats eye injuries due to sports every 13 minutes. Though most of these injuries occur to those age 25 and younger, only 15% of children wear protective eye wear during sports activities (PBA, 2007).

The incidence of various types of eye injuries varies with the age and sex of the child. Ocular injuries occur more frequently to boys than to girls (Forbes, 2001; Tomazzoli, Renzi, & Mansoldo, 2003), presumably because of the more active nature of their play. Young children are prone to falls and sustain traumatic injuries from toys, scissors, or furniture more often than children in other age groups. They are also more likely to ingest toxic products such as antifreeze (methyl alcohol) and may spill chemicals on themselves, causing injury.

During early and middle childhood children are inquisitive and very active. Eye injuries are most often caused by participation in a sports activity or other extracurricular activity without the necessary protection. School-aged children and teenagers may use sports equipment, guns, common tools, or toys to inflict injury on their peers. Children may also sustain blunt force injuries inflicted by another child's hand or foot. Glue injuries of the cornea and eyelashes are increasingly common in middle childhood (Forbes, 2001).

An increasing source of ocular injuries among children in recent years is from youth participating in the sport of paintball. In a national study, the rate of ocular injuries from paintball more than doubled between 1998 and 2000. More than 40% of these injuries (1,200) were to children, most of whom were playing in unsupervised settings and with no eye protection. The AAP and others have recommended the development of rules and regulations for sale and use of paintballs to protect children's vision in the future (AAP, 2004; Listman, 2004).

KidKare ■ Participants in paintball "war games" should always wear approved face shields with eye protection and be supervised by adults. Be sure to discuss these concerns with parents.

Eye injuries may also be caused by fire burns, fireworks, or other explosives such as chemical mixtures that children or teens experiment with or encounter. Fireworks can cause burn injuries in and around the eyes, contusions and lacerations of the eye, and penetrating injuries from exploding debris. Of all persons with burn injuries, 30% sustain burns to the head and neck. When tissues surrounding the eyes are burned, edema may cause the eyelids to swell shut. This condition is not only

frightening to the patient, but also makes assessing the eye difficult.

Abuse must be ruled out in any injury sustained by a child. Calzada (2003) found that ocular injury (traumatic hyphema) can be the result of corporal punishment with a belt that accidentally strikes the child in the face. Shaken baby syndrome has different, but distinctive, effects on the retina and often results in blindness caused by bilateral retinal hemorrhages and bleeding into the vitreous humor (Blumenthal, 2002; Forbes, Christian, Judkins et al. 2004).

Pathophysiology

Eye injuries are classified according to the anatomic parts involved: extraocular, anterior globe, or posterior globe injuries. *Extraocular injuries* include eyelid lacerations, soft-tissue injuries with bruising, or fractures of the orbit. *Anterior globe injuries* are subdivided according to whether they are perforating or nonperforating injuries. *Nonperforating injuries* include corneal abrasions, foreign bodies on the conjunctiva, subconjunctival hemorrhage, and hyphema (Olitsky, Hug & Smith, 2007). *Perforating anterior globe injuries* include ruptured globe, perforated cornea, and conjunctival laceration. *Posterior globe injuries* include retinal edema, vitreous hemorrhage, and retinal detachment. Injury to the posterior globe often is accompanied by injury to the anterior globe or extraocular structures as well.

A common injury in childhood is the blunt force injury, which causes hemorrhage in and around the eye. When bleeding occurs around the eye (extraocular), it causes discoloration, commonly known as a *black eye* (Fig. 28-8). When small blood vessels of the conjunctiva are

Alert! A large amount of bleeding into the globe of the eye, called *hyphema*, could result in increased intraocular pressure. Ensure that this injury is examined by an ophthalmologist as soon as possible. Increased intraocular pressure could damage the optic nerve.

torn by an injury, subconjunctival hemorrhage may be seen as redness across a portion of the conjunctiva.

Facial burns from a chemical or fire may affect the eyes; however, eyes are usually well protected by the eyelids, which can close in 1/30th of a second, thus protecting the cornea. Most eye burns are caused by chemicals seeping into the eye or by sudden explosions involving steam or debris.

Eye injuries caused by blunt force (a blow to the head) or by repeated reciprocal movements of the head, as occurs when an infant or child is shaken, result in retinal tearing or intracranial bleeding involving the visual center located in the occipital region of the brain. These are injuries to the posterior globe, optic nerve, and brain parenchyma (Levine, 2004).

Paintball injuries are often severe, because the size of the paintball (14 mm) enables it to slip past the bony orbit and hit the globe with much of the force with

FIGURE 28–8. Eye injuries can cause temporary loss of vision as a result of swelling and bruising of the orbital area.

which it was propelled out of the gun, even though the eyelid closes spontaneously. Paintball injuries include hyphema (77%), retinal detachment/tear (27.5%), cataract development (28%), vitreous hemorrhage (33%), and ruptured globe (4.7%) (Listman, 2004). These are serious injuries, with poor visual outcomes. Visual acuity after treatment reached only 20/200 or worse in 43.1% of patients in one study, and only 44% had a satisfactory visual outcome (20/40 or better) (Listman, 2004).

Assessment

Assessing an eye injury begins with a detailed history of the events leading to the injury, to identify the possible injuries the child may have sustained and the possible elements involved. Identification of the location and extent of the injury is made by the physician with appropriate diagnostic testing.

Diagnostic testing may include facial radiographs to identify possible orbital fracture, and retinal examination to identify internal eye injury, damage, or bleeding into the eye. Computed tomography is helpful in identifying injury-related conditions that are not visible on x-rays.

Assessment for injury by chemicals and debris must be made very early during the treatment process to prevent corneal abrasion and burning. Chemicals should be washed away with copious amounts of water, and the debris should be removed immediately because edema of damaged tissues quickly makes both washing and examination difficult.

caREminder

Trauma victims who are unconscious when admitted to the healthcare facility should have their eyes cleaned as soon as possible if injury to the eyes is suspected.

Interdisciplinary Interventions

The provider of first aid must follow appropriate protocols for removing small foreign bodies from the eye by everting the lid and using a cotton-tipped applicator to lift the foreign body from the surface of the conjunctiva. If the damage is more extensive, the person providing first aid should encourage the child to close and cover the eye, keeping movement of the eye and lid as still as possible. For chemical injuries, the first-aid provider begins the washing process prior to arrival of trained emergency technicians. Wash the eye with copious amounts of flowing water. In the case of injury with a blunt object, the first-aid provider will cover the eye and transport the child to a care facility. Most eye injuries require a follow-up visit to an ophthalmologist. Because of the intricacy of eye structure, even small injuries in a growing child can result in larger problems at a later date.

Community Care

In most cases, eye injuries are preventable. Children need to be encouraged to use safety equipment designed for specific sports or activities and to avoid misusing sports equipment, tools, and common objects as pencils, blackboard erasers, sticks, stones, rubber bands, balls, paper wads, and toys (Fig. 28–9). Nurses, teachers, parents, and primary healthcare providers play key roles in stopping dangerous activities and in

FIGURE 28–9. Safety equipment helps protect the child's eyes during sports activities.

COMMUNITY CARE 28–2

Preventing Accidental Eye Injuries

At Home

- Always set a good example by using safety equipment and following safety rules.
- Begin childproofing the home as the infant becomes more mobile. Pad the corners of low tables (or temporarily remove the low table).
- Prevent access to toxic chemicals and cleaning supplies. Store them in a locked cupboard, well out of reach or outside the house where child has no access.
- Prevent access to automobile or lawn and garden chemicals, which the child may decide to taste.
 - Antifreeze smells and tastes good; however, ingestion can be lethal.
 - Garden chemicals often feel like coarse sand and come with colored pellets; however, they contain toxic substances.
- Prevent access to lawn and garden equipment that could cause injury.
 - Do not let young child ride on the riding mower.
 - Avoid letting the child play in the lawn while it is being mowed, because flying debris can hit the child. When debris is thrown into the eye with the force of a mower, damage can occur.
- Buckle children securely into automobile safety seats and buckle the seat into the vehicle according to manufacturer's instructions. Teach older children to use seat belts correctly.
- Provide the child with age-appropriate, safe toys and play equipment.
 - Avoid toys with sharp points, sharp edges, shafts, spikes, or rods.
 - Avoid giving BB guns, pellet guns, bows and arrows, or darts to children as toys.
 - Keep toys meant for older children away from younger children.
- Teach children safety with toys and play equipment.
 - Avoid throwing toys.
 - Do not use toys as weapons.
 - Never pretend to point a gun at another person.
 - Avoid swinging on the swing when another child is too close.
 - Do not run while carrying any sharp or pointed objects—for example, scissors or sticks.
- Teach older children the proper use of safety equipment designed to prevent eye injuries.

- Wear protective glasses when using a string trimmer or other lawn and garden tools and equipment.
- Wear protective glasses when preparing and dispensing household or other lawn and garden chemicals.
- Follow the directions when preparing and using any equipment or chemicals.
- Teach older children proper use of safety equipment designed to prevent eye injuries.
 - Wear helmets for inline skating and bike riding. Be sure that the helmet fits well enough to allow the child to see where he or she is going.

At School

- Set a good example for safety.
- Teach proper use of playground sports equipment—for example, swing sets with soft material (fabric or leather) seats, proper use of sliding boards.
- Consistently require appropriate use of classroom equipment—for example, scissors with rounded ends for young children.
- Set protective rules and require compliance.
 - Do not throw sand, toys, or other missiles.
 - Never hit another person in the face (or anywhere else).
 - Use school supplies (e.g., pens, pencils, rulers) for their intended purpose.
 - No throwing of any supplies or equipment.

During Sports Activities

- Consistently require the appropriate use of sports safety equipment.
- Teach proper use of equipment for organized sports activities and backyard or street sports.
- Use protective gear supplied.
 - Use batting helmets with polycarbonate face protector in youth baseball.
 - Use helmets with face protectors or face guards for ice and street hockey, football.
- Abide by the rules.
- Assign penalties for violation of the rules.
 - Hockey sticks are to be kept low, not used as weapons.
 - Bike helmets are to be worn whenever riding a bike or scooter.

educating and discussing ways to help children adopt behaviors that avoid endangering eyesight of themselves and other children (Community Care 28–2). Providing information to the child concerning potential danger

can help the child in his or her own decision-making process. Safety can become an internal motivator rather than a condition externally imposed by the parent or other adult.

Sports are classified as high risk, moderate risk, or eye safe based on the risk of eye injury to the unprotected player. The AAO (2003) and the AAP (2004) recommend protective eyewear use, including polycarbonate face shields, in any sport in which risk of eye injury exists (see [thePoint](#), Evidenced-Based Practice Guidelines). The incidence of all types of injuries from high-impact sports (e.g., skateboarding, roller blading) is lower when participants wear safety equipment (Levine, 2004).

KidKare ■ Wearing a helmet while riding a bike is the law in many states. Help children to remember to do so. This may help protect their head as well as other parts of their face from injury.

Protective eyewear should be mandatory for any sports participant who is either “functionally one eyed” or who has had eye surgery or trauma and whose ophthalmologist recommends eye protection. “Functionally one eyed” is defined as anyone who has visual acuity of 20/40 or worse in the eye with the poorest vision (AAP, 2004).

Retinopathy of Prematurity (ROP)

QUESTION: As Gabriella’s nurse, you know that she has ROP and you know her parents are worried about how well she will be able to see. What are some of the roles that you can fill to meet the needs of Gabriella and her parents?

ROP is the term currently used to designate the aberrant and abnormal vascularization of the retina that occurs in some low-birth weight preterm infants, causing impaired vision or blindness (AAO, 2006). The condition was first identified in 1942 and was called *retrolental fibroplasia*. The name was changed in 1984 after an international team of ophthalmologists met to identify a generally agreed on classification system to describe the stages and severity of the disease process.

During the late 1940s and early 1950s, ROP occurred in epidemic numbers among premature infants. After the use of high concentrations of oxygen was curtailed in the mid 1950s, the incidence of ROP declined to almost zero. As technologic advances have enabled greater numbers of preterm infants to survive, the incidence of ROP is again increasing with approximately 14,000 to 16,000 infants a year affected in the United States (Harrell & Brandon, 2007). White infants are more likely than African American infants to develop ROP. There are no differences in incidence between the genders. Oxygen therapy is a risk factor in the development of ROP, yet such therapy is a necessary element in the care of premature newborns. The use of blood products has shown no relationship to the development of ROP. The more severely ill the child at birth, the more likely he or she will develop ROP (Harrell & Brandon, 2007).

Pathophysiology

In the normal newborn, retinal blood vessels are immature and the macula has yet to complete its development. The retinal blood vessels begin their development near the disk and grow toward the periphery of the retina between 16 and 44 weeks’ gestation. Great variability exists with respect to the time of completion of this process; thus, when an infant is born prematurely, the status of eye development is not predictable.

ROP involves injury to the developing blood vessels and tissues of the retina, leading to regrowth or overgrowth of retinal vessels. Two factors are involved in the development of ROP. Vascular endothelial growth factor (VEGF) is the growth factor that is normally stimulated by hypoxia (low PaO₂) in utero and stimulates vessel growth. Insulinlike growth factor 1 (IGF-1) is provided to the fetus in utero from the placenta and amniotic fluid. IGF-1 also contributes to the development of vascularization, and IGF-1 levels immediately decrease after delivery. Thus, a premature child will experience immediate cessation of vascularization.

ROP is divided into two phases. During phase 1, the child has termination of normal vessel growth and regression of some existing vessels. Levels of IGF-1 will slowly reestablish through endogenous production. Administration of supplemental oxygen after birth inhibits VEGF and causes death to the vascular endothelial cells. Subsequently, the lack of blood vessels in the retina initiates anaerobic metabolism and enhances the existing hypoxic situation. The retina becomes oxygen deprived and its metabolic needs are not met. This hypoxic condition stimulates VEGF, which begins phase 2 of ROP (Harrell & Brandon, 2007, p. 372).

During phase 2, IGF-1 levels return to normal (as a result of endogenous production) and act on the VEGF to cause vessel growth. However, this vessel growth is now considered pathologic and the resulting vessels are abnormal. As stated by Harrell and Brandon (2007, p. 372), “ROP is caused by too little or too much oxygen at specific times during retinal vascularization, as well as by the suppression or stimulation of growth factors such as IGF-1 and VEGF at inappropriate times.” In many of these infants with ROP, this overgrowth ceases or regresses spontaneously. In some, the overgrowth continues, making the development of useful vision unlikely because of the fibrotic changes of the retina or because of retinal detachment.

Assessment

All infants exposed to oxygen as well as those weighing less than 1,500 g at birth or at gestational age of 30 weeks or less require assessment and screening for ROP by an ophthalmologist (AAO, 2006). In addition, selected infants with a birth weight between 1,500 and 2,000 g or a gestational age greater than 30 weeks who have had an unstable clinical course or who have required cardiorespiratory support may be identified as at risk for ROP and therefore need to be assessed (AAO, 2006). Timing of the first eye examination is based on the child’s

gestational age at birth. The youngest infants at birth take the longest time to develop serious cases of ROP (AAO, 2006). Thus, timing for the examination varies between 31 and 36 weeks' postmenstrual age of the infant. For example, an infant who is born at 22 weeks' gestation will have an initial examination at 31 weeks' postmenstrual gestation (or 9 chronologic weeks after delivery); an infant who is born at 32 weeks' gestation will have an initial examination at 36 weeks' postmenstrual gestation (or 4 chronologic weeks after delivery; see [thePoint](#)® Evidenced-Based Practice Guidelines). The schedule for follow-up examinations to monitor the progress of retinal vascularization is based on the findings from the initial examination and varies from 1 week or less in more severe cases to 2 to 3 weeks in less severe cases. ROP is not likely to develop in infants of 42 weeks' postconceptional age or older. The extensiveness of the acute form of ROP is described as stages 1 to 3, based on the amount of overgrowth of the retinal blood vessels.

Assess the family's adjustment to the condition. Also, assess parent knowledge and understanding of the condition, growth, and development of the premature infant with a potentially disabling condition.

Provide assistance to the ophthalmologist during screening procedures. The child's pupils are dilated with mydriatic eye drops given 30 minutes before the examination. A binocular ophthalmoscope is used to examine the eyes. The procedure is uncomfortable and may increase stress responses in the vulnerable and compromised infant. A topical anesthetic may be applied to the eyes prior to the examination to decrease the child's discomfort. Swaddle the infant during the examination and provide oral sucrose and/or pacifiers. Monitor vital signs during the examination because the mydriatic drops coupled with the ocular pressure may cause bradycardia, apnea, and hypertension. Applying nasolacrimal pressure and wiping away excess fluid can help prevent systemic absorption of the ophthalmic medications used during the examination.

Interdisciplinary Interventions

Interventions focus on preventing ROP. Prevention of premature birth is by far the best way to decrease the number of infants born before their eyes are fully developed. It is well known that prenatal care decreases the incidence of premature birth; thus, any effort to decrease premature births also would decrease the incidence of ROP. Nurses play a key role in preventing premature births and subsequently in preventing the disabling effects of ROP.

Monitor and limit the amount of oxygen the infant is receiving. Ideally, major swings between periods of hypoxia and hyperoxia should be avoided. Research studies have recommended strict management guidelines that include maintaining oxygen saturation levels between 85% and 93%. These studies have indicated a decrease in the incidence of ROP when an infant's normal oxygen saturation range is maintained in this range (Chow, Wright & Sola, 2003; Vanderveen, Mansfield & Eichenwald, 2006).

When ROP occurs, treatment focuses on arresting the growth of new and aberrant blood vessels in the retina, to prevent complications such as detached retina, and to enable continued normal development of vision. During the premature infant's hospital stay, the ophthalmologist monitors the progression of the condition with weekly eye examinations.

Surgical intervention to arrest the growth of retinal vasculature may be necessary. The choice and timing of treatments with cryotherapy or laser photocoagulation surgery is based on the progression of the disease and is determined by the ophthalmologist. Cryotherapy uses an extremely cold probe that is applied repeatedly to the eye to cauterize the hypoxic areas of the retina. An incision into the conjunctiva is required for this surgery. Complications include retinal scarring, cell destruction, and detachment of the retina. Laser photocoagulation involves use of an argon or a diode laser to condensate the protein material in the eye, halting vessel growth. This procedure is less harmful to the eye than cryotherapy. Complications of the procedure include scarring; hemorrhage; burns of the cornea, iris, or lens; and development of cataracts (Harrell & Brandon, 2007).

The prognosis for infants with ROP is variable, and parents often require considerable support to be able to accept the long periods during which they will not know the degree of damage that their child has sustained. A referral to social services or clergy may be necessary to assist parents in adjusting to the possibility that their infant has permanent damage.

Community Care

When the infant is discharged, follow-up by both primary healthcare provider and ophthalmologist is essential. All persons involved need to be aware of the increased risk for retinal detachment that exists in infants with ROP. If the infant has a poor visual outcome, parents may need guidance in how to best assist the infant to continue development in as near a normal pattern as is possible. Referral to a support group or to national organizations that provide assistive materials may be in order (see [thePoint](#)® Organizations).

ANSWER: To meet Gabriella's needs, one role the nurse assumes is that of educator. The nurse spends more time with the parents than some other members of the healthcare team. The nurse should clarify and verify the parents' understanding of the diagnostic testing, the medical problem, and the potential treatments. Although many other members of the healthcare team also see themselves as educators, the role of facilitating parent–infant bonding is almost exclusively nursing. Bonding is about falling in love and occurs best when a family can spend time together, having eye-to-eye contact and lots of touching. All the senses are involved and stimulated in parent–infant bonding. Nurses who care for hospitalized infants, especially those with potential sensory impairments, must play the role of matchmaker and facilitate time and space for families to study each other's faces, hear each other's voices, and to fall in love.

FIGURE 28–10. Cataracts may develop in infants or children of any age.

Cataracts

Cataract refers to any opacity of the lens. Cataracts may be congenital or acquired after birth. Congenital cataracts may be observed at birth or may not be seen until later in infancy (Fig. 28–10). Congenital cataracts may result from exposure to infectious agents, such as rubella, toxoplasmosis, cytomegalovirus, herpes simplex, syphilis, and possibly varicella. Prematurity and genetic factors also contribute to the development of congenital cataracts. Cataracts are common in children with Down syndrome, although they are not always severe enough to be removed.

Cataracts may also be acquired during childhood as a result of trauma, toxic agents, metabolic, endocrine, or other disorders. Trauma to the eye, such as from penetration injuries or contusions, may lead to scarring and thus be a major cause of cataracts during childhood.

Pathophysiology

During the fourth and fifth weeks of fetal development, the lens capsule forms as a clear membrane. If the forming lens is attacked by an organism, it becomes milky white and cloudy, and may fail to continue to develop. This opacification is called a *cataract*.

The optic nerve and internal ocular structures continue to develop normally during fetal life unless the etiologic agent attacks these as well. Ocular development and visual development continue after birth. Also after birth, the infant's eyes develop the ability to transfer images to the visual cortex of the brain. If a cataract is present, the visual image cannot reach the brain and the visual cortex fails to continue to develop. If the cataract is removed before the infant is 2 months old, the visual center of the brain is able to resume development.

Assessment

Some cataracts may be detected easily during physical examination of the eye, whereas others may not be externally visible and may not be detected until visual acuity testing is done prior to school entrance. The

absence of the red reflex and a white, opaque appearance of the lens are characteristic. Impaired visual acuity that accompanies a cataract may result in nystagmus (rapid oscillating movement of the eye) or strabismus (wandering eye) in the affected eye. Thus, carefully assess a child with any other ocular disorder or diminished acuity such as strabismus, amblyopia, or nystagmus because of the risk for an associated internal or superficial cataract.

Be alert for any history of poisoning with a toxic substance or history of severe infection, particularly with varicella or other viral condition, and for facial scars from burns, abuse, or other trauma.

Interdisciplinary Interventions

The primary goal is the preservation of or the development of useful vision for the child. The achievement of this outcome depends on the nature of the condition, the child's age when the cataract is identified and removed, and the diligence of the child and family in maintaining the visual therapy program.

Congenital cataracts must be surgically removed before the infant is age 6 weeks (Vasavada & Nihalani, 2006; Wagner, 2003) to prevent amblyopia and loss of useful vision. Cataract removal is done by an ophthalmologist on an outpatient basis. Three types of surgical interventions can be performed. A **lensectomy** is typically carried out on children 18 months and younger. During this procedure, the whole lens and some of the vitreous “jelly” behind it are removed. For older children, and some younger children, an **aspiration** procedure is used, during which part of the lens is removed and some of the outer capsule of the lens remains. It is often possible to place an intraocular lens into the remaining capsule, either at the time of the procedure or at a later date. Last, an **intraocular lens implant** may be performed. In this case, the lens is removed and replaced by a permanent plastic lens. Intraocular lenses are not used with infants because of the rapid growth that occurs over a short time in the infant eye.

Postoperatively, although infections are rare, antibiotic drops may be prescribed prophylactically. If a child needs surgery in both eyes, the operations are usually completed within a week of each other to ensure one eye does not see before the other, and thus become the stronger eye.

Corrective lenses are often recommended by the ophthalmologist after removal of the cataracts to replace the function of the natural lens for those children who did not receive an intraocular lens implant. Contact lenses that can be adjusted in power as the eye changes yield better results for young children. Use of contact lenses in infants and young children with cataracts is currently being studied, particularly with respect to difficulties faced by parents with insertion and removal of the lenses in very young children. Ma (2003) found that in children younger than 8.1 years of age, contact lenses were well tolerated and were not found to be major stressors for the children or their parents (see Tradition or Science 28–1 earlier in this chapter).

Community Care

Teach parents how to administer eye ointment or drops correctly to avoid pressure on the globe of the eye. A patch and an eye protector made of hard plastic or metal is left in place (except for medication administration) until the follow-up visit with the ophthalmic surgeon. Instruct the parents to look at the eye as they instill medications and to look for any unusual redness, swelling, or drainage and to report this immediately to the ophthalmologist.

KidKare ■ The child must be prevented from rubbing the eye while awake or asleep. For young children, elbow restraints may be obtained from the hospital or doctor's office to prevent the hands from reaching the eyes.

The infant who has undergone cataract surgery also requires aggressive treatment of amblyopia to achieve useful vision (see discussion earlier in this chapter). The success of treatment largely depends on the infant's age at diagnosis and removal, and the cooperation of infant and family with the occlusive patching regimen designed to stimulate the development of the weaker eye. Wilson et al. (2003) found that infants who had cataract removal by 6 weeks of age and whose parents were consistent with the patching regimen had visual acuity outcomes of 20/45 on average. For these parents, the age between 18 and 30 months was a difficult time to gain the child's cooperation with the patching routine. Parents were instructed to do their best during that time and to resume regular patching at 2½ years of age, when the child is more cooperative. The outcome was highly successful. The outcome was much less successful for children whose families abandoned the patching routine when the child objected to wearing the patch.

Adherence to follow-up, including evaluation of intraocular pressure, is important in minimizing the risk of **glaucoma** (increased intraocular pressure; discussed in the next section) resulting from cataract surgery.

When the child returns to the primary healthcare provider for well-child care, provide follow-up assessment of vision and monitor adherence to the therapeutic regimen developed by the ophthalmologist. As the child grows older, further assessment of visual status, using the assistance of developmental specialists, educators, and family support groups, may be necessary, depending on the amount of useful vision that develops. Support the family in their role as advocates for the child as they learn to access the services needed to facilitate the healthcare and education of their child.

Glaucoma

Glaucoma is a rare but potentially devastating condition when it occurs in infants and young children. Glaucoma is a general term used to indicate elevated pressure within

CHART 28-2 CLASSIFICATION OF CHILDHOOD GLAUCOMA

Primary (Developmental) Glaucoma

- Primary congenital glaucoma
 - Newborn congenital glaucoma
 - Infantile congenital glaucoma
 - Juvenile congenital glaucoma
- Juvenile open-angle glaucoma
- Developmental glaucoma associated with systemic diseases (e.g., Sturge-Weber syndrome, neurofibromatosis trisomy 13)

Secondary (Acquired) Glaucoma

- Examples: traumatic glaucoma, glaucoma with intraocular neoplasms, glaucoma related to corticosteroids, glaucoma associated with increased venous pressure

the eye that leads to damage to the optic nerve with visual field loss. Glaucoma in children is classified as primary or developmental and secondary or acquired (Chart 28-2). Primary glaucoma is characterized by abnormal circulation and drainage of aqueous humor from the intraocular space. As the aqueous humor collects in the eye, intraocular pressure increases. Secondary glaucoma is associated with other ocular or systemic abnormalities.

The most common type of glaucoma is congenital/infantile glaucoma. The incidence of this glaucoma in infants and young children has been estimated at 1 in 15,000 infants in western countries (Hamel & Levin, 2003). It occurs more frequently in males and is usually bilateral. Among infants who have had surgery for congenital cataract removal, 6% to 45% will develop glaucoma (Kirwan & O'Keefe, 2006; Swamy et al., 2007). About 50% of primary glaucoma in children is related to other congenital conditions such as Marfan syndrome, neurofibromatosis, homocystinuria, Lowe syndrome, or congenital rubella. A few isolated cases of familial genetic transmission have been identified.

Pathophysiology

Congenital/infantile glaucoma results from a defect in the trabecular meshwork of the eye that prevents drainage of the aqueous humor out of the eye. The backup and accumulation of fluids causes increased pressure in the eye. The prognosis is good, although lifelong follow-up is required. *Juvenile glaucoma* is a disease with onset after age 3 years, usually secondary to some other disease process. Both infantile and juvenile glaucoma may occur secondary to a coexisting pathologic process. For example, in Marfan syndrome (an autosomal dominant congenital disorder affecting connective tissue, osseous development, and heart and eye structures), abnormal connective tissue of the trabecular meshwork is thought to prevent normal circulation of the aqueous humor out of the

intraocular space, thus increasing intraocular pressure. Infantile and juvenile glaucoma may also be an acquired condition, resulting from an injury that causes scar tissue formation. If left untreated, infantile glaucoma progresses steadily and results in blindness.

Conditions such as trauma, ocular inflammatory disease, ocular tumors, and intraocular hemorrhage are also causes of glaucoma in the pediatric population. Such conditions may create elevated and sustained pressure within the eye that may lead to permanent nerve damage.

Assessment

Infants and children with glaucoma may experience a sudden or gradual onset of symptoms that includes epiphora (tearing), photophobia (sensitivity to light), and blepharospasm (eyelid squeezing). Signs and symptoms may be noted within a few days of birth or may develop insidiously. Parents' descriptions of the child's behavior are particularly important. Infants and young children may demonstrate unexplained behavior changes, such as irritability and episodes of unexplained crying, which alert the parents that something is wrong. Some parents may hesitate to mention behavior changes unless the healthcare provider specifically asks. Parents may not associate these behaviors with disease.

Alert! Infants who have episodes of unexplained irritability and crying or unexplained behavior changes should be examined for eye pain and glaucoma, particularly if they have had cataracts removed.

Ask the parents about rubbing the eyes. Infants who are at least several months old and who have the dexterity to rub their eyes with their hands will do so if their eyes hurt. Parents may consider this behavior another minor occurrence, without recognizing its potential importance to the diagnosis.

Assess the child for the comparative size of the eyes, corneal clouding (hazy white area over the lens; Fig. 28–11), blue tinge to the sclera, tearing or excess watering of the eyes without evidence of infection (*epiphora*), photophobia (sensitivity to light) even under low-light

FIGURE 28–11. Corneal clouding in an infant with glaucoma.

conditions, and blepharospasm (involuntary closure of eyelids). Inspect the eyes for buphthalmos (enlargement of one or both eyes), which parents may not have associated with disease, particularly if the condition is bilateral and if they consider large eyes a desirable trait. A difference in pupillary size of even 1 mm is considered abnormal, but deciding whether the smaller eye or the larger eye is abnormal may be difficult. Diagnosis at an early age is difficult, because of lack of symptoms and difficulty in evaluating vision in infants and young children.

Assessment of the older child includes testing of visual acuity, pupil dilatation, and visual field. Assessment of intraocular pressure, tonometry, must be done by the specialist and often under anesthesia for infants, young children, and those who are unable to cooperate during the test. The “puff” test for intraocular pressure measurement may be used by the eye care specialist while testing children as young as age 4 to 4½ years; however, prior to this age, obtaining an accurate pressure measurement without anesthesia is difficult.

KidKare ■ Before the “puff” test, the child needs to be fully prepared, usually by a parent, so that he or she will cooperate fully. The young child is much better able to cooperate if the test is approached as a game and the child is given the responsibility to hold his or her eyes “open wide” until the “puff” comes, then “you can close them tight.” The eye care specialist performs the test first on one side and then on the other.

All infants should be screened in the newborn nursery and at each well-child visit. Any suspicion of glaucoma must be treated urgently, with an immediate referral to an ophthalmologist. Prognosis improves with early diagnosis and treatment. During late adolescence, screening is recommended for those 20 years of age and older as part of a comprehensive eye examination (U.S. Preventive Services Task Force, 2005).

Interdisciplinary Interventions

The ophthalmologist may first administer medication to temporarily decrease ocular edema, clear the cornea, and improve visualization of both the surgical site and the iridocorneal angle. Oral acetazolamide, a carbonic anhydrase inhibitor, is the most effective initial therapy. Dorzolamide, a topical (ophthalmic) carbonic anhydrase inhibitor may also be used. Topical beta blockers suppress aqueous formation and may be used in conjunction with topical or systemic carbonic anhydrase inhibitor.

Surgery to either increase the outflow of fluid from the eye or to decrease the production of fluid within the eye may also be used to reduce the intraocular pressure. The goal is to have a level of equilibrium at which the eye will produce enough fluid to maintain its integrity yet allow enough fluid to exit to provide a normal intraocular pressure (Hamal & Levin, 2003, 2004). The type of

surgical technique is based upon the pathophysiology of the child's condition. Goniosurgery, also known as *goniotomy* and *trabeculotomy*, are the surgeries of choice for congenital glaucoma. During these procedures a surgical opening is made into the drainage area of the eye (the trabecular meshwork drainage system), establishing a more normal anterior chamber angle that allows the fluid to drain more freely. Children with more severe defects of the filtration channels often do not respond to goniosurgery, and filtration procedures may be required to bypass the malfunctioning system, creating a new egress passage for the aqueous humor. If filtration surgery is not effective, implants may be used to drain the aqueous fluid from the eye by way of a silicone tube to an episcleral reservoir (Walton, 2007).

Postoperative care may be provided initially by the nurse and later by parents. Eye patches or a protective eye shield may be used for a short time after the surgery to protect the child's eyes. Elbow restraints may be used to prevent the child from rubbing his or her eyes.

Community Care

The infant with glaucoma needs regular follow-up with the ophthalmologist throughout life. Both the nurse and the primary healthcare provider should encourage and facilitate such visits. Children do not outgrow glaucoma. Glaucoma is controlled so that further damage to the eye is avoided. Constant vigilance is necessary to ensure that pressure does not increase and damage delicate structures of the eye.

When the child enters school, urge parents to inform the school nurse of the child's past history of health problems. During the school years, the school nurse may be able to assist or encourage the family to obtain the healthcare follow-up that the child needs to prevent deterioration of vision. The school nurse also functions as a liaison among healthcare professionals, educators, and the family to help such children achieve their maximum potential.

Special attention should be given to the developmental and educational progress of children who have had a poor visual outcome. They may need alternative learning tools to make best use of limited visual acuity.

Visual Impairment: Blindness

Blindness is defined by educational and governmental agencies as having vision no better than 20/200 in the better eye or a visual field no better than 20 degrees at its widest diameter regardless of visual acuity. Persons with these limitations are said to be *legally blind*. However, they may still have considerable useful vision and may be able to use print as their major means of learning.

Partially sighted is the term used to describe the visual ability of those with visual acuity of more than 20/200 but worse than 20/70 in their better eye with correction (Federal Regulations, PL-142, 1975). Both legally blind and partially sighted children are classified as *visually impaired*. They have certain rights in the community and in the educational system, which are addressed by the Americans with Disabilities Act.

CHART 28-3 CAUSES OF VISUAL IMPAIRMENT

Congenital defect: chromosomal abnormality

Systemic disease

Injury

- Head injury, occipital
- Penetrating injury to the ocular globe
- Blunt force injury to the head or globe
- Injury to the anterior globe with scarring

Infection (local or systemic)

- Maternal rubella
- Maternal infection with *Chlamydia trachomatis*
- Maternal gonorrhea
- Maternal varicella
- Infantile varicella
- Neonatal conjunctivitis caused by infection

Neisseria gonorrhoeae

Chlamydia trachomatis

- Meningitis
- Encephalitis

Other

- Retinopathy of prematurity
- Poisoning (e.g., methyl alcohol ingestion)

WORLDVIEW: Visual impairment affects millions of people worldwide. Two thirds of all cases of blindness in the world are either preventable or curable, particularly those caused by infections and those caused by poor nutrition. Infections (with *C. trachomatis* and *N. gonorrhoeae*), parasites (onchocerciasis), and cataracts account for a large portion of blindness in adults and children in developing countries with poor nutrition (vitamin A deficiency) and limited access to soap and clean water. Visual impairment in more developed countries may be caused by genetic inheritance or by a local or systemic disease process that is acquired either prenatally or postnatally (Gilbert & Awan, 2003).

Any condition that causes damage to, or prevents development of, ocular structures may diminish the child's visual capacity (Chart 28-3).

Pathophysiology

The pathophysiology of visual impairment depends on the causative factors. The pathophysiology seen in shaken baby syndrome is that of bilateral retinal hemorrhages usually greater than compatible with injury described by the parent. The shaken baby may also have other indicators of new or old injuries (see Chapter 29).

Ocular structures do not regenerate; thus, damage to the eye is permanent and may result in blindness. Blindness is the result of either optic nerve damage or damage to other parts of the eye that normally would help to focus the image on the retina. Blindness may also result from damage to the visual centers of the brain (cortical blindness). Visual impairment caused by injury or disease is usually not progressive; however, some

genetic conditions are progressive over time and with physiologic development.

Assessment

Visual impairment is assessed grossly using eye screening and standard eye and vision assessments. The child with visual impairment requires follow-up by an ophthalmologist. Because of the difficulty of examining the ocular fundus in an infant, any infant who is suspected of having retinal damage caused by abuse should be examined by a specialist as soon as possible. If the assessment of the ocular fundus indicates that the child has been a victim of abuse, and it is supported by other test results, immediate action is taken to protect the child and involve the local authorities. Other tests and radiographs may be completed to assist in the diagnosis.

caREminder

Be particularly aware that complications can develop rapidly in eye conditions; thus, any time an eye disorder is suspected, ensure that the child is referred and seen immediately. The “wait-and-see” approach has no place in a child’s care when vision is at risk.

Interdisciplinary Interventions

Sudden onset of blindness or visual impairment requires immediate evaluation to determine the cause of visual loss and the extent of damage. When possible, interventions can be taken to correct the underlying problem (e.g., cataract surgery). Return of full sight may not be possible. When a child experiences any loss of vision, the goal is to assist the blind/visually impaired child to grow up and become a productive, fully functioning, independent adult.

There is no one “right” way to interact with blind or partially sighted infants and children. However, several interventions can facilitate care and increase the comfort of the visually impaired child and his or her family. Always keep in mind the child’s developmental level. For example, a blind child who has not sustained brain damage usually has the capacity to reach the same developmental level and the same conceptual understanding of the world as his or her sighted peers, but the child may not have done so because of lack of experience. For this reason, the blind child may not understand the healthcare provider’s descriptions at a level expected of a sighted child of the same age. Persons who work with blind or partially sighted children must provide the necessary information to help the child to understand the concepts being presented. Blindness does not affect the child’s cognitive capacity, but it does affect how the content is presented.

Immediate interventions to ensure the child’s safety are required when a child’s visual impairment is suspected to be the result of abuse. The child should not be released from the office or emergency department without first having been fully assessed and a plan made for safe care, possibly admission for observation for further signs of

injury. Infants with retinal hemorrhages or detachment, common in shaken baby syndrome, will have a substantial loss of vision and need immediate assessment by the ophthalmologist.

Community Care

Parents, teachers, and healthcare specialists need to assist the child in developing compensatory skills to deal with the environment. A child with limited or no visual ability must develop auditory and tactile senses earlier and to a greater skill level than their sighted peers. Parents can begin the process at home using games similar to those played with sighted children for identification of objects, sizes, shapes, sounds, and textures. Children who have limited vision can benefit from having their attention drawn to specific objects or qualities to enhance their understanding of them. For example, sighted young children are very active, learning how to safely move about their space and conquer its challenges. Nonsighted children need to learn to feed themselves, bathe and dress themselves, and begin school as any child would do. Nonsighted children need the same degree of activity and the same physical challenges. They need to run, play, climb, jump, and manipulate their environment. Obviously, adults will structure playtimes for safety, always mindful of the activity needs of the age. These children need to have responsibilities at home and at school, and to learn to make new friends wherever they find themselves.

Visually impaired children may be taught to read Braille very early in life. They can learn to use devices that transfer the printed page to a tactile format. They may be taught to type very early, to prepare them for computer use. Using the computer, a vast array of materials can be converted to Braille directly from the printed page (see [thePoint](#), Organizations).

Creative play is frequently slower to develop in children with visual impairment; thus, these children benefit greatly by participation in a nursery school setting, where individual attention is possible and a wide variety of toys and activities are available.

Social interaction needs to be encouraged very early in life and sometimes taught to compensate for the child’s inability to see facial expressions and nonverbal social responses of others. D’Allura (2002) found that when given a structured environment in which each child had something specific to contribute to a project, nonsighted preschoolers interacted with their peers at the same rate as their sighted peers. Prior to this research, nonsighted children had interacted far less than their sighted classmates. Galati et al. (2003) studied facial expressions used by sighted and nonsighted children age 8 to 11 years and concluded that nonsighted children may need to be taught to purposefully use facial expressions more frequently to improve interpersonal communication.

Physical fitness skills are equally as important for the visually impaired child as for the sighted child. These children need help in developing skills of jumping, hopping, running, and other gross motor activities. Activities in which the visually impaired child can actively

participate include swimming, gymnastics, and other individual sports, rather than team sports such as basketball. The Special Olympics provides a wide variety of opportunities for persons with visual impairment to participate in sports activities.

Nurses are assuming greater responsibility in monitoring the well-child healthcare needs in the community and are frequently available to families of children with chronic disabilities. Nurses must be knowledgeable about the affect of visual impairment on child and family development, educational options, community resources, and general healthcare needs.

ALTERATIONS IN HEARING

Hearing and listening form the foundation for spoken communication. Infants and young children spend much of their day engaged in passive and active listening as a means of gathering information about their world; thus, hearing impairment during infancy and early childhood can have devastating effects on a child's development. Hearing deficit prevents the developmental stimulation provided by the auditory route and also prevents the child from learning speech by imitation, hindering the child's ability to verbally communicate needs, desires, and thoughts.

Approximately 1 to 2 newborns/1,000 live births have moderate, severe, or profound bilateral neural hearing loss. An additional 1 to 2 newborns/1,000 live births have milder or unilateral impairments. Hearing loss can occur at any time during childhood; thus, by age 19 the prevalence of hearing loss is double the statistics cited for newborns (Haddad, 2007b).

WORLDVIEW: In developing countries, the incidence of congenital bilateral hearing loss is 2 to 4 per 1,000 live births. Two thirds of people with hearing impairments worldwide live in developing countries. Although the cause of hearing loss is unknown in as many as 40% of all cases, known factors of hearing loss include congenital cytomegalovirus, rubella, and toxoplasmosis, and the deleterious outcomes of measles, meningitis, mumps, and OM acquired by children who have not been vaccinated against such diseases (Olusanya & Newton, 2007).

Always keep in mind that *any* infant or child being examined or cared for could be one of a large number of children with an undiagnosed hearing deficit. Early identification of even partial hearing loss is essential to development of communication skills and the lifelong learning process. Nurses are frequently in strategic positions in primary care settings, schools, hospitals, or home care to identify children at risk or who are suspected of having hearing deficit.

In children, alterations in hearing are most commonly caused by infections, blockages, or injuries that impair transmission of sound through the ear canal and inner ear structures. In these cases, prompt intervention is necessary to prevent permanent damage to the anatomic components of the auditory system. Congenital hearing loss is also of concern in the pediatric population. Early

identification of these conditions will assist the child and family to make the necessary adaptations to ensure that the child meets appropriate developmental milestones.

Otitis Media

OM is an inflammation of the middle ear and may be classified as superlative, also called *acute OM* (AOM), or nonsuperlative, also known as *OM with effusion* (OME). Superlative or AOM, characterized by inflammation, is a middle ear infection with sudden onset, middle ear effusion (MEE), and inflammation, and lasts 3 weeks or less. Nonsuperlative or OME is characterized by the presence of fluid in the normally air-filled space behind the tympanic membrane. This fluid exerts pressure on the tympanic membrane, causing pain as it bulges outward.

AOM is one of the most common diseases of childhood. Eighty percent of children have had at least one episode of AOM by 3 years of age, although the greatest incidence is between 6 and 18 months of age. The incidence increases during winter and spring, paralleling the increased incidence of upper respiratory infection and sinusitis infections (Revai et al., 2007) (Clinical Judgment 28–2).

AOM and OME are both associated with MEE, or middle ear mucosal infection. MEE results in the conductive hearing loss that is associated with OM. MEE persists for more than 3 months in 10% to 25% of cases (Kerschner, 2007).

Factors that contribute to AOM and OME include young age, allergies, human immunodeficiency virus infection, genetic predisposition, craniofacial abnormalities, Down syndrome, and presence of other siblings. Breast-fed infants often have a lower incidence of OM, possibly because of the composition of the breast milk itself and the immune factors provided from the mother. Infants who use a bottle or “sippy” cup for milk or juice at bedtime have a higher risk of developing OM than those who do not. Infants who use pacifiers are at higher risk for OM (AAP, 2004; Kerschner, 2007; Marter & Agruss, 2007; Story, Hold, & Sofka, 2002).

Children who attend daycare have a higher incidence of both AOM and chronic OM, and a higher incidence of OME than those who do not attend daycare. These children also have more upper respiratory infections. Exposure to passive smoke increases the incidence of OM. Passive smoke damages the mucosa of the nasopharynx and eustachian tubes, thus increasing the susceptibility of the child to bacterial and viral invasion.

A study of 7,538 children age 2 to 11 years nationwide indicated a strong and significant association of a history of asthma and wheezing to frequent ear infections (three or more). The study identified an association between wheezing and ear infections, stating that specific pathogens that repeatedly invade the middle ear and cause recurrent ear infections may possibly play a role in the development of asthma and wheezing. Another possibility for the association between ear infections and asthma is that antibiotics commonly used to treat ear infections increase the risk of asthma (Eldeirawi & Persky, 2004).

CLINICAL JUDGMENT 28–2

A Visit to Urgent Care

Brothers Christian, age 4 years, and Matthew, age 7 months, are brought to an urgent care facility on a Saturday night. Christian told his mom earlier in the evening, “I have a sword in my ear.” Matthew has been pulling and scratching at his right ear.

Otoscopic examination of Christian’s ears reveals red, bulging tympanic membranes with no visible landmarks. He is crying and wiggling during the examination.

Matthew’s right ear also has a red tympanic membrane and no visible landmarks. The cone of light was difficult to assess because of the excessive wax in his ear. He did not cry during the examination.

Questions

1. What questions would you ask the mother about the boys’ current condition?
2. What can cause the tympanic membrane of the ear to be red?
3. What do you suspect is Christian’s diagnosis? Matthew’s diagnosis?
4. How does examination with the otoscope help differentiate a normal ear from an ear with otitis media?
5. Antibiotic therapy is ordered for the boys. The order is for amoxicillin 40 mg/kg/day to be given three times a day. Christian weighs 15.9 kg; Matthew weighs 9 kg. Calculate the dosage of medication for each child.

Answers

1. Any presence of fever, complaints of hearing loss, pain in or around the ear, dizziness, impaired balance, or vomiting? How long has the child been pulling or tugging at the ear? Has the child been diagnosed with otitis media in the past? When?
2. Crying, acute otitis media, infection
3. Acute otitis media with effusion for both boys
4. The normal ear has a pearl-gray tympanic membrane, with a visible cone of light and mobility of tympanic membrane observed with the pneumatic otoscope. The child with otitis media exhibits a swollen, opaque, and discolored (red or yellow) eardrum with no visible landmarks and little or no mobility. An air–fluid level may be seen.
5. Christian should receive 636 mg/day, or 212 mg per dose. Matthew should receive 360 mg/day, or 120 mg per dose.

Pathophysiology

Organisms, most commonly pneumococci, *Haemophilus influenzae*, and *Moraxella catarrhalis*, gain entrance to the middle ear through the eustachian tube, which forms a normal connection between the pharynx and the middle ear. The infant’s eustachian tube is shorter, wider, and more horizontal than those of older children and adults. Additionally, the infant’s eustachian tube is made of cartilage and muscle with a flutter valve opening in the oropharynx. Its purpose is to equalize pressure between the ear and the environment, and to drain normal fluid from the middle ear. This anatomic difference is thought to increase the infant’s susceptibility to infection of the middle ear. Usually, the ear infection appears a few days after the onset of an upper respiratory infection. It is theorized that the flutter valve fails to prevent organisms from the oropharynx from entering the eustachian tube and subsequently the middle ear.

Inflammation and suppuration that result from the bacterial invasion prevent normal aeration and fluid drainage from the middle ear. When the middle ear fills with fluid, sound conduction is diminished because the vibration of the incus, stapes, and malleus is hindered by fluid. During this time, the infant does not hear as well as would be expected if the inflammatory process were not

present. If the infectious process is long-lasting, the infant may miss developmental milestones in speech and language development.

Fluid that remains in the middle ear after the acute infection has abated may take 6 weeks to 3 months to clear. This fluid does not clear any faster with medication (antihistamines) and does not indicate an ongoing infectious process. It does, however, diminish hearing during this time.

The degree of hearing impairment in OM depends not on the severity of the infection but on the degree to which sounds are prevented from reaching the inner ear. Children with few OM infections catch up quickly when the effusion clears and hearing returns; however, the degree of hearing impairment is a critical factor in the progress of normal cognitive and language learning processes for the young child.

Assessment

Clinical manifestations of OM vary widely in infants and children. There may be evidence of ear pain, as manifested by irritability, tugging or holding of the ear; changes in sleep or eating patterns; or complaints by the child that the ear hurts. Fever may be present, as well as signs and symptoms of an upper respiratory infection and/or sinusitis. Purulent, bloody drainage from the ear

may be present if the tympanic membrane has ruptured. The older child may complain of a sense of fullness or pressure in the ear, hearing loss, balance difficulties, or disequilibrium.

The primary healthcare provider examines the tympanic membrane using the otoscope to view the auditory canal and the tympanic membrane. For young children, the pinna must be pulled up and back for clear visualization. For older children and adults, the pinna is pulled either straight back or down and back to see the tympanic membrane fully. If the tympanic membrane is obscured by cerumen, this would be removed prior to progressing with an otoscopic examination. The tympanic membrane is observed for contour, color, translucence, structural changes, and mobility. Otoscopic examination typically reveals a pearly gray, translucent tympanic membrane that is slightly concave in its contour. The tympanic membrane should be free of structural changes (scars, perforations) and is mobile. Pneumatic otoscopy is used to assess motility. When the ear is insufflated with a puff of air, the tympanic membrane usually moves. With OME, the tympanic membrane does not move. Figure 28–12 depicts an algorithm for differentiating between OME and AOM (AAP & AAFP, 2004).

The child with AOM will have a tympanic membrane that may be full or bulging, or extremely retracted. Ery-

thema may be a sign of inflammation or infection. Abnormal whiteness of the membrane may be a result of scarring or the presence of liquid in the middle ear cavity. Impairment of motility would indicate MEE.

caREminder

Crying may cause the tympanic membrane of the infant or young child to appear red.

Tympanometry, a test to indirectly assess the compliance (mobility) and impedance of the middle ear, can be done in the office to confirm the diagnosis of OME. The test demonstrates an abnormal curve on the tympanometry graph if fluid is present in the middle ear. Tympanometry is usually not valid when done in infants younger than age 7 to 8 months, because achieving a good fit between the instrument and the infant’s ear is difficult.

Laboratory work that may be helpful in assessing the child with AOM includes a culture of the throat and any ear drainage that may be present. In addition, a complete blood count provides information about the white blood cell count (elevated in bacterial infections) and the hemoglobin level. Low hemoglobin is associated with increased susceptibility to infection. Follow-up assessment is essential after treatment for OM to determine

Algorithm for Differentiating Otitis Media With Effusion (OME) From Acute Otitis Media (AOM)

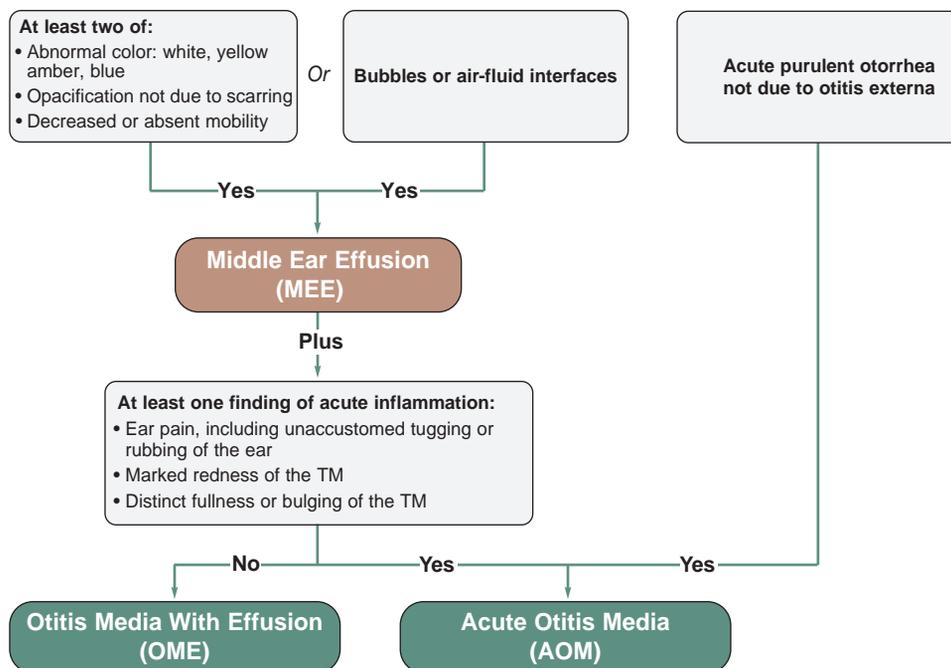

FIGURE 28–12. Algorithm for managing acute otitis media. Algorithm for differentiating otitis media with effusion (OME) from acute otitis media (AOM). The algorithm involves two steps: (1) determining whether MEE is present by finding, on pneumatic otoscopy, either at least two of the three listed signs of effusion, or bubbles or air-fluid interfaces, and (2) if MEE is present, determining whether AOM is present, by finding at least one of the listed indicators of acute inflammation. If none of these indicators are present, the diagnosis is OME. From: The Johns Hopkins University School of Medicine and The Institute for Johns Hopkins Nursing. (2004). A view through the otoscope: Distinguishing acute otitis media from otitis media with effusion. Retrieved on May 28, 2009 from <http://www.aap.org/sections/infectdis/content/monograph.pdf>. Used with permission.

whether the OM has cleared. Follow-up assessment of the child with middle ear effusion after AOM has cleared should be done monthly to assess developmental progress and to look for clearing of the effusion.

Nursing Diagnosis and Outcomes

In addition to those in the Nursing Plan of Care 28–1, the following nursing diagnoses are appropriate for the child with OM. Additional information regarding care management for the child with an acute condition can be found in Nursing Plan of Care 11–1.

Risk for infection related to middle ear inflammation, anatomy of eustachian tubes (in children younger than 3 years of age), and pooling of fluid and secretions in the pharyngeal cavity

Outcomes: Child will be free of infection.

Child will not experience hearing loss as a result of OM.

Risk for injury (hearing loss) related to inner ear condition and use of antibiotics (aminoglycosides)

Outcome: Child will experience no damage to hearing related to onset of OM, administration of antibiotic therapy, or physical injury to the ear.

Risk for imbalanced fluid volume related to increased insensible fluid loss, fever, and decreased fluid intake

Outcome: Child will demonstrate signs and symptoms of adequate hydration.

Interdisciplinary Interventions

According to the guidelines for management of AOM, developed by a joint committee of the AAP and the AAFP, a definitive diagnosis of AOM is made when the child has (1) history of acute onset of signs and symptoms, (2) presence of MEE, and (3) signs and symptoms of middle ear inflammation (Ebell, 2004; National Guideline Clearinghouse, 2006; Zacharyczuk, 2004). A child who does not display all three criteria is said to have “uncertain diagnosis of AOM” (Ebell, 2004). The treatment protocol is different from that for the child with a definitive AOM diagnosis.

Interventions for children with acute or chronic OM, with or without effusion, always include pain management with analgesics (acetaminophen, ibuprofen, or topical drops) and medication to treat the infection, when appropriate (Tradition or Science 28–2). Recent research has found that in children 6 months to 2 years of age who are generally healthy, OM frequently clears spontaneously in 48 to 72 hours without the use of antibiotics, and the risk of complications is no higher when antibiotics are not used (Ebell, 2004). In addition, unnecessary use of antibiotics has a negative effect on the recurrence of AOM; children who receive antibiotics were shown to have a greater likelihood of recurrence of AOM than those who do not receive antibiotics (Damoiseaux, 2004). Nurses need to understand the long-term benefit of using fewer antibiotics to treat conditions that have been shown to clear spontaneously.

TRADITION OR SCIENCE 28–2

Should steroids be used to treat otitis media?

EVIDENCE-BASED PRACTICE

Steroids given orally have been suggested by some practitioners as treatment for persistent middle ear effusion; however, the current guidelines do not recommend the use of steroids because of the limited scientific evidence of their benefit and the known adverse effects of steroid use. Steroids given in the ear canal are still used to decrease local inflammation. Antihistamines and decongestants are also not recommended as treatment measures, because research has proved them to be ineffective in the management of ear infections (AAFP, AAO-HNS, & AAP, 2004; Grassia, 2004).

OM, regardless of whether it is treated, may leave residual effusion (MEE), particularly if the child is subjected to passive smoking or is in daycare (where frequent upper respiratory infections make OM common). The child with frequent OM should be assessed regularly for possible language delay and, if it is found, should be referred to an ear, nose, and throat specialist for possible tympanostomy tube placement.

Antibiotic Therapy

AOM is often treated initially with antibiotics given orally, although new evidence-based guidelines recommend observation only for selected children (age 6 months–12 years, otherwise healthy, with acute-onset OM), for 48 to 72 hours. If pain is present, it should be treated with appropriate pain medication. Children should be reexamined in 48 hours and released to their normal activities if the OM is resolved. If the OM is no better, they should be treated with antibiotics ((AAP & AAFP, 2004; Ebell, 2004; Rosenfeld et al., 2004a; Rosenfeld et al., 2004b) Rosenthal, 2004a).

Antibiotics must be used judiciously. Antibiotics change the flora of the respiratory and intestinal tracts, thus increasing the chance of allergy or undesirable side effects (diarrhea), decreasing the child’s likelihood of developing immunity to the invading organism, and increasing the chance of the organism developing resistance to the antibiotic. With antibiotics, children may return to daycare 1 day sooner during an episode of OM, but because of the side effects, they may develop more illness in the future (Damoiseaux, 2004; Wellbery, 2004).

Surgical Management

Controversy currently exists concerning whether the trauma and risks of surgery for tympanostomy tube placement are outweighed by developmental outcomes (Pettinger & Force, 2003). Paradise et al. (2003) found no developmental difference at age 3 years between children who received tympanostomy tubes during their first

3 years of life and those who did not, even though all had a similar number and severity of MEEs. Surgery for OM is indicated when episodes of AOM occur frequently; MEE persists too long and is accompanied by difficulty hearing; complications manifest such as mastoiditis, labyrinthitis, and facial paralysis; or symptomatic eustachian tube dysfunction exists (DeRosa & Grundfast, 2002). Surgical options for treating OM include the following procedures, performed by the specialist:

- Tympanocentesis: Aspiration of fluid from the middle ear via puncture of the eardrum to manage AOM or persistent OME in neonates or an immunocompromised child (DeRosa & Grundfast, 2002)
- Myringotomy: Incision of eardrum to allow fluid drainage from middle ear; to alleviate pain associated with AOM; to provide drainage of infected middle ear fluid when complications such as mastoiditis, labyrinthitis, or facial paralysis occur; and to obtain purulent middle ear drainage for a sample culture (DeRosa & Grundfast, 2002)
- Tympanostomy: Insertion of tube to improve middle ear ventilation after fluid removal and to allow pressure equalization and normal drainage of middle ear; tubes usually fall out by themselves in 6 to 18 months
- Adenoidectomy and tonsillectomy: Removal of adenoids and tonsils (see Chapter 16); adenoidectomy indicated for children with chronic OME requiring repeat myringotomy and tympanostomy tube placement; tonsillectomy as a controversial treatment for OM

Community Care

Nurses play a key role in teaching parents how to reduce possible risk factors for OM. In particular, support the healthcare prescriber's plan of care and teach families that antibiotics are not always the best treatment. If a particular child's condition makes him or her a candidate for the observation approach, urge the parent to bring the child back in 2 to 3 days for a reevaluation. If the condition has worsened, appropriate medication will be prescribed. If the condition has improved, the child is spared the necessity of taking antibiotics for a number of days and enduring any side effects that may develop.

The nurse is also responsible for teaching the child and parents about myringotomy and tympanoplasty, including ear care after surgery. Instruct the parents in measures to keep the ears dry, usually with insertion of a molded earplug or small cotton plugs whenever the child is around water. Tympanostomy tubes are tiny, possibly bordered on one end by a round, plasticlike plate. The tubes come in various styles, shapes, and sizes. Inform parents about the appearance and size of their child's tubes so that they can recognize them if and when they fall out.

If the child has a chronic condition, parents who smoke, or other risk factors, the OM may not clear, even with an initial round of antibiotics. Stress to the family the necessity of a follow-up ear examination, even if the child is feeling and acting well. To prevent development of chronic OM, the condition must be eradicated completely, and a second round of antibiotics may be prescribed for up to another

3 weeks. If treatment is not effective in eliminating the infection, the possibility of complications remains. Complications include generalized sepsis, meningitis, or mastoiditis.

OM may result in diminished hearing; thus, it is both a medical problem and an educational problem. Children whose hearing ability fluctuates from day to day cannot maximally benefit from any learning situation that involves voice or sound. They miss not only direct learning opportunities but also incidental learning opportunities that help a child fit into his or her social group.

If OME persists without resolution for 3 months, the child should have a hearing test. If the child's hearing is found to be deficient in the tonal range occupied by the spoken voice, a referral to the ear, nose, and throat specialist is made. Tympanostomy tubes could allow drainage of the fluid and restoration of hearing.

Otitis Externa (OE)

Otitis externa (OE), also called *swimmer's ear*, is an inflammation of the tissue of the external auditory canal. Although it seldom threatens hearing, it can be very painful. Children who spend long hours in the swimming pool are prone to develop OE as a result of chronic irritation and maceration from excessive moisture in the ear canal. Inflammation of the ear canal may also be the result of herpesvirus, varicella zoster, various skin exanthems, and eczema.

Pathophysiology

Normally, cerumen found in the external auditory canal protects the thin layer of skin from the effects of moisture. If cerumen is removed with cotton-tipped applicators or is washed out by frequent introduction of water, as occurs when children swim for long periods, the skin is vulnerable to organisms in the environment. The warm, moist atmosphere of the ear canal provides an ideal place for growth of bacterial or fungal organisms. The most common organisms is *Pseudomonas aeruginosa*, although *Staphylococcus aureus*, *Enterobacter aerogenes*, *Proteus mirabilis*, *Klebsiella pneumoniae*, streptococci, staphylococci, and fungi have also been known to cause OE (Haddad, 2007a). Inflammation causes the tissues to swell, which in turn causes pain. The swelling may extend from the external auditory canal to surrounding tissues of the face.

Assessment

The history presented by the child with OE may reflect extended periods in or around the water, or a child with skin infections that affect the face (eczema). The child who washes his or her hair at night and goes to bed with wet hair is also prone to develop OE. The onset is usually sudden and without history of fever or upper respiratory symptoms. The classic sign of acute OE is pain on movement of the pinna or pain on pressure over the tragus. Edema, erythema, and thick, clumpy otorrhea (drainage) of the ear canal are present. Lymph nodes in the periauricular area may be palpable and tender. Ooscopic examination of the affected ear may not be possible, because inserting the speculum causes extreme pain. When

otoscopic examination is possible, it often shows that the tympanic membrane is not affected.

Interdisciplinary Intervention

Eardrops that provide antibacterial and antifungal medication to the external auditory canal are usually sufficient to eradicate the infection within 7 days, although the discomfort is gone in 2 to 3 days. Oral antibiotics are usually not necessary. Ear pain may be managed with Auralgan or other otic analgesic drops applied directly to the ear canal, or with acetaminophen or ibuprofen taken orally. The child should avoid getting the ears wet either by swimming or shampooing until the OE has cleared, usually about 7 days.

Community Care

Prevention of OE is the goal with the following:

- Avoiding the use of cotton-tipped applicators in the ears
- Drying the ears well after shampooing or swimming
- Instilling dilute alcohol or 2% acetic acid eardrops after swimming or bathing

These eardrops may be purchased OTC or made at home by mixing equal parts rubbing alcohol and white vinegar. Vinegar changes the pH of the ear canal to discourage growth of organisms, and the alcohol encourages drying of the tissue.

caREminder

Caution parents not to use cotton-tipped applicators to remove cerumen because of the danger of either pushing the cerumen against the tympanic membrane or directly damaging the tympanic membrane with the cotton-tipped applicator stick.

Hearing Impairment: Deafness

QUESTION: Is the Goldman family in a unique situation regarding Gabriella's potential hearing loss? How similar might the experience be for other families of premature infants?

Hearing deficit is classified as minimal, mild, moderate, severe, or profound depending on the decibel threshold of sound required before the child can hear it. Normal speech has an intensity of 40 to 50 dB; thus, a child who requires a sound to be 50 dB before it is heard is unable to hear most speech with the unaided ear. Amplification (use of a hearing aid) may improve functional hearing. Hearing impairment is also classified according to the location of the defective hearing pathway (Table 28–3).

Each type of hearing deficit is managed differently; therefore, it is essential to obtain an accurate diagnosis as early as possible. The assistance of the audiologist in making the diagnosis is essential. A deficit may be temporary, as in transient OM, or permanent, as occurs when nerve damage is present.

ANSWER: Prematurity alone is a risk factor for hearing loss, and the smaller and sicker the infant, the greater the risk for hearing loss. Most families of premature infants will have a similar experience to the Goldmans'. This experience includes the understanding that their child may have a hearing loss, the search for more information or a period of denial, and, as the child gets older, more diagnostic measures needed to determine the extent of hearing loss and appropriate interventions.

TABLE 28–3

Types of Hearing Impairment

Type and Definition	Possible Causes
Conductive hearing impairment: inability of the outer and middle ear to transmit sound to the inner ear	Blockage by cerumen or foreign object Congenital malformation of external or middle ear Otitis media with effusion (fluid in the middle ear) Scarring of the tympanic membrane
Sensorineural hearing impairment: inability of the inner ear to transmit sound impulses to the brain	Congenital malformation of the inner ear Genetic deterioration of the inner ear Damage to inner ear by disease or injury, child abuse, meningitis, encephalitis
Central hearing impairment: inability of the hearing centers of the brain to receive or process sound impulses	Congenital malformation or disorder of auditory center Brain damage by disease or injury Damage to cranial nerve VIII by disease or injury such as child abuse, meningitis, encephalitis, poisoning
Mixed hearing impairment: any combination of conductive and sensorineural factors	Blockages, malformations, damage to the ear by disease or injury

The origin of hearing deficit in infants and children is varied. Some types of hearing deficits are congenital, whereas others are acquired and related to identifiable events. The prevalence of congenital hearing loss ranges from 1 to 2 per 1,000 births in the U.S. (Haddad, 2007b). Congenital hearing deficits may be familial, genetic, or associated with maternal infection (such as maternal rubella during the first trimester) or known congenital syndromes, such as Down syndrome or Turner's syndrome.

Risk factors for acquired hearing deficit include prematurity (possibly because of the fragile nature of the nerve endings in the inner ear), environmental noises (especially in older children and teenagers), and infections such as meningitis or encephalitis during infancy or early childhood, or chronic OM, which can lead to scarring of the ossicles or tympanic membrane.

Pathophysiology

Hearing loss can be a result of malformation, damage, or disease process involving any of the four portions of the hearing mechanism: outer ear, which directs the sound waves to the eardrum; middle ear, which transmits the sound by means of vibrations of the malleus, the incus, and the stapes; inner ear, in which the cochlea transmits sound to the auditory nerve; and auditory center in the brain. Each requires different interventions with respect to medical or surgical management, sound amplification, and communication style.

Conductive Hearing Impairment

Conductive hearing impairment exists when malformation, inflammation, obstruction (such as cerumen or foreign object occluding the ear canal, or fluid collection in the middle ear), or damage involves the outer or middle ear (such as perforation of the tympanic membrane), thus preventing sound from reaching the auditory nerve. Scarring of the tympanic membrane may also result in conductive hearing impairment. The most common cause of conductive hearing impairment, however, is OM (Kenna, 2004; Kochlar, Hildebrand & Smith, 2007).

Cerumen production is a normal process; however, excess production of earwax can cause cerumen impaction and hearing impairment. Approximately 10% of children either produce more than normal amounts or have difficulty with cerumen removal that results in hearing impairment. Cerumen is typically gold colored when it is fresh and very dark when it is old. Normally, cerumen is moved to the external canal opening by constant movement of hair cells in the ear canal. In the outer ear area, the cerumen dries and flakes off. Cerumen impaction may develop in a child who wears hearing aids, because the daily use of the ear mold prevents the cerumen from leaving the ear canal. All children who wear hearing aids should be monitored for this possibility.

Other conditions that can cause conductive hearing loss include congenital anomalies such as external audi-

tory canal atresia or stenosis, abnormalities of the tympanic membrane, and ossicular malformation or fixation. Acquired abnormalities, such as tympanic membrane perforations and ossicular erosion resulting from middle ear infection or cholesteatoma, can also cause conductive hearing loss.

Sensorineural Hearing Impairment

QUESTION: If Gabriella does have sensorineural hearing loss, what does this really mean for her and her family? What does she hear?

Sensorineural hearing impairment exists when the cochlea does not relay sound pattern information received from the middle ear. The usual cause is absence or malformation of, or damage to, some or all of the tiny structures in the inner ear (the hair cells, organ of Corti, membranes that form the cochlear partitions, or nerve fibers that link the hair cells to auditory nerves). This type of hearing impairment can be a result of many different factors affecting both the inner ear and the brain pathways. Risk factors include heredity; infections in the brain; exposure to intrauterine infections such as rubella, cytomegalovirus, and herpes simplex viruses; exposure to loud sounds; use of ototoxic medications; and prematurity. Infants who are premature and of low birth weight are more prone to development of hearing deficit after intraventricular hemorrhage, anoxic periods, Rh incompatibility, or bilirubin encephalopathy. These tiny babies are more prone to nerve damage and hearing center brain damage than are full-term infants (Kenna, 2004).

When nerve damage occurs, the volume and pitch of hearing is affected. The sounds heard are distorted, with certain sounds being lost altogether. For example, the “f,” “s,” and “d” sounds are frequently not heard, thus affecting the child's ability to understand speech. Persons with sensorineural hearing impairment often do not benefit greatly from amplification of sound by hearing aids because sounds are still distorted and verbal communication remains fragmented.

ANSWER: If Gabriella does have sensorineural hearing loss, she most likely will have hearing frequency loss. This means she does hear, but certain frequencies are distorted or lost. A positive aspect of Gabriella's situation is that assessment and intervention will be begun very early. Gabriella should be enrolled in early intervention to clarify the articulation of her speech sounds.

Mixed Hearing Impairment

Mixed hearing impairment is caused by a combination of conductive and sensorineural factors that contribute to the hearing deficit. For example, OM may develop in a child with a mild sensorineural hearing loss, thus diminishing further his or her ability to hear and understand the sounds in the environment. Typically, the conductive portion of the child's hearing loss can be effectively

treated with amplification, but the sensorineural portion cannot be treated as effectively.

Central Hearing Impairment

Central hearing impairment is caused by damage or malformation within the brain itself or in the nerves that carry auditory information to the auditory portion of the brain. It results from direct damage to this portion of the brain or is secondary to sensory and experiential deprivation. Usually, the child with central hearing loss has difficulty paying attention to sounds and with recognizing, remembering, associating, and comprehending the significance of specific sounds.

This type of impairment is sometimes called *neural impairment* and is considered part of sensorineural hearing impairment, but, because the symptoms and the management are somewhat different, it is considered separately in this chapter. The conductive system and the auditory nerve pathways are intact through the inner ear, but the brain is unable to receive and process or assign meaning to the sounds. This inability prevents the child from understanding the sounds in the environment, including language. It may be a result of trauma, neurovascular changes such as may occur with perinatal asphyxia or intracranial hemorrhage, or a disease process. Usually, the child has difficulty in paying attention to sounds and in recognizing, remembering, and associating sounds with specific events. Only in rare cases do infections such as meningitis cause central deafness.

Assessment

Presenting signs and symptoms obvious to the outsider are usually the same in all types of hearing deficit; however, with testing, the audiologist can identify the type and degree of loss, which facilitates long-range plans for therapy, assistive devices, family teaching, and the child's educational needs. Physical assessment of a child with possible hearing impairment follows the pattern described previously. Frequently, however, deciding who to assess is a larger question than deciding how to assess hearing.

In 1993, the National Institutes of Health Consensus Development Conference recommended that all infants be screened for hearing loss before being discharged from the hospital. Screening tests often yielded false-positive results, thus causing undue stress for many families. For this reason, the AAP (1999, 2007) set guidelines and standards for the implementation of hearing screening programs. Technology has improved so that testing can be done rapidly and more accurately. At least two tests are in common use for newborn testing: the otoacoustic emissions test and the ABR (Kochhar et al., 2007; Widen & Keener, 2003) (see Tests and Procedures 28–1).

All infants who are at high risk for hearing deficit should be screened regularly at each well-child visit and at least annually by an audiologist. Any infant who has had repeated episodes of ear infection should also

FIGURE 28–13. Children's hearing should be tested regularly.

be screened annually. During school years, children should be screened at least every 2 years, with children who have had repeated or extended episodes of OM or effusion being screened annually. Children who are old enough to cooperate with the examiner may be given the standard “hearing test” that measures the child's ability to hear different tones at different volumes (Fig. 28–13).

Alert! Screening devices used in schools and clinics provide only a rough estimate of the child's ability to hear. Even after screening, if parent, physician, nurse, or child suggests that a problem exists, referral to an audiologist for testing with more sophisticated equipment is appropriate (see criteria for referral to an audiologist earlier in this chapter).

When deciding whether to refer the child for more precise assessment, healthcare providers must consider the implications of not referring the child. For example, a child who frequently misbehaves in the classroom, fails to follow directions at home or at school, or suddenly does less well in school than usual is at risk for psychosocial and emotional effects as well as achievement delays in school. Early identification of hearing deficit can facilitate its treatment and avoid potential psychosocial, emotional, academic, and vocational problems. Waiting until development is lagging behind normal in early childhood or until behavioral effects of hearing deficit have developed in middle childhood is waiting too long.

Assessment should include history, particularly focusing on ear infections and on the previously mentioned behavioral factors as well as ear, nose, and throat examination. Fluid accumulating in the middle ear can substantially decrease hearing in the affected ear. Use of tympanometry in the office or clinic may be helpful in identifying an unrecognized MEE. Also be alert for psychosocial manifestations of hearing impairment including communication difficulties, academic performance difficulties, and difficulty in social adjustment.

Interdisciplinary Interventions

QUESTION: What is the role of the nurse in caring for Gabriella and her family, and families like hers who may be dealing with children with a hearing impairment?

Interventions that are useful in managing hearing loss focus first on accurate diagnosis and second on identification of methods to facilitate normal development through life. Interventions must always involve the family as well as the child. A team approach is essential if the child is to benefit most from the available technology and therapy.

The primary care provider is often the interdisciplinary team leader, treating existing problems and referring the child as necessary for diagnosis or management of problems requiring a specialist. The nurse has a clear supportive role in assisting the family through the diagnostic process. The nurse may also have a role in assisting the family to accept the problem and participate in the treatment program. The audiologist identifies the nature and severity of the problem and makes recommendations to the family concerning its management. If necessary, the audiologist refers the child to a speech–language pathologist who works with both the parent and the child to provide speech readiness exercises or speech therapy for the child and training for the parent. The audiologist makes recommendations to the family for the use of amplification devices. The speech–language pathologist teaches the child and family how to make best use of the amplification devices and monitors the child’s progress. When the child is old enough to attend school, the school nurse, speech therapist, and teachers become involved as they provide an educational program for the child. Each person needs to have full information concerning the child’s educational and speech therapy program.

Amplification Devices

Amplification devices (hearing aids) are more useful as assistive devices for children with conductive or mixed hearing deficit than they are for children with sensorineural hearing impairment. For these children, the device helps them to hear sounds in the environment and to learn to respond appropriately. Both the parents and the child need to learn to manage and care for the hearing aid (see TIP 28–1).

Children with sensorineural hearing impairment may benefit somewhat from amplification devices; however, nerve damage may prevent amplification from improving the ability to understand the spoken language. They may need to learn to communicate through signing, lipreading, or both.

caREminder

Children’s hearing aids must be kept clear of cerumen. The audiologist will show the child and family how to clean the individual unit the child receives. Remind the child and family to clean it regularly, to avoid dropping it by always working over a folded towel, and to never get the aid wet.

Cochlear Implant

Cochlear implant is recommended for children who are born with profound hearing loss or sustain damage or injury that causes auditory nerve damage after initial speech has been learned. Children with bilateral severe to profound sensorineural hearing loss who do not benefit from conventional hearing aids are often candidates for cochlear implants.

Cochlear implants convert speech and environmental sounds into electrical signals and send these signals to the hearing nerve. The implant consists of a small electronic device, which is surgically implanted under the skin behind the ear, and an external speech processor. A microphone is worn outside the body as a headpiece behind the ear to capture incoming sound. Currently available devices have a magnet that holds the external system in place next to the implanted internal system. The external system may be worn entirely behind the ear and the speech processor may be worn in a pocket, belt pouch, or harness (Fig. 28–14A). The speech processor translates the sound into distinctive electrical signals. These signals or “codes” travel up a thin cable to the headpiece and are transmitted across the skin by radio waves to the electrodes implanted in the cochlea. The electrodes’ signals stimulate the auditory nerve fibers to send information to the brain, where it is interpreted as meaningful sound. The brain learns to recognize this signal and the person experiences this as “hearing” (Fig. 28–14B).

To receive an implant, the child undergoes a 2- to 3-hour outpatient procedure under general anesthesia. An incision is made to implant the device, thus the child will have a dressing on his or her head postoperatively and will require information about care of the dressing and assessment of the incision site for infection. Most children are able to go home the same day. Approximately 2 to 4 weeks later, the child returns to the implant center to have the external components of the device programmed and activated. The audiologists determines the child’s threshold levels—that is, the minimum electrical current required to produce a response. Until this is done, the child is not able to hear from the device.

Alert! When the implant is turned off or not in use (while swimming, bathing, sleeping), the child cannot hear and is profoundly deaf.

After the initial activation, the child will have several appointments with the audiologist within the first year to ensure maintenance and optimal performance of the device. Thereafter, annual appointments are scheduled to monitor the device. Speech and language therapy are initiated immediately after the device is activated and continue as long as needed to meet the individual needs of the child.

Cochlear implants are being used in children who have lost their hearing before the development of speech. Although these children cannot immediately tell us what they are hearing, observation by parents and subsequent

FIGURE 28–14. Cochlear implant device. (A) The external components of this cochlear implant device consists of an earpiece microphone, an external magnet to be placed near the internal device, and a speech processor. (B) The external components of a cochlear implant device are held in place by magnets placed in both the headpiece and the implant.

testing demonstrate that these children do at least as well in communication as those in whom cochlear implants were done at a later age (Rubinstein, 2002). The cochlear implant does not restore hearing to a normal range for deaf children; rather, profoundly deaf children can detect sounds in the mild to moderate range of hearing loss. Thus, although the cochlear implant may dramatically affect speech and language development, the device alone does not guarantee the acquisition of spoken communication (DesJardin, Eisenberg & Hodapp, 2006). Experts agree that parental involvement and ability to follow through with prescribed strategies to help the young child with hearing loss are critical to the child's ability to acquire language skills (DesJardin, Eisenberg & Hodapp, 2006). Young children with cochlear implants have the potential to achieve language acquisition skills at the same level as their hearing peers.

WORLDVIEW: Cochlear implants support communication within the home using spoken language. Studies have shown that exposure to a second language at home does not impair language acquisition in young children with cochlear implants. Children with cochlear implants can learn multiple spoken languages and parents need not fear introducing multiple languages to the child (Thomas, El-Kashlan & Zwolan, 2008).

Community Care

Two different approaches to communication are taken by educators and parents of children with a hearing deficit. Some subscribe to the oral approach and others to the signing approach. Children raised with the oral approach do not learn signing but depend on lipreading and amplification to communicate. Persons who subscribe to this approach believe that learning to sign distracts the child from attending to speech and alienates him or her from the hearing world. When communicating with the child who uses the oral approach, face the child when speaking, speak in a normal tone, and enunciate clearly. Keep environmental noise such as air condi-

tioners or other equipment sounds at a minimum (Community Care 28–3).

Communication through sign language is a second approach (Fig. 28–15). Sign language used by the deaf in the United States is called American Sign Language, a complete language in itself. The syntax is different from English and persons using it do not voice the words as they communicate. Sign language used by hearing persons to communicate with the deaf is usually a system of converting English into a manual code. Voicing words usually accompanies signs. Finger spelling may also be used. Working with children who sign is usually facilitated by the children themselves and their families who have developed a variety of coping skills for communicating with the hearing world. If the child is old enough to write, a pencil and paper may facilitate communication. If the child does not yet write, ask the parent for information concerning some of the more common signs the child uses to indicate his or her needs and desires. A series of pictures from a magazine can be put together to use as a dictionary and can be very helpful in understanding what the child needs when nursing personnel are not familiar with sign language.

caREminder

There is no single best method for communicating with the deaf child. Healthcare providers must have patience, be willing to learn, and be prepared to attempt any form of communication used by the child and family.

Children with profound hearing loss may have other comorbid chronic conditions or may experience developmental delays in social, gross, and fine motor areas related to their inability to hear. Care of the child with a hearing loss involves assessing all aspects of the child's life and providing medical care and habilitation as needed to ensure the child has the opportunity to meet all developmental norms for their age.

COMMUNITY CARE 28–3

Needs of the Child With Hearing Impairment

Hearing Disability	Sounds First Audible At	What Is Heard Without Amplification	Home and Educational Needs
Normal hearing	0 to 15 dB	All speech sounds	Prevent auditory damage through trauma, infection, or prolonged exposure to loud sounds.
Slight hearing impairment	16 to 25 dB	Voiced vowel sounds are heard clearly; may miss unvoiced consonant sounds like “p,” “th,” and “s.” The child may display mild dysfunction. Possible demonstration of fatigue in trying to hear normal speech. Possible failure to hear and understand directions. Possible demonstration of effects of feeling left out (social isolation). Environmental sounds possibly preventing hearing voiced words clearly.	Be sure the child is paying attention. Ask the child to look at the speaker. Speak distinctly. Enunciate clearly. Encourage auditory training. Encourage speech therapy. Provide preferential seating in classroom. Evaluate need for hearing aid. Encourage social inclusion.
Mild hearing impairment	26 to 40 dB	Only louder voiced sounds audible Seldom hearing enough of social interactions to benefit from social learning. Even with amplification, possible missing of full context of classroom interactions and directions.	Turn off environmental noise when possible (e.g., radio, television, air conditioner, dishwasher). Use language frequently and consistently. Ask the child for input into conversations and discussions. Anticipate the need for possible sound amplification through use of hearing aid. Use same techniques as noted earlier. Encourage the child to request clarification if words are unclear. Encourage social inclusion. Teach social skills. Teach peers how to interact and include this child. Provide directions in writing and provide summary of classroom interaction to assist in understanding its full content.
Moderate hearing impairment	41 to 65 dB	Failure to hear most speech sounds in normal conversational tones	Use amplification. If hearing impairment occurred prelingually, anticipate need for speech therapy or use of sign language.
Severe hearing impairment	66 to 95 dB	No speech sounds heard at normal conversational levels	Use amplification. Anticipate use of sign language for maximal communication. The child may be a candidate for cochlear implant.
Profound hearing impairment	96+ dB	No speech or other sounds heard, but possible ability to feel vibrations from some sounds	Anticipate possible amplification (child may benefit somewhat). Use sign language for maximal communication. The child may be a candidate for cochlear implant.

FIGURE 28–15. Sign language can be used by the child with a hearing impairment or by the child who has difficulty in communicating verbally as a result of his or her physical condition.

Deaf children born into hearing families require adaptation of the family. The family must learn to be an advocate for the child until he or she can do so alone. The family needs to adopt a philosophy with respect to communication and teach other family members to use that method.

ANSWER: Nursing focuses on the families' response to each aspect of the problem: the diagnostic process, the diagnosed problem, and the treatment or interventions. The nurse also evaluates the response of the individuals and the family as a unit.

ALTERATIONS IN COMMUNICATION

QUESTION: Is Gabriella at risk for a communication disorder? Why or why not?

The processes of receiving, sending, and processing are associated with different physiologic and cognitive abilities. The ability to receive verbal information is usually associated with the ability to see and hear. The ability to comprehend verbal information or information in symbols may be associated with the function of the central auditory centers or processing centers of the brain. The ability to send verbal or symbol messages (as in the case of sign language or gestures) is associated with cognitive abilities needed to formulate the message as well as coordination of speech centers and neuromuscular control centers needed to form the words so that others can hear and understand.

Children are said to have a communication disorder when their ability to receive, send, or process concepts or verbal, nonverbal, or graphic symbol systems is impaired. Thus, a child with a communication disorder may have a hearing, speech, or language disorder or some combina-

tion of these. Hearing disorders were discussed previously. A **speech disorder** includes impairment in articulation of speech sounds (forming words), fluency (saying words and sentences), or voice (tonal quality), whereas a language disorder includes impairment in comprehension (**receptive language**) or use of language in verbal, written, or symbol form (**expressive language**). A child with a speech disorder may have difficulty saying certain sounds after the time when he or she should have learned those sounds developmentally, or may stutter after the time when brief repetitions or pauses are normal. The child with a **language disorder** (abnormality in formulating the content of speech) may be unable to understand what is being said to them or may have difficulty responding appropriately—for example, putting words together to express an idea intelligibly. A language disorder is frequently the first indication that a child has autism (Charman, 2004; Charman & Baird, 2003). The child has altered ability in receptive and in expressive language. Children with any of the types of communication disorders must be assessed by the appropriate professional. Therapy is directed toward the specific communication disorder.

Remember that the child's ability to develop socially both within and outside the family unit depends largely on his or her ability to communicate. For this reason, early diagnosis is needed to make best use of the critical period for development of language—the first 36 months of life. Also remember that delayed development of speech and language ability is one of the most common indicators of developmental delay in children but does not always indicate that developmental delay is present. Speech disorders, including various dysfluencies, as well as delay, are more common and more readily observed than language disorders. Both speech disorders and language disorders occur more often in boys than in girls. Children who are learning two languages at the same time will do so more slowly, but will catch up later.

Language Disorders

Delay in a child's ability to use language as a means of communication may be a normal response to an environment that does not require verbal communication, it may indicate a language disorder, or it may be secondary to some other factor such as hearing impairment, autism, or brain damage. Language delay can also result when the child is developmentally occupied with learning other things such as concepts, motor skills, or some other aspect of life.

Children with a limited need to communicate may include twins who develop a personal communication system between each other, a younger sibling born into a family with several older children who speak for the younger sibling, or possibly a child whose parents do not encourage independent speech. A child with limited comprehension of word symbols will be delayed in the use of words. Additionally, children with hearing impairments are likely to have language delays.

Disorders of Articulation

Articulation disorders may include atypical production of speech sounds that can interfere with intelligibility of speech. Children may substitute “th” for “s,” may be unable to say certain sounds, or may add or omit other speech sounds from words.

Disorders of articulation often accompany structural anomalies such as cleft lip and palate, neuromotor disorders such as cerebral palsy, or hearing impairment. When a structural anomaly is corrected, the child’s ability to form speech clearly is improved. For this reason, correction of structural defects is done as early as possible so that the child learns to speak at normal times. If the structural abnormality cannot be corrected, the speech and language pathologist or the speech therapist may be able to assist the child to learn to form words in a way that improves intelligibility.

For the child with neuromotor disorders, speech problems may be affected by a variety of issues such as poor respiratory control (resulting from weak muscles, laryngeal and soft palate dysfunction), an inability to articulate words (dysarthria; resulting from imprecise oral–facial structures, paralysis, spasticity of the muscles used in speaking), or emotional stress.

Developmental assessment is an essential component of the intervention process (see Chapter 3 for a discussion of developmental assessment tools that can be utilized by nurses and other healthcare professionals). In cases when the child has confounding or comorbid conditions that affect speech development, speech and language therapists and habilitation specialists (see Chapter 12) are involved to assist with feeding, drinking, and swallowing problems as well as muscular disabilities that may affect speech and language production. Speech and language therapists will work with parents and teachers to develop a program that focuses on the child’s difficulties, including those that may affect development of social and motor skills. Speech and language therapists will also seek to provide communication devices to help the child with major speech and language difficulties.

Disorders of Fluency

The most common fluency disorder is stuttering. Stuttering is the repetition of syllables or sounds, with frequent blockages in speech that can manifest as uncomfortable pauses accompanied by unusual mannerisms. It is found in about 1% of the pediatric population (Baker & Blackwell, 2004).

Stuttering must be differentiated from normal dysfluency that occurs in young children between 2 and 4 years of age. At this age, children are learning the complexities of language structure as well as developing physical control of the oral movements needed to produce speech. Repetition of syllables or sounds at this age is usually part of normal development and does not require intervention.

Differentiating the normal dysfluency from the mild stammerer is often difficult. Baker and Blackwell (2004) suggested that children with normal dysfluency stutter using only one to two repetitions of the syllable and in fewer sentences (less than 1 in 10 sentences). Stutterers have more dysfluencies (i.e., more than 1 in every 10 sentences), and individual dysfluencies contain a greater number of repetitions of grammatic units. For example, the child with normal dysfluency may say “li-li-like,” whereas the child with early stuttering would include three or more repetitions of the syllable before the word is completed, and the dysfluency would occur every two to three sentences during the conversation.

The causes of true stuttering are largely unknown; however, 15% of stutterers have a first-degree relative who does currently stutter or did so in the past. Research has also shown that muscle coordination of the oral structures actually changes during stuttering and that stress, anxiety, and rate of speech also affect the dysfluency (Baker & Blackwell, 2004).

Persistent dysfluency causes an increase in tension for the child who may then develop secondary characteristics that accompany the dysfluency. The child may blink the eyes, squint, and move the lips and face in particular ways in response to the dysfluency. These increase the psychological effect of dysfluency and increase the tension the child feels.

The true stammerer needs to be referred to the speech–language pathologist for evaluation and treatment as early as possible. About 74% of children who are true stutterers experience remission within 4 years; however, 26% of stuttering persists beyond that time (Baker & Blackwell, 2004). Healthcare providers and family members can provide support to the child who stutters by modeling speech patterns that assist the child to feel comfortable while engaging in dialogue with others (Community Care 28–4).

Disorders of the Voice

Voice disorders are characterized by sounds, pitch, volume, or voice quality that are abnormal for age or sex. A normal voice should have a pleasing quality and should not distract the listener. Young children learn to use their “inside voice” and their “outside voice.” Some may also develop a “get-mother’s-attention” voice, which is high pitched and unpleasant to listen to. They need to be taught socially appropriate ways to get the attention they need.

A wide variety of etiologies may contribute to voice disorders: voice misuse or abuse; vocal cord nodules, polyps, or paralysis; or gastroesophageal reflux disease (GERD). Both GERD and voice abuse can cause the development of nodules. Children with GERD are likely to present with hoarseness, sensation of a lump in the throat, pain on swallowing, frequent throat clearing, and dry cough. Hoarseness is a common symptom in voice disorders and may be caused by frequent upper respiratory infection or by overuse, as teens are prone to do at sports events.

COMMUNITY CARE 28-4

Supporting the Child Who Stutters

- Model slow and relaxed speech (not so slow that it sounds abnormal, but unhurried speech with many pauses). Modeling relaxed speech is better than telling the child to slow down.
- Set aside a few minutes every day where you do nothing but listen. Let the child talk about whatever is on his or her mind.
- When the child talks, pause a moment before answering. Doing so helps make talking less hurried and more relaxed.
- Try not to be upset or annoyed when the child stutters. He or she is learning many new skills, thoughts, ideas, concepts, and words all at the same time.
- If the child is frustrated or upset when stuttering happens, reassure him or her. Tell the child, “I know it’s hard to talk sometimes, but it’s OK. Lots of people get stuck on words sometimes.”
- Reduce the number of questions you ask the child. Instead, comment on what the child has said.
- Let the child know you are listening to the content of what they have said rather than how he or she is talking.
- Be aware of how you are interacting with the child. Try to decrease criticism of the child’s speech, and decrease your own rapid speech patterns, interruptions, and questions.
- Help family members to learn to take turns talking. Avoid interruptions while the child is talking.

Children found to have nodules on the vocal cords should also be evaluated for GERD (Baker & Blackwell, 2004).

Children with voice disorders should be referred to the otolaryngologist or speech–language pathologist if hoarseness persists longer than 2 weeks, tonal quality is distracting (too loud, too soft, too high, or too low), frequent coughing or throat clearing occurs, or noisy breathing occurs at any time of day or night with normal activity or with exercise.

ANSWER: The potential for a visual disorder compounded by the possibility of sensorineural hearing loss does make Gabriella at risk for a communication disorder. She is at risk for a speech disorder—specifically, impairment in articulation of speech sounds. It is unknown whether she may have a language disorder, but “learning disabilities,” or information-processing disorders, are more prevalent in premature infants than the general population.

THE CHILD WITH MULTIPLE CHALLENGES IN SENSORY FUNCTION

The infant or child who has multiple deficits in sensory function and communication presents the greatest challenge to parents. Before widespread use of the rubella vaccine, congenital rubella was a major contributor to multiple sensory deficits. Since that time, prenatal or postnatal injury and illness have become the major etiologic agents for multiple sensory deficits. These deficits are sometimes accompanied by developmental delay and cognitive impairment.

Multiple Deficits

The loss of both hearing and sight may be a result of congenital defect, acquired illness or injury, or a combination of these. In many cases, the combination of hearing and vision losses can affect language acquisition. Additionally, vision and hearing deficits are seldom complete; thus, the child’s residual abilities must be identified and used to provide maximal benefit for the child. The desired outcome when working with a child with multiple sensory function challenges is for the child to have the opportunity to develop to his or her maximal potential. This requires the effort of parents, family, and the entire healthcare team.

Assessment

QUESTION: How is the assessment of an infant born prematurely with potential vision impairment (ROP stage II) and potential sensorineural hearing loss, like Gabriella, different from a child without risk factors?

Assessment of a child with multiple sensory deficits, such as compromised vision and hearing, must include an assessment of the family strengths available to assist them in their care and teaching of the child. Initially the family must deal with their sense of loss of the normal child they expected or once had and then implement coping strategies to facilitate family life and participation in the child’s treatment program. Assessment of the child, then, must include assessment of parental adaptation to the needs of this infant or child.

Assess the child’s impairments early and periodically as the child grows. Also include assessment of residual vision and hearing, and of the child’s ability to use these senses meaningfully. In addition, assess the child’s other senses of touch, taste, and smell.

Cognitive and behavioral assessment provides information concerning the child’s ability to explore the environment and learn from other senses. This is an area in which family members can contribute greatly in

providing stimulation for the child. Anticipate performing these assessments regularly throughout infancy and childhood to foster optimal developmental progress. For the child in school, school systems commonly are responsible for cognitive and behavioral assessments. However, encourage parents to take an active part in securing these services and in providing information and follow-up.

Reinforce with parents of children with multiple disabilities that their observations of the child's abilities and responses are very important in the assessment process. For example, a child who has limited cognitive ability may demonstrate discomfort or pleasure in ways not common to other children. A parent's knowledge of how the child demonstrates discomfort may be critical to the assessment of pain and care of this child during hospitalization for illness or while undergoing therapy. Parents' observations should be recorded for the benefit of all healthcare providers as they care for the child.

ANSWER: Sensory impairment and learning impairment are known problems (morbidity) for premature infants. Gabriella's parents are aware of the possibility of sensory impairment before her discharge from the hospital. The healthcare team and her parents will make certain that there is early detection and intervention for any problems that do appear. In addition, Gabriella will be monitored and regularly evaluated by a healthcare team with whom the family has already established a positive and trusting relationship.

Interdisciplinary Interventions

QUESTION: Consider the spectrum that exists for children with multiple disabilities. Gabriella may need to wear glasses to see clearly and she may have difficulties hearing certain sounds. The other end of the spectrum is total blindness and deafness. How can nurses facilitate and support healthy relationships and healthy growth and development for children with known disabilities?

A child with multiple sensory challenges and his or her family can benefit greatly from the efforts of an interdisciplinary team of specialists. The pediatrician and developmental pediatrician can monitor the child's growth, development, and general health. The nurse also assists in monitoring growth and development, and in providing support and teaching for the family. Other team members may include any person whose specialty and services the child may need, such as an ophthalmologist, speech pathologist, audiologist, social worker, or child life specialist. In addition, particularly when the etiology of the child's condition is unknown, referral to specialists in metabolic disorders and specialists in assessment of genetic disorders may be helpful. The family has a right to know whether the identified deficiencies are part of a

genetic or metabolic syndrome that could recur in the family or whether the child's condition is a sporadic event. A young family thinking of having another child certainly needs to know the likelihood of having another child with multiple disabilities.

The nurse often works with the physician and assists in recommending referrals to other team members when consultation or therapy is needed. The nurse may function in a supportive role or as educator for a parent with questions about the general care, developmental stimulation, or health of an infant or child. The nurse needs to know when to consult the physician and when to refer the parent to the physician or other healthcare professional.

In the role of educator, the nurse helps the parent plan ways to stimulate the child's remaining senses of touch, taste, and smell, to encourage the child to learn the same things that normal children of the same age are learning. This is done by bringing experiences to the child rather than waiting for the child to reach out and learn. Early in life, an infant learns to differentiate among people. For instance, the visually and hearing impaired child makes differentiations by touch or smell. Encourage the parent to reserve a specific and different action to identify each person. Offer suggestions about how to introduce the small child to different textures, and associate the texture with an activity.

Suggest stimulating residual vision, even if only for light and darkness, by placing the child in different light intensities for different activities. Propose stimulating residual hearing by using different types of sounds, such as music or sounds made by automobiles, trains, or drums. Taste and touch can be similarly stimulated and made part of the infant's learning environment.

A social worker may be needed to help the family access assistance from agencies that can help the child develop to his or her maximal potential. The child needs experiences outside the home, and the parent needs time to do things without the child. A daycare experience for a portion of each week is an excellent opportunity for the child. The family may require funding assistance from an outside source to make these activities possible.

Daycare play opportunities during early childhood can assist greatly in school readiness. Play opportunities become learning opportunities in a special class where the teacher is knowledgeable in teaching children with deficits. A child with cognitive deficiency needs much stimulation and one-on-one assistance to learn. The child with vision and hearing impairment needs early development of the sense of touch in preparation for finger spelling. Persons working with disabled children should not expect them to reach out to learn when they can neither see nor hear what is happening around them; rather, bring the learning experience to the child. Other children may need to be encouraged to participate in the teaching and stimulation process. Teach the child's peers and siblings about the challenges and how they can help the child to learn, regardless of whether the child is developmentally delayed or has normal cognitive

ability. Chapter 12 provides additional information regarding care and home management of the child with a chronic condition and those requiring habilitation services.

ANSWER: Nurses will be present as a part of the healthcare team from birth when impairments may first be suspected, through the development of individualized education programs in the school setting. Children are amazingly resilient and adaptive, and experienced nurses have wonderful success stories to share with parents. Nurses help the child and the family to see the character traits and the senses that compensate for impairment. Nurses provide resources, not only organizations, but also specific individuals who will have a positive affect on a family. Nurses support families through long-term, caring relationships and by empowering families to advocate for their child.

The Child With Altered Mental Health

Case History

Remember Ashley Tran from Chapter 7 and 24. Ashley has several issues occurring simultaneously and she feels as if she just can't deal with it all. A continuing source of conflict is school. Ashley's parents tell her that she must bring her grades up. They are watching her do her homework each evening. She still does not understand her precalculus problems. She feels she cannot meet her parents' expectations and that she has no control over her ability to get an A.

Another ongoing issue is social freedom. According to her parents, Ashley is not allowed to "date" until she is 18. Her parents discourage her from just hanging out or going out with her friends. She is supposed to focus on her studies and not be distracted by dating. Ashley resents the restrictions her parents have imposed and feels they are so unfair compared with the freedoms some of her friends from school have. "It is so hard going back and forth from the Vietnamese world in my parents' home to the American culture of school and work. I feel like the

cultures are polar opposites and it is pulling me apart."

The most recent issue for Ashley is that her brother has been diagnosed with osteogenic sarcoma. He may lose his leg; he may even die. She feels guilty that she is not the one with cancer. She is the one who causes the most family conflict. Her brother always does exactly as her parents wish.

At school she is talking to her history teacher about her brother's diagnosis. Her teacher asks, "How about you, Ashley? How are you doing?" At first she says that she is okay, she just hasn't been sleeping much. Then she begins to cry. The words start out slowly. Ashley starts to cry harder and the words spill out. "My brother has cancer in his bone and he may die. I can't do anything right. I never make my parents happy. I am just useless. I wish I would die instead of my brother." Her teacher has been worried about Ashley because of her change in mood, but now she is frightened for her and walks with her to the school nurse.

CHAPTER OBJECTIVES

1. Describe the mental status examination and the techniques used to assess alterations in children's mental health.
2. Explain the purpose and the use of the interdisciplinary categories (from the *Diagnostic and Statistical Manual*) used to diagnose, communicate, and treat alterations in children and adolescents' mental health.
3. Identify the criteria that indicate a need to refer children and adolescents to mental health professionals.
4. Describe interventions used to treat altered mental health in children and adolescents.
5. Describe the relation between cultural variables and alterations in mental health.
6. Discuss the influence of growth and development in relation to altered mental health.
7. Describe the behavioral, emotional, physical, and cognitive effects of abuse and neglect.

See **thePoint** for a list of Key Terms.

As many as 20% of children and adolescents struggle with some form of disabling mental illness (Belfer, 2008). Most problems these children experience will go unnoticed, and those identified will go without treatment for an average of 7 years. More than 12% of adolescents experience depression and are at very high risk for suicide. An increasing number of younger children also have depression. An estimated 3% to 20% of children experience anxiety symptoms and disorders (Tomb & Hunter, 2004). The primary care provider is usually the person who first assesses the child or adolescent for emotional or behavioral issues. Because these illnesses have lifelong affects on overall growth and development, family and peer relationships, academic achievement, and future employment and economic potential, identifying and treating them is crucial. Regard every contact with a child or adolescent, no matter the reason for the contact, as an opportunity to screen for emotional, behavioral, and mental illness.

DEVELOPMENTAL AND BIOLOGIC VARIANCES

QUESTION: As you read the following material, what are the factors that you believe are contributing to Ashley's depression?

Mental health disorders in children and adolescents can originate from a variety of sources. For instance, the normal processes of growth and development may be sources of stress and emotional dysfunction for some children. How the child views the world, the meaning attached to events, and objects in the youngster's world provide important clues to the evolution of thought and behavioral disorders.

The neurobiologic functioning of the brain is the foundation of all emotional or behavioral disorders and mental illness in children. Stress, genetics, environmental factors, or situational factors can affect the chemistry of the brain, or an injury, genetic influences, or illness may cause structural changes. The brain controls thoughts, feelings, and behaviors; organizes and integrates incoming stimuli; and determines responses to stimuli, which are carried out through motor potential in other parts of the body. Dysfunction can be caused by a structural or chemical disorder. Brain function may be inherently impaired, as in autism and schizophrenia, or functional patterns may become distorted or impaired as a result of inappropriate stimuli, such as abuse, illness, or injury, or as a result of genetic expression or psychosocial disruptions during the developmental processes.

Genetic expression is implicated in mental and behavioral alterations that affect children and adolescents. Studies of twins (monozygotic and fraternal) and family studies suggest that vulnerability for disorders such as schizophrenia, anxiety disorders, and mood disorders is transmitted genetically.

Certain physical illnesses are strongly correlated with alterations in mental health that can affect children. Endocrine function is increasingly believed to be a causative or precipitating factor in mental illness. People with endocrine dysfunction, such as Cushing's syndrome and Addison's disease (disorders of adrenal function), have a high incidence of depressive disorders (Kunzel et al., 2003). Anxiety and depression are highly correlated with hyperthyroidism and hypo- or hyperparathyroidism. Levels of melatonin (a hormone produced in the pineal gland) are strongly correlated with the incidence of seasonal affective disorder; serotonin, norepinephrine, and dopamine also play a role (Leviton, 2007).

The symptoms of mental illness can be relatively difficult to identify in children and adolescents (Fig. 29-1). Children differ in their rate of emotional and physical growth. Children also tend to regress more readily than adults. Regressive symptoms are not always considered important in diagnosing altered mental status, because they represent normal developmental reactions rather than true pathologic findings. If these behaviors persist, however, concern may be warranted.

The nurse must take the cultural context of the child and the family into account. Based on culture, the family's behavioral expectations for the child, discipline, and definitions of abusive behavior may vary. For instance, in some cultures, families encourage a quiet and peaceful nature, so do not automatically assess a child who is very quiet and passive in school as having school phobia or a learning disorder. Some culturally based practices can be physically harmful, however, and are inappropriate in the care of children. Some legal standards of behavior cross cultural lines, especially when distinguishing abusive from nonabusive behavior. In mental health nursing, as in other aspects of child healthcare, acknowledge the family's culturally based views, resources, and practices, and show respect for them. Use culturally acceptable treatment approaches if possible, and work with the family to develop a shared definition of improvement in the child's behavior and level of functioning.

Some theorists believe maladaptive behavior is learned and reinforced by positive stimuli in the child's environment.

Children with endocrine dysfunction have a higher incidence of depressive disorders.

Suicide is the third leading cause of death among adolescents (15–24).

Many children with mental disorders have developmental delay.

Research studies have suggested that some mental disorders may have been transmitted genetically.

Use of substances interferes with development of problem-solving skills and use of effective coping devices.

The physical manifestations of maturation (i.e., muscular tension, overwhelming fatigue, increased heart rate) can be interpreted by the adolescent as signs of physical illness and lead to undue stress and anxiety.

Severe childhood stress is believed to first occur at times when neurons are easily shaped by experience.

Children regress more quickly than adults. These regressive symptoms may be the result of developmental stresses rather than represent true pathology.

Some theorists believe that the child's mental health is influenced by interpersonal life experiences.

Acting-out behaviors may mask depression in children and adolescents.

Assessing family norms and culture is a critical element in evaluating the presence of mental health concerns in children in the family.

FIGURE 29–1. Developmental and biologic variances: mental health.

ANSWER: Ashley's depression has multiple sources: developmental challenges, cultural and intrafamily conflicts, and perhaps biologic vulnerability.

ASSESSMENT OF THE CHILD WITH ALTERED MENTAL HEALTH

View the child holistically, recognizing that many factors influence development and mental well-being. Many mental health problems have a biologic base, but also consider the child's interaction with the environment, his or her nutrition, temperament, genetic influences, physical health, and developmental status. Economic factors, living environment, peer interactions, resources available to the family, and the spiritual and cultural perspective of the family and community are important influences on children's mental health.

Thoroughly investigate any concern about emotional or behavioral problems. Early identification of possible mental health issues can assist with prompt diagnosis and treatment (Canty-Mitchell, Austin, Jaffee, et al., 2004). Assessment of mental health in a child or adolescent is complex. The nurse must assess a variety of systems and work with the child and the family to identify the behaviors that are acceptable, unacceptable, and most problematic.

Focused Health History

QUESTION: Cultural perspectives on mental health vary considerably. Ashley's parents see her depression as a shameful situation and do not wish to be involved in her care. Who would be involved in Ashley's assessment?

To assess a child or adolescent, gather information not only from the child or adolescent, but also from the people who have meaningful relationships with the patient. Ideally, compile information from the child's teacher, family, case worker, and other healthcare providers. Tools are available to make assessment easier. *Bright Futures in Practice* (Jellinek, Patel, & Froehle, 2002a), developed by the U.S. Department of Health and Human Services in partnership with the National Center for Education in Maternal and Child Health at Georgetown University, is a tool kit designed to help primary care providers promote mental health in children and adolescents and their families. It includes narrative guidelines, assessment tools, tool descriptions, and interviewing guides. The National Association of Pediatric Nurse Practitioners has developed the KySS (Keep your children/yourself Safe and Secure) Program (Melnyk, Moldenhauer, Tuttle et al., 2003), a survey for care providers and parents to assess mental health and psychosocial problems.

ANSWER: Unlike younger children, Ashley can be the primary historian. Her parents are not currently involved in her assessment and at this time are unwilling to be involved. Ashley is receiving her initial assessment from the school nurse. Ashley's history teacher also met with the school nurse to share her concerns.

Child and Family

Elicit the child or adolescent's perspective on the problem for which they are being referred. By listening, the nurse is better able to establish a therapeutic alliance with the child, one of the nurse's primary objectives. Interview the parents separately, then bring child and parents together to share information. Include the child's siblings, if possible, in the family session. During this session, observe patterns of family functioning and interview all family members about their perceptions of the family's strengths, problems, and reasons for referral. Focus interviews with children or adolescents on their strengths and weaknesses, including the reason for referral and the level of functioning within the school, family, and peer group. Ask questions in a way that is appropriate to the child's developmental level (Chart 29–1).

caREminder

A child or adolescent's developmental level and chronologic age can vary widely. Many disorders and injuries in psychiatric patients lead to developmental delays. For example, a 9-year-old with a conduct disorder may need to be assessed at a 4-year-old level developmentally.

Assess the child or adolescent's ability to attend and participate in an interview. Some children and adolescents may be too hyperactive, too anxious, too depressed, or too angry to participate fully in an intake interview. However, give such children the opportunity to do so. The nurse must quickly assess the child's condition, prioritize family concerns, and gather the most important information.

When dealing with children and adolescents who may be angry and anxious about referral, ask open-ended questions in a nonjudgmental manner. To decrease the child's anxiety, begin the interview by gathering non-threatening information.

Typically, when a child or adolescent is referred for assessment, the entire family is in crisis. Often, one or more major events precipitate the referral. Gather information about the child's physical, emotional, behavioral, and cognitive states from birth to present (Focused Health History 29–1).

caREminder

Parents may feel stressed, angry, embarrassed, resentful, exhausted, out of control, and scared. They may also fear that the referral will culminate in the child being taken away from them.

CHART 29–1 CHILD AND FAMILY INTERVIEWS

Child Interview

1. What name do you like to be called?
2. How old are you?
3. What grade are you in at school?
4. What is your favorite subject at school?
5. What subject do you not like?
6. What grades do you usually get in school?
7. Tell me about your teacher.
8. Tell me about why you are here today.
9. How do you get along with the kids in your neighborhood?
10. How do you get along with the kids in your class?
11. What do you usually do when you get mad?
12. What kinds of problems do you have in your family?
13. What things are you good at?
14. If you had three wishes, what would they be?
15. What are your favorite toys?
16. What kinds of things do your parents do that make you mad?
17. What do your parents do to let you know they love you?
18. What are three things that scare you?
19. How are you feeling right now?
20. Have you ever thought of hurting yourself? When? How?
21. Have you ever tried to kill yourself? When? How?
22. Has anyone ever touched you or tried to touch you in your private parts?
23. What is the worst thing that has ever happened to you?
24. Who do you miss the most?
25. What is the best thing that has ever happened to you?
26. Have you ever tried any drugs, alcohol, or cigarettes?
27. How often do you use them?
28. Are you sexually active? (as appropriate) (obtain specific information, e.g., oral sex, intercourse)

Parent/Legal Guardian Interview

1. Tell me about your main reasons for bringing your child here today.
2. What problems did you have during pregnancy?
3. How old was your child when he/she walked and was potty trained?
4. Have you ever wondered if your child was delayed in any area of development? Describe.
5. Describe your child's temperament.
6. What health problems has your child had since birth?
7. What medications does your child take?
8. Who lives in the household with your child?
9. How many hours per week has your child been in daycare?
10. Who cares for your child when you are gone?
11. How does your child get along with other family members?
12. How many friends does your child have?
13. Who does your child seem to get angry at? Why?
14. How old are your child's friends?
15. Does your child play mostly with boys, girls, or both?

16. How does your child get along with other children in school or the neighborhood?
17. In what areas does your child do well in school?
18. In what areas does your child have problems in school?
19. How does your child get along with his/her teachers?
20. Has your child ever been expelled from school?
21. What grades does your child usually get in school?
22. Is your child in a special program at school?
23. Who are your child's teachers and counselor?
24. What major stressors has your child been through?
25. How many homes has your child lived in?
26. Have you ever suspected that your child has been sexually molested?
27. Does your child use sexual language or have inappropriate sexual knowledge?
28. Does your child act or play sexually?
29. Have you ever noticed any trauma, bleeding, discharge, or redness to your child's genitalia?
30. Does your child play with matches or set fires?
31. Does your child ever urinate or defecate in his/her clothing?
32. Does your child ever do so when he/she is angry?
33. Have you ever noticed your child vomiting after meals?
34. Do you think your child has an eating problem? Describe.
35. What does your child do when he/she is angry?
36. How often does your child
 - Hit
 - Kick
 - Bite
 - Spit
 - Pinch
 - Butt head
 - Use profanity
 - Tear up property
 - Hurt animals
 - Throw tantrums
 - Lie
 - Steal
37. Do you suspect your child has used drugs, alcohol, or tobacco products?
38. How much drug and alcohol use is there by other family members in the home?
39. Do you think your child has ever intentionally tried to hurt himself/herself?
40. Has your child ever talked about or attempted suicide?
41. Do you think your child is sexually active?
42. Describe your child's self-esteem.
43. What losses has your child been through?
44. How do you discipline your child?
45. Have you ever noticed your child responding to things that aren't there?
46. Does your child ever say or do things that make no sense to you?
47. What do you enjoy about your child?
48. Which of the issues we have talked about is most problematic to you?

49. What treatment has your child received for these problems and where?
50. Is there anything else we need to know about your child that we have not covered?

Discussions often become emotionally charged when professionals question families about their child-rearing practices. Remember that contact with healthcare providers often occurs when families are under threat or stress from their child's illness. The family may perceive such questions as a challenge or a loss of control and may respond with increased anxiety and by becoming more controlling within the family. Families may become defensive, resentful, and angry. Families are an important resource for learning about the child's history and current behavior, and need to be included in assessment, goal setting, planning, and evaluation (Finke, 2004).

Remember, also, that having a child with a mental illness or emotional problem carries a great deal of stigma. Although mental disorders, just as any illness, have biologic bases, society often finds fault with the individual or family if a child is diagnosed with a mental disorder. Fear of what others will think or of how the child will be judged causes families to delay seeking treatment for their children.

Information From Other Sources

Professional communication with involved teachers, counselors, advanced practice registered nurses (APRN; in psychiatric nursing), social workers, probation officers, psychiatrists, psychologists, psychometrists, and physicians provides a more comprehensive picture of a child or adolescent's history and current level of functioning. Occasionally, the perceptions of family and professionals are vastly different. Typically, written referral summaries from involved psychiatric professionals provide the nurse with most necessary information. Further contact with psychiatric professionals does *not* require parental consent. Communication with psychiatric professionals who are currently involved in the patient's care can provide vital information about family history, previous treatment, any placements outside of the home, and any legal entanglements in which a child may have been involved.

School personnel are knowledgeable about the children and families they serve. Before contacting school personnel, obtain a consent form signed by the child's legal guardian that permits the agency staff and the school to exchange information.

Focused Physical Assessment

QUESTION: Do you anticipate Ashley's physical assessment will reveal any unusual findings?

Any child or adolescent referred for treatment should receive a thorough physical examination. While conducting

FOCUSED HEALTH HISTORY 29–1

The Child With Altered Mental Health*

Current history	Presence of delusions, loose associations, hallucinations, illusions, depression, mania, anxiety, phobias, obsessions, compulsions, impulsiveness, suicidal thoughts or behaviors, aggression (physical or sexual)
Past medical history	Chronic sore throat or difficulty swallowing (forced oral sex, STI) Prenatal/Neonatal History Maternal drug or substance use Birth trauma or injury Previous Health Challenges History of mental health disorder, suicidal thoughts or attempts, aggressive behaviors, homicidal thoughts, substance use Results of any neuropsychological testing Reports of sexual abuse or other forms of abuse Any allergies that cause child to appear highly distracted and unable to concentrate
Nutritional assessment	Recent weight loss or weight gain, decreased appetite, nausea, vomiting Child's perception of his or her weight Child's eating patterns/habits
Family medical history	Genetic and family history of mental health disorders, including depression, suicide attempts, substance/alcohol use
Social and environmental history	Presence of stressful events at home or school Child's peer group and its usual activities School performance Results of academic achievement tests Nature of relationship with parents/siblings Child's perception of how others view him or her
Growth and development	Child's plans for the future Child's perception of himself or herself (self-esteem) Previous exposures to stressful events Coping mechanisms used when encountering stressful events Any variations from achieving significant normal growth and developmental milestones

*This history focuses on altered mental status. See Chapter 8 for a comprehensive format.

the physical assessment of a child with emotional, behavioral, or mental illness problems, pay special attention to several areas of the examination that may indicate that the child's overall physical health is at risk or that there are signs of physical or sexual abuse (Focused Physical Assessment 29–1). A common dilemma is whether to routinely conduct pelvic examinations on all girls suspected of having a psychiatric disorder. A child or adolescent may not have time to build up enough trust with the nurse to disclose sexual abuse, so a pelvic examination can provide useful information. On the other hand, pelvic examinations conducted on young girls, regardless of whether they have been sexually abused, can be traumatic for them. Chapter 8 provides a detailed summary of the pediatric physical assessment. Note any signs that indicate nutritional deficit (e.g., coarse, thin hair; gum and dental problems; delayed healing) and injury to the body that may have been inflicted by the child or others.

ANSWER: A physical assessment of Ashley by the school nurse reveals no unusual findings. Ashley confides that she is sexually active and the school nurse refers her to the Planned Parenthood clinic for a pelvic examination.

Mental Status Examination

QUESTION: As you explore the various means to assess for a mental health condition, which means would you consider appropriate to assess Ashley?

An important part of the mental health assessment is the mental status examination. When assessing older adolescents and adults, it typically includes questions such as “What year is it?” “Who is president?” “What city are

FOCUSED PHYSICAL ASSESSMENT 29–1

The Child With Altered Mental Health

Assessment Parameter	Alterations/Clinical Significance
General appearance	Flat affect, depressed facies, unresponsive, lethargic, hyperactive related to specific mental health alteration; tremors, rigid movements, confusion, sedation may be side effects of medications
Integumentary	Presence of cuts, burns, abrasions, contusions, bruising, other unusual marks on skin possible indication of self-inflicted mutilation or physical abuse Split fingernails; soft, sparse body hair related to malnutrition Unusual hair loss patterns may be caused by trichotillomania (an anxiety disorder in which the individual pulls out body hair to decrease anxiety)
Mouth, throat	Eroded dental enamel, reddened and inflamed gums may be caused by frequent, chronic vomiting (bulimia) Red, inflamed throat possibly resulting from trauma from self-induced vomiting, sexually transmitted infection (STI), forced oral sex
Vision, hearing	Deficits may be caused by physical abuse, may be misdiagnosed as oppositional behavior, related to violent children repeatedly destroying their glasses or hearing aids
Genitalia	Bleeding or discharge (complaints of burning, itching) from genitalia may result from sexual abuse, STI

we in?” Children often do not know these things, so the mental status examination focuses on behavioral observations made of the child or adolescent’s appearance and behavior during 2 to 3 hours of interview. With children and adolescents, the mental status examination also includes information from parents and teachers about how the child interacts with peers.

A mental status examination conducted with a child or adolescent follows guidelines similar to those for the initial interview. Play can be used, especially for children younger than 7 years. While observing play, a skilled clinician can assess most components of the mental status examination. Components of the mental status examination that cannot be observed can be obtained through non-threatening verbal questioning. Conduct the mental status examination in a manner that decreases the child or adolescent’s anxiety. An ability to establish a rapport with children and adolescents is essential in gathering necessary information while not making the child overly anxious.

For older children and adolescents, the nurse gains most necessary information from a relaxed discussion, which could occur in an office, while observing their play, or while playing a game with them.

ANSWER: Ashley’s assessment would be most appropriate through a mental health examination with an advanced practice psychiatric nurse practitioner with adolescent expertise.

Diagnostic Criteria for Evaluating the Child’s Mental Health Status

Evaluation of the child should be performed by a health professional with mental health expertise. Tools for diagnosing a child’s mental health status include imaging

studies, which can detect physical anomalies, and the specific criteria outlined in the Diagnostic and Statistical Manual of Mental Disorders (DSM), which can help identify disorders with less tangible characteristics.

Brain Imaging Techniques

Recent advances in radiography, sound wave, and computer techniques have made imaging of the brain possible. Each technique produces different information, although positron emission tomography and single photon emission computed tomography produce similar images (Tests and Procedures 29–1). These techniques are used to diagnose some disorders.

DSM Criteria

The American Psychiatric Association (APA), World Health Organization (WHO), Veterans Administration, and other professional organizations have developed and refined a classification system for mental disorders that is clinically focused. This system is described in the *Diagnostic and Statistical Manual of Mental Disorders* (4th edition, text revision), or **DSM-IV-TR**, which has become the internationally accepted standard for diagnosing mental disorders.

The purpose of the *DSM-IV-TR* is to provide clear descriptions of diagnostic categories. Common categories enable clinicians and researchers to diagnose, communicate about, study, and treat mental disorders systematically and consistently. The common language system also facilitates reimbursement. The use of the *DSM* diagnostic system demonstrates a commitment in the field to use research-based data to understand alterations in mental health (APA, 2000).

The *DSM-IV-TR* is used by a variety of mental health professionals, including advanced practice psychiatric nurses. However, it is inappropriate for professionals without the necessary knowledge base to assign a *DSM-IV-TR*

Tests and Procedures 29–1 Evaluating Alterations in Mental Status

Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
Regional cerebral blood flow	Identifies cerebral perfusion abnormalities. The child sniffs radioactive gas. Several radiographs delivered as a beam pass through the tissues. Radiographs are layered through computer technology.	An image of the brain is computed. Different sections of brain can be visualized to demonstrate blood flow through the brain tissue. Hypoperfusion or abnormal cerebral blood flow is seen in many brain disorders (e.g., depression, attention deficit disorder, schizophrenia)	Assess child for any allergic reactions to radioactive gas. Assure parents that the dose of radioactive substance is no greater than that used for diagnostic radiographs.
Magnetic resonance imaging (MRI)	Uses magnetic fields to visualize brain structure. Several pulses of energy (sound waves) are used to stimulate atoms within tissue. An image of the brain is computed.	Images show structure of the brain, anatomic deviations, and tissue damage.	Ensure that hairpins, eye makeup (with a metallic base), and watches and other jewelry are removed, and that child's gown does not have a metal snap. Prepare child for sounds of the machine. Child may need a sedative prescribed beforehand to assist him or her in lying quietly during the lengthy procedure.
Positron emission tomography (PET)	Involves very small amount of radioactive water injected into the arm, accumulating rapidly in the brain. Positrons are emitted and multiple images are obtained and input into a computer. Produces images of the brain and corresponding physiology.	PET scans can measure cellular processes, cerebral metabolism, cerebral blood flow, membrane transport synthesis, and receptor binding. They identify specific areas of the brain that are functioning or malfunctioning.	Assist children to lie still during procedure. They may need a sedative administered beforehand to assist them in keeping still. Assure parents that, although procedure is lengthy, the actual radiation exposure is less than during a regular radiographs.
Single positron emission computed tomography	The child is given a radioactive substance and multiple radiographs obtained and input into a computer.	Images of normal and abnormal brain function are produced; these are similar to PET images but are less costly.	Same as for PET

diagnosis. Use of the *DSM-IV-TR* requires considerable training and experience in mental health. Most funding agencies and insurance boards require the mental health professional who makes the diagnosis to have a master's or doctoral degree.

The *DSM-IV-TR* diagnoses are made by assessing five “axes,” or categories of symptoms (Chart 29–2). The first two axes include all psychiatric diagnoses and their corresponding classification numbers. Symptoms overlap and may fall under different axes, depending on the duration and possible cause of symptoms. Under axis V, a numeric score indicates the patient's current level of functioning. It is also common, under axis V, to find a numeric range, which indicates the patient's lowest to highest level of functioning within the past year. The range of function-

ing on the global assessment scale is 0 (indicating the lowest level of functioning) to 100 (indicating the highest possible level of functioning).

TREATMENT MODALITIES

QUESTION: As you read about the following types of therapy, what might be possible treatment options for Ashley?

The needs of the child and the particular mental health alteration determine the treatment plan. Several

CHART 29-2 DSM-IV-TR DIAGNOSTIC CLASSIFICATION

Axis I

- Clinical disorders
- Other conditions that may be a focus of clinical attention

Axis II

- Personality disorders
- Mental retardation

Axis III

- General medical conditions

Axis IV

- Psychosocial and environmental problems

Axis V

- Global assessment of functioning

disciplines are represented on mental health teams such as the nurse generalist, APRN, psychiatrist, psychologist, social worker, occupational therapist, recreational therapist, special educator, parents, and patient. Role boundaries tend to be blurred; each of the disciplines contributes to planning care and performs some part of the overall therapeutic plan. In many settings, all the disciplines are involved in the daily routine. In other settings, every team does not have all the potential members. Available resources, economic issues, and need play a major role in the number and kinds of members assigned.

Cognitive–Behavioral Therapy (CBT)

Cognitive–behavioral therapy (CBT) is one of the few evidence-based treatment methods, other than medication, available to treat mental health disorders. It requires a healthcare provider with specialized training, such as an APRN. CBT is based on the assumptions that thoughts mediate behavior, that causes assigned to behavior are related to how one perceives and assigns meaning to an event, and that changing one's patterns of dysfunctional thoughts (cognitions) and responses helps one cope with the event (Dowd, 2004; Southam-Gerow & Kendall, 2000). Thus, CBT focuses on cognitions, emotional responses, and the resulting behaviors, and views them as inextricably intertwined. Cognitions include the individual's perception of his or her world and the events and objects within it, including the self. Cognitions also include values, beliefs, attitudes, and causal attributions. Understanding the patient's cognitive system is the beginning step in CBT.

The therapeutic process helps the individual reframe perceptions, change ideas about a situation, or view a situation from a different perspective. Next, the patient is helped to see the relations among their thoughts and

beliefs and their emotional responses. Finally, patients are encouraged to use problem solving to identify alternative solutions or ways of behaving. A variety of techniques based on CBT have been developed, such as coping skills therapy, assertiveness therapy, problem solving, and self-control therapy. In all CBTs, patients are taught specific skills such as thought stopping, reframing, relaxation skills, and assertive communication skills. Self-rights and the rights of others are emphasized. CBT is recommended for patients with many disorders including depression, anxiety disorders, behavioral disorders such as conduct and oppositional defiant disorder (ODD), and obsessive–compulsive disorder.

Individual Therapy

Individual therapy is an interpersonal process in which the patient and care provider together discover, explore, and resolve the patient's conflicts, behavioral problems, doubts, and anxieties. Individual therapy also requires specialized training.

The nature of the therapeutic sessions is determined by the patient's age, developmental status, and preference for interacting with the therapist. Play therapy is often used for young children. Activity therapy (structured activities such as clay modeling, drawing, and games) along with discussion works well with many school-aged children. Talk therapy is preferable for adolescents. The broad goals of individual therapy include resolving conflicts, restoring developmentally appropriate functioning, improving self-understanding, and reducing symptoms. Individual therapy may be provided in outpatient clinics, community mental health centers, schools, inpatient hospital units, residential settings, or the patient's home. APRNs who provide therapy in homes or residential settings often carry a variety of toys, games, craft materials, or books to use in their sessions.

Play Therapy

Play therapy is one form of individual therapy developed to address the needs of children through play. However, it also may be used in the family or group context. It allows children the freedom to experience their concerns and fears in a nonthreatening environment with an accepting and attentive adult. Play therapy is based on the assumption that play is therapeutic. During therapy, play becomes the medium by which the child explores life problems, developmental issues, and interpersonal conflicts. The child is free to test new assumptions, feelings, and different kinds of behavior. The therapist provides and ensures safety, and encourages the child to develop a more positive self-concept and realistic perception of the world. Behaviors that help the child to manage daily stressors are encouraged. Play therapy is especially useful with children who have limited verbal abilities, those who have experienced trauma, and those who have experienced family separations or disruptions in early life.

Group Therapy

Group therapy is used to prevent and treat childhood and adolescent mental health alterations. Group therapy is conducted in many settings including schools, residential placements, hospitals, clinics, neighborhood centers, and community mental health centers. An advanced practice psychiatric nurse may be the therapist; alternately, a staff nurse may lead the group. Group therapy is directed at improving socialization, promoting communication, and facilitating behavioral change. Various group models are used with children and adolescents. Children of preschool age benefit from play groups. Elementary school-aged children relate best in groups that are focused and use some structured activities and discussion. Adolescents often respond well to a variety of group interventions, such as recreational, occupational, communication, and self-esteem building.

Therapeutic effects of group therapy include expressing and sharing feelings, gaining a sense of community, inspiring hope, obtaining information and support, and role modeling. The peer group provides opportunities for youth to meet as equals within their own age group, communicate, understand others' perspectives, get along with others, compare themselves with others, define their social role, and perfect their social skills.

Family Therapy

Many models of family therapy exist, with diverse applications. All models focus on family dynamics. Interventions may be designed to develop family-based coping strategies, such as problem solving or stress management. In some families, the needs may include strengthening parental roles, improving communication, or improving interpersonal relationships. In families with young children, play therapy is often incorporated to relax expectations and rules that might prevent children from expressing their feelings and needs. In families with adolescents, the focus may be on relaxing or strengthening rules and expectations to allow adolescents the appropriate amount of freedom to achieve their developmental tasks.

One form of nursing intervention that is especially helpful to families with a severely and persistently mentally ill member is family education. Family education, often provided by a staff nurse, provides information to help families understand the neurologic basis of the illness and the factors that may exacerbate or reduce symptoms of illness. Another goal of family education is to validate feelings associated with loss of the mentally healthy child or adolescent, improve problem solving, promote stress management, and access resources. The needs of families may go even further—individualized care based on these needs.

Milieu Therapy

Milieu therapy, environmental structuring and management, is conducted in dynamic, specially structured set-

tings designed to assist in the overall therapeutic process. Milieu therapy usually occurs in inpatient units, but may be used in school settings, residential treatment settings, and the home. During milieu therapy, the environment is arranged to promote therapeutic goals, such as diminishing aggressive behavior and developing adaptive and social skills. The therapeutic environment includes the people, activities, programs, and physical factors involved (Nursing Interventions 29–1). Children placed in therapeutic environments have usually experienced many failures and disruptions in their lives, such as not progressing in school, not meeting normal developmental tasks, or not having playmates. The milieu provides a safe and supportive environment for children and adolescents who are acutely ill, highly aggressive, and at high risk for abuse or self-harm. Therapeutic milieus incorporate a variety of therapy strategies, such as family therapy, recreational and educational therapy, group therapy, social skills training, and behavioral management, used in conjunction with individual therapy. Active involvement of each child or adolescent is expected and facilitated. Successful milieus require excellent interdisciplinary collaboration.

Behavioral Management

Using **behavioral management**, the nurse collaborates with team members to develop appropriate goals, expectations, consequences (for failure to meet expectations), and rewards (for positive achievements). A problem-solving approach to behavior management, in which the team works with the child and family to identify needs and strengths, is optimal to help children change behavior and integrate new thoughts about themselves and their world. For change to occur, children need to experience their world and the people in it as caring and not just punitive, an experience that simulates the socialization process that most healthy children have experienced.

Behavior management is built on a triad of components: empathy (understand and respect the child), communication (ask questions, listen, clarify, and give feedback), and discipline, which includes positive rewards (attention, celebration of positive behaviors) and negative consequences (inattention, reprimands, natural consequences, logical consequences, and penalties).

Community-Based Wrap-Around Services

An effective treatment for children with severe emotional or behavioral disorders is *community-based wrap-around services* (Furman & Jackson, 2002). This treatment keeps the child in his or her home and school by providing the family and school with the professional support needed. This support may be an aide in school, individual and family therapy, medications, and occasional respite care for the family or any combination of supports that give the child, family, and school the assistance they need to avoid hospitalizing the child. Wrap-around services are less costly than traditional hospitalization and build on the strengths and resources of the family and

NURSING INTERVENTIONS 29–1

Maintaining a Therapeutic Environment for Inpatient Child/Adolescent Psychiatric Unit

Goal: Maintain safety of patients, families, and staff.

Interventions

- Ensure environment is safe and risk free.
- Make patient safety rounds every 15 minutes to ensure safety of patient.
- Provide structure for unit and maintain unit routine, making adjustments when needed.
- Monitor closely behavior of all patients and anticipate escalation of aggression, anxious behavior, or any threat to safety of patient, staff, or peers.
- Deescalate aggressive or anxious behavior and take action to maintain safe and secure milieu.
- Role model appropriate interaction with patients, family members, and other staff members.
- Provide adequate staffing.
- Encourage family involvement and facilitate appropriate interactions.
- Provide structured activities such as training in social skills, communication techniques, coping skills, and stress management.
- Post rules and be sure all patients, family members, and staff know them.
- Provide family and patient with copy of unit rules and behavioral guidelines.
- Educate and train all staff in strategies to deescalate out-of-control behavior.
- Review with staff any situations that lead to disruptions on the unit.
- Implement strategies to closely monitor any suicidal or at-risk patients.
- Maintain restraint-free environment.
- Provide opportunity for patient and family feedback.

Goal: Implement evidence-based plan for each patient.

Interventions

- Develop individual plan for each child with interdisciplinary team, including family and child; assess parent and child understanding of treatment plan.
- Implement plan, including social skills training, communication techniques, stress management, coping skills, and symptom management.
- Assess overall health and effects of medication and therapeutic interventions; educate patient and family regarding importance of medication adherence.
- Document outcomes and celebrate successes with child and family.
- Review plan frequently with team, family, and child, and make changes as needed.

community. Nurses can help to keep the child in the home environment by connecting the child and family to community resources and providing education to, and serving as an information resource for, teachers. Advanced practice psychiatric nurses may conduct therapy in the school.

Psychopharmacology

A variety of medications is currently used to treat childhood and adolescent mental and behavioral disorders (Table 29–1), often **off label** (in a manner not recommended on the product labeling; for example, antipsychotics may be given to calm a child with attention deficit–hyperactivity disorder [ADHD] who is taking Ritalin). Medications are begun at low dosages and titrated to an effective level. A combination of medications may be more effective than one individual medication. Effectiveness of medications also changes over time, possibly because of the physical growth of the child and chemical changes in the body. Frequent changes in dos-

ages and medications therefore may be needed to optimize therapeutic effect. Medications are usually used in combination with other forms of therapy.

The nurse's role in administering medications and observing and reporting responses, including therapeutic and adverse effects, is critical. Nurses often serve a vital role in helping parents to understand the need for the medication, the goals and expected outcomes, and how and when to administer medication. When medication does not appear to produce the desired results, nurses can help uncover patient and parental factors that may be preventing success. Parents and children have a right to information about the medication, and their consent and cooperation must be elicited. Nurses serve an important function in school settings in monitoring medication administration and possible side effects. Nurses also teach teachers, helping them understand the use, potential benefit, and side effects of prescribed medications. The nurse may act as liaison between school personnel, parents, and treatment team members.

TABLE 29-1

Common Psychotropic Medications Used in Child and Adolescent Psychiatry

Classification and Examples	Disorder	Side Effects
Stimulants		
Methylphenidate (Ritalin), dextroamphetamine (Dexedrine), pemoline, amphetamine (Adderall)	ADHD, possibly depression	Insomnia, decreased appetite, weight loss, headache, tics
Antidepressants*		
Tricyclics: imipramine, nortriptyline	ADHD, depression, tic and anxiety disorders	Anticholinergic effects (dry mouth, constipation, blurred vision), weight loss
Monoamine oxidase inhibitors: amitriptyline (Elavil), dibenzepin (Noveril)	As above	Dietary restrictions required, weight gain, drowsiness, insomnia, hypotension
Selective serotonin reuptake inhibitors: fluoxetine (Prozac), sertraline (Zoloft), paroxetine (Paxil), citalopram (Celexa), mirtazapine (Remeron), trazodone (Desyrel)	Depression, obsessive-compulsive disorder, anxiety	Irritability, insomnia, gastrointestinal distress, headaches, nausea, increased blood pressure
Antimanic Agents		
Lithium	Bipolar disorders, depression, hyperaggression	Polyuria, polydipsia, tremor, nausea, diarrhea, weight gain, drowsiness; lithium requires close monitoring
Anticonvulsant Medications		
Carbamazepine (Tegretol), valproic acid (Depacon, Depakene, Depakote, Divalproex), lamotrigine	Seizure, bipolar disorders, occasionally refractory depression, conduct disorder	Bone marrow suppression, dizziness, drowsiness, sedation, nausea
Antianxiety Agents		
Buspirone	Anxiety disorder, rage disorder; adjunct in mania, psychosis, depression, Tourette's syndrome	Drowsiness, disinhibition, agitation, confusion, depression
Noradrenergic Agents		
Clonidine	Tourette's syndrome, ADHD, aggression/self-abuse, agitation; alternative to stimulants	Sedation, hypotension, dry mouth, confusion, depression, constipation, urinary retention, rebound hypertension
Antipsychotic Agents		
Phenothiazides: thioridazine (Mellaril), chlorpromazine (Thorazine), haloperidol (Haldol)	Psychosis, mania, aggression, self-injurious, explosive, and violent, destructive behavior	Anticholinergic effects, extrapyramidal effects (dyskinesia, dystonia), drowsiness
Atypical Antipsychotics		
Risperidone, clozapine, olanzapine (Zyprexa), quetiapine (Seroquel)	Schizophrenia, pervasive developmental disorder, bipolar disorders	Granulocytopenia, seizures, agitation, headache, nausea, sedation, weight gain, dyslipidemia, parkinsonism, dizziness, dry mouth, constipation

*The U.S. Food and Drug Administration requires warning labels about the increased risk of suicide with antidepressant agents.

ANSWER: The school nurse refers Ashley to an APRN who determines that CBT is an appropriate intervention and that a support group for adolescents may also benefit Ashley. Family therapy could also have been beneficial, but Ashley's parents are not willing to come to counseling with her at this time. Medication may be an appropriate intervention in conjunction with another form of therapy for Ashley. The APRN prescribes paroxetine (Paxil), a selective serotonin reuptake inhibitor (SSRI). Education regarding medication is critical. The importance of taking the medication daily is stressed. It may take several days or even weeks for Ashley to feel any different. It is also very important that she not discontinue the medication abruptly. Teenage suicides have occurred when adolescents receiving SSRIs stop taking the medication. Although these suicides have received a great deal of publicity, they have not changed the value of pharmacotherapy, but rather have emphasized the need for education, monitoring, and interpersonal therapy.

NURSING PLAN OF CARE FOR THE CHILD WITH ALTERED MENTAL HEALTH

The nurse, as educator for both parents and children, plays a critical role in helping the parents make informed decisions in the best interest of the child. Refer children who are identified with a severe emotional or behavioral problem or mental illness to a mental healthcare provider. The APRN has an important role in assessing and treating children and adolescents with mental health problems and their families. He or she can perform mental and physical examinations, prescribe medications, and conduct individual, group, and family therapy.

QUESTION: What nursing diagnosis would you develop for Ashley?

A variety of nursing diagnoses may be selected to address the needs of the child with an alteration in mental health status (Nursing Plan of Care 29–1). Altered thought patterns and behavior affect the child's self-esteem, ability to cope, and ability to interact appropriately with others. Another aspect to consider is the effect of mental status on the child's developmental and physical status. Stress reduction activities may help the child to cope adaptively with issues and challenges in his or her life (Nursing Interventions 29–2).

Changes and stressors within the family may contribute to the child's mental health condition or may be an outcome of the child's altered thought processes and inappropriate behaviors. Therefore, when developing a plan for the child's care, include the family as an integral part of both the problem itself and the strategies to assist the child in meeting emotional, cognitive, and physical needs.

ANSWER: There are many diagnoses that would be applicable. One example is hopelessness related to situational and developmental stressors resulting in thoughts of worthlessness.

ALTERATIONS IN CHILDREN'S MENTAL HEALTH

Alterations in children's mental health vary widely in scope and severity, from sleep disturbances and separation anxiety to childhood schizophrenia.

ATTENTION DEFICIT AND DISRUPTIVE BEHAVIOR DISORDERS (ADHD)

An array of common childhood mental health problems falls under the category of attention deficit and disruptive behavior disorders. These disorders, which are common reasons that children need mental health treatment, generate a great deal of difficulty for the child, his or her family, and the educational system. These disorders include ADHD, conduct disorder, ODD, and disruptive behavior disorder. ADHD, conduct disorder, and ODD are most prevalent.

Attention Deficit–Hyperactivity Disorder (ADHD)

The *DSM-IV-TR* identifies three subtypes of ADHD based on symptoms (APA, 2000):

1. Predominantly inattentive, characterized by inability to attend to tasks and activities, tends to make careless mistakes, poor listener despite having normal hearing, often loses possessions
2. Predominantly hyperactive–impulsive, includes excessive motor activity, inability to sit or stay in one place, excessive fidgeting, excessive talking, impulsive behavior
3. Combined inattentive and hyperactive–impulsive

Prevalence of ADHD is 8.7% in children 8 to 15 years of age; it occurs twice as often in boys as in girls (Froehlich, Lanphear, Epstein et al., 2007). ADHD is serious and chronic, affects several areas of a child's life and functioning, and is highly comorbid with other disorders. The rate of comorbidity with externalizing disorders (e.g., ODD, conduct disorder) is about 50%, and is about 25% with anxiety and depression (Ollendick, Jarrett, Grills-Taquechel et al., 2008). Increasingly, these disorders are being viewed as potentially lifelong disorders.

Pathophysiology

ADHD is strongly linked to genetic and biologic factors, but psychosocial factors appear to interact in complex ways with such factors. In biologic parents of children with ADHD, 25% to 33% have ADHD (Cormier, 2008). Dopamine transmitter and receptor genes have been linked to ADHD, and abnormalities of brain structure and function have been noted (Cormier).

NURSING PLAN OF CARE 29–1: THE CHILD WITH ALTERED MENTAL HEALTH

Nursing Diagnosis: Acute confusion related to effects of mental health alteration

Interventions/Rationale

- Obtain medical history.
Helps identify conditions that may be causative factors for mental status changes.
- Obtain baseline assessment of mental status.
Provides baseline data to evaluate changes in child's status and facilitates early detection of changes.
- Adapt communication style to the child's needs and level. Speak slowly and calmly, avoid sudden movements, use short phrases, allow child time to process information. Use pictures or props (e.g., a doll, puppet). Ask for clarification of child's statements if indicated.
Simplifying communication may help the child process information and helps reduce stimulation. Clarification may help link seemingly incongruent statements to logical events.
- Interview child in familiar environment and reduce environmental stimuli (e.g., reduce noise, avoid too-bright lights, limit number of persons in area).
Excessive stimuli may overload the child and promote disorganization.
- Orient the child (e.g., call by name, introduce yourself with each contact, mention date, time, and place). Maintain routine and consistent staff if possible.
Reinforces reality. Predictable routines promote security.

Expected Outcomes

- Child will remain oriented to person, place, and time.
- Child will communicate in a lucid manner.
- Child and family will identify internal and external factors that trigger or contribute to delusional episodes.
- Child will identify and perform activities that decrease delusions.
- Child will adhere to medication regimen to help modify psychological causes.

Nursing diagnosis: Risk for self or other-directed violence related to antisocial and aggressive character, excitement, or self-destructive behaviors

Interventions/Rationale

- Inform child and family of expectations for behavior and consequences for failure to meet the expectations.
Provides structure for the child and makes child responsible for own actions.

- Assess child for risk factors for violence (previous violent behavior, low frustration tolerance, impulsivity, ineffective coping skills, substance abuse, bipolar disorder, conduct disorder).
Knowing risk factors may enable structuring of the environment to avoid inappropriate behavior.
- Monitor the environment for situations that could precipitate violence; intervene to deescalate the situation.
Early intervention may prevent violent behavior or reduce its intensity.
- Observe the child for feelings of anger (verbalization, facial expression of anger such as clenched jaw, eyebrows drawn together, increased restlessness, rigid posture) and acknowledge these feelings.
Early recognition of potential escalation enables early intervention. The child may be unable to identify angry feelings; identifying these feelings may help the child to implement calming measures.
- Intervene to deescalate. Keep calm; speak in a low, even voice; minimize external stimuli; help the child implement self-calming and coping measures; assist the child to redirect energy into physical activity.
Early intervention may prevent violent behavior or reduce its intensity. Physical activity may deplete excess energy.
- Remove others from the vicinity of a violent child.
Minimizes risk to others.

Expected Outcomes

- Child will not harm self or others.
- Child will discuss feelings that precipitate destructive and violent acts.
- Child will learn to control outbursts of rage, self-destructive behavior, or violence.
- Child will use positive coping strategies when he or she feels frustrated.
- Child and family will identify resources for crisis prevention and management.

Nursing diagnosis: Impaired verbal communication related to altered mental status or neurologic impairment

Interventions/Rationale

- Keep statements simple; use short sentences and concrete terms. Convey that you have time to listen to the child and allow time for the child to respond. Use communication aids if indicated (letter/picture board, erasable slate).
By maintaining simplified speech patterns, verbalizations are easier to understand, and communication patterns will be more effective. Allowing the child time may reduce anxiety and encourage communication.

- Encourage the family to provide child with familiar objects (toys, pictures, books, clothing) that evoke a positive response from child.

Objects that are considered “friendly” will enable staff to attempt to engage child in a conversation that is nonthreatening and will enhance trust building.

- Do not prod the child to engage in dialogue. After several attempts, gently disengage and offer to return at a later time.

If the child is not ready to communicate verbally, all attempts to force him or her to do so will lead to further alienation.

Expected Outcome

- Child will demonstrate increased ability to communicate, as evidenced by verbal and nonverbal behaviors.

Nursing diagnosis: Ineffective coping related to sensory overload, lack of previously learned positive coping skills

Interventions/Rationale

- Discuss past and present coping mechanisms. Assist child to identify effective and ineffective coping mechanisms.
Identification of coping mechanisms as effective or ineffective can provide guidance for selection of appropriate methods.
- Instruct the child in use of relaxation techniques (e.g., deep breathing, meditation, journaling). Role-play adaptive coping skills; support and reinforce use of these skills.
Practicing the methods may help the child to use them when faced with a stressful situation.

Expected Outcomes

- Child will understand the relation between emotional state and behavior.
- Child will accept responsibility for his or her behavior.
- Child will identify effective and ineffective coping techniques.
- Child will use available support system (friends, family, therapist) to develop and maintain effective coping skills.

Nursing diagnosis: Risk for situational low self-esteem related to actual or perceived problematic relationships with family members or peers

Interventions/Rationale

- Note manner of dress and state of hygiene and grooming (e.g., disheveled, unkempt appearance).
Appearance may reflect self-perception.
- Actively listen while engaging child in dialogue regarding feelings about self and personal appearance (e.g., likes/ dislikes, strengths/weaknesses).

May reveal self-perceptions and allow discussion of reality versus perception. A child with altered mental status may have a distorted view of self in relation to the physical/social/emotional environment. Comparing self with a distorted environment can alter sense of self and subsequently decrease self-esteem. Dialogue enables discussion of methods to address perceived weaknesses and to focus on strengths; provides opportunity to educate the child regarding hormonal implications during puberty.

- Explore child’s feelings about changes in body with onset of puberty.
Pubertal changes can be stressful and require changes in self-perception.
- Encourage and reinforce positive self-statements; discuss ways to highlight good feelings about self (e.g., improving grooming, hygiene). Reinforce any attempts toward improvement in hygiene/grooming. Support socialization and conflict resolution skills. Introduce concept of accepting differences to promote individuality.
Reducing negative thoughts can help increase self-esteem. Socialization skills may increase social support, and ability to resolve conflicts may increase sense of belonging, both of which may provide positive validation.

Expected Outcomes

- Child and family will describe areas of conflict.
- Child will openly express feelings toward family members and peers.
- Child and family will select measures to reinforce the child’s positive qualities.
- Child will be able to describe his or her own positive qualities.

Nursing diagnosis: Impaired social interaction related to effects of child’s mental status or aberrant, antisocial behaviors

Interventions/Rationale

- Convey that you have time to spend with the child. Actively listen and observe verbal and nonverbal communication; verify communication.
Can convey caring and increase child’s trust and comfort with you.
- Model and role-play appropriate social interactions.
Observing appropriate responses and productive interactions may help the child to develop a repertoire of positive responses.

Expected Outcomes

- Child and family will identify causes of problems in social interactions.
- Child will exhibit interactions and communication skills that enhance social interactions.
- Child will demonstrate behaviors that are socially acceptable.

NURSING PLAN OF CARE 29–1: THE CHILD WITH ALTERED MENTAL HEALTH (CONTINUED)

- Child will report feeling less isolated as social interactions improve.

Nursing diagnosis: Disturbed sleep pattern related to anxiety, mental status, or effects of medications

Interventions/Rationale

- Encourage consistent routines for sleep preparation.
When routines are expected, child may find it easier to relax.
- Allow the child time for quiet transition by playing music or reading soothing materials.
By decreasing stimuli, sleep will be induced naturally.
- Offer the child a massage.
Decreasing muscle activity through therapeutic touch modalities often induces relaxation and sleep.

Expected Outcomes

- Child's sleep patterns will be adequate for rest.
- Family sleep patterns will be adequate for rest.

Nursing diagnosis: Interrupted family processes related to changes in family relationships, roles, and responsibilities

Interventions/Rationale

- Assess family's interaction patterns, family roles, stress levels, and coping mechanisms.

Provides baseline data to develop plan of care, building on family strengths.

- Actively listen to family's perception of family functioning and concerns; acknowledge feelings.
Feeling of "being heard" may help decrease anxiety and initiate problem-solving and coping behaviors.
- Assist the family to identify strengths and methods to develop effective interactions, improve ability to meet family members' needs, and facilitate individual growth. Videotape family interactions (preferably in the home), assist family to identify positive and negative interactions, and role-play to build on positive interaction patterns.
Building on strengths helps the family feel hope that they can achieve their goals. Role playing helps develop adaptive functioning patterns.

Expected Outcomes

- Family members will discuss changes in family dynamics and identify methods to deal with change in a therapeutic manner.
- Family members will seek appropriate resource services as needed to optimize family processes.
- Parents will understand the cause of the child's condition and available treatment modalities.
- Parents will support the child, discipline the child in a therapeutic manner, and remain involved in the child's treatment.

Assessment

The diagnosis of ADHD is most often made during the early school years. Symptoms of the disorder must be present for at least 6 months and must be observed before the child is 7 years old. The criteria fall into three areas of functioning: concentration, impulse control, and goal-directed behavior. The symptoms may not be demonstrated in early and short-term one-on-one situations, but after the child is comfortable in a situation, the behaviors begin to emerge.

Major problems for these children include interpersonal problems with age-matched peers, teachers, and, often, parents. Because of their impulsivity and poor problem-solving skills, children with ADHD are vulnerable to developing behavioral problems and a comorbid diagnosis of oppositional disorder or conduct disorders. These children are also susceptible to low self-esteem, anxiety, and depression. Behaviors associated with ADHD make them vulnerable to failure and negative feedback, which may contribute to these comorbid conditions.

ADHD should be assessed and diagnosed by an interdisciplinary team, because several areas of functioning may be impaired. Psychometric testing helps to define the individual's cognitive and learning deficits. Children at various developmental levels function differently; thus, the evaluator must be familiar with age-appropriate norms. Obtaining information from teachers and parents is helpful, because each is able to provide feedback about behavior in a different setting. Data obtained about the child's strengths can be used to enhance the program of interventions.

Interdisciplinary Interventions

Interdisciplinary interventions may include psychological assessment and assessment of the child's specific learning problems and intellectual ability. Psychology and special education experts are usually called upon for these assessments and to make recommendations for the individual educational plan (see Chapter 12). Children are hospitalized for these disorders only if there is a comorbid

NURSING INTERVENTIONS 29–2

Stress Reduction Activities

Stress is a generalized, nonspecific response of the body to any demand, change, or perceived threat and is unavoidable. Stressors are the circumstances or events that elicit this response and may be real or anticipated, positive or negative. Distress is damaging or unpleasant stress. Stress reduction techniques are usually most effective for children older than 6 years of age.

Techniques	Nursing Interventions
Develop effective coping mechanisms.	Role-play various different ways of dealing with stressors. Discuss which ones would be the easiest and most useful for child and parents.
Begin daily exercise program.	Suggest methods to reduce stress through exercise (e.g., walking, running, dancing, swimming, participating in sports, body movement exercises, yoga). Assist child in developing a plan of regular activity. Evaluate extracurricular school activities that would help the child deal with stressors. Refer to school and community gyms, health clubs, YMCA, Boys' and Girls' Clubs. Advise parents to consult with child's primary care provider about contraindications to exercise program.
Develop alternate ways to relax.	Identify activities that the child enjoys (e.g., drawing, pottery, carpentry, writing, music, photography, reading); assess for relaxing activities (e.g., watching the sunset, taking a bubble bath).
Practice relaxation techniques.	Guide child through a relaxation exercise to experience its usefulness. Begin relaxation with deep breathing. Use guided imagery to induce relaxation (e.g., "Take another deep breath and let all the tension release. With each breath you become more relaxed. Now imagine yourself in a peaceful, quiet setting [garden, beach, and so forth] ..."). Refer child to audio media, books, and classes on learning and practicing relaxation techniques.
Practice diaphragmatic breathing and periodic deep breathing.	Practice diaphragmatic breathing with child: <ul style="list-style-type: none"> • Sit or recline in a comfortable position with legs uncrossed. • Place one hand on chest and other hand on diaphragm, approximately 2 in below bottom center of breastbone. • Inhale so diaphragm expands and hand covering diaphragm moves out while other hand remains almost still. • As you exhale, diaphragm relaxes, and hand covering it moves inward.
Make positive affirmations.	Teach child to <ul style="list-style-type: none"> • Write out affirmation statements and place them in a visible area (e.g., mirror, steering wheel, refrigerator, desk) • Repeat the statements several times daily • Be specific, positive, and brief (e.g., "I am relaxed," not "I am not tense") Use the present tense—"I am," not "I will" (e.g., "I am learning to express my feelings." "I am expressing anger in a positive way." "I am lovable.")
Improve self-care.	Discuss personal habits that contribute to distress: <ul style="list-style-type: none"> • Poor nutrition • Neglecting early warning signs of tension • Nonassertiveness • Drinking, smoking, substance abuse • Sexual activity (promiscuity resulting from peer pressure, lack of birth control)

(Continued)

NURSING INTERVENTIONS 29–2

Stress Reduction Activities (*Continued*)

Techniques	Nursing Interventions
Demonstrate positive ways to express and become more aware of feelings.	Discuss importance of setting priorities, taking one thing at a time.
Increase organizational skills.	Use strategies such as pocket folders or color-coded labels on shelves or boxes. Use calendar or list of things to do. Use reward system with stickers or small incentives.
Balance school and recreation.	Teach importance of <ul style="list-style-type: none"> • Regular study schedule so as not to overwhelm self with all the work at one time and to be able to see progress • Learning to take relaxation breaks

condition such as conduct disorder with very aggressive behavior. A mental health therapist (e.g., APRN, psychotherapist, or psychiatrist) may be needed when self-esteem is severely impaired or if the child is depressed. Psychiatric expertise is often involved in assessment when comorbid mental health disorders include conduct disorder or oppositional disorder.

Management of children with ADHD includes medication to control behaviors associated with these disorders (see Table 29–1). Stimulant medications are generally more effective than nonstimulants (Farone, Biederman, Spencer et al., 2006). Methylphenidate (Ritalin, Concerta), dextroamphetamine (Dexedrine), and dextroamphetamine and amphetamine (Adderall) are commonly prescribed and demonstrate a decrease in symptoms of ADHD (Gilchrist & Arnold, 2008). When stimulant medication fails or causes adverse effects, alternative forms of treatment are tried. A treatment algorithm, applied in the order presented, is recommended: a tomoxetine (Strattera), bupropion or tricyclic antidepressants, other antidepressants, and alpha agonists (Pliszka, Crismon, Hughes et al., 2006).

Health promotion and maintenance of general health are important considerations. Routine medical care should include all that is provided for the child without behavioral problems, such as immunizations, physical examinations, and dental and eye examinations and care. Assessment of nutritional status and physical growth and development are important, because high activity levels and side effects of medication may decrease appetite and slow the rate of growth. Monitor to determine whether medications are having the desired effects on the child's behavior and whether side effects are occurring. Ensure that other members of the healthcare team know how treatment is going. Teach the child and parents how to look for side effects and therapeutic effects of the child's symptoms and behavior.

Community Care

Nurses at school and in home care are responsible for parent education (TIP 29–1). Positive reinforcement is effective for children with ADHD; educate parents and teachers to respond to (reward) positive behavior and to use consequences for or ignore negative behavior (Vierhile, Robb, & Ryan-Krause 2009). Teach them to use “time-outs,” having the child sit on a chair for a short period of time, to use when behavior persists. Behavior management is fairly effective in managing overactivity, but is less effective in curtailing problems of inattention.

Conduct Disorder

Conduct disorder is persistent and repetitive patterns of behavior in which the rights of others are ignored, and social norms and rules are violated. Anxiety and feelings are externalized and result in harmful behavior toward others. The behavior may be observed in a variety of settings (home, school, community) and interactions. For example, the child may act aggressively with the interviewer while denying his or her aggressive behavior. These children tend to use others as a scapegoat, initiate fights, and often use dangerous objects (sticks, hard objects, broken glass, knives, or guns). Their behavior may involve stealing, setting fires or otherwise destroying property, rape, assault, and, in its severest form, homicide. Lying, deceitfulness, and a lack of accountability for their behavior are characteristic of such children. Conduct disorders are a common reason that children are referred for mental healthcare.

TIP 29–1 Teaching Intervention for the Child With ADHD

Nursing diagnoses and outcomes

- **Impaired social interaction related to inability to control actions and behaviors**

Outcomes:

- Child gradually learns self-control and the ability to share peer acceptance and enjoyment in peer relations.
- Child completes self-care tasks and cooperates in school setting.
- Child follows instructions and is successful in academic activities.
- **Chronic low self-esteem related to negative response from others regarding behavior**

Outcomes:

- Child identifies own strengths.
- Self-esteem is enhanced as seen by child's comments about self and about personal accomplishments.
- **Risk for injury related to child's activity level and impulsiveness**

Outcome:

- Child's safety is ensured to the best extent possible.
- **Readiness for enhanced knowledge: Medication side effects**

Outcomes:

- Child maintains adequate nutritional status.
- Child maintains adequate sleep pattern.
- Parents express confidence in their ability to manage the medication regimen.

Teach Child/Family

Managing Child's Activity

- Encourage parents and teachers to decrease stimuli when concentration is important.
- Monitor adherence to medication regimen and reaction to medication.
- Decrease choices that child must make (limit to two for young child, three to four for older children).
- Practice problem-solving strategies with child.
- Give positive feedback for success (tokens, rewards), consequences for undesirable behavior.
- Tutoring may be necessary. Subdivide learning tasks so child is not overwhelmed and can maintain concentration.
- Give frequent positive feedback. Directions for each task should be clear, short, broken into segments. For example:
 - Take your book out of your desk.
 - Open the book to page 10.

- Read the second paragraph to yourself.
- Answer the first question below the paragraph.
- Now, answer the second question.
- Provide information about the characteristics and problems associated with ADHD.
- Assist parents with problem-solving ways of managing child's behavior and needs (e.g., a token reward and behavior management program).
- Assist in identifying community resources.
- Encourage assertive behavior with school system to obtain needed resources for the child's learning experience.
- Provide written resources and list of references that parents may use to increase understanding of the child's disorder and effective ways to manage child's behavior.

Safety

- Encourage parents to establish clear limits on where child may play or ride bike and when higher risk activities may be undertaken. Monitor child's activities frequently.
- Reinforce positive behavior with feedback and intermittent rewards.

Improving Social Interactions and Self-esteem

- Provide supervision of peer play activities for the young child. Hold and soothe child when unable to provide self-control. Use time-outs (5 minutes for children in early childhood, 7 to 10 minutes for children in middle childhood). Young children benefit from structured pre-school programs.
- Middle childhood: Consider social skills training in small groups to encourage
 - Turn taking
 - Making appropriate requests
 - Communicating feelings and empathy
 - Problem solving in conflictual situations
 - Saying no to inappropriate behaviors
 - Expressing anger in appropriate (socially acceptable) ways
- Identify child's strengths and provide feedback to enhance positive self-thoughts.
- Reward positive behavior, provide limit setting as needed, but avoid negative comments that the child is "bad." Remove attention or special privileges for negative behavior. Help child to develop skills such as with individual lessons to learn a special skill or with group activity that assists child to learn something of interest (a hobby, a sport, or area of knowledge).

(Continued)

TIP 29–1 Teaching Intervention for the Child With ADHD (Continued)

Medication Administration

- Teach parents to administer medication after meals, decreasing amount in afternoons if it interferes with sleep, provide quiet activities before bedtime, and decrease stimulation at mealtimes.
- Explain what the medication is and how it works, its benefits, and its potential side effects.
- Discuss modifications for side effects.
- Assist in establishing a routine to prevent forgetfulness in giving the medication.

Contact Healthcare Provider if:

- Child appears very drowsy
- Child is unable to concentrate
- Child physically harms self or others
- No improvement is seen in school performance

WORLDVIEW: The culture and circumstances in which a child lives have enormous implications for development of conduct disorder. Children living in high-poverty and crime-ridden areas, whose family structure is chaotic, and who experience multiple losses are especially likely to develop conduct disorder behavior.

Actual etiologic factors are unknown, but one of the most frequently cited characteristics of children with conduct disorder is temperament (the habitual style of reaction to situations). Other risk factors include parental factors (mental illness, criminal behavior, or conduct disorder behavior), parental abusive and coercive behavior toward the child, learning disability or ADHD, substance abuse, intrauterine insults, neurologic impairment or injury, and frequent observance of crime or domestic violence, especially abuse of the mother.

The incidence of conduct disorder varies by gender and age. The range for male children (including adolescents) is 0.5% to 5.4%. For girls, the range is 0.2% to 3.3%. Conduct disorder was found to be significantly more common in boys than girls and increased in prevalence with age (Maughan et al., 2004). Two developmental pathways appear to exist, one beginning during childhood and one during adolescence. Most children with adolescent onset have a good chance of becoming responsible and productive adults (Scarpa & Raine, 2004).

Assessment

Assessment of the youth with conduct disorder is complex. A physical examination, including a neurologic examination, is recommended. Include the data outlined in Focused Health History 29–1. In addition, address possible involvement in gangs, cults, or unlawful behavior and previous involvement with law and justice systems. Ask about involvement in sexual behavior (coercive or non-coercive) and childhood sexual abuse perpetrated by another. The types of acts committed and the situational context of the behavior (e.g., being involved with a gang or older group involved in crime, response to abusive

behavior) should be clearly defined. Children with conduct disorders may have a previous or current diagnosis of learning disability, ADHD, or ODD. Assess the child for depression, suicidal or high-risk (self-harm) behaviors, and the intent or thought of bringing harm to others.

Conduct disorder must be differentiated from aggressive episodes caused by psychomotor seizures, brain injury, and posttraumatic stress disorder (PTSD). The aggressive outbursts occurring in these disorders are random and spontaneous, whereas the aggression of a child with a conduct disorder is more consistent and predictable. Conduct disorder is also not “delinquency.” Delinquency implies committing criminal or illegal acts. It is a legal term, whereas *conduct disorder* is a diagnostic term. The behavior of the individual being assessed may indeed include acts that are illegal. The acts committed may include aggression toward people and animals, destruction of property, deceitfulness or theft, or serious violation of rules established in the home or by the school system.

Interdisciplinary Interventions

Interventions for children with conduct disorder include individual therapy, milieu therapy, recreational therapy, group therapy, family therapy, and social skills therapy. In some severe cases, the child may be placed in a special classroom where behavior can be more easily contained. A primary goal is to ensure that such children no longer harm others or seek to harm themselves. Remove all potentially harmful objects from the child’s environment.

Alert! Youth with conduct disorder who have comorbid depression are at very high risk for suicide. Implement suicide precautions.

In the inpatient setting, place the child in a secure environment to prevent the child from running away.

CLINICAL JUDGMENT 29–1

The Child With a Conduct Disorder

Nancy is 13 years old and has a history of sexual abuse starting at 7 years of age. The perpetrator was 14 at the time and the sexual abuse occurred over several months. Nancy is the oldest of two siblings. Her mother and father are divorced and she lives with her mother. Her father was injured in a hunting accident 3 years ago and has been a paraplegic since the accident. He wants to return home to live with his ex-wife and children. Nancy was referred by the school counselor to the community mental health center when she was 9 years old. She was seen three times and was then enrolled in an after-school learning improvement program by her mother. From the time Nancy was 9 through 13, she had five inpatient psychiatric hospitalizations for behavioral problems. Nancy was recently admitted to the state hospital youth unit. She was expelled from school because of repeated assaults on younger children, persistently destroying books and papers of other students (which she denied), and finally because of physically assaulting one of her teachers. Nancy's mother reported that, during the past year, Nancy had killed her younger brother's two rabbits, deliberately broke several objects at home when enraged, and repeatedly stolen money from her mother and brother. Most recently, her mother had found a stash of sharp knives, a baseball bat, and bullets (no gun) under Nancy's bed. Nancy's mother said that she was totally unable to control Nancy and said, "I hope you find a place for her where everyone will be safe from her." Nancy's mother has been treated

for depression for the past 6 years. She compared Nancy with Nancy's father, saying, "She just doesn't care who or what she hurts, just like her father."

Questions

1. Is Nancy's family at risk for violence at this time?
2. Which of Nancy's behaviors indicate a conduct disorder?
3. What goal must take first priority at this time?
4. What nursing interventions will assist Nancy and her family in meeting this goal?
5. During therapy, what should be the outcomes for the behaviors displayed by Nancy?

Answers

1. The family is at risk. Nancy has the potential to harm a family member.
2. She often bullies, threatens, or intimidates others; she often initiates physical fights; she has been physically cruel to animals; she has deliberately destroyed others' property; she has stolen items of nontrivial value without confronting a victim
3. Ensure the safety of others.
4. Teach Nancy conflict resolution skills, help Nancy practice appropriate expression of anger, routinely assess and remove potential weapons from the environment and the patient, and work with Nancy to improve her self-esteem.
5. Positive rewards should be given for positive behavior; developmentally appropriate consequences should be given for negative behavior.

Develop a behavioral management contract with the child that includes safety expectations and sanctions for violations of these expectations. Pharmacologic interventions, dispensed and monitored by the nurse, may be used to control excessive violence or to treat underlying depression. To help children reduce feelings of anger and rage, therapy focuses on teaching new problem-solving and stress management techniques. Children must learn to reinterpret the behaviors of others and to ask questions to clarify the intent of others' behaviors, to reduce their own feelings of threat or harm. Feelings of inadequacy potentiate the aggressive behavior. Therefore, children must learn to interact with others in nondefensive ways. In addition, children are encouraged to have a realistic view of themselves and to accept responsibility for their own behaviors. Group therapy can be used to focus on the communication skills of listening, reflecting, giving and receiving feedback, sharing feelings, expressing needs, and expressing desires in an assertive manner (Clinical Judgment 29–1).

Oppositional Defiant Disorder (ODD)

ODD is a pattern of negative, resistant, and hostile behavior. It is usually manifested after early childhood and before puberty. However, some of the behaviors are seen during the early childhood years. It often develops gradually, with increasing expression of defiance, negativism, argumentativeness, loss of temper, and hostility. During the prepubertal years, the disorder is more common in boys, but equal gender prevalence is seen in adolescence. The incidence of ODD, using full *DSM-IV-TR* criteria, is 1.4% of girls and 3.2% of boys. *DSM-IV-TR* criteria preclude a diagnosis of ODD in children who meet the criteria for conduct disorder; therefore, these incidence figures greatly underestimate the occurrence of clinically important oppositional behaviors in this population (Maughan et al., 2004). A child with ODD, particularly one who engages in physical aggression, has an extremely high likelihood of later being diagnosed with conduct disorder.

Causative factors, or factors with a strong correlation to ODD, are irritable temperament, history of abusive treatment, and ineffective coping strategies (e.g., projection, denial of own feelings, pain, hurt, or sadness). This disorder is also frequently comorbid with mood disorder (45.8%), anxiety (62.3%), and ADHD (35%) (Nock, Kazdin, & Hiripi, 2007).

Potential outcomes for children with ODD vary. In many cases, without early and effective treatment, conduct disorder and even criminal behavior ensue, resulting in incarceration. Other less severe problems are academic difficulties or failure, and continuous peer conflict, which may result in injury. These children often create enough family stress that treatment is sought; conflicts related to this stress may also precipitate parental separation and divorce.

Parents often react to ODD with rigidly controlling and authoritarian behavior, which becomes increasingly detrimental as the child's opposition increases.

Assessment

To be given the diagnosis of ODD, the child must exhibit certain behaviors for 6 months or longer (Chart 29–3). When analyzing and synthesizing the assessment data, consider the developmental status of the child: Are any of the behaviors and concerns considered normal for the child's age?

Evaluate children with ODD for depression. The underlying problem may be continuous, unmanageable life stresses and multiple losses. Dysthymia or depressive traits may mimic ODD. ODD is also strongly associated with anxiety disorders. Mismanagement and lack of recognition of these underlying problems may lead to ODD.

Interdisciplinary Interventions

Placement in a therapeutic foster home or residential facility may be necessary to relieve family stress and break the cycle of control and opposition. Interdisciplinary

intervention for ODD may include medication. Many children show some improvement in mood and behavior when given an SSRI (see Table 29–1). Counseling or problem-solving therapy with a mental health therapist is recommended. Nursing care includes working with the child and family to improve communication, problem-solving, and negotiation skills. Group therapy designed to develop listening, open communication, problem-solving, and perspective-taking skills is beneficial in helping these children to express themselves in more appropriate ways. Therapeutic communication and behavior management techniques are helpful in decreasing resistance and stubborn refusal to engage in or complete expected activities. Teach parents behavior management strategies for communicating and negotiating with their child with ODD. School interventions include providing teachers with information about the disorder and teaching behavior management techniques.

ANXIETY DISORDERS

Anxiety is a common phenomenon of childhood. Children experience multiple fears as they develop and as they encounter new experiences (see Chapters 4–7 for a discussion of typical fears in children). Approximately 20% of children age 8 to 17 years have scores above the clinical cutoff on brief anxiety screening (Keeley & Storch, 2009). Anxiety is manifested in disorders such as generalized anxiety disorder, separation anxiety disorder, selective mutism, obsessive-compulsive disorder, social phobia, acute stress disorder, and PTSD.

Various factors are associated with, and may cause, anxiety disorders. Although most individuals are provoked to high anxiety at various times throughout childhood and later life, more than just the stressful experience is implicated in these disorders. Insufficient coping strategies, resources, or social support may contribute; some persons may be at higher risk because of genetic phenomena, disease states, neurotransmitter deregulation, or structural deficits in the brain. The amygdala is implicated in anxiety disorders as well as dysfunction of norepinephrine, dopamine, serotonin and gamma-aminobutyric acid systems, and abnormal chemoreceptor reactivity (Keeley & Storch, 2009). As the system becomes overwhelmed, patterns of deregulation may become established in the brain, resulting in continued manifestation of disabling anxiety.

Anxiety in children often manifests in somatic complaints such as feeling unsteady and dizzy, stomachaches, nausea, diarrhea, and sleeping difficulties (Keeley & Storch, 2009). Frequent somatic complaints should arouse some suspicion of an anxiety disorder or other mental health issue. Anxiety disorders have common characteristics as well as specific symptoms, so differential diagnoses can be challenging. Most of the disorders are treated similarly, with cognitive and behavioral therapy. Some respond to medications; others do not. Educating the child and family about the disorder, the implications for growth and development, and the importance of the treatment plan are always a part of the nursing role.

CHART 29–3 DIAGNOSTIC CRITERIA FOR OPPOSITIONAL DEFIANT DISORDER*

- Often loses temper
- Often argues with adults
- Often actively defies or refuses to comply with adults' requests or rules
- Often deliberately annoys people
- Often blames others for his or her mistakes or misbehavior
- Is often touchy or easily annoyed by others
- Is often angry and resentful
- Is often spiteful or vindictive

*Must exhibit at least four of the behaviors for at least 6 months.

NURSING INTERVENTIONS 29–3

Child Experiencing a Panic Attack

- Stay with the child or adolescent.
- Remain calm.
- Speak slowly, firmly, and reassuringly.
- Ask other persons to move away, or move the child to a quiet, comfortable area.
- Encourage relaxation, focusing on a specific object or soothing thought.
- Administer medication if ordered.

When a child is observed having a panic attack in a school or healthcare setting, implement immediate interventions (Nursing Interventions 29–3), then refer the child to his or her mental healthcare provider or primary healthcare provider.

caREminder

The most immediate goal of the nurse in panic and phobic disorders is to reduce anxiety to a manageable level and to reduce the child's physical discomfort.

In addition, encourage the child to master relaxation techniques and to avoid catastrophic thinking. Continued attacks suggest a need for antianxiety medication or behavior or cognitive therapy with a skilled mental health professional.

Separation Anxiety/School Refusal Disorder

The prevalence of separation anxiety disorder is cited as 3.5% to 5.4%, but many more children have subclinical disturbances that are not diagnosed (Jurbergs & Ledley, 2005). Separation anxiety disorder is characterized by excessive anxiety when the child is separated from the home or the parents (primary attachment figure). School refusal or phobia (as it is commonly known) is a prime example of separation anxiety disorder.

Assessment

Factors that place children at risk for separation anxiety disorder are death of a parent or sibling, divorce, relocation, and chronic illness. Thus, a family history and assessment of current functioning are important. Conduct a physical examination, also, to determine any contributing physical problems. Alcoholism, depression, agoraphobia, and panic disorder are relatively common among parents of children with separation anxiety disorder. Other family stressors (loss of home, emergency hospitalization, community violence, death in the family) should also be assessed. Observe the parent–child interaction; assess parental discipline, nurturance, dependence

on the child, and encouragement of age-appropriate independence.

Findings often include problems associated with school. If the child has an academic deficit, is shy, or is awkward, he or she may be teased by peers. Family disruptions, chaos, or marital discord may compound the anxiety aroused by any problems experienced in school. In addition, extended absence from school may cause a child to fear embarrassment and ridicule by peers or punishment from teachers or school officials.

Nursing Diagnoses and Outcomes

In addition to the nursing diagnoses listed in Nursing Plan of Care 29–1 that are applicable to the child with separation anxiety or school phobia, the following diagnosis could be used to guide care:

Anxiety related to separation from parent or caregiver

Outcomes: Child will attend school, experiencing no anxiety related to separation or expectations at school.
Child will stay overnight at a peer's house, experiencing minimal anxiety.

Interdisciplinary Interventions

Children with school refusal are best served when referred to a mental health professional skilled in treating anxiety disorders. The best approach is to involve the child and the parent. The therapist (psychiatric APRN, psychiatrist, psychologist, or social worker) must act as a liaison between the school and parent. Cognitive–behavioral approaches produce the best results (Keeley & Storch, 2009). The therapist makes an alliance with the child, who is encouraged to think of his or her anxiety as an enemy that must be overcome and that he or she has the skills to keep this enemy from having control. Additional steps in the therapy process include desensitization of the feared object (school or leaving home). Pictures of thermometers are often given to the child to indicate the amount of fear experienced and to evaluate progress. Children may be hospitalized if the parent is unable to adhere to the treatment plan. Parents who experience marital discord, are heavily dependent on the child, have depression, or have substance abuse problems need to be referred for their own therapy.

Community Care

Nurses working in schools may be the first to recognize the problem of school refusal. Children are usually sent to the school nurse for somatic complaints. Frequent visits for minor complaints, especially if the child insists on going home, should alert the nurse to the potential of school refusal. The school or community health nurse may also be responsible for visiting children who have been absent for several days, and when illness is not verified, school refusal should be suspected (Clinical Judgment 29–2).

Nurses working in schools can prevent the anxious child from developing school refusal. Careful assessment and identification of the child's problems and needs can result in early referral for academic and learning disorders assessment. The nurse may teach stress management

CLINICAL JUDGMENT 29–2

The Child With School Refusal

Nine-year-old Billy was brought to the community mental health center by his mother after a visit from the district truancy officer. Mrs. Johnson reported that Billy had refused to attend school for the past 3 weeks and had several absences since the school term began (3 months previously).

Recent history acquired by the psychiatric nurse included the remarriage of Billy's mother 2 weeks before the beginning of school. Mrs. Johnson reported that Billy had always been a clinging child and, at 4 years of age, when she returned to work and placed Billy in a daycare center, he cried every day for more than an hour after she left him. The crying behavior continued for several months, although for shorter periods of time. This episode of school refusal actually began after Billy had been home for 3 days with a sore throat. During his 3-day illness, his stepfather returned home early on the first 2 days and became involved in very loud arguments with Billy's mother. On the second day of arguing, Mr. Johnson hit his wife, and then Mr. Johnson left the house, only to return several hours later, drunk but contrite and begging forgiveness. Billy had beseeched his mother to take him and their cat and leave the house, but his mother refused. After reluctantly being back in school for 3 days, Billy began refusing to go to school or to play with peers. Mrs. Johnson reported getting Billy to school on 2 days, but soon after she arrived at work, the school nurse called to request that Mrs. Johnson take Billy home because he was vomiting. Each morning since, Billy complained of feeling ill and remained

in bed. Mrs. Johnson reported that there had been no more instances of Mr. Johnson's drunken assaultive behavior.

Questions

1. What additional information would you gather about Billy?
2. What elements of the history indicate Billy is at risk for alterations in mental health status?
3. What nursing diagnosis would be applicable to Billy at this time?
4. What steps can be taken to alleviate the school refusal and return Billy to school?
5. What other referrals should be made to assist this family?

Answers

1. Developmental and health history, family health history, academic achievements or difficulties, peer relationships
2. Remarriage of Billy's mother, history of difficulty of separating from mother, witness to arguing and physical abuse between his stepfather and mother
3. Ineffective coping related to changes in family life and anxiety related to school attendance
4. Refer for play therapy or individual therapy to decrease anxiety regarding attending school and to determine other sources of stress for the child
5. Refer mother and stepfather to family counseling and further assess home situation for spousal abuse and possible child abuse

and provide support to the child returning to school. Stress caused by family chaos, inappropriate parenting, or unfavorable family relationships may be discovered. The nurse may also inform the family of the child's anxiety and refer them to a mental health clinic, although in managed care plans, the primary healthcare prescriber might have to make the referral. Individual and family therapy will be completed by an APRN or someone with advanced training in managing psychological issues (see [thePoint](#)). Care Path: An Interdisciplinary Plan of Care for the Child With School Refusal).

Posttraumatic Stress Disorder (PTSD)

PTSD is a reactionary anxiety disorder that occurs after a life-threatening event (or one that is perceived as life threatening or dangerous to physical integrity). PTSD may follow a single traumatic event or longstanding and

repeated traumatic events, such as child abuse (especially sexual abuse). War, shootings, catastrophic environmental events (hurricanes, floods, earthquakes), and accidental disasters (automobile, airplane crashes) may evoke PTSD in the vulnerable child or adolescent. The event that triggers PTSD usually would be perceived as traumatizing by almost anyone experiencing it. The prevalence of PTSD in children and adolescents varies, based on type of trauma and measurement tool; the average incidence in children exposed to traumatic events is 36% (Brown, 2005).

Acute stress disorder is a diagnosis that is emerging from the PTSD literature. *DSM-IV-TR* (APA, 2000) criteria for acute stress disorder include exposure to an extreme event accompanied by intense fear, horror, or helplessness; at least three dissociative symptoms; recurrence of the trauma; and extreme anxiety. The symptoms occur within 1 month after exposure and cause marked impairment.

Assessment

PTSD is characterized by repetitive uncontrolled memories (visual, auditory, physical sensations, and intrusive cognitions), repetitive behavior representative of the trauma and often observed in the child's play, trauma-specific fears, hyperalertness, and changed attitudes. Children with PTSD as a result of single-event trauma more often exhibit denial, **dissociation** (a defense mechanism in which a group of mental processes are segregated from the rest of a person's mental processes to avoid emotional distress), psychic numbing, depersonalization, and rage. Regression, separation anxiety, and fearfulness may also be exhibited.

When assessing the child or adolescent suspected of having PTSD, a careful psychosocial and developmental history is imperative. Document exposure to trauma and the type and length of exposure. Clear examples of behavior such as numbing (inability to feel psychic pain), sadness, avoiding activities, inappropriate responses to seemingly innocuous events, and increased physiologic arousal are clues to the disorder. Teachers and parents may describe behavior changes and identify the time when changes began. Anxiety scales for children may be helpful in assessing the degree of anxiety experienced. A developmental history with a description of the previous coping style may provide information about the child's vulnerability. A neurologic examination should be conducted to eliminate the possibility of misdiagnosis. A few scales may be useful in assessing stress symptoms in children. The Clinician-Administered PTSD Scale for Children and Adolescents (or CAPS-CA), which rates the frequency and intensity of symptoms, includes pictorial scales for use with young children and offers reliability and validity testing (McLeer, 2002). The Children's PTSD Inventory (or CPTSDI) has shown good reliability and validity when used in children between 7 and 18 years of age (McLeer, 2002). The Child Stress Disorders Checklist (or CSDC), an observer-report instrument that measures acute stress and posttraumatic symptoms in children, has demonstrated good reliability and validity (Saxe et al., 2003).

PTSD must be differentiated from phobic anxiety and conduct disorder. Phobic anxiety is related to a specific feared object, whereas PTSD is characterized by intrusive images that may be evoked by unrelated stimuli. Because of the potential for reactionary aggressive behavior in PTSD, it may be confused with conduct disorder. Unlike PTSD, conduct disorder is characterized by a continual and pervasive disregard for the rights of others.

Nursing Diagnoses and Outcomes

In addition to those presented in Nursing Plan of Care 29-1, the following nursing diagnosis and outcomes are applicable for the child with PTSD:

Posttrauma syndrome related to response to accidental injury, assault, or other unexpected life event

Outcomes: Child will describe feelings and fears related to the traumatic event.

Child will express feelings of safety.

Child will use effective coping mechanisms to reduce fear.

Interdisciplinary Interventions

Cognitive-behavioral therapy (CBT) is most effective for treating PTSD and related emotional and behavioral problems in children (Ollendick et al., 2008). Implement crisis intervention and family support measures immediately after the traumatic event. Help children to develop or improve their coping skills to help them manage anxiety, and educate parents to equip them with the skills that will facilitate their child's recovery.

Although well-designed, randomized, controlled trials of medication efficacy are lacking, medications are helpful in treating debilitating symptoms or comorbid conditions associated with PTSD (Brown, 2005). Selective serotonin reuptake inhibitors (SSRIs) target anxiety, mood, and reexperienced symptoms. Adrenergic agents, such as clonidine, may be used when symptoms of hyperarousal and impulsivity are problematic. In children with severe symptoms, mood stabilizers may be used (Brown, 2005).

EATING DISORDERS

Eating disorders comprise a complex group of disorders, including anorexia nervosa (AN), bulimia nervosa, and binge eating disorder. *AN* is a disorder that is characterized by a distorted body image and the refusal to eat sufficient food to maintain normal weight. Those affected by AN often exercise compulsively and suffer from severe malnutrition. *Bulimia nervosa* is binge eating of large amounts of food, followed by forced vomiting, excessive use of laxatives, enemas, or diuretics (Fig. 29-2). Children and adolescents affected with bulimia may also exercise compulsively. Binge eating is present when the child or adolescent frequently binge eats but does not purge the body, as those with bulimia do.

Eating disorders are common among children and adolescents. Disordered eating behaviors and attitudes are reported in about 33% of girls and 15% of boys; this is particularly prevalent in those who are overweight (Herpetz-Dahlmann, Wille, Holling et al., 2008). Eating disorders are often comorbid with other disorders such as depression, obsessive-compulsive disorder, personality disorders, and substance abuse. Adolescents with eating disorders also are more likely to have a history of abuse or trauma.

Risk factors associated with eating disorders include poor communication with parents, dissatisfaction with appearance or weight, lack of regular meals, use of tobacco, family dysfunction (enmeshment or chaos), and negative family food-related experiences (Hautala, Junnila, Helenius et al., 2008; Kluck, 2008). Other factors include sexual abuse, participation in activities that require attention to weight (e.g., ballet, gymnastics, wrestling, horse racing, modeling), and being adolescent and female (see Chapter 7 for further discussion). Genetic vulnerability is suspected as one potential cause. Psychological factors contributing to risk include low self-esteem,

FIGURE 29–2. The adolescent with bulimia eats a large meal and then forces herself to vomit what she ate.

perfectionist personality, distorted body image (perception of being fat), peer pressure, and media images (Cain, Bardone-Cone, Abramson et al., 2008; Courtney, Gambox, & Johnson, 2008). Anorectic individuals display isolation tendencies, whereas bulimic individuals tend to have an extroverted personality type. Most bulimic individuals are seen late in their disease because they are able to hide their behavior and maintain a more normal weight. Anorectic individuals are noticeable because of their failure to eat and their extreme weight loss. However, they may become quite skillful at hiding the weight loss under baggy, oversized clothes. Eating disorders contribute to profound metabolic disturbances in addition to weight loss. Potential physical disturbances may include growth failure and cognitive deficits.

Assessment

Signs of AN in females include underweight, delayed puberty, short stature, bradycardia, cardiomyopathy, osteoporosis, hair loss, and death if the disorder is not abated. Males often have similar signs, but, perhaps because they present to medical care later in their disease course, they are more commonly tachycardic and experiencing heart failure (Muisse, Stein, & Arbess, 2003). With bulimia, individuals display substantial alterations in health status, including sore throat, abdominal pain, constipation, and destruction of dental enamel (Mehler, Crews, & Weiner, 2004).

Note the child's current weight and elicit a history of the child's weight gain and loss patterns. Ask children about their diet and what methods they have used to control their weight, if any. Also ask about the child's perception of his or her body image and the motivation for being thin. The assessment in cases of bulimia should include the history of eating (how much, how often) and the compensatory behaviors used to maintain weight.

The feelings associated with the behavior are important in making the diagnosis; they involve craving and inability to control eating and purging (forced vomiting).

Conduct a complete history and physical examination, emphasizing menstrual history; skin turgor; condition of the hair, teeth, and mucous membranes; and Tanner staging (see Chapter 3).

Physical examination may reveal gingivitis, parotid gland enlargement, and callused and irritated knuckles from using the finger to induce vomiting. Amenorrhea is a diagnostic criterion for AN, but may be more a reflection of weight and nutritional status than diagnostic, because it has not been found to distinguish between amenorrheic and menstruating women with AN (Roberto, Steinglass, Mayer et al., 2008). All children with eating disorders need a psychiatric assessment that includes assessment for previous or ongoing abuse, and a family system assessment to determine personal, interpersonal, and social factors contributing to the disorders. Assessment of the family's parenting style (e.g., values, discipline, nurturance, communication, and the parents' perception of the problem) provides important data for treatment planning.

Other factors may be responsible for weight loss. If the desire of "thinness" and irrational body image of "fat," characteristic of AN, are not present, other possible causes must be explored. These possibilities include depression and physical disorders such as Addison's disease, Crohn's disease, or brain tumors. Laboratory investigations are indicated to rule out such possibilities.

Nursing Diagnoses and Outcomes

In addition to the nursing diagnoses presented in Nursing Plan of Care 29–1, the following nursing diagnoses

may be used to guide care interventions for the child or adolescent with an eating disorder:

Disturbed body image related to inaccurate messages (self and others)

Outcomes: Child or adolescent will acknowledge health condition, express positive feelings about food, and concede that exercise and weight loss have been excessive.

Child or adolescent will participate in an eating disorder intervention program.

Child or adolescent will express positive feelings about self.

Impaired oral mucous membranes related to poor nutritional status and practices

Outcomes: Child's oral mucous membranes will remain intact.

Child or adolescent will demonstrate good oral hygiene practices.

Interdisciplinary Interventions

Treatment of eating disorders involves multimodal therapy to attend to the child's physical, social, and interpersonal needs, which are affected by the eating disorder. A primary goal is to restore weight and reverse physical signs and symptoms of fluid, electrolyte, and nutritional imbalances. Treatment may involve hospitalization, ideally before the child exhibits medical instability such as vital sign changes (orthostatic hypotension with a heart rate increase of 20 bpm, a 20-mm Hg decrease in standing blood pressure, a heart rate of less than 40 bpm or more than 110 bpm, or inability to sustain body temperature [APA, 2006]), cardiac dysrhythmias, or electrolyte disturbances. A weight gain of 2 to 3 lb/week while hospitalized, and 0.5 to 1 lb/week in outpatient programs, is targeted (APA, 2006). Caloric intake is increased gradually to avoid refeeding syndrome (fluid and other electrolyte disorders, particularly hypophosphatemia, and cardiac and neurologic dysfunction), which has significant risk, including coma and death; monitor serum electrolytes and vital signs.

The healthcare team works with the child and family to develop appropriate weight maintenance strategies and to improve the child's eating behaviors. Nursing interventions do not merely focus on the child's weight but include a holistic approach that encompasses dietary management, provides support to address the child's fear of excessive weight gain, monitors weight and adherence to the activity schedule, uses behavioral contracting, and provides behavior management to prevent purging behavior, excessive exercising, and to maintain the plan of care.

Psychiatric referral is strongly recommended to address cognitive distortions related to food and body image, and to improve the child's social functioning skills. Directive and active individual therapy, family therapy, behavior therapy, and group therapy are all recommended as interventions. Cognitive behavior therapy is superior to other psychological and drug treatments for treating bulimia nervosa (Wilson & Shafran, 2005). Young people with severe and protracted cases of anorexia or bulimia are hospitalized on inpatient psychiatric units to more closely attend to their medical and psychological needs (Clinical Judgment 29-3).

MOOD DISORDERS

QUESTION: Why is it important for nurses to screen adolescents, such as Ashley, for depression?

The major mood disorders in children include major depressive disorder, dysthymia (depressed or irritable mood, less intense than major depression but more persistent), and bipolar disorder. Seasonal affective disorder also occurs in children and adolescents.

Mood disorders such as depression are characterized by a disturbance in mood (irritability, sadness, oppositionalism, negativity) that lasts for most of every day for a period of at least 2 weeks. Mood disorders in children and adolescents are common and serious for a number of reasons. Risk for suicide is common in youth with mood disorders (Rihmer, 2007). Family, social, and peer relationships deteriorate severely, and school failure and poor academic achievement are common.

Studies of mood disorders in children demonstrate that a wide variety of factors are associated with alterations in mood and emotional states. Social factors such as family conflicts, bereavement, and physical, psychological, and sexual abuse have been implicated (Hamrin & Pachler, 2005; Shugart & Lopez, 2002). Familial vulnerability (genetic), psychological factors (cognitive processing, cognitive distortions, temperament, and lack of adequate coping strategies), social and environmental factors (poverty, abuse, neglect), and biologic factors are all implicated or associated with depression in preschool, elementary, and adolescent years. Among disorders found to co-occur with depression are attention deficit disorder, ADHD, PTSD, anxiety disorders, disruptive behavior disorders, and learning disabilities. Depression may result from excessive stress or an inherent error in the neurotransmitter system, especially the system associated with serotonin. Physical alterations caused by some endocrine, autoimmune, metabolic, and neurologic disorders also are associated with depression.

Major Depressive Disorder

Major depressive disorder has a prevalence rate of 2.8% in children younger than age 13 years and 5.6% in 13- to 18-year-olds (Costello, Erkan, & Angold, 2006). Depression is being diagnosed more frequently in middle childhood as criteria for childhood disorders are clarified and differentiated. A gender disparity is not found until adolescence, when the rate of depression is 5.9% in girls versus 4.6% in boys (Costello et al., 2006).

ANSWER: Depression is the most common mental health condition in adolescence. It also is present in combination with other mental health conditions and may be overlooked. Suicide risk is high in adolescence and must always be considered and ruled out.

CLINICAL JUDGMENT 29–3

The Adolescent With an Eating Disorder

Emily, a 14-year-old female, was admitted to the inpatient adolescent unit of the children's hospital after collapsing at school. She was 5 ft 2 in tall and weighed 79 lb. During the 5 months preceding admission, she had lost 26 lb. After losing 15 lb, she had been taken to the family's managed care facility. The physician prescribed an antidepressant and told her mother to restrict activities and to monitor Emily's diet. Emily continued to lose weight. Emily had been an A student, but her grades had begun to deteriorate to Cs and Ds. She complained of fatigue and difficulty concentrating. She said whenever she got sleepy when studying, she would "relax" by exercising. Emily said she believed she was "too fat." Emily's history indicated eating had been a conflictual issue between her and her parents since she was a baby. Emily's mother said that when Emily was little, they were concerned she would be too fat. Her mother said, "But losing this much weight is just ridiculous! I think sometimes she is trying to kill herself." Emily's dad said, "Last year she looked really great! The boys were ogling her all the time. I couldn't stand it, but this weight loss has just gone too far!" Further investigation into family dynamics revealed that Emily's father was flirtatious with Emily and was outspoken about "keeping the boys away." His flirtations with Emily and constant reminder to his wife that Emily was his "little doll" caused considerable conflict between her parents. During the assessment, Emily revealed that she believed she was the cause of her parents' fights, and she was worried about how her father would handle her dating boys. She said that she avoided all boys because they were only interested in her body.

Questions

1. What data are significant in determining the presence of an eating disorder?
2. Why might Emily have developed an eating disorder?
3. What are the priority nursing diagnoses you could use to begin a care path for an adolescent with an eating disorder?
4. List one outcome goal for each of your diagnoses.
5. How would you determine whether Emily is in control of her eating disorder?

Answers

1. Current weight compared with height norms; history of weight loss; exercise patterns; and complaints of fatigue, sleepiness, and difficulty concentrating
2. Family conflict about her eating from an early age, adolescent rebellion against parents' control of social life, fear of growing up and becoming attractive, fear of losing father's attention
3. Imbalanced nutrition, less than body requirements; compromised family coping; disturbed body image
4. Emily develops a plan to eat a balanced diet (including sufficient calories) on or before day of discharge, family members sign a contract to participate in family therapy sessions for at least 8 hours, and Emily and parents state the importance of achieving the patient's target weight
5. Emily maintains adequate weight for age, eats balanced meals that meet her caloric needs, and relates a positive self-identity

Assessment

QUESTION: If you were the nurse assessing Ashley, what questions would you ask her?

Assess for severity (number of symptoms) and duration of symptoms. The interview with the child provides information about subjective symptoms of fatigue, suicidal ideation, and feelings of worthlessness. Parents and teachers are best at providing information about the sequence of events and observable behaviors. Psychologists often perform psychometric testing to determine cognitive factors that may increase vulnerability. The

school nurse may be able to provide information about somatic complaints, their frequency, and their response to nursing intervention. Teachers can provide important information about the child's progress or decline in academic performance, mood states, and coping and adaptation in the classroom. They also have information about peer relationships. Parents may report on change occurring in appetite, weight gain or loss, and change in attitude and behaviors at home, such as increasing isolation, anxiety, loss of pleasure in usual activities, and oppositional and aggressive behavior (Fig. 29–3). The child is most likely able to provide subjective information about how he or she feels, about sleep disturbance, and about worries.

FIGURE 29–3. Adolescents are at risk for depression as they deal with the physical, emotional, and social changes that characterize this developmental stage.

caREminder

Children frequently exhibit depression in physical symptoms, irritability, and school failure. Adolescents may sleep excessively, appear sad, exhibit poor concentration and isolation, and complain of headaches. School performance often deteriorates. Assessing for suicidal thoughts or behavior is essential.

Conduct a physical examination to rule out or identify illnesses or physical problems that might cause depression. The assessment is usually best done through a semi-structured interview to allow flexibility and to enable you to explore areas that appear problematic. For instance, if a child indicates that he or she has thoughts of suicide, obtain additional information regarding any established plan and its lethality. Determine what resources are needed to ensure the safety of the suicidal youth.

Self-report measures may be used to help verify the diagnosis by trained mental health professionals. Some useful instruments are the Center for Epidemiological Studies Depression Scale for Children (or CES-DC) available through *Bright Futures in Practice: Mental Health, Volume II—Tool Kit* (Jellinek, Patel, & Froehle, 2002b), the Children's Depression Inventory (or CDI) for children and the Beck Depression Inventory for Youth for adolescents (Krefetz, Steer, Gulab, et al. 2002; Timbremont, Braet, & Dreesen 2004).

ANSWER: There are many ways to elicit the same information. Here are some examples of questions to ask a depressed adolescent:

“How are you sleeping? When do you usually go to sleep and when do you wake? On the weekends when you don't have school, how do you sleep?”

“Tell me about feeling sad. Are there times when you feel okay? When is the worst time of day? Do you drink alcohol or take any drugs to help you feel better?”

“What things do you worry about?”

“Have you ever thought about hurting yourself?” (If the answer is yes, determine exactly how the adolescent is envisioning suicide and take measures to prevent an attempted suicide.)

Interdisciplinary Interventions

Interventions for selected mood disorders in children, including depressive disorder, are listed in Nursing Interventions 29–4. Interventions should also fit the specific situation (Tradition or Science 29–1). For instance, if the child has experienced a major loss, the intervention should be directed at resolving the grief process.

NURSING INTERVENTIONS 29–4

Mood Disorders

- Teach parents and child about illness, associated symptoms, and behaviors. Explain therapeutic regimens: medications, psychotherapy, or behavior therapy; photo (light) therapy for seasonal affective disorder.
- Monitor child's response to medication, report lack of improvement or untoward side effects, and report changes from depression to manic and vice versa.
 - For depressive disorders, tricyclic antidepressants or serotonin reuptake inhibitors will likely be prescribed. Monitor for cardiotoxic effects of medication and for suicidal risk.
 - For bipolar disorder, lithium, carbamazepine, or valproate will likely be prescribed. Monitor blood levels of medications as ordered.
 - For seasonal affective disorder, light therapy or antidepressant medication will likely be ordered.
- Teach parent and child about the medications: purpose, signs of improvement, side effects, when to report side effects, and withdrawal or termination of medication.
- School nurse: Monitor adherence and changes (or lack of) in school behavior, attitude, and performance in collaboration with teachers.
- Caution: All antidepressant medication takes 10 to 21 days to begin showing an effect.

TRADITION OR SCIENCE 29–1

Is there an increased risk of suicide when antidepressants are used in children?

MORE INQUIRY NEEDED

Studies have shown a trend toward suicidal thinking or behavior in children and adolescents who are taking antidepressants (Jick, Kaye, & Jick, 2004; Martinez et al., 2005). Whittington et al. (2004) demonstrated that the risks of SSRIs outweighed the benefits when unpublished data were included in a meta-analysis, whereas others have demonstrated no effect on the likelihood of suicide attempt (Isaacsson, Holmgren, & Ahlner, 2005; Valuck et al., 2004). A more recent meta-analysis demonstrated that benefits of antidepressants were greater than risk from suicidal ideation (Bridge, Iyengar, Salary, et al., 2007). Possibly influencing the issue, more children are being identified as depressed and more children are being treated with antidepressants. Suicides in the past, especially by children, were classified as accidents. More inquiry is needed to determine whether there is a true association between use of antidepressant medications and suicide in children; in the interim, risks and benefits of use must be evaluated and children closely monitored.

Bereavement therapy would be recommended. If no associated stressors are identified and no physical reason is suspected, then medication such as a tricyclic antidepressant or SSRI would be recommended, usually with cognitive-behavior therapy (CBT).

School-based behavioral interventions can be effective in decreasing depressive symptoms and improving coping skills (Puskar, Sereika, & Tusaie-Mumford, 2003). These programs include psychoeducational interventions. The school nurse can provide information about self-concept, relationships, communication, and coping, and can promote acquisition of these skills by engaging the adolescent in experiential learning such as role playing with other adolescents to identify the issues they are dealing with and engage them in problem solving to deal with them effectively.

Bipolar Disorder

Recognition is growing that children and adolescents experience bipolar disorder (also called *manic depression*). *Bipolar disorder* is a mental illness that manifests itself by extreme changes in mood, activity, and behavior. Children often cycle through the mood swings very quickly, swinging several times an hour. Because of the rapid mood swings, the **mania** (a phase of bipolar disorder characterized by expansiveness, elation, agitation, hyperexcitability, hyperactivity, and increased speed of thought or speech) or depression may be missed by care providers. These children often present as depressed children with aggressive acting out or with ADHD. Medications prescribed for depression frequently worsen the acting-out

symptoms. Making a definitive diagnosis in young children is sometimes difficult.

Bipolar disorder affects an estimated 1% of adolescents, similar to adult prevalence rates; prevalence is much lower in preadolescents, about 0.1% (Lack & Green, 2009). A strong genetic link to the disorder seems to exist. First-degree relatives of individuals with bipolar disorder have elevated rates of bipolar disorder and major depressive disorder (APA, 2000). When one parent has bipolar disorder, the risk of each child also having the disorder is 15% to 30%. When both parents have the disorder, the risk of each child having the disorder increases dramatically, to 50% to 75%. For example, if a couple who both have bipolar disorder have twins, both children have roughly a 70% chance of having the disorder. Individuals with a mood disorder among their first-degree relatives are prone to early onset of the disease.

Assessment

Bipolar disorder manifests itself differently in children than in adults. Children often appear to be having a continuous mood disturbance that is a mix of mania and depression (Chart 29–4). Parents often report that as infants these children had sleeping problems, demonstrated labile mood, and were hard to soothe (Faedda, Baldessarini, Glovinsky, et al. 2004).

Because of the rapid cycling of behavior and varying symptoms, it is helpful for the parents to keep a log of their child's daily behavior. The mental healthcare providers can use the log to monitor behavior and response to treatment.

Children diagnosed with other disorders such as depression, conduct disorder, and ODD may actually have bipolar disorder or may develop bipolar disorder as a comorbid condition. Close monitoring and exploration for other conditions should continue.

CHART 29–4 SYMPTOMS OF BIPOLAR DISORDER*

- Irritable mood, depression
- Extreme changes in mood lasting a few hours to a few days
- Explosive rages
- Separation anxiety
- Defiance of authority
- Hyperactivity, agitation, and distractibility
- Sleep disturbances
- Enuresis
- Night terrors
- Cravings for sweets or carbohydrates
- Impulsivity and or racing thoughts
- Daredevil behavior or grandiose beliefs of own abilities
- Inappropriate or precocious sexual behavior
- Delusions or hallucinations

*May include several.

Interdisciplinary Interventions

Treatment for children with bipolar disorder is complex and involves a great deal of trial and error, because little research currently exists, and the most effective treatment for these children remains undetermined. Antipsychotic (e.g., olanzapine) and mood-stabilizing (e.g., lithium) medications are the mainstay of treatment (McDougall, 2009). Lithium blood levels must be monitored closely, because too low a dose is not effective, but a high blood level can be toxic. Anticonvulsants such as carbamazepine (Tegretol), valproic acid (Depakene, Depakote), and oxcarbazepine (Trileptal) are effective for some children. Closely monitor children on these medications for side effects.

Diets rich in omega-3 fatty acids have been found helpful for children with bipolar disorder and are increasingly recommended. Light therapy, used for seasonal affective disorder, has helped some children with bipolar disorder as well.

Individual and family therapy is critical for these children and their families. The children struggle with many emotions, such as depression, anxiety, and guilt. These children are often very destructive and violent during their rages and afterward must deal with their feelings of remorse and guilt. Caring for these children takes a large toll on parents and siblings. Family therapy and support groups are helpful ways to share problems and solutions. Families may need help in developing structure and limits for their child; behavior management programs can also be useful.

School programs also must provide structure and support. Nurses should work with families to advocate for a classroom aide if needed, as well as tutors and in-school counseling. Families and healthcare providers should work with the school system to develop individual educational plans for these children that will provide the educational assistance they need. Interventions include identifying a designated “safe place” where the child can refocus and calm down, arranging to seat the child away from distractions, allowing transition time between activities, and performing routine multidisciplinary reviews of student status (performance, effectiveness of interventions, medication effectiveness and side effects) (Olson & Pacheco, 2005). Use a calm and reassuring manner when interacting with the child whose behavior is worsening.

SUICIDE

Suicidal events, which include acts of self-destruction, life-taking acts, and threats of self-harm, are common among teenagers. Persons attempting or thinking about suicide experience hopelessness and despair, and can think of no satisfactory way to solve their problems or to find satisfaction in daily living.

For young people 10 to 19 years old in the United States, suicide is the third leading cause of death (Martin et al., 2008). Male adolescents are much more likely to commit suicide than females (Mann, 2004); the risk for suicide is the greatest among white males, but the rates are rapidly increasing for black males. Experts warn that suicides actually could be even more common, because many suicides are not identified as such, for the sake of the family.

WORLDVIEW: Suicide is a major public health problem worldwide. Ethnic and cultural factors appear to play a role in the incidence of suicide (Bhugra & Mastrogianni, 2004). Cultural and religious belief systems may mask the incidence of suicide in children and adolescents.

Thoughts of suicide are frequently communicated to someone but are often ignored. Many myths still pervade societal thinking about suicide; thus, many children contemplating self-destruction are ignored, are reassured inappropriately, or are just told to “shape up” (Chart 29–5). Many risk factors are associated with suicide, including altered mental health status (e.g., depression, anxiety disorders); relational stress with parents, friends, or significant others; abuse; academic failure; public embarrassment; low self-esteem; relocation of family or friends; availability of firearms; and having a friend or peer who committed suicide.

Assessment

Most children give clues when they are thinking about suicide.

caREminder

When youngsters appeal for help or ask to talk about “a friend” who is upset and talking about suicide, the healthcare provider or teacher should be alerted to the potential risk of suicide. The child may be indirectly talking about, or asking questions about, his or her own concerns.

CHART 29–5 TRUTHS ABOUT SUICIDE (TO COUNTER COMMON MYTHS)

People contemplating suicide usually tell someone about it.

Suicidal threats are real and must be taken seriously.

Children and adolescents from good, intact homes do think about or commit suicide.

Anyone thinking about or who commits suicide is or was not crazy; they cannot or could not see other alternatives.

One should ask about thoughts or plans for suicide; this does not plant the idea, but imparts the message that it is something that can be talked about.

If a person talks about suicide, they have been thinking about it and may implement their plan.

Accidents, gunshot wounds, and substance abuse are problems that can be associated with self-destructive and suicidal behaviors.

Someone who is thinking about or who actually commits suicide is not always depressed.

Suicidal persons can be helped to perceive other options and not to act on their thoughts.

A common way for youth to communicate about suicidal thoughts is through a friend. They may pass a note to a classmate or ask the friend for advice about doing “it,” or they may make threats in anger.

Conduct an assessment for suicidal thinking for adolescents and children who present with high-risk behaviors and high-risk factors in their life (Nursing Interventions 29–5). Ask all children and adolescents with depressive disorders, bipolar disorder, and substance abuse, or who are despairing, feeling hopeless, and indicating despondency and powerlessness, about suicidal thoughts, ideation, and plans. *Ideation* refers to thoughts and feelings that suicide is the only way to end the problem or misery that one is experiencing.

During assessment for suicide risk, children and adolescents may initially indicate suicidal thoughts or ideation but later deny them. This denial should not deter the caregiver from providing for the safety of the child.

Risk for suicide (at levels from low to high) is diagnosed based on the hopelessness and despondency of the child, the degree of lethality of a plan (if one exists), the intensity and frequency of thoughts about suicide, the quality and availability of resources and social supports for the child, and the child’s ability to negotiate other ways of managing problems and feelings. Commonly used highly lethal methods of suicide include using a gun (and having one available), jumping from a height, hanging, crashing in an automobile, carbon monoxide poisoning, and taking prescription sleeping pills. Children and adolescents often plan to run in front of a bus, truck, or train. Methods low in lethality include cutting wrists and taking nonprescription drugs (excluding aspirin and acetaminophen) or low-potency tranquilizers. All children who may be at risk should be evaluated.

NURSING INTERVENTIONS 29–5

Guidelines for Assessing Suicidal Intent

- Establish rapport (show interest, actively listen, initiate talking in a friendly, respectful way).
- Use direct, simple questions (avoiding open-ended questions).
- Use language that the child can understand.
- Allow the child to tell his or her own story.
- Ask questions matter-of-factly, without judgment.
- Convey empathy and allow expression of feelings.
- Determine the intent, whether a plan has been formulated, and the degree of lethality.
- Ask about the child’s support system and available resources.
- Discuss the need for protection and measures for prevention.

Nursing Diagnoses and Outcomes

In addition to the nursing diagnoses presented in Nursing Plan of Care 29–1, the most important nursing diagnosis is related to the degree of risk for self-directed harm. Nursing diagnoses specific to the child with suicidal ideation include the following:

Risk for poisoning related to cognitive or emotional difficulties

Outcomes: Child or adolescent will not be exposed to or ingest dangerous substances.

Child or adolescent will understand and accept the need for self-protection.

Chronic low or situational low self-esteem related to feelings of inadequacy or perceptions of other’s negative feedback

Outcomes: Child or adolescent will voice feelings related to self-esteem.

Child or adolescent will engage in interventions and interactions with others that promote positive self-esteem.

Child or adolescent will identify options other than suicide to stop emotional pain.

Child or adolescent will use problem-solving skills to identify ways to cope with feelings.

Child or adolescent will use adult support and resources when feeling helpless and despondent.

Risk for suicide related to emotional distress and feelings of low self-worth

Outcomes: Child or adolescent will not harm self.

Child or adolescent will report suicidal thoughts to others.

Interdisciplinary Interventions

The primary short-term goal is to ensure the child’s safety and prevent self-harm. Nursing intervention must include referral to the appropriate resources. First and foremost, notify the child’s family (parents, guardian). Referral for emergency care such as psychiatric assessment and crisis intervention may also be warranted. In some cases, the child may need to be hospitalized.

Community Care

School nurses should participate in educational programs for the community, parents, school personnel, and children, and implement strategies for suicide prevention (Chart 29–6). Suicide prevention contracts are a good idea after a relationship is established and the assessment is completed, and before terminating the assessment session. The contract is best written by the child. The nurse may suggest sentences, words, and resources. The contract must be dated and signed by the child and the nurse. School-based prevention programs have proved effective, even with high-risk groups (Eggert, Thompson, Randell, et al. 2002).

Suicide often raises fear in a community because of its contagion effect. Suicide contagion occurs when one suicide initiates a cluster of subsequent suicidal behaviors among the contacts of that person. Contagion effect can be seen in schools, communities, or inpatient settings. To prevent contagion effects, experts recommend that friends, siblings, and classmates of the person who commits suicide receive immediate crisis intervention by mental health

CHART 29-6 STRATEGIES FOR PREVENTING YOUTH SUICIDE

- Train school and community leaders to identify young persons at highest risk for suicidal thoughts, threats, and attempts
- Educate young persons about suicide, risk factors, and interventions
- Implement screening and referral programs
- Develop peer support programs
- Establish and operate suicide crisis centers and hot lines
- Restrict access to highly lethal methods of suicide
- Intervene after a suicide to prevent other young persons from attempting or completing suicide

experts. Few school systems have enough professional mental health personnel to successfully manage this type of crisis. It is therefore imperative that school systems make formal links with mental health agencies to handle school crises. Each system should have a well-developed plan to handle crises that should include family contact, support, and referral; interventions with siblings, peers, and classmates; identification and referral of at-risk individuals; community information; media relations; staff support and consultation; links with mental health professional services; and internal communication.

SLEEP DISORDERS

Sleep disruptions are common in children ages 3 to 7 years of age and may include nightmares, sleep terrors, or sleepwalking (Chart 29-7). With reassurance, appropriate bedtime activities (reading, quiet discussions), and comforting strategies by parents, most episodes last only a short while (see Chapters 4-7 for a summary of normal sleeping patterns of children of all ages).

Sleep disturbances usually erupt after times of high stress in the family or the child's daily routine, a frightening situation, or when self-expectations or parental expectations for the child have increased. From age 3 to 7, children learn new skills rapidly. Although the child can take pride in new accomplishments, expectations are increased as well; thus, they have the "stress" of success. Children of this age do not always have the language to express their feelings and worries, and parents may not always find the time for quiet nurturing activities (e.g., reading, singing, talking, holding, or cuddling) before bedtime. For these reasons, feelings and thoughts may spill over during sleep in the form of various sleep disturbances. A family history is common in arousal disorders, which include confusional arousals (occur primarily in infants and young children during which moaning progresses to agitated, confused behavior with crying), sleepwalking, and sleep terrors (also called *night terrors* where the child looks terrified, has staring eyes, increased heart rate and sweating, and cries) (Stores, 2009).

CHART 29-7 TYPES OF SLEEP DISORDERS

Sleep disruptions: Unusual nighttime awakenings occur frequently, with no immediately known or observable cause (nightmares, sleep terrors, sleepwalking, confusion, and arousal).

Nightmares: Child wakes during deep sleep, is frightened but alert, and is able to report on what was frightening and usually has difficulty returning to sleep. Nightmares occur in approximately 10% of children 3 to 6 years of age.

Sleep terrors: Episodes occur usually after 1 to 2 hours of sleep; the child or adolescent looks terrified and very agitated. This form of sleep disruption is not remembered by the child. Sleep terrors are a developmental variable and not caused by anxiety or undue stress.

Sleepwalking: The individual walks about while asleep. Sleepwalking usually occurs during the first part of the sleep cycle. Sleepwalking may be calm or agitated.

Assessment

When assessing complaints about sleep disturbances, consider the child's overall health and developmental status. Document daily activities, bedtime routines, and a description of the sleep environment. It is important to elicit the parent's perception of the child's sleep disturbance and the effect it has on family life. Obtain a thorough description of the sleep disturbance, including any precipitating events, the length of time the disturbance has been occurring, the frequency of the occurrence, any interventions used, and their success. The diagnosis of a sleep disorder is made when the precipitating event has passed and usual interventions to promote sleep have been tried for at least 1 month but have failed to bring about a change. Note any other physical or mental health conditions.

Interdisciplinary Interventions

Educate the parents and the child to promote understanding of the disorder and its management. Safety factors in the home of the sleepwalker should be identified and modified if warranted. For instance, the home should be secured so that the child cannot easily leave the house, and items that the child could run into or easily break should be relocated. Discussing frightening or distressing events and the feelings aroused by them may help decrease occurrence of nightmares and sleep terrors. Spending time with the child at bedtime (singing, reading, quietly talking) may help the child relax and sleep more restfully. The child needs reassurance that parents are available during the night to provide support, give reassurance, and help the child relax.

If the child is experiencing anger, frustration, or anxiety as a result of other underlying problems such as difficulty

in school, family disruptions or parental conflict, recent or current trauma (e.g., such as sexual abuse), or anticipated trauma (e.g., anticipated loss of parent, punishment for wrongdoing, or recurrence of some tragedy), the underlying problem must be sorted out and addressed.

Parents often allow children with sleep problems to sleep with them. It is best to discourage this intervention. It reinforces the child's belief that the child is unable to master the problem. It also may (and usually does) give the message to the child that the parent is "frightened," unable to solve the problem, and perhaps needs to rely on the child. See Nursing Interventions 29–6 for other techniques that are helpful to prevent and treat sleeping disorders.

If the problem persists and the dreams do not abate, seek consultation with an APRN, psychiatrist, or other mental health professional. Persistent nightmares, sleep terrors, and sleepwalking require psychiatric attention.

PHYSICAL ABUSE, NEGLECT, AND EMOTIONAL MALTREATMENT

Child abuse is a global problem, deeply rooted in cultural, social, and economic practices. The abuse of children and adolescents is so widespread that no one knows its full cost. The effects of child maltreatment are profound: It is linked to most mental illnesses and addictions, and causes human suffering; family disruption; increased violence; participation in gangs; absenteeism from work; lifelong unemployment; financial costs of acute and chronic hospitalization; welfare dependency; addictions; deaths from suicide, murder, and drunk driving; and perpetuation of the abuse upon future generations. Child abuse includes physical abuse, sexual abuse, neglect, and emotional or psychological abuse (Table 29–2). Children may be subjected to more than one type of maltreatment, and emotional abuse is usually a component of the other forms of abuse. Physical abuse suffered as a child has been found to contribute substantially to psychological and physical problems in adulthood (Woods & Wineman, 2004).

Each country and each state in the United States has its own legal definitions of physical abuse, neglect, and sexual abuse. Some definitions are more narrow than others. For example, some states limit prosecution only to parents, excluding other perpetrators such as neighbors or other family members. Many definitions of abuse and neglect, which use phrases such as *resulting in bodily injury*, *deviant sexual conduct*, and *compelled by force or imminent threat of force* are vague and open to interpretation. If healthcare professionals and individual states cannot reach consensus on definitions of abuse, it is difficult for professionals to exercise any authority in removing children to safer environments or in treating the victims and abusers. These unclear definitions, and the difficulty they create in substantiating abuse, create a system in which the abused child is often left in danger and untreated.

Worldwide, 31,000 children younger than 15 years were victims of homicide in the year 2002 (Butchart & Harvey, 2006). Because many child deaths are not investigated, it is difficult to know the true extent of the problem. The highest rates of fatal child abuse are found among children age birth to 4 years, with the most common cause of death being head injury, followed by abdominal injuries and intentional suffocation (Butchart & Harvey, 2006). Millions of children are victims of nonfatal abuse and neglect; rates vary by country, with 25% to 50% of children reporting severe and frequent physical abuse (Butchart & Harvey).

Incidence data for child abuse or neglect rely on substantiated reports of maltreatment; according to maternal self-report, however, these official statistics underestimate actual maltreatment (Theodore et al., 2005). In the United States, in 2005, an estimated 899,000 children were victims of maltreatment and 1,460 children died as a result of abuse or neglect (U.S. Department of Health and Human Services [DHHS], Administration on Children, Youth and Families, 2007). Neglect is the most common form of maltreatment. In 2005, 62.8% of victims were neglected, 16.6% were physically abused, and 9.3% were sexually abused (U.S. DHHS, Administration on Children, Youth and Families, 2007). Because of different cultural norms regarding disciplining adolescents, abuse and neglect of adolescents are probably severely underestimated.

Vulnerability to child abuse depends, in part, on the child's age and sex. Young children are most at risk of physical abuse; girls are at greater risk of sexual abuse than boys (Butchart & Harvey, 2006). Perpetrators of abuse are often female (almost 58%) and a parent (>90%) (U.S. DHHS, Administration on Children, Youth and Families, 2007) (Chart 29–8). In most cases of sexual abuse, the child knows the perpetrator. Common offenders are parents, step-parents, other adult relatives, trusted family friends, neighbors, or baby-sitters. Occasionally, more than one family member is involved in sexually abusing the child.

Substance abuse and child maltreatment are strongly related. Substance abuse tends to heighten sexual arousal while simultaneously decreasing inhibitions. This combination results in adults being far more aggressive and

NURSING INTERVENTIONS 29–6

Parental Teaching to Prevent and Manage Sleeping Disorders

- Leave a night light on.
- Leave the child's bedroom door open.
- Provide the child with a comforting blanket or stuffed animal.
- Avoid excessive anger and abusive discipline.
- Set and maintain realistic limits during the day.
- Reward the child for success.
- Keep expectations reasonable.

TABLE 29-2**Types of Child Abuse**

Category	Description
Physical abuse	An injury intentionally inflicted on a child by a caregiver, paramour of a parent, or anyone residing in the child's home
Sexual abuse	The use of a child for sexual gratification or financial gain, by an adult or older child, whether by physical force, coercion, or persuasion; includes activities such as exhibitionism, pornography, genital fondling, attempted or actual anal, vaginal, or oral intercourse
Neglect	Acts or omissions by the perpetrator that fail to meet the child's needs for basic living, including food, hygiene, medical care, clothing, and a safe environment
Emotional or psychological abuse	Pattern of damaging interactions between parents and child (belittling, shaming, threatening or committing violence against the child or child's loved ones or objects, making the child feel unsafe, encouraging developmentally inappropriate behaviors, unreasonably limiting activities or social interactions, rejecting the child) that result in impaired growth, negative self-image, or disturbed child behavior

CHART 29-8 RISK FACTORS FOR CHILD MALTREATMENT**Child**

- Prematurity
- Difficult temperament
- Chronic illness
- Multiple birth
- Developmental or physical disabilities

Parent

- Poor impulse control and problem-solving skills
- Low self-esteem
- Mental health conditions
- Developmental delay
- Unrealistic/rigid expectations about child's needs and development
- Negative perception of child and child's actions
- History of childhood abuse

Family

- Social isolation
- Homelessness
- Disorganized, lack of cohesion
- Intimate partner violence
- Negative parent-child interactions
- Socioeconomic disadvantage: poverty, unemployment
- Stress
- Substance abuse
- Unrelated male adult living in the home

Community

- Violence
- Lack of support (child care, crisis intervention services)
- Socioeconomically disadvantaged

sexually violent. One in four families is reported to have problems with substance abuse (Finke et al., 2003).

Assessment

The effects of physical abuse, emotional abuse, and neglect are enormous and manifest in multiple ways. Emotional abuse may be inflicted without physical injury to the child, but it is what most seriously affects children. They may also be physically or sexually abused, but the psychological impact of the abuse remains with the child after the bruises, burns, and broken bones have healed, often leading to a variety of psychological disorders.

Many abused children respond in a manner that goes unnoticed by most adults, such as extreme efforts to please, withdrawal, and generalized anxiety. During assessment, in addition to physical signs, note the child's behavior (e.g., wary of adults, cringes with sudden movements, apathetic, excessive daydreaming, or any signs of anxiety or depression; does not turn to parent for support, attentive to other children crying, poor hygiene [dirty, severe diaper rash, skin rash], and dress [Is it appropriate for the weather? Long sleeves and pants may be worn to cover injuries even in warm weather; dirty clothing or inadequate attire for the weather may signal neglect]). Additional effects of abuse and neglect upon school performance include a lack of motivation to achieve, fear of failure, an inability to establish positive relationships with unfamiliar adults, poor performance on standardized tests, lower grades, a higher dependence on teachers, more trips out of the classroom as a result of behavioral problems, more suspensions, and lower social competence.

Include a sexual assault assessment in every history of a child or adolescent. Keep in mind that victims often do not easily disclose the abuse and must be supported.

Assessment for signs of abuse are listed in Nursing Interventions Classification (NIC) 29-1. Assess injuries

NIC 29–1 Nursing Interventions Classification: Abuse Protection Support: Child

Definition: Identification of high-risk, dependent child relationships and actions to prevent possible or further infliction of physical, sexual, or emotional harm or neglect of basic necessities of life

Activities:

- Identify mothers who have a history of late (4 months or later) or no prenatal care
- Identify parents who have had another child removed from the home or have placed previous children with relatives for extended periods
- Identify parents who have a history of substance abuse, depression, or major psychiatric illness
- Identify parents who demonstrate an increased need for parent education (e.g., parents with learning problems, parents who verbalize feelings of inadequacy, parents of a first child, teen parents)
- Identify parents with a history of domestic violence or a mother who has a history of numerous “accidental” injuries
- Identify parents with a history of unhappy childhoods associated with abuse, rejection, excessive criticism, or feelings of being worthless and unloved
- Identify crisis situations that may trigger abuse (e.g., poverty, unemployment, divorce, homelessness, and domestic violence)
- Determine whether the family has an intact social support network to assist with family problems, respite child care, and crisis child care
- Identify infants/children with high-care needs (e.g., prematurity, low birth weight, colic, feeding intolerances, major health problems in the first year of life, developmental disabilities, hyperactivity, and attention deficit disorders)
- Identify caregiver explanations of child’s injuries that are improbable or inconsistent, allege self-injury, blame other children, or demonstrate a delay in seeking treatment
- Determine whether a child demonstrates signs of physical abuse, including numerous injuries in various stages of healing; unexplained bruises and welts; unexplained pattern, immersion, and friction burns; facial, spiral, shaft, or multiple fractures; unexplained facial lacerations and abrasions; human bite marks; intracranial, subdural, intraventricular, and intraocular hemorrhaging; whiplash; shaken infant syndrome; and diseases that are resistant to treatment and/or have changing signs and symptoms
- Determine whether the child demonstrates signs of neglect, including poor or inconsistent growth patterns, failure to

thrive, wasting of subcutaneous tissue, consistent hunger, poor hygiene, constant fatigue and listlessness, bald patches on scalp or other skin afflictions, apathy, unyielding body posture, and inappropriate dress for weather conditions

- Determine whether the child demonstrates signs of sexual abuse, including difficulty walking or sitting; torn, stained, or bloody underclothing; reddened or traumatized genitals; vaginal or anal lacerations; recurrent urinary tract infections; poor sphincter tone; acquired sexually transmitted diseases; pregnancy; promiscuous behavior or prostitution; a history of running away, sudden massive weight loss or weight gain, aggression against self, or dramatic behavioral or health changes of undetermined etiology
- Determine whether the child demonstrates signs of emotional abuse, including lags in physical development, habit disorders, conduct learning disorders, neurotic traits/psychoneurotic reactions, behavioral extremes, cognitive developmental lags, and attempted suicide
- Encourage admission of child for further observation and investigation, as appropriate
- Record times and durations of visits during hospitalizations
- Monitor parent–child interactions and record observations
- Determine whether acute symptoms in child abate when child is separated from family
- Determine whether parents have unrealistic expectations for child’s behavior or whether they have negative attributions for their child’s behavior
- Monitor child for extreme compliance, such as passive submission to invasive procedures
- Monitor child for role reversal, such as comforting the parent, or overactive or aggressive behavior
- Listen to pregnant woman’s feelings about pregnancy and expectations about the unborn child
- Monitor new parents’ reactions to their infant, observing for feelings of disgust, fear, or disappointment in gender
- Monitor for a parent who holds newborn at arm’s length, handles newborn awkwardly, asks for excessive assistance, and verbalizes or demonstrates discomfort in caring for the child
- Monitor for repeated visits to clinics, emergency rooms, or physicians’ offices for minor problems

Establish a system to flag the records of children who are suspected victims of child abuse or neglect

Monitor for a progressive deterioration in the physical and emotional state of the infant/child

Determine parent's knowledge of infant/child basic care needs and provide appropriate child care information, as indicated

Instruct parents on problem solving, decision making, and child-rearing and parenting skills, or refer parents to programs where these skills can be learned

Help families identify coping strategies for stressful situations

Provide parents with information on how to cope with protracted infant crying, emphasizing that they should not shake the baby

Provide the parents with noncorporal punishment methods for disciplining children

Provide pregnant women and their families with information on the effects of smoking, poor nutrition, and substance abuse on the baby's and their health

Engage parents and child in attachment-building exercises

Provide parents and their adolescents with information on decision-making and communication skills and refer to youth services counseling, as appropriate

Provide older children with concrete information on how to provide for the basic care needs of their younger siblings

Provide children with positive affirmations of their worth, nurturing care, therapeutic communication, and developmental stimulation

Provide children who have been sexually abused with reassurance that the abuse was not their fault and allow them to express their concerns through play therapy appropriate for age

Refer at-risk pregnant women and parents of newborns to nurse home visitation services

Provide at-risk families with a public health nurse referral to ensure that the home environment is monitored, that siblings are assessed, and that families receive continued assistance

Refer families to human services and counseling professionals, as needed

Provide parents with community resource information that includes addresses and phone numbers of agencies that provide respite care, emergency child care, housing assistance, substance abuse treatment, sliding-fee counseling services, food pantries, clothing distribution centers, health care, human services, hot lines, and domestic abuse shelters

Inform physician of observations indicative of abuse or neglect

Report suspected abuse or neglect to proper authorities

Refer a parent who is being battered and at-risk children to a domestic violence shelter

Refer parents to Parents Anonymous for group support, as appropriate

Bulechek, G. M., Butcher, H. K., & Dochterman, J. M. (2008). *Nursing interventions classification (NIC)* (5th ed.). St. Louis, MO: Mosby. Reprinted with permission.

in the context of medical, social, and developmental history; the explanation given; and the patterns of injury. Specific areas of the body are associated with accidental injury; other areas, with nonaccidental injury (Fig. 29-4). Bruises in nonmobile infants, over soft-tissue areas, and those that resemble an implement (e.g., loop marks of a hanger or doubled-over belt, linear petechiae resembling fingers on a cheek) suggest abuse.

WORLDVIEW: Healing practices common in some cultures can resemble child abuse (see *Worldview, Chinese Folk Practices*, in Chapter 25), and injuries caused by these practices may warrant further investigation. Such practices can often be distinguished from abuse, based on history and physical examination. Ask the family what was done to treat the child.

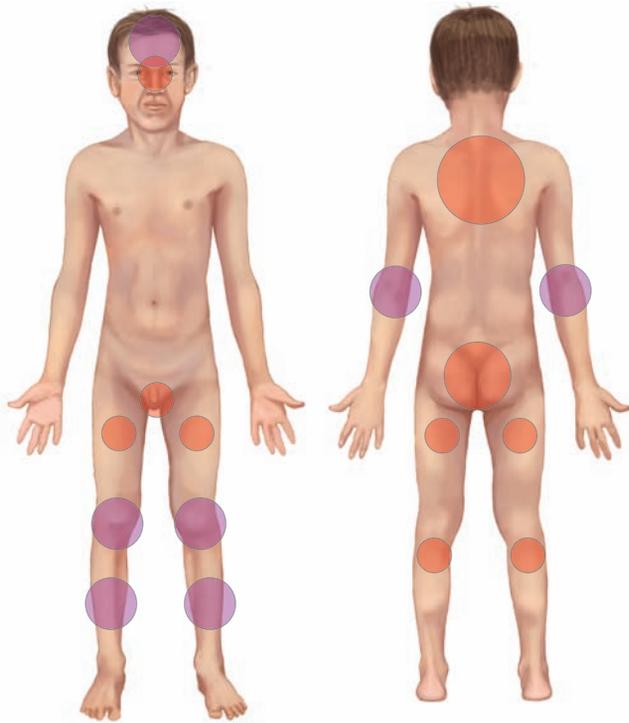

Some medical conditions may mimic a clinical picture (e.g., bruises with leukemia or idiopathic thrombocytopenic purpura) or skeletal findings that are associated with abuse (e.g., osteogenesis imperfecta, congenital syphilis, scurvy, rickets, copper deficiency). Be cognizant

of these conditions and include history questions and explore laboratory and diagnostic studies as indicated.

Diagnostic evaluation of child abuse depends on the symptoms and history. A primary screening tool in suspected abuse is a radiographic survey, including skull series, extremities (including hands and feet), and ribs. A bone scan is recommended when the skeletal survey is negative but a strong clinical suggestion of injury exists. Computed tomography and magnetic resonance imaging may be ordered, depending on the symptoms. Ultrasonography may be done if visceral injury is suspected. If abdominal trauma is suspected, urine and stool should be screened for blood. Blood studies should include bleeding studies to rule out a bleeding diathesis; serum calcium, phosphorus, and alkaline phosphatase if bone disease is a possibility; and liver and pancreatic enzymes if damage to these organs is suspected.

Alert! Children who have been sexually abused must be evaluated for sexually transmitted infections (STIs). Conversely, if an STI is found in a prepubescent child or a sexually inactive adolescent, one must strongly consider sexual abuse.

● Common non-intentional injury sites ● Common intentional injury sites

FIGURE 29-4. Nonintentional injuries are typically seen in specific sites (purple areas). The nurse should suspect physical abuse in children with injuries in intentional injury sites (red areas).

Children are not given a psychiatric diagnosis when they are assessed immediately after abuse. When children have later behavioral manifestations thought to be related to the abuse, diagnoses are based on the behavioral manifestations. Common diagnoses for abused children include conduct disorder, major depression, borderline personality disorder, and oppositional defiant disorder.

Interdisciplinary Interventions

The nurse does not have to *prove* the abuse or neglect has occurred, but is obligated to report suspicion of either to the proper authorities. Often, reporting involves a judgment call on the part of the nurse. The purpose of reporting is to protect the child and other children in the home or others at risk, and to help the parents. Mandated reporters are provided immunity from civil or criminal liability as a result of making a required report of known or suspected child abuse, unless reporting is done with malicious intent. Mandated reporters who fail to report suspicious findings may be subject to criminal prosecution and sanctions imposed by licensing boards. Each state has a form for reporting suspected abuse or neglect (check with the state's attorney general's office); this form may also be used for reporting suspected medical neglect.

Treatment includes managing the acute condition. Collect evidence within 72 hours of the event to document the occurrence of sexual abuse or assault. To do so, use an evidence kit, available in most emergency departments, that contains the necessary swabs, cultures, tubes, and envelopes to seal the specimens. Send any clothing worn during the abuse or assault with the medical specimens for investigation.

caREminder

If an abused or assaulted child is referred from your facility to another facility for specimen collection, instruct the child and family not to bathe the child or change his or her clothing so that evidence from the assault is not destroyed.

For an adolescent who is not pregnant at the time of evaluation and not using birth control, offer postcoital contraception. This treatment is effective only up to 72 hours after the rape.

According to existing literature, nurses can perform several interventions that are thought to be successful in helping the child cope with the abuse (Nursing Interventions 29-7).

Without accusing the parents, tell them that child protective services are being notified (e.g., "The symptoms are ..., indicating they may not be accidental"). Encouraging the parent to ask questions about the report may help the parent to understand the process and anticipate social work visits and calls at home. Emphasize that the priority is to ensure the child's safety and well-being.

Provide emotional and social support for the family. Refer the parents to support groups, self-help groups, or parenting classes, as needed. Remember that the goal is to facilitate change so that the family can live together as a functional, healthy unit.

Child Sexual Abuse

One of the most profound and tragic results of sexual abuse occurs when a parent is the abuser and the abuse affects the relationship between the victim and the nonoffending parent (Chart 29-9). Often, the nonoffending parent (in this discussion, the mother) has no knowledge of the sexual abuse until the child discloses it, yet is treated with contempt and blame by family, friends, and professionals for "allowing" the abuse to continue. Occasionally, nonoffending parents have some knowledge or suspicion that sexual abuse is occurring and choose to continue to subject their children to abuse rather than give up their relationship with the perpetrator.

Victims may expect that the mother will always protect them from harm. When she does not, the victims may direct their rage at the mother. Often, the intensely conflictual feelings of love and hate for the actual perpetrator, who has a tremendous amount of power in the child's mind, are too threatening for the child to deal

NURSING INTERVENTIONS 29–7

Abused and Neglected Children and Adolescents

Teach child anxiety-reducing techniques:

- Gradual relaxation
- Relaxation to music
- Visual imagery
- Exercise
- Talking with safe, appropriate people about feelings
- Choosing, building, and maintaining positive support systems
- Ensuring personal safety
- Setting boundaries
- Establishing a safe, supportive relationship
- Clarifying expectations and rules
- Self-soothing techniques

Assist child in managing his or her feelings:

- Teach child to identify feelings.
- Teach child to express feelings appropriately.
- Teach child to modulate and control feelings.
- Teach child to identify events that elicit strong positive and negative feelings.
- Teach child to express feelings verbally instead of physically.
- Teach child to normalize feelings resulting from abuse.
- Teach child to share feelings appropriately with peer group.
- Teach child to find commonality and support within group for feelings resulting from abuse.

Teach child assertiveness skills:

- Teach child to identify differences between assertiveness, passivity, and aggression.
- Teach child to practice assertiveness skills.
- Teach child to identify boundaries.
- Teach child to understand when someone violates boundaries.
- Teach child to practice responses when someone violates boundaries.

Assist child in developing problem-solving skills:

- Provide simple problem-solving model.
- Increase awareness of child's control and decision making.

- Teach child to generate a list of possible solutions to problem situations.
- Help child look at consequences of each solution.
- Help child make best choice.
- Help child give self positive and gentle negative feedback.
- Coach problem solving with actual situations as much as possible.
- Teach good touch/bad touch.
- Teach refusal skills.

Teach age-appropriate sexual expression.
Teach effects of substance abuse.

Assist child in value building and clarification:

- Define values.
- Identify role of values.
- Assist child in identifying and verbalizing values.
- Help link child's values to child's actions.
- Assist child in development of values.
- Help child practice value-based decision making.

Assist child in enhancing his or her coping mechanisms:

- Teach child to practice positive self-talk.
- Help child set realistic expectations for self.
- Assist child in learning to nurture self.
- Teach child to practice relaxation.
- Teach child to practice assertiveness and appropriate expression of feelings.
- Assist child in learning to accept defeat and failure.
- Help child identify and build skills and hobbies.
- Encourage child to identify and focus on strengths.
- Help child set and accomplish goals.
- Assist child in developing organizational skills.

with. It is therefore easier for a child to direct the rage at a less threatening person, such as the mother or younger sibling. Although the child's behavior becomes understandable after the abuse is disclosed, it is extremely difficult to live with on a daily basis.

The nonoffending parent is also thrown into crisis by the events. Often, the mother must terminate an important relationship, perhaps even end a marriage; deal with

the stigma of incest; cope with the blame; and deal with the trauma to the child. She is often left to deal with this crisis alone, while simultaneously receiving the brunt of the child's anger.

When abuse is disclosed, the perpetrator is removed from the home. The nonoffending parent then must struggle alone to meet family needs, while attempting to provide the necessary psychiatric care with less time, money, and

CHART 29–9 FACTORS THAT PREVENT CHILDREN FROM DISCLOSING SEXUAL ABUSE

- Child's young age
- Child's developmental level
- Dependency on adults for meeting basic needs
- Shame
- No witnesses to validate the abuse
- No observable physical injuries
- No outward manifestations of the sexual violation
- Disbelief and rejection by adults upon disclosure
- Threats (such as the perpetrator threatening to kill the victim's mother if the victim discloses the abuse)
- Force and aggression used by the perpetrator
- Fear of family breaking up
- Fear of abandonment
- Fear of loss of home
- Fear of foster placement
- Negative affect on the child's relationship with the nonoffending parent
- Parental disbelief and being labeled a "troublemaker"
- Loss of privacy and shame resulting from investigation and court proceedings
- Fear of reprisals, such as worsened physical and sexual abuse
- Fear that child will not be believed

resources. It is imperative that nurses do not blame the nonoffending parent, but rather take a supportive stance.

Shaken Baby Syndrome

Abusive head injuries among infants result in mortality rates of 13% to 30% and substantial neurologic impairments in at least half of the survivors (Dias et al., 2005). *Shaken baby syndrome* involves intracranial trauma (e.g., subarachnoid or subdural hemorrhage or diffuse cerebral edema) and retinal hemorrhages, usually in the absence of skull fracture or external signs of traumatic injury, caused by vigorously shaking an infant. Shaking causes sudden deceleration of the infant's head, which tears the bridging vessels between the skull and the brain and causes hemorrhage. Fractures of the long bones or ribs, not readily apparent, also may be present. The ribs are compliant in young children; however, cardiopulmonary resuscitation has not been found to cause rib fractures in children Bulloch, Schubert, Brophy et al., 2000. Posterior rib fractures are more common, caused by the mechanical stress at the costovertebral junction when the child is grasped and shaken.

The child with shaken baby syndrome is typically younger than 2 years of age and commonly presents with complaints of lethargy, seizures, hyperirritability, poor feeding, bulging fontanel, breathing problems, or, in severe instances, coma or cardiopulmonary arrest. Hypothermia is a common finding in these children and is sec-

ondary to the occult central nervous system trauma. Consider abuse when presented with a child with encephalopathy without an obvious source.

The child who has been shaken is treated symptomatically. If trauma is suspected, immobilize the cervical spine. Assess airway, breathing, and circulation; support and stabilize; and frequently reassess. Continually monitor the child's neurologic status for signs of increasing intracranial pressure. Because shaking results in traumatic head injury, it is treated in the same way that trauma is managed (see Chapter 31).

Munchausen Syndrome by Proxy

Munchausen syndrome by proxy is a rare form of abuse in which the child is subjected to an "illness" that is induced or fabricated by the parent or caregiver. The affected parent or caregiver seeks medical care for the child's fictitious illness and provides a fictitious history to support the illness. The fabricated or induced illness often results in the child being subjected to numerous unnecessary, invasive laboratory studies, hospitalizations, or surgeries. The syndrome can result in disability or death of the child.

The child's reported symptoms typically occur only when the parent is present and stop when the parent is not. Most cases present with some sort of neurologic disturbance, such as seizures or apnea. Less common presentations include hematuria, gastrointestinal bleeding, hypernatremia, or hyponatremia. The perpetrator may suffocate the child to produce apnea or seizures, or may add her or his own blood to the child's urine or stool sample to fabricate bleeding.

The mother is the perpetrator in nearly all cases and often has a healthcare background or is well versed in medical terminology (Galvin, Newton, & Vandeven, 2005). The mother is typically quite attentive to the child and is involved in the child's care, but often lacks parental concern. For example, she may appear calm, not cry, and carry on with normal activities despite providing this dramatic, worrisome history. Assessment and interventions are summarized in Nursing Interventions 29–8.

The long-term outcome for these children has not been well researched. Mortality rates are estimated at about 10% (Galvin et al., 2005); actual incidence is difficult to estimate because of the difficulty in identifying the diagnosis. When poisoning or suffocation is involved, mortality rates are as high as 33% (Galvin et al., 2005). Many children develop a self-image as an ill or disabled person, which seriously harms the child's emotional and social development, causing emotional disorders, school-related problems, and poor concentration and school attendance. The victimized children are at risk of later developing the syndrome themselves and often have behavioral problems.

ADJUSTMENT DISORDERS

A number of behavioral adjustment problems may occur in children who experience loss or other traumatic life situations such as natural or man-made disasters, wars, abuse (especially sexual abuse), neglect, or exposure to violence. Continual unabated stress of poverty, homelessness, or

NURSING INTERVENTIONS 29–8

Munchausen Syndrome by Proxy

Assessment

Social History

- Family history of previous, unexplained infant deaths/sibling illness
- Family dysfunction
- Marital discord, emotionally distant spouse

Child History

- Description of a prolonged, unexplainable illness that, despite medical attention and therapies, has not been resolved
- Discrepancy between clinical findings and history
- Symptoms that do not occur when others are present

Parental Behavior

- Seeming lack of concern for the child's condition and interest in performing many tests and procedures
- Remains calm when child is very ill (e.g., in cardiac arrest)
- Exemplary caregiver to child when healthcare members are present; ignores child when others are not present

Interventions

- Separate suspected perpetrator and child and see if symptoms persist.

- Try to talk with verbal children alone, away from the suspected perpetrator.
- Attempt to involve the other parent, if absent.
- Ask parents separately how they are coping; suggest appropriate referrals.
- Objectively document: use nonaccusatory, fact-specific, detailed observations of behavior and interactions with the child, staff, and spouse (e.g., 12:01: mother standing on left side of bed where IV tubing is; 12:04: child became lethargic—blood glucose tested 40 mg/dL, IV tubing leaking, appears to be small puncture hole in tubing).
- Document relevant negatives (e.g., symptoms do not occur when the mother is absent).
- Covert video surveillance may be needed; follow institution protocol.
- Notify child protective services, institutional risk management, and local police.
- A multidisciplinary team will confront the perpetrator; the child may need to be protected at the same time as the perpetrator is confronted (e.g., a court order in place so the perpetrator cannot remove the child from the facility).
- Evaluate child's and parent's responses to interventions; they likely will require long-term follow-up and psychiatric referrals.

family conflict or disintegration may have devastating effects on children or adolescents. They may be genetically vulnerable or physiologically vulnerable (e.g., chronically ill), or they may not have sufficient coping strategies or support to manage the psychological assaults. Many disorders occur as a result of life disruptions; this section addresses only those not previously discussed.

Symptoms overlap among adjustment disorders and mood disorders. For example, a child may have an adjustment disorder with depressed mood or disturbance in conduct. The distinction is the cause of the problem. **Adjustment disorder**, defined as a disturbance in behavior that develops as a result of adverse life circumstances and personal inability to cope with the resulting stress, is a common reason that children are referred for mental health services. The essential feature of adjustment disorder is clinically important emotional or behavioral symptoms within 3 months of an identifiable stressor that overtaxes the individual's coping abilities. Bereavement is not considered to be an adjustment disorder, unless it incapacitates the individual beyond 6 months. Stressors

may be relocation (new school, new home), family changes (new sibling, parental separation or divorce), or an accomplishment of a developmental milestone (starting school, going to camp). Bullying by another child is receiving increased attention as a possible cause of adjustment problems (Nansel, Craig, Overpeck, et al. 2004).

An adjustment disorder of even a short duration (6 months or less) is of clinical importance, because risk for suicide increases and potential for academic difficulties is high. With timely and appropriate intervention (support, understanding, and restabilization of family life), most children recover rapidly. In most children, a more severe disruptive disorder does not develop, and the conflict resolves, or the child adjusts to the change.

Assessment

Young children often manifest an adjustment disorder by whining and clinging behavior or by increased aggressive behavior or isolation. Children in the elementary school years and in adolescence often manifest adjustment

disorders through somatic symptoms (stomach pains, nausea, headaches, fatigue), academic difficulties, or problems in social relationships. An adjustment disorder may be accompanied by anxiety or mood disturbance. Whenever children are seen with the foregoing complaints, and when no physical reason is found for the behavior change, the nurse should investigate changes in the child's life situation. Nursing assessment must include information about the precipitating stressor, its timing and severity, history of any previous alterations in mental health and behavior, and coping strategies. A suicide assessment is essential.

Interdisciplinary Interventions

Interventions that could be helpful are education (helping the youth and his or her family to understand the child's feelings and behaviors) and advocating for reduced stress and resources for the child. Providing family support, facilitating communication about the stressor, and assisting the child in the development of effective coping strategies are important interventions for preventing further deterioration. Advocating for classroom changes by helping teachers to understand the reason for the child's behavior can help to relieve additional stress caused by educational pressures. If the child does not recover with brief problem-oriented therapeutic strategies, refer the child to a mental health clinic.

PERSONALITY DISORDERS

A *personality disorder* is a long-term pattern of behavior that deviates substantially from socially acceptable behavior (APA, 2000). The pattern of behavior affects functioning and is not caused by substance use. Personality disorders include borderline personality disorder, dissociative disorder, antisocial personality, and obsessive-compulsive personality. Personality disorders are strongly associated with childhood and adolescent sexual abuse.

Personality disorders are most often diagnosed in the adolescent or young adult years. The prevalence of personality disorders ranges between 12.7% to 14.6%, increasing with age to an estimated lifetime prevalence of 28.2% at age 33 years (Johnson, Cohen, Kasen, et al., 2008).

Self-injurious behaviors, such as cutting and scraping skin, and high-risk behaviors, such as substance abuse and sexual acting out, are seen in most cases. These high-risk behaviors make the child more susceptible to further victimization. Children or adolescents with dissociative disorder are poorly understood by most persons, and they are often accused of lying and being untrustworthy. Some adults often believe the child deserves abuse because of his or her strange, incomprehensible behavior.

Assessment

The features of personality disorders are difficult to identify. In general, observe for rapid mood changes, seeming inattention, and rapid shifts in details when recounting events. Other areas that should receive special emphasis in suspicion of a personality disorder include any history of amnesia, self-harm behaviors, abuse, substance use, or

high-risk behaviors. Observe the child for regressive states that cause the child to appear younger, such as voice changes or changes in the quality of speech that make the child sound much younger.

Borderline personality disorder is the category most frequently used for children. To diagnose any personality disorder in individuals before the age of 18, the characteristics must be present for at least 1 year. Antisocial personality disorder is not usually used as a diagnosis in children younger than 18. Rather, conduct disorder would be the diagnosis until a long-term pattern is established. Children at varying stages of development manifest behaviors characteristic of normal growth and development that also are features of a personality disorder. Only when the behaviors persist and interfere with the developmental process and social well-being are they then applied to a diagnosis.

Interdisciplinary Interventions

If abuse is a causative factor, report it immediately. Reporting is both a legal obligation and helps ensure the future safety of the child. The second most important intervention is to develop a trusting relationship with the patient to provide appropriate feedback and interventions. Components of the treatment program used with borderline and dissociative disorders are a therapeutic behavior management program, group therapy, social skills training, recreational therapy, and participation in special education until discharged.

Nurses need to develop an accepting, open approach to the youth with personality disorder. Safety precautions are imperative, because these children will use almost anything for self-harm when they are in a state of upset or feeling empty or "dead." Examples of potential weapons include pencils; erasers; sharp pieces of plastic, metal, or glass; and objects that may cause burns, such as matches or curling irons. The "dead" feeling is related to numbing of painful feelings and intrusive memories or images.

Clearly explain rules and firmly yet empathetically adhere to them. Respond to unreasonable demands and expectations truthfully and realistically. These children often use abusive language and manipulation when realistic limits are set and reinforced. Remain calm but firm in insisting on appropriate behavior and adhering to rules established for the unit and the individual patient.

SUBSTANCE ABUSE

Substance abuse is defined as a pattern of continued and inappropriate use of substances that causes substantial emotional, psychological, and physiologic effects. Marijuana is the illicit drug most widely used by children and adolescents (Johnson, O'Malley, Bachman, et al. 2005). Use of inhalants such as butane, glue, aerosols, paint, and computer cleaner is increasing, however, and is being seen in younger children. Substance use often begins as early as fourth grade (Finke et al., 2003) (Chart 29–10). Most adolescents are poorly informed about the effects of

CHART 29–10 RISK FACTORS FOR SUBSTANCE ABUSE

- Early age at first use
- Poor school performance
- High value for independence
- External locus of control
- Poor self-esteem
- Favorable attitude to use of psychoactive substances
- High risk-taking behavior pattern
- Poor social skills
- Sexual and physical abuse
- Aggressive or impulsive behavior patterns
- Peer group influence
- Family influence (approval, exposure, abuse)
- Presence of psychiatric disorder, especially depression

substance abuse. Adolescents and children who are using substances in a continuous and inappropriate way may experience repeated failure in school, difficulty in sports and social relationships, and conflict with the legal system. Youths who abuse substances are at increased risk for displays of aggression, of being the recipient of aggressive acts, of serious accidents, and of homicide and suicide.

Assessment

The goals of assessing children and adolescents for suspected substance abuse include identifying the level of involvement, motivating the child or adolescent toward treatment, and matching the child's needs to the appropriate level and method of treatment. See Chart 29–11 for signs of substance abuse; as the problem progresses, signs become increasingly obvious and interpersonal problems arise. Gather information from school, family, and peers about the child's activities and behaviors to note any recent changes in the child's behaviors or issues that may influence the current abuse activities. Alcohol use (beer, wine) and cigarette smoking are early indicators of potential substance abuse; alcohol and tobacco are considered "gateway" substances.

When interviewing the child and family, ask direct, specific questions (Chart 29–12). If the adolescent resists talking or sharing information, asking for information about peers and being nonjudgmental about their behavior may assist the child to share information about his or her own abuse. Question the parent in the presence of the child to convey support of open, honest communication; both parents and child often deny the scope of the problem.

Diagnostic Tests

Urine screening for substance abuse detects marijuana abuse for up to 3 to 4 weeks. Other substances of abuse

CHART 29–11 SIGNS AND SYMPTOMS OF SUBSTANCE ABUSE*

- Reddened eyes
- Dilated/pinpoint pupils
- Runny or stuffy nose (constant)
- Gastrointestinal upset (diarrhea)
- Weight loss or gain, change in eating habits
- Signs of needle tracks
- Slurred speech
- Unusual sleep patterns
- Restlessness or drowsiness, hallucinations or disorientation
- Awkward or clumsy physical movement, tremors
- Frequent minor illnesses (flu, colds)
- Change in friends; withdrawal from friends, activities, and family
- History of bizarre behavior
- Diminished academic performance

*Dependent on substance abused; manifest in different signs of intoxication and withdrawal.

are present in urine for only 1 to 2 days. Adolescents who are abusing substances will strongly resist providing urine for a drug screen; they question the examiner's trust in them or feign embarrassment.

Nursing Diagnoses and Outcomes

In addition to the nursing diagnoses and outcomes presented in Nursing Plan of Care 29–1, the following diagnoses can be applied to the child using substances:

CHART 29–12 INFORMATION TO OBTAIN WHEN INTERVIEWING THE CHILD/ADOLESCENT ABOUT SUBSTANCE ABUSE

- Personal strengths of the child
- Coping strategies previously used successfully
- Dietary habits
- Use of over-the-counter medications
- Use of prescribed medications
- Use of other substances
 - Smoking cigarettes
 - Use of beer, wine, and other alcoholic drinks
 - Smoking marijuana
 - Use of other substances (e.g., inhalants, cocaine)

If substance use is revealed

- When used/surrounding what other activities (especially if participating in activities that require mental concentration such as driving, school, work)
- Where used
- With whom

Decisional conflict: Substance use related to support system deficit, peer pressure, poor coping skills, unclear personal values

Outcomes: Child or adolescent will express feelings about substance use.

Child or adolescent will describe family, school, and peer issues and their potential effect on his or her substance use.

Child or adolescent will make choices that are consistent with his or her personal values and are legally sanctioned.

Risk for poisoning related to substance abuse

Outcomes: Child or adolescent will express understanding of the harmful and potentially lethal effects of alcohol, tobacco products, and drugs.

Child or adolescent will identify stressors or triggers that are likely to precipitate an episode of substance use.

Child or adolescent will not ingest alcohol, tobacco products, or illegal drugs.

Interdisciplinary Interventions

A variety of methods is used to treat substance abuse, and a variety of disciplines may be involved. The services that are actually provided depend on a number of factors, including the child's socioeconomic status, the length and severity of the problem, who is harmed by the abuse, and the type of problems exhibited by the individual child.

Education should be provided by persons that understand the brain-body connection and the effects that alcohol or other abused substances have on the body, its organs, neurotransmitters, brain cells, and observable behavior. Cognitive therapy with a strong confrontational component is used in individual and group therapy. Motivational therapy is a harm-reducing approach that helps the adolescent to identify problems that the use of alcohol or drugs causes for them and then to problem solve about reducing alcohol or drug use (Tevyaw & Monti, 2004).

Family therapy is essential. The family must come to grips with any communication and nurturing deficits. A very structured and supportive environment is needed to assist the individual to remain drug free.

A three-pronged approach that includes education about substances, adult supervision when not in school, and the development of skills to resist peers and family members who may urge drug use has proved useful to prevent substance use by children and adolescents (Finke et al., 2003). Most children and adolescents are exposed to substance use by peers or by family members, such as older siblings and parents.

The nurse can educate and promote skills to resist drug use. Help children and adolescents identify situations in which they are at high risk to use substances, then assist them in finding ways to avoid or modify such situations. Help them to develop a repertoire of cognitive and behavioral skills for modifying their routine responses to high-risk situations and thus reducing their risk for drug use. Adaptive actions might be to talk with friends or do something physical, such as play basketball.

CHILDHOOD SCHIZOPHRENIA

Schizophrenia is a severe brain disorder involving psychosis and deterioration in adaptive abilities as its primary feature. It has an insidious onset and results in severe and lifelong cognitive deficits and disordered behavior. Features of the disease must be present for 6 months before a diagnosis can be made (APA, 2000). In many cases, developmental difficulties are noted during infancy or very early childhood, but the diagnosis is most often made during adolescence or even young adulthood.

Assessment

Making a diagnosis of schizophrenia in childhood can be difficult, because the essential features may manifest differently with developmental level. Children manifest disorganized speech and behavior, which are seen in several other disorders. Adolescents and young adults diagnosed with schizophrenia are at especially high risk for suicide (APA, 2000), so give special attention to assessing this risk. During the prodromal period (before complete manifestation), these children often exhibit deficits in several areas: peer relations, school performance, speech, motor milestones, unusual behaviors (hand flapping, twirling, rocking, unusual fascinations with light, smells, or textures). Other symptoms are unusual fears, unstable moods, inappropriate response in emotions or to social situations, perseveration (difficulty in moving from one activity to another), and ritualistic behavior. These same behaviors also are common among children with autism or mental retardation.

Assessment of childhood schizophrenia should include a complete physical examination, including a neurologic examination. Neurophysical findings demonstrate slow reaction times and abnormalities in eye tracking (ability to follow an object passed slowly from one side of the head to the other, or up and down). Afflicted children are often awkward. They may show neurologic "soft signs," such as perseveration, right-left confusion (older children and adolescents), poor coordination, or mirroring (doing exactly the same behavior as the examiner). If you observe such signs, consider referring the child to a specialist.

Interdisciplinary Interventions

Initial studies have demonstrated the efficacy of neuroleptic agents with children and adolescents, but more research in children is needed (Kranzler et al., 2005; Shaw et al., 2006). Neuroleptic agents used to treat schizophrenia are believed to block a specific dopamine receptor (D2). Although most neuroleptic agents are effective in treating the so-called positive symptoms (psychotic symptoms) of schizophrenia, they do not improve the negative symptoms. Negative symptoms include flat **affect** (the external expression of emotion attached to the ideas or representation of objects), lack of motivation, and poverty of speech. One problem with neuroleptic agents is sedation. This problem can be modified with lower (than adult) doses of the medication. Therapeutic effects usually occur in 7 to 14 days, and the drugs should

be given a 4- to 6-week trial before a different medication is tried. Children and adolescents are susceptible to side effects of the medication (sedation and movement disorders such as dystonia, akathisia, tardive dyskinesia, and parkinsonian syndrome) even on low doses.

Additional interventions include clarifying the meaning of events and situations, to counter cognitive distortions, **hallucinations** (sensory impressions, such as sights, sounds, tastes, or smells that have no basis in external stimulation), and **delusional thoughts** (false beliefs that are firmly maintained despite proof to the contrary and despite the fact that others do not share the belief). Help orient the patient to situations and provide needed protection (e.g., from peers or self-harm). Interventions that promote independence and self-care are needed, including information concerning medication. Structured play activities, including social skills training, are recommended. Group therapy that is structured, skills oriented (e.g., communication and social skills), and presented in sessions of short length may be helpful.

Family interventions are also an important part of treatment. Parents need help understanding the disorder and the medications (their purpose, side effects, and actions). They often need information on managing the behavior and promoting normal growth and development. Childhood schizophrenia is an extremely difficult experience for families. They must cope with the stress of losing the “healthy” child and manage the problems associated with the illness every day, while promoting the child’s maximal development. Accurate diagnosis of the disorder may take several years. Stigma is associated with any mental illness, but especially with a disorder such as schizophrenia. Parents may experience blame, guilt, and isolation. It is essential that nurses offer support and convey the message that parents are not the cause of the disorder. Mutual support groups are helpful for many parents.

Interventions also include consultation with a variety of personnel at the child’s school (e.g., teacher, counselors) and involved community agencies. The nurse is frequently involved in accessing services for children with altered thought processes. Educating teachers about manifestations of these disorders is important. Teachers need to understand effects and side effects of medication. They need to understand that children tend to act out their hallucinations and delusions, whereas adolescents are more verbal. Various treatment options are used to promote independence, social relationships, and health maintenance. These interventions include supportive therapy, social skills training, job coaching, symptom management, teaching activities of daily living (such as self-care, shopping for food and clothes, and using transportation), money management, housekeeping, and therapeutic ways to use leisure time.

The Child With a Developmental or Learning Disorder

Case History

Remember the Currccio family? Joey is the soccer player who had a concussion and Nick went to Boy Scout camp and came home with poison ivy. Moira and Manny Currccio are expecting a baby. Their three sons, Nick, Joey, and Andrew, are 13, 11, and 8, respectively. This is an unexpected pregnancy and Moira is 41. Moira is of Irish heritage and Manny's family is Italian. They are practicing Catholics. During Moira's pregnancy, Manny and Moira decided not to have an amniocentesis despite Moira's age. This decision was made after much thought and discussion based on the premise that they would not choose to abort the fetus even if they did discover genetic abnormalities. Cecilia is born a few days before Christmas. She has reddish brown hair and dark eyes, but she also has epicanthal folds on her eyes, a short neck, protruding tongue, and hypotonia. The pediatrician and Moira's obstetrician visit the couple. They congratulate them on having a beautiful and healthy baby girl, but they recommend sending blood work to determine whether Cecilia has Down syndrome. Moira had expressed her worries during the pregnancy to her husband. She seems not to be shocked that Cecilia is born with Down syndrome. Her concerns are focused on the present. Is Cecilia getting enough to eat? Manny is supportive. He says to his wife, "We've always taken what life has given us and made the best of it." Her older brothers are curious and fascinated with the new baby girl. The fact that she is

a girl represents more of a novelty in this household of boys

than the fact that she has Down syndrome. They vie for the privilege of burping and rocking her.

Moira expects to breast-feed her fourth baby and perseveres through the first very trying week. Moira is an experienced mother, having nursed her sons, but Cecilia has a weak suck and an uncoordinated suck-swallow. Moira learns to position Cecilia sitting virtually upright in front of her. The nurses show her how to place gentle rhythmic pressure on Cecilia's chin to facilitate her efforts. Moira is fortunate that despite Cecilia's weak suck, she is producing an ample amount of milk. After 2 weeks, the results of the genetic workup return; Cecilia is a child with Down syndrome.

As Cecilia turns 3, she still has not yet learned to walk independently. Her father has built a set of parallel bars. Her parents, brothers, nurse, and physical therapist are all encouraging her to support herself within the bars, trying to get her to walk independently, but without much success. What does fascinate her is their large family dog! Whenever she is on the floor, she scoots over and hugs her dog. The dog gets up slowly and Cecilia, desperate not to be separated from the dog, holds on tightly to his fur. As the dog moves, Cecilia supports her own weight and moves with the dog. The motivation to stay with the dog is much more powerful than anything the parallel bars had to offer. Cecilia eventually learns to walk with help from the family pet.

CHAPTER OBJECTIVES

1. Discuss adaptive functional and educational responses of children with a developmental disorder.
2. Explain the importance of early identification and intervention with children who have a developmental disorder.
3. Discuss strategies to help parents navigate the healthcare system and advocate for their child to ensure that their child receives needed healthcare.
4. Identify strategies for including a child with a developmental disorder in typical environments in the community.
5. Support families in their efforts to identify and use community resources that best meet the individual child and family's needs.

See **thePoint** for a list of Key Terms.

Developmental disorders are most often detected early during a child's development or during the first years of formal education. These disorders cover a broad range of diagnoses, all of which involve delay in acquiring age-appropriate skills in **adaptive functioning** (life skills) or **educational response** (reading and writing skills). The delays range from motor skill delays, communication disorders, and intellectual delays to impairment in social interaction to disruptive behavior. The most common developmental disorders include learning disorders, intellectual disability, and autism.

Labels for these diagnoses may change depending on the funding source or educational program, but regardless how they are labeled, the behavior and treatment remain the same. Labels for intellectual disability include cognitive disability, cognitive deficit, and intellectual deficiency. The term *developmental delay* implies that the child will “catch up.” This outcome may or may not occur; therefore, other terms are more appropriate. The term *mental retardation* is still used in legislation and in the *DSM-IV-TR* (American Psychiatric Association [APA], 2000). However, *intellectual disability* is the term preferred by persons with this disability, their families, and many professionals working in the field of developmental disabilities and is the term used throughout this chapter. Learning disabilities and autism spectrum are typically not associated with decreased intellectual capacity. Developmental disability is used as a general reference to all conditions discussed in this chapter.

WORLDVIEW: In England, the term *learning disabilities* includes children with mild intellectual disability.

DEVELOPMENTAL AND BIOLOGIC VARIANCES

The center of cognition—the brain—undergoes massive development in utero and during the first few years of life

(see Chapter 21 for a more detailed discussion of central nervous system embryology and brain development). This development may be disrupted by perinatal and postnatal insult, and by environmental factors, resulting in cognitive impairments or neurodevelopmental dysfunction (see Chapters 14, 21, 26, and 27).

Children are also vulnerable to social and emotional factors. A child's cognitive development is related to the quality of mother–infant interactions (Smith, Landry, & Swank, 2006). Low socioeconomic status and poor maternal education have also been shown to have a significant positive correlation with lower Mental Developmental Index scores (Chatoor, Surles, Ganiban, et al., 2004). Lack of nurturing and stimulation has deleterious effects that may permanently alter brain development.

caREminder

For most developmental disorders, causes cannot be attributed. Families should not be blamed for causing the child's developmental problems, but should be helped to accept the child's delays and work to facilitate the child's progression.

ASSESSMENT OF THE CHILD WITH A DEVELOPMENTAL DISORDER

As with other disabilities, detecting developmental disorders early is important to enable intensive intervention to help the child progress toward his or her potential. The American Academy of Pediatrics (2006) mandates that all children be screened for developmental disorders. Diagnosing developmental disorders can be difficult and may require a multidisciplinary approach. Assessment includes a health history and physical assessment; some diagnostic tests are also useful. Information from these multiple assessments may aid diagnosis.

Focused Health History

QUESTION: What are the risk factors in Moira's health history that place her at risk for having a child with Down syndrome?

The history is always critical for a complete assessment (Focused Health History 30–1). Evaluate whether the child has achieved age-appropriate developmental and biologic milestones, and assess current behavioral, social, and cognitive functioning. Use these parameters to help determine whether the child's patterns of development are normal, delayed, or regressed.

caREminder

Listen carefully to parental concerns. A child's failure to achieve developmental milestones may indicate a developmental disorder.

FOCUSED HEALTH HISTORY 30–1

The Child With a Developmental or Learning Disorder*

Current History	<p>Ability to meet developmental milestones such as crawling, walking, or communicating</p> <p>Grades in school, presence of academic problems, ability to perform age-appropriate tasks and keep up with peers, ability to interact socially in an age-appropriate manner</p> <p>Behavioral problems (poor self-esteem, school avoidance, acting out, depressive symptoms), which may result from learning disorders</p> <p>Sleep patterns</p>
Past medical history	<p>Prenatal/Neonatal History</p> <p>Maternal infection or other prenatal insult; fetal exposure to drugs, including cigarettes and alcohol; poor maternal nutrition</p> <p>Results of alpha-fetoprotein, amniocentesis, or chorionic villi sampling</p> <p>Gestational age at birth, prematurity</p> <p>Apgar scores</p> <p>Birth weight: low birth weight may indicate maternal malnutrition; large for gestational age associated with birth injuries</p> <p>Head circumference plotted on growth chart</p> <p>Any pre-, peri-, or postnatal events that caused clinically important asphyxia, trauma, jaundice, or apnea</p> <p>Did mother and baby go home at the same time?</p> <p>Feeding (include ability to suck and swallow) and sleeping patterns</p> <p>Previous Health Challenges</p> <p>Results of genetic, neurologic, or developmental testing</p> <p>Central nervous system infections or insults; epilepsy; metabolic disorder (e.g., phenylketonuria, storage disorders); hyperbilirubinemia; chronic conditions</p>
Nutritional assessment	Poor nutrition or malnutrition during first years of life
Family medical history	<p>History of pica</p> <p>Consanguinity</p> <p>History of fetal loss</p> <p>Presence in other family members of symptoms similar to those for which the child is being evaluated</p> <p>Intellectual disabilities</p> <p>Neurocutaneous lesions</p> <p>Hypotonia</p> <p>Learning problems</p> <p>Grade retention</p> <p>School dropout</p> <p>Attention deficits</p>
Social and environmental history	<p>Exposure to environmental toxins (e.g., lead, mercury, environmental tobacco smoke)</p> <p>Maternal depression or cognitive impairment</p> <p>Child's ability to make and keep friends (as age appropriate)</p> <p>Perceived stressors for the child or among other family members</p> <p>Changes in lifestyle</p> <p>Changes in academic performance</p> <p>Domestic violence, neglect, or emotional abuse</p> <p>Unusual emotional responses (e.g., laughing at a car accident)</p> <p>Support systems available</p>
Growth and development	<p>Age at acquisition of developmental milestones, particularly delayed speech acquisition</p>

*This history is focused on the child with altered development or cognition. See Chapter 8 for a comprehensive format.

To help determine current cognitive functioning for a school-aged child, examine the child's history of school achievement, current school placement, and any need for special education support.

ANSWER: The health history in this family focuses on the maternal risk factors and not the infant's history. Moira is at increased risk for having a child with Down syndrome because of her age. According to the National Institutes of Health, the incidence of a pregnant woman younger than 30 having a child with Down syndrome is less than 1 in 1,000. However, a woman's chance of having a child with Down syndrome increases to 1 in 400 at age 35 and 1 in 60 at age 42. Despite these statistics, between 75% and 80% of children with Down syndrome are born to younger mothers because they are the age group having significantly more children.

Focused Physical Assessment

QUESTION: Review Focused Physical Assessment 30–1. What would you anticipate finding in Cecilia's newborn physical assessment?

Conduct a physical assessment of the child, including a neurologic examination and vision and hearing screening, to detect any underlying or associated medical problems (see Focused Physical Assessment 30–1). Assess for dysmorphic features, congenital anomalies, or constellations of physical findings (e.g., a long face, large ears, and large testes [in postpubertal males] are associated with fragile X syndrome, the most commonly identified genetic cause of intellectual disability) that may be associated with developmental disability.

ANSWER: Cecilia shares some of the distinctive physical features that are recognizable in individuals with Down syndrome. One feature is the shape of the eyes. Cecilia's eyes are slanted upward with palpebral fissures and epicanthal folds. She has a short neck and a slightly protruding tongue. She has poor muscle tone and a weak suck. She also has a single palmar crease.

Diagnostic Criteria

QUESTION: Genetic testing determines that Cecilia is indeed a child with Down syndrome. How can some of the tests identified in [thePoint](#), Supplemental Information: Select Tools for Assessing Cognitive and Adaptive Functioning be used as Cecilia gets older?

Developmental disorders may result from a variety of causes. They may be genetic; related to prenatal or

perinatal insult; or acquired as a result of illness, injury, and environmental exposures. Various diagnostic studies are available to assist healthcare practitioners in diagnosing neurocognitive disorders. Tests and Procedures 30–1 presents select procedures and lists specific considerations for each test. The nurse's role in helping children and their families who are undergoing these tests includes referring the child for testing and counseling, teaching parents and child about what to expect, and preparing the child before the test for any necessary invasive procedures. A trained genetic counselor performs genetic counseling.

Tests of cognitive and adaptive functioning help to diagnose developmental disorders or to plan appropriate interventions (see [thePoint](#), Supplemental Information: Select Tools for Assessing Cognitive and Adaptive Functioning). Tests should be selected according to the child's current level of developmental functioning and not on the basis of chronologic age. Tests also should be appropriate for the type of communication the child uses, whether it is speech, head nodding, or pointing. The term *cognitive functioning* is more appropriate than *intelligence*, because results on tests such as the Bayley-III are poorly correlated with intelligence in adulthood. The younger the child is when the test is administered, the lower the correlation the test result has with adult IQ. Findings at age 6 years would be more highly correlated with abilities in adulthood than findings at age 2½ years. Typically, psychologists administer most tests of cognitive functioning. Nurses may administer the Bayley-III and the Vineland Adaptive Behavior Scales after having been trained and educated to do so. Nurses also play an important role in assisting parents to interpret the results of diagnostic testing and relate that information to their child and other family members. Assessments are conducted in schools to determine the programming or intervention a child needs to promote development. School nurses may assist with this assessment, interpreting findings, and developing appropriate intervention for the child.

caREminder

Diagnostic evaluation often is a new situation for the child—one that may elicit anxiety or fear; thus, assessment may not reflect the child's capabilities accurately. Pay close attention to parents' reports, because parents are familiar with their child and can provide valuable information about the child's usual or typical behavior. Always ask the parent to provide feedback on how typical the child's behavior is during testing compared with the child's usual, day-to-day behavior.

Query parents about the child's achievement of developmental milestones and ask if they have any concerns about the child. Testing on more than one occasion, using the same test or different tests, may be needed to obtain an accurate picture of the child's abilities. If the same test is used, retesting at an appropriate interval,

FOCUSED PHYSICAL ASSESSMENT 30–1

Developmental and Learning Disorders

Assessment Parameter	Alterations/Clinical Significance
General appearance	<p>Difficulty interacting or not engaging with others may indicate cognitive disorders or autism spectrum disorders.</p> <p>Development that is not consistent (e.g., age-appropriate gross and fine motor skills but delayed speech and language) may indicate cognitive disorders.</p> <p>Self-stimulating behaviors (e.g., arm flapping, head banging, twirling) may be present with intellectual disability and autism spectrum disorders.</p> <p>Dysmorphic features (e.g., overly large tongue or testes) may be present with certain genetic syndromes that cause intellectual disability.</p> <p>Clusters of abnormalities may indicate a syndromic disorder (e.g., cardiac and palatal anomalies in velocardiofacial syndrome).</p> <p>Overactivity, poor attention can be associated with intellectual disability.</p>
Integumentary system (skin, hair, nails)	<p>Signs of self stimulation such as patches of hair missing, pinch marks, or bite marks may indicate intellectual disability or autism.</p> <p>Steely hair or unusual hair line may indicate a genetic syndrome.</p>
Head and neck	<p>Head circumference less than the fifth percentile indicates microcephaly, which is associated with intellectual disability.</p> <p>Changes from child's head circumference growth trajectory may indicate hydrocephalus (if increasing) or malnutrition and decelerating brain growth (if decreasing), both of which can lead to intellectual disability.</p>
Ears	<p>Low-set ears are present in some genetic syndromes (e.g., Down syndrome) that are associated with intellectual disability. Failure to respond to voice or sounds may indicate hearing deficit, which if not corrected may result in delayed speech acquisition and learning.</p>
Face, eyes, nose, and oral cavity	<p>Wide-set eyes and epicanthal folds are characteristic of some genetic syndromes. Similar facies are characteristic of some disorders—for example, a long face, prominent jaw, and large prominent ears are characteristic of males with fragile X syndrome; a flat facial profile, eyes with upward and slanted palpebral fissures and epicanthic folds, macroglossia, a short neck, and speckled irises (Brushfield spots) are characteristic of children with Down syndrome. Short palpebral fissures, thin upper lip (abnormal philtrum), and hypoplastic midface are associated with fetal alcohol syndrome.</p> <p>Inattention to visual stimuli may indicate visual impairment, neurologic injury. Difficulty with vision may result in difficulty learning and mastering developmental tasks.</p>
Neurologic system	<p>Impaired verbal and nonverbal communication, short- and long-term memory, and inability to perform age-appropriate activities of daily living may indicate cognitive impairment.</p> <p>Motor difficulties (e.g., clumsiness, problems writing or using scissors) may be associated with learning disability.</p> <p>Not performing age-appropriate developmental milestones may indicate cognitive impairment.</p> <p>Not sitting, crawling, or walking within normal time frames may indicate neuromuscular problems or cognitive disorder.</p>

such as 3 to 4 months, may be required to eliminate the possibility that the child might learn the testing items.

abilities. Individuals with Down syndrome have a very wide range of intellectual abilities.

ANSWER: As reported in the case study, Cecilia is 3 years old and not yet walking. She is delayed in her motor skills. The Bayley-III includes three areas of skills, including motor skills. At this age, it can be used to quantify Cecilia's skills and to identify her strengths. As Cecilia gets older and attends school, intelligence testing will help assess her

TREATMENT MODALITIES

QUESTION: How will nurses help the Currccio family implement effective interventions for Cecilia as a newborn?

Tests and Procedures 30–1 Diagnosing Neurocognitive Disorders

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
Magnetic resonance imaging (MRI) of brain	<p>Imaging without radiation by radiofrequency emissions that are converted to computer images</p> <p>To detect anatomic abnormalities; to evaluate myelination of white matter tracts, volume of white and gray matter</p>	MRI provides sharp anatomic detail and information about the chemistry of living tissue. May reveal decrease in brain size, damage to the basal ganglia, or reduced size of the cerebellum. Loss of brain tissue affects cognition.	<p>Teach child that MRI machine makes loud humming and intermittent tapping noises. Ear plugs or headphones may be used to dampen noise. Use music as distraction.</p> <p>Child is supine and placed in a tube that encases a strong magnet. Depending on scanner, study takes 45 to 60 minutes. Avoiding motion during this time is critical. Sedation is indicated if child is restless or dislikes confined spaces. Most children younger than 6 to 7 years of age require sedation.</p> <p>Remove all metal or magnetic items; surgical implants such as pace-makers, bone pins, or cerebral clips are contraindications.</p> <p>Contrast MRI requires intravenous access. Noncontrast study is painless.</p> <p>If age appropriate, child may benefit from seeing MRI in operation before study.</p>
Computed tomography (CT)	<p>Radiographic study to view the brain in three dimensions</p> <p>Radiographic beam scans cranium in successive layers (cuts), and computer digitizes image</p> <p>Differentiates density of bone (lighter) and air (darker)</p> <p>Test invasive if radioisotope dye injected to enhance views of blood vessels, vascular lesions, and localized changes in blood–brain barrier.</p>	Promotes effective visualization of tumors, ventricles, brain tissue, cerebrospinal fluid, hematomas, and cysts.	<p>Child is supine, on a movable table, with head immobilized.</p> <p>CT takes about 20 to 30 minutes. Motion destroys clarity of scan; child may require sedation.</p> <p>If CT is enhanced with radioisotope dye, child must have intravenous access.</p> <p>Noncontrast study is painless.</p>
Chromosomal analysis/DNA analysis/fluorescent in situ hybridization	To detect chromosomal or genetic abnormalities	Deviation from normal 23 pairs of 22 autosomes and 1 sex chromosome, or deletions or addition of parts of chromosomes, may result in conditions associated with intellectual disability.	<p>Follow laboratory instructions for specimen collection and storage.</p> <p>Prepare child based on how specimen is obtained (via blood, skin, and so forth).</p> <p>Family counseling should be performed by a trained genetic counselor.</p>
Metabolic screening	Blood tests to detect inborn errors of metabolism, endocrine problems (thyroid function), amino acid and organic acid disorders (refer to Chapters 26 and 27)	Deficiency or accumulation of substrates, depending on specific disorder (e.g., metabolic disorders such as galactosemia, aminoacidemias such as homocystinuria and phenylketonuria, organic acidemias such as maple	<p>Adequate samples are needed to obtain accurate results. Abnormal results require immediate follow-up.</p> <p>If tests are performed before a newborn is 24 hours old, the test should be repeated at 1 to 2 weeks of age.</p>

(Continued)

Tests and Procedures 30–1 Diagnosing Neurocognitive Disorders (Continued)

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
		syrup disease), may cause brain damage or other problems (cataracts, liver damage). Low T ₄ and high thyroid-stimulating hormone levels may indicate hypothyroidism.	Note child's diet prior to test. Parenteral nutrition may influence the measurement of certain amino acids. Parenteral antibiotics may inhibit the growth of bacteria used in some assays.
Heavy metal assay (e.g., lead, mercury, arsenic)	To detect abnormal blood levels of heavy metals that may impair neurologic functioning	Abnormal levels can cause cognitive impairment and encephalopathy, leading to intellectual disability and behavioral impairment.	Venous sampling is preferred to capillary sampling because the chances of false-positive and false-negative results are less. Immediately notify healthcare prescriber of abnormal levels.

Although much time and effort is spent trying to find the cause of the child's disorder, a cause often is not found. In as many as 80% of cases of mild intellectual impairment, the etiology cannot be identified (Rauch, Hoyer, Guth, et al., 2006). Whenever possible, turn the emphasis away from finding a cause for the disorder to focusing on the strengths of the child and family, and using those strengths to address the child's limitations and assisting the child and family to progress toward the child's potential.

A child's development is influenced by the quality of parent-child transactions, family-orchestrated child experiences, and health and safety provided by the family. Parent-child transactions that encourage development include maintaining affectionate, developmentally sensitive patterns of caregiver-child interactions; structuring the environment appropriately; and building on previous learning. Family-orchestrated child experiences refer to the stimulation provided by the environment, including varied and developmentally appropriate toys and materials, and positive contacts with other adults and children. Some facets of these experiences are represented in the HOME Inventory (Bradley et al., 1992) (see [thePoint](#), Chapter 3 Tests and Procedures: Developmental Screening Tools). Educate parents about the disorder and about strategies to provide stimulation and move the child's functioning forward. Refer the family to resources as appropriate to assist the child's further development and support the family. See Chapter 12 for information about habilitation, the process of helping the child master new skills to achieve his or her maximum potential.

KidKare ■ To maximize the child's potential, the family must consider the child's interests, abilities, and special needs when planning activities.

Health and safety provided by the family includes health promotion and maintenance (e.g., routine healthcare, immunizations, activity, and nutrition) and protection from abuse, bullying, and violence. Become familiar with the health issues and comorbidities associated with developmental disorders, and educate parents and family members on managing these issues. Remember, however, that all children have typical childhood illnesses. Avoid attributing such illness to the developmental disorder. Help parents to get past the disability and view their child as a child.

Referral to early intervention programs may help the child reach his or her optimal potential. Comprehensive interventions that include physical and intellectual stimulation can continually move the child's development to a higher level. The stimulation includes interventions that provide parent education, resources and social support, developmental or therapeutic interventions (healthcare, physical therapy, occupational therapy, speech therapy, education aimed at the child's developmental needs and skills), and quality daycare programs for the child. Parental involvement improves the effectiveness of programs, because children spend a large part of their day with parents.

Nurses often educate parents and other professionals (nurses) about the health needs of children with developmental disorders. Nurses can also help parents normalize their lives as they adjust to the day-to-day routines of providing care and attention to a child with special needs. For example, the nurse can assist a parent to adapt tube feeding to fit into the family's routine, minimizing disruption of the family's typical routine yet ensuring that the child receives needed nutrition. Parents often adapt health-related procedures; nurses can help parents to understand when these adaptations are safe and when they may harm the child.

Caring for a child with a developmental disorder is stressful for the family and can be lifelong depending on

the severity of the disorder. Siblings may experience a sense of isolation or loneliness because parents must spend more time with the child with a developmental disorder. Inform parents about sibling support resources such as Sibshops or other sibling support activities (see [thePoint](#), Organizations). Parents often feel responsible for the disorder and may think something done or not done during pregnancy or early infancy caused the problem. They may receive these messages from ill-informed family members, friends, or educators. Even healthcare providers may tell them that the child's delays are caused by poor parenting. Acting-out behavior common among children with a developmental disorder can cause additional stress and guilt. Parents may feel that if they set limits more consistently or tried a different approach, the child's behavior would be more manageable. Families can become exhausted and often need community support services to help them care for the child or to provide interventions to assist the child's progress. Early interventions to educate families about the specific disorder, the common emotional struggles the family may experience, and available resources help decrease the anxieties and fears that are common among families with a child diagnosed with a developmental disorder (Pelchat, Lefebvre, Prouix, et al., 2004). Family therapy may be valuable to some families to help promote positive communication and coping.

ANSWER: The nurses will help the Currccio family to meet Cecilia's physical needs—for example, helping with breast-feeding. Nurses will make sure that at discharge from the hospital the family has the ability to access resources for a family with a child with Down syndrome.

NURSING PLAN OF CARE FOR THE CHILD WITH A DEVELOPMENTAL DISORDER

QUESTION: At the time of Cecilia's birth, which of the nursing diagnoses listed in the Nursing Plan of Care 30-1 is most applicable?

Approach the family by focusing on their strengths and resilience (Early & GlenMaye, 2000). The strengths perspective is based on a partnership between the nurse and family to access resources, learn skills, and develop new behaviors. The resiliency model also combines the past experiences of the family, perceptions of current problems, and possible resources to solve current problems the family is facing (Kosciulek, McCubbin, & McCubbin, 1993). The nurse can connect the family to resources and, through teaching, help them form accurate perceptions of the child's disorder and future potential. Through these efforts, the

nurse assists the family to become more resilient and to cope with the demands of caring for a child with a developmental disorder (Fig. 30-1). It is important to treat the whole child, not just his or her condition or deficits, in the context of the family (Nursing Plan of Care 30-1).

Children with developmental disabilities may also have special health needs. If so, they often interact with many different healthcare professionals (nurses, pediatricians, occupational therapists, physical therapists, psychologists, and speech-language pathologists) and may require adaptive modifications for school to maximize attendance and learning (e.g., assistance from health aides, nursing care, modifications for regular classes, special education classes, barrier-free facilities). A key nursing role is advocating to obtain services and care that will enable these children to fully participate in and benefit from their educational experiences (see Nursing Interventions 30-1 for other nursing roles).

The Individuals with Disability Education Act mandates that the child with a disability receive appropriate education in the least restrictive environment to meet the child's needs, and promotes early intervention and special education programs (see Chapter 2 for further information). Integrating the child into the regular classroom provides an enriched experience for the child, enables the child to participate with typical same-age peers, and enables peers to benefit from interacting with a child with developmental disabilities. If a regular classroom does not meet the child's needs, he or she may be pulled out for periods during the day for special education resource classes. Education can also be provided in a self-contained special education class. Teach the parents to advocate for their child's educational needs (TIP 30-1). Although pull-out classes and self-contained classrooms still exist, a regular classroom with appropriate supports should be the goal. Be familiar with available community resources and facilitate coordination of care. Early intervention programs can build on the child's strengths to optimize outcomes and minimize the child's limitations. Use every interaction with a child to perform developmental surveillance, evaluate the child's development, monitor the success of current intervention, and refer the child for further assessment as indicated.

Discuss sexuality at the appropriate age as a routine part of healthcare. When children with developmental disorders approach puberty, encourage parents to discuss sexuality and, as the adolescent ages, family planning; this measure is particularly important in the presence of genetically transmitted diseases. As children with developmental disorders grow into adolescents and adults, they will transition to adult care services (see Chapter 12). Assist adolescents to become their own advocates in the healthcare system. Support families to encourage independent functioning to the extent of the adolescent's or young adult's abilities. Issues of guardianship and custodial care are also important but are beyond the scope of this text.

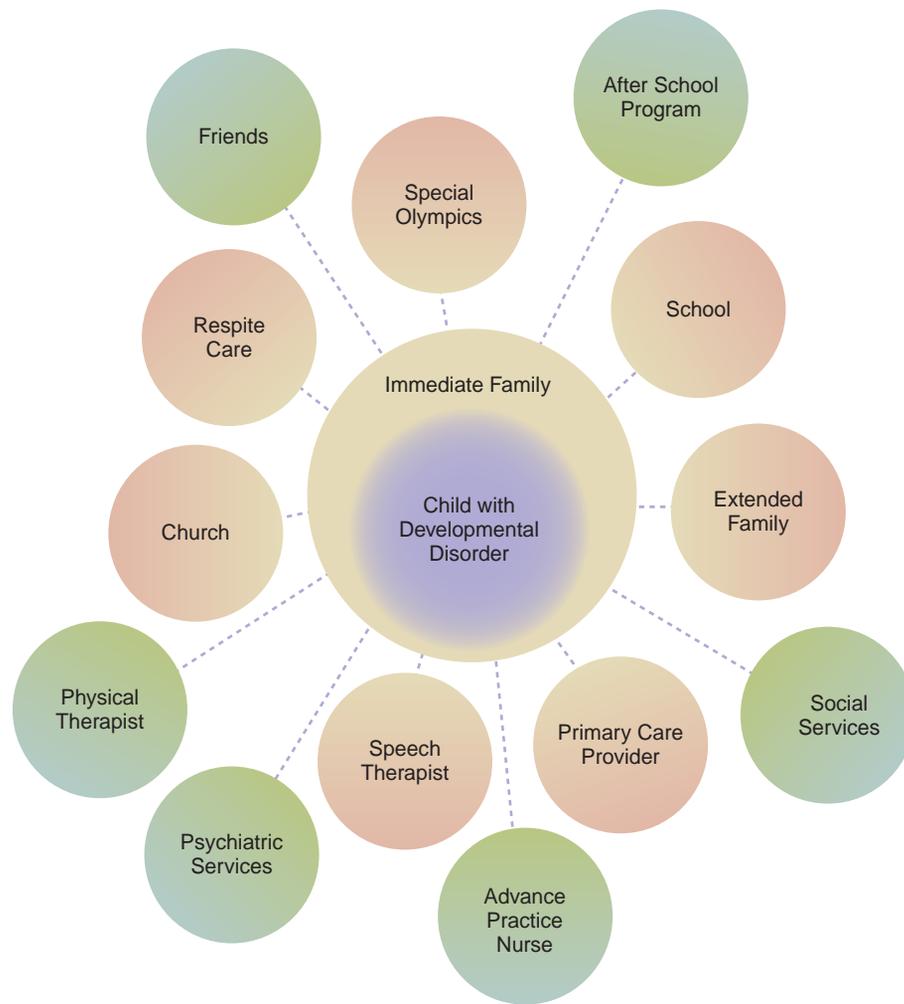

FIGURE 30-1. An ecomap demonstrates potential resources for the child and family.

ANSWER: At the time of diagnosis, the family may be completely overwhelmed and an appropriate diagnosis is “Compromised family coping related to child’s developmental disorder.” Cecilia also requires care that is different from her brothers. Another appropriate diagnosis at the time of birth is “Deficient knowledge: Child’s developmental potential, treatment, skills necessary to care for child.”

LEARNING DISORDERS

Learning disorders are the most common developmental disorders. The term *learning disorder* is used here as the diagnosis identified in the *DSM-IV-TR* (APA, 2000); educators use the term *learning disabilities*. Learning disorders include problems with reasoning, comprehension, verbal skills, reading, writing, or math. Learning disorders become evident in childhood, and they remain with the individual throughout life. The estimated prevalence among the population is 8%, with a greater incidence detected among boys (Bloom & Cohen, 2007).

Reading difficulties are most common (Shaywitz, Morris, & Shaywitz, 2008), with 5% to 10% of children in English-speaking countries having severe difficulties in learning to read (Maughan & Carroll, 2006). Children with learning difficulties have a higher incidence of emotional/behavioral difficulties and psychiatric disorders (Maughan & Carroll).

Although learning disorders may be associated with genetic predisposition, perinatal injury, environmental exposures, and neurologic and medical conditions, these factors do not necessarily predict a learning disorder (APA, 2000), and in most cases, the etiology is unknown. Children with a learning disability process information differently than children who respond to traditional teaching methods. The “wiring” or architecture of the brain differs from that of a child without a learning disorder, and the biochemical balance may differ as well. Learning disorders do not predict intelligence or learning capabilities and thus should not be viewed as deficits, but as different responses to information input. Children with a learning disorder in one area may have unusual talent in another area. For example, a child

NURSING PLAN OF CARE 30–1 FOR THE CHILD WITH A DEVELOPMENTAL DISORDER

Nursing diagnosis: Delayed growth and development related to effects of mental/emotional/cognitive deficit

Interventions/Rationale

- Provide anticipatory guidance for parents regarding realistic expectations for attaining developmental milestones.

Parents who understand what is realistic for their child are better able to provide a nurturing environment for the child to achieve his or her developmental potential.

- Assist parents to individualize expectations for child's growth and development; help develop methods to promote achievement of milestones.

Parents may not have realistic expectations regarding growth and development of their child, especially if the condition was sudden in onset and the child lost previously achieved developmental milestones.

- Discuss and promote the concept of “normalizing” experiences (e.g., eating meals with others, music therapy in groups).

Such experiences promote self-sufficiency, adjustment, and mental growth.

- Model age-appropriate and cognitively appropriate caregiver skills (e.g., communicate with child as appropriate to cognitive level; provide toys, games, educational supplies, and teaching). Give the child responsibilities appropriate to cognitive level. Maintain dignity in all interactions with child.

Gives parents an example to follow of appropriate interventions. Children with developmental disabilities learn differently or more slowly than others and may reach a lower overall level of functioning.

- Encourage family involvement in care, particularly for hospitalized children, whenever possible without exceeding the parent's and family's emotional and physical limits.

Consistent interaction with family diminishes normal separation anxiety, increases child's ability to cope, and may limit regressive responses to stress.

- Provide personal space so child's belongings are accessible; encourage child to care for the physical environment if appropriate.

Fosters self-efficacy, self-worth, autonomy, and responsibility.

- Identify coexisting health conditions that may be contributing to altered development and refer child to a specialist if indicated.

Comorbid conditions often are present (e.g., anxiety, depression); managing these conditions may increase child's potential.

Expected Outcomes

- Child will achieve optimal developmental potential based on existing abilities, extent of disability, and functional age.
- Parents will express understanding of their child's growth and developmental potential as defined by the child's condition.
- Child and parents will participate in activities to enhance child's achievement of developmental milestones.

Nursing diagnosis: Risk for injury related to effects of developmental disorder

Interventions/Rationale

- Institute safety precautions as appropriate (e.g., observe frequently, check safety rails frequently, restrain if necessary [only as last resort], stay with anxious child, do not underestimate child's strength). Do not wait for child to call you; plan regular checks.

Cognitive and physical limitations associated with developmental disability may preclude the child's understanding of dangers, using safeguards, and requesting help appropriately in dangerous situations.

- Plan for mobility aids as needed (e.g., wheelchair, walker, other special equipment).

Mobility aids optimize the child's potential.

- Observe for mouthing of nonfood items.

Mouthing, a self-stimulating behavior, is a risk for aspiration and toxic ingestions.

- Remain with the child until medications are swallowed safely. Be alert to medication side effects that may interfere with child's function and safety.

Observation may prevent aspiration or unsecured medications. Allows early intervention and potentially avoids problems.

- Explain and demonstrate procedures and equipment (e.g., suctioning, gavaging) in advance.

Because the child may adapt slowly to new activities, situations, and environments, familiarity can induce less fear or resistance when procedures are implemented or equipment is used.

Expected Outcomes

- Child will cooperate, as able, with rules regarding safety.
- Child will be free from preventable injury.

Nursing diagnosis: Compromised family coping related to reaction to child's developmental disorder

Interventions/Rationale

- Provide opportunities for parents and other family members to discuss feelings (e.g., anger, guilt,

(Continued)

NURSING PLAN OF CARE 30–1 FOR THE CHILD WITH A DEVELOPMENTAL DISORDER (CONTINUED)

hostility); accept these expressions with nonjudgmental words and actions.

The family may struggle with adapting to life with a disabled child in a world of nondisabled persons.

- Note and emphasize positive attributes of the child and family.
- Provide information about changes in child's level of function, strengths, and weaknesses.

Knowing the child's level of function may facilitate realistic goals and expectations.

- Ensure that parents, family members, and child, as appropriate, are part of the team in planning individual programs and routines for the child.
- Support families through the times when they are separated from the child. Provide opportunities for families of children in residential programs to discuss their feelings about home visits; assist them in planning for visits.

Families are the experts on what works best for them and what their personal resources are. The child's inability to perform age-appropriate tasks and the need for specialized training and "normalizing" experiences force the family into an adjustment process that includes developing alliances with professionals.

- Provide opportunities for the family to interact with other families with children who have developmental disorders.

Change in family routines may alter interaction and coping patterns; discussion and anticipatory guidance may prevent problems.

- Refer family to counseling or appropriate agencies for information and support.

Referral helps family to access appropriate resources.

Expected Outcomes

- Family members will express their feelings and concerns.
- Family members will participate in decision making about child's program.
- Family members will interact positively with the child.
- Family will partner with healthcare team and use available resources, as appropriate.

Nursing diagnosis: Impaired verbal communication related to effects of developmental disorder

Interventions/Rationale

- Encourage and allow time for child to express feelings and understanding in his or her own way. Use sign language or communication equipment as appropriate (e.g., picture boards, letter boards). Use visual cues to communicate.

Children with developmental disorders have intellectual and emotional limitations that make it hard for them to adapt to changes in caregivers and routines, and limit their ability to express feelings. Acceptance and an unhurried approach may increase the child's sense of well-being, reduce the child's anxiety, and increase the child's ability to communicate, as may alternative methods of communicating. The child may have better visual than auditory comprehension.

- Ask family for assistance in correctly interpreting the child's communication and behavior; encourage family to provide care when possible.

Family members may help reassure the child and typically are familiar with child's communication methods.

- Provide consistency in nursing care. When possible, have the same staff members care for the child each time, and have a written schedule and plan of care to facilitate consistency between caregivers.

Familiarity with the child increases knowledge of communication patterns and ability to correctly interpret child's messages.

- Assess for nonverbal communications (e.g., facial grimacing, unmoving, guarded posture with pain; gaze aversion or moving away from stimuli to indicate unwillingness to engage).

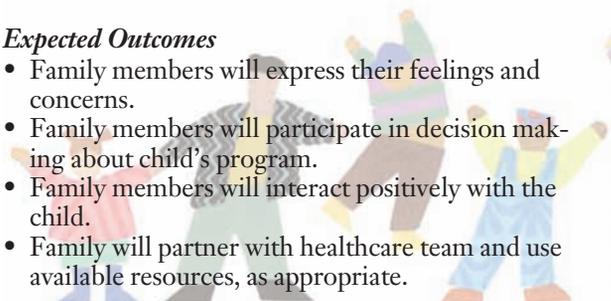

Nonverbal cues may readily communicate feelings or needs.

- Assess whether the child is aversive to touch; if not, use touch as appropriate. Avoid touching the child unexpectedly. Ask permission or tell the child prior to touching.

Tactile defensiveness (aversion to touch) may be present in individuals with developmental disorders. Touch can convey caring and can help calm, comfort, and have a positive effect, but it should not be forced on a child who is averse to it.

- Convey messages at the child's developmental level.

Using developmentally leveled terms will increase understanding. Even if the child is nonverbal, words or voice inflection may be understood or comforting.

Expected Outcomes

- Child's communication will be correctly interpreted.
- Communication to the child will be directed at the appropriate developmental level.
- Child will demonstrate understanding of the communication to the best of his or her abilities.

Nursing diagnosis: Deficient knowledge: Child's developmental potential, treatment, skills necessary to care for child

Interventions/Rationale

- Assist the family members to learn technical skills as well as behavioral techniques that are necessary to care for the child (e.g., scheduling, routines, equipment).

If the family has a deficient knowledge, the child's behaviors and health problems cannot be appropriately managed, nor can individualized educational, social,

and recreational experiences be planned to meet the child's special needs.

- Teach and review information regarding medications (e.g., dosage, time, method of administration, side effects) and concurrent medical diagnoses; verify family's understanding.

Teaching provides necessary information for delivering care appropriately and optimizing child's potential. Review identifies any need to correct misinterpretation.

- Help the family identify community resources for continuing information and support.

Additional resources may help increase knowledge level, improve care of child, and support family coping.

Expected Outcomes

- Child will maintain or improve functioning.
- Family members will provide child's care, and demonstrate indicated care skills and procedures.
- Family members will identify available community support services.

may have limited verbal speech, but may be a talented artist or athlete. Such discrepancies can make the learning disorder difficult for families and educators to understand.

Early recognition and diagnosis of learning disorders is imperative, because secondary emotional and social prob-

lems frequently develop. Without diagnosis and adequate intervention, children and adolescents with learning disorders use undue energy to compensate for or even to hide their problem. Children with learning disorders have lower social standing among peers (Estell, Jones, Pearl, et al., 2008), fall behind in academic performance, and become easy targets for ridicule by peers. Their self-esteem suffers, putting them at high risk for emotional, social, and family problems.

Assessment

Children with learning disorders exhibit diverse learning problems that may include difficulties with written language, spoken language, mathematics, reasoning, and executive functions (e.g., the child's ability to organize and plan, the child's working memory, and the way the child relates to time). Symptoms include delayed language development; difficulty discriminating among sounds; difficulties with reading, spelling, and writing; and difficulty managing time (Kelly & Aylward, 2005). These symptoms typically affect academic performance negatively but may also affect functioning in other settings, such as home and community.

If a learning disorder is suspected, discuss the matter with the parents. If parents raise concerns, investigate those concerns. Assess for behavioral or emotional problems that may occur as a result of learning disorders. Also assess for problems with family members, peers, and teachers. Adolescents who have not been diagnosed may experience undue anxiety and psychological trauma.

Perform a thorough physical examination of the child to determine whether physical health problems may be exacerbating or causing the learning problem. A neurologic examination is essential. Assess motor function, speech, vision, and hearing. Attention deficit disorder

NURSING INTERVENTIONS 30–1**Providing Services to the Child With a Developmental Disorder**

- Conduct home visits to assess living conditions and patterns of parent–child interactions.
- Assess and provide services related to basic family needs and any problems in family functioning.
- Conduct developmental assessments of the child in the context of the family.
- Provide education regarding social skills–building activities for child and parent.
- Link families to resources such as parent support groups.
- Coordinate multiple services.
- Plan for transition between services (e.g., between early intervention and preschool services, transitioning to adult care providers).
- Provide support for family through community resources and parent groups.
- Evaluate adequacy of services delivered in meeting the needs of the child and family.

TIP 30-1 A Teaching Intervention Plan to Prepare Parents to Advocate for the Educational Needs of the Child With a Developmental or Learning Disorder

Nursing diagnosis and outcomes

Deficient knowledge: Rights and responsibilities of child with developmental needs in a public education system

Outcomes:

- Parents will voice knowledge of education rights and responsibilities of child and school system.
- Child will reach academic potential in public education system.
- Parents will express comfort partnering with school personnel to develop and reach child's educational goals.

Teach the child/parents

Legislation

- Inform parents of federal and state laws that provide free public education for children with special education needs. Explain federal and state laws and school policies that ensure free public education for children with a disability from birth to age 21 years.
- Rehabilitation Act of 1973, Section 504 (civil rights of child with special education needs) requires schools to
 - Identify and locate all unserved children
 - Provide free appropriate education
 - Educate disabled students with nondisabled
 - Institute appropriate evaluation procedures
 - Support right to participate in nonacademic programs
- The Buckley Amendment (family rights and privacy of records) gives parents the right to
 - See all child's school records
 - Amend school records
 - Know who accesses school records and when they are accessed
- Individuals with Disabilities Education Act applies to children 3 to 21 years old and states that schools must
 - Serve all children
 - Provide free appropriate education
 - Provide nondiscriminatory, multidisciplinary evaluation
 - Institute an IEP for each child affected
 - Ensure right to due process
 - Require parents to participate in developing the IEP
 - Make educators accountable for implementing the IEP
 - Give parents the right to examine records

Individualized Education Plan/504 Plan

- Specific state laws and school system policies must comply with federal laws. Explain that the school must provide free, multidisciplinary, appropriate evaluation of child's learning needs.
 - Parents can request an evaluation of child.
 - Evaluation must be in child's native language or method of communication.
 - Child must be tested in all areas related to suspected disability (e.g., psychological, health, vision, hearing, social, academic performance, communication, motor ability). Parents can request specific areas.
 - School system is responsible for costs.
 - School must have parents' permission to evaluate child.
 - Children cannot be placed in or out of a program based on IQ alone.
 - Evaluation must be done every 3 years or sooner.
 - Parents are part of the evaluation.
 - Parents are entitled to a copy of the evaluation.
- Inform parents how to request an evaluation and how to develop and implement an IEP or 504 Plan.
 - Submit request in writing to superintendent of school system; include specific areas to be evaluated.
 - Ask to meet with each evaluator before child is evaluated.
 - Keep copies of all requests and reports.
 - Research and visit program options that may meet needs of your child.
 - Make a list of child's strengths.
 - Attend all IEP or 504 meetings; bring advocate if you feel uncomfortable with evaluators and school personnel.
- Explain related services to assist child to meet educational goals.
 - All services needed to meet child's educational goals must be provided by the school for free.
 - These services may include speech therapy, psychological counseling, physical and occupational therapy, recreation, social work services, parent training, and so on.
 - Services include after-school programs open to all children.
- Encourage parents to use resources in community.
 - Connect parents to social services in community.
 - Connect parents to recreational resources.
 - Connect parents to respite care providers in community.
 - Connect to parent advocacy resources in community.

(also called *attention deficit hyperactivity disorder*) is common among children with learning disorders, with approximately 10% to 25% affected (APA, 2000). Diagnostic tests such as electroencephalography and magnetic resonance imaging should be done to rule out other disorders, such as seizures or a metabolic problem.

Interdisciplinary Interventions

No specific treatment exists for children with a learning disorder. Special educators and other experts are needed to determine the best methods for helping the child to compensate. Special educational techniques are needed to help these children develop their own unique way of learning. The primary responsibility for intervention lies with educators and parents (Fig. 30–2). A child with a learning disorder, just like any child with a disorder that hinders education, is entitled to a free appropriate education from birth to age 21.

KidKare ■ Techniques that aid children in organization, such as different colored notebooks or folders, may be helpful. Arranging clothing on shelves instead of in closed drawers may help them to stay organized and keep them from forgetting items.

Children with a learning disorder that involves poor visual or altered perception may be at risk for injury. Teach parents to rid the child's environment of possible risks, such as ensuring that items are put in their proper storage areas, not left lying on the floor. Repeated teaching about risks is also needed, because the child may not apply learning from one situation to new situations.

Children and adolescents with learning disorders are susceptible to failure and frustration, particularly in the academic setting. Before a learning disorder is recognized, these children are often referred for alterations in behavior and emotional problems. Children who have

FIGURE 30–2. A child with a learning disability may benefit from special tutoring.

difficulty in reading and mathematics, expressive or receptive language difficulties, or motor coordination problems are often the objects of teasing by peers, frustration by their teachers, and criticism or teasing by parents and siblings. Many, if not most, of these youngsters develop low self-esteem and self-worth, and other emotional and behavioral problems. Such problems compound their learning difficulties, making academic achievement and accomplishment of normal developmental stages and life goals increasingly difficult (Clinical Judgment 30–1). Children with a learning disorder respond well to extra praise for desired behavior. Visual indicators of progress, such as gold stars or stickers for improved work, may help a child develop a more positive self-image. Encouraging a child to pursue activities that will build on existing strengths may have a positive effect as well. Behavior support plans may be developed for the child and should be followed at school and home, and by all persons working with the child, including nurses. These plans are part of the child's individualized education program (IEP) (sometimes referred to as *individualized education plan*), which nurses may help to develop and implement. In addition, the school nurse may develop an individual healthcare plan for the child (see [thePoint](#)). Organizations: The National Association of School Nurses for more information).

Family interventions are essential and may be provided by a nurse who is knowledgeable about the specific disorder. Emphasize the child's strengths and the child's unique way of learning. Family conflicts aroused by the child's problems need to be discussed, and the nurse should facilitate problem-solving techniques to resolve the conflicts. Help parents understand the child's specific difficulty and any compounding problems. They may need guidance in helping other family members to modify attitudes and behavior toward the child. The nurse can support and guide parents as they advocate within the school system for services to meet the child's needs (see TIP 30–1). If family conflicts or child behavioral problems persist, family and individual therapy may be needed. Referral to a qualified professional (e.g., advanced practice psychiatric nurse or psychologist) may be recommended. Encourage parents to be advocates for their child to ensure use of appropriate learning strategies and attention to any special individual needs. Special recreational programs, especially those that help children learn motor skills, use their bodies effectively, and provide effective outlets for frustration, are recommended for children with learning disorders. Enhancing the child's skills is the goal of intervention.

Teachers may need consultation on how to explain the child's problem to classmates. They may need guidance in how to manage malingering and other behavioral manifestations of the child. Work with the teaching staff to help the child meet their optimal educational goals.

INTELLECTUAL DISABILITY

Intellectual disability is another disorder that falls under the category of developmental disorders. Intellectual dis-

CLINICAL JUDGMENT 30–1

The Child With a Learning Disability

Danyaël was diagnosed with specific learning disabilities at age 10 and with inattentive attention deficit hyperactivity disorder as an adolescent. She had mild gastroesophageal reflux as an infant and only had a bowel movement, which was normal, every 5 days. In early childhood, she had no interest in having books read to her. She socialized well but did not appear to be interested in the environment around her. She did not show interest in watching television. She learned to read at grade level, but by fourth grade, it was determined that she did not comprehend most of what she read. While rote learning, such as spelling, was at grade level, all other subjects were below level. Danyaël was repeatedly told that she didn't pay enough attention to her studies or to directions; she was kept in from recess to redo work that wasn't considered neat enough.

Danyaël was a second child to a mother who understood child development. The mother expressed her concerns repeatedly to the pediatrician and teachers. She sought second opinions without receiving a diagnosis. The mother arranged tutoring twice a week, but Danyaël continued to receive failing grades on tests that measured understanding, even though she had repeated the information accurately to the tutor. Finally, without being informed of her rights under the Individuals with Disabilities Education Act, Danyaël's mother took her daughter for a comprehensive psychological assessment. It was this evaluation that resulted in a diagnosis of learning disabilities. However, it was another 2½ years before the elementary school acknowledged the disabilities, because no one relayed the test result to the school psychologist. The school continued to give Danyaël failing grades on examinations and to tell her mother she worried too much.

As the new nurse at Danyaël's high school, you have met Danyaël, having seen her a few times in your office for minor maladies. You have been reviewing her file and realize she has not had an IEP in more than a year.

Questions

1. What could have been done to assist the parents and the child in the past?
2. How were the repeated failures affecting Danyaël's self-esteem?
3. What could have been done to assist Danyaël until a diagnosis was made?
4. Who should have been an advocate for this family?
5. How can you, as the pediatric nurse, help the family to differentiate normal alterations in growth and development from pathologic and abnormal conditions?

Answers

1. When the mother first had concerns, she should have been encouraged to keep a list of the behaviors that concern her or a log of her child's behaviors. As her concerns were presented to teachers and school administrators, she should have been provided information on the Individuals with Disabilities Education Act and have been informed of her right to have her child tested at no cost in the school system.
2. Repeated school failures can further diminish academic performance as the child learns to "give up." The child's self-esteem during middle childhood years is greatly tied to mastery of new concepts. When the child receives constant negative reinforcement about his or her learning, self-esteem is bound to suffer.
3. Provide alternative learning strategies and document to see what works and what does not. Identify her strengths and promote them. Learn from the family what measures they implement at home to help her achieve, and incorporate those same techniques in the classroom.
4. If symptoms are identified in children younger than age 3, advocate for an evaluation by the state's early intervention team. After the child reaches age 3, the public school system is obligated to serve as an advocate to ensure that the child is provided additional resources to enhance learning when a learning disorder is identified.
5. Provide information on developmental parameters to assist the mother to recognize the ranges of what is considered "normal."

ability is defined as substantially subaverage intellectual functioning that is accompanied by considerable limitations in adaptive functioning in two or more of the following areas: communication, self-care, home living, social interpersonal skills, use of community resources, self-direction, academic skills, work, leisure, health, or

safety (APA, 2000). The determination of intellectual disability should not be tied only to an IQ score. Because of the nature of the intellectual delays, any standardized testing is difficult; also, determining the validity of an IQ test is difficult, particularly in children with communication problems. Terms commonly used to describe the degree

of intellectual disability, such as *profound*, *severe*, *mild*, and *moderate*, shed little light on actual ability to function or what intervention, if any, is needed. The incidence in the United States is about 1% to 3% (National Library of Medicine, 2007).

Intellectual disability is not in and of itself a mental health disorder; however, mental health issues may arise in the family. The child is at increased risk for adjustment disorders because the child's coping strategies are not understood or recognized and his or her range of adaptive strategies may be reduced. Coping, adaptation, and social skills development are greatly dependent on abstract thinking and the ability to generalize from one situation to another. Abstract thinking is impaired in intellectual disability. The long-term stress of families caring for and advocating for a child who has an intellectual disability can lead to burnout and the need for respite.

Numerous factors have been implicated as causes of intellectual disability, and a few associations are supported by evidence. Environmental factors include exposure to environmental toxins, such as lead poisoning, and fetal exposure to drugs or to alcohol. Organic factors include head injury; antenatal, prenatal, and postnatal infections; chromosomal mutations; and physiologic disorders such as untreated hypothyroidism (see Chapter 26) or phenylketonuria (see Chapter 27). Numerous disorders are associated with the presence of intellectual disability, including fetal alcohol syndrome (covered in Chapter 14) and genetic aberrations such as Down syndrome, Turner's syndrome, Klinefelter syndrome, and fragile X syndrome (all described in Table 14–2). Individuals with intellectual disability may be vulnerable to organic diseases and neurologic structural problems. Self-concept deficits, depression, anxiety disorder, and behavior problems are among the most common psychiatric problems associated with intellectual disability. A comorbid mental illness may exist, just as in individuals without intellectual disability. Diagnosing comorbid illnesses is difficult, because children may have poor verbalization skills and therefore may not be able to report symptoms accurately.

Assessment

QUESTION: You are the nurse visiting the home of the Curcio family at the time Cecilia is learning to walk. Based on your knowledge of growth and development, what are other milestones that you would assess?

The child suspected of having intellectual disability, like all other children, should have a thorough physical and neurologic examination (see Chapter 8). Determining whether health factors such as hearing, vision, or motor deficits are causing or contributing to the child's developmental disorder is important. The child should be screened for infection, blood lead level, genetic and chromosomal problems, and neuroendocrine problems, all of which can cause or contribute to intellectual disability.

When assessing a child with known intellectual disability, focus on functional ability. Determine the child's ability to communicate, perform self-care activities, use social and interpersonal skills, and follow directions. When assessing an older child or adolescent, include an evaluation of leisure activities and academic skills.

Children who have intellectual disability are often uncomfortable with unfamiliar surroundings and people. Time is needed to build relationships, and preplanning can aid the nurse. Children often perform best in their own environments; thus, perform developmental assessment in the home or another familiar environment whenever possible. Observe whether the child performs self-care activities and at what developmental level. See Chapter 3 and [thePoint](#). Supplemental Information: Select Tools for Assessing Cognitive and Adaptive Functioning for assessing developmental and cognitive abilities and self-care skills. It is also important to assess social skills and determine whether the skills can be generalized to other settings. During the assessment, note the following:

- Are the child's social skills consistent, or nearly so, with the child's chronologic age?
- How does the child relate to you?
- Does the child cling to the parent, appear afraid or shy, or become friendly after a period of observing and watching?
- Does the child bring you toys or make other attempts to engage you?
- What is the child's general activity level?

Weigh all observations of the child in light of the child's chronologic age, expected developmental level, and what the child can do and actually does. For instance, does the child demonstrate appropriate gross and fine motor skills but have deficits in speech and language? Does the child have speech comprehension with little verbal language?

Gather assessment information from family members as well. The functional abilities of the child as demonstrated over time can best be described by those who spend the most time with the child.

Children with intellectual disabilities may display self-stimulating behaviors, such as arm flapping or head banging. Feelings of despair, helplessness, and fear of being abandoned can cause clinging behavior. Frustration in communicating needs and feelings may lead to acting out behavior.

Carefully review medications, being alert for potential interactions of multiple medications. Assess possible side effects as well, because these children may not communicate symptoms, or their disability may mask side effects and interactions. (Clinical Judgment 30–2).

ANSWER: Assess the areas of language, fine motor skills, other gross motor skills, and social skills. "What can Cecilia say?" "Does Cecilia feed herself?" "What sorts of things does she pick up?" "What is she doing that is new?" "How does she let you know she is content or distressed?"

CLINICAL JUDGMENT 30–2

Appropriate Dosage of Medication

Summer, 8 years old, has been on haloperidol for the past year to decrease self-stimulating behaviors of head banging and hand biting. Her father reports that lately that she has been “not doing so well.”

Questions

1. What questions would you ask about medication dosage, medication administration, side effects, and behavior of the child?
2. What would be the signs of drug interactions, side effects, or inappropriate dose?
3. Summer has grown about 2 in and gained 10 lb during the past year, but her father reports that she is taking the same dose that was initially prescribed. She does not like to take it and fights administration. Sometimes the parents are just too tired to fight her, so she gets the dose about 5 days a week. During the past few weeks, Summer has been head banging and hand biting much more frequently than she did when she first started taking the medicine. Do you think she is receiving the appropriate dose of medication?
4. What steps would you take to change the drug dosage? What should be included in parental and child teaching?
5. What outcomes would indicate that the dosage has been adjusted to the most effective dose?

Answers

1. What dosage is Summer taking and how is medication administered? Does Summer resist taking medication? Do the parents have difficulty administering the medication? Has Summer grown, or gained weight or lost weight? What does the father mean when he says “not doing so well?” If he reports that she is demonstrating negative behaviors, how long have these behaviors been present? Has there been a change in child’s physical or mental well-being or other changes in the child’s behavior?
2. Possible signs of drug interactions or side effects include nausea, diarrhea, change in sleep patterns, confusion, change in activity or speech, tics, and muscle weakness. Receiving subtherapeutic dosages may result in reoccurrence of the negative behaviors.
3. Summer is increasingly demonstrating negative self-stimulating behaviors (head banging and hand biting), possibly indicating that the medication is no longer having the desired effect.
4. Measure Summer’s current height and weight and compare with her previous measurements and growth trajectory. If Summer has grown or gained weight during the past year, she will require a higher dosage of her medication to maintain therapeutic levels. Find out who prescribed the medication and how the prescriber can be contacted. Determine whether it would be best to communicate directly with the prescriber or whether the parents should contact the prescriber. Discuss the value of keeping a record of medication administration and parental observations of behavior. If Summer resists taking the medication, provide suggestions about administering the medication or consider a different form or route for medication, such as a liquid instead of pills or two small-dosage pills instead of a large capsule. Discuss with parents the desired effects of the medication for Summer and behaviors that may indicate lack of efficacy; medication interactions and possible side effects; and indicators that the dosage may need to be adjusted such as child’s growth, increased stress, or changes in the child’s other medications.
5. After a change in dosage of the medication, the negative behaviors abate and the desired behavior is observed

Interdisciplinary Interventions

QUESTION: One of the objectives of this chapter is to learn how to support families in their efforts to identify and use community resources that best meet the individual child and family’s needs. How you would do this for the Curcio family?

Interventions planning for a child with a developmental disorder should include the child, family members, teachers, and other care providers. Some children can participate more than others, and ability to provide input changes as the child’s developmental level increases. A multidisciplinary approach encourages coordination of the many services that will be needed. Realistic and consistent short-term and long-term goals should be set, so progress can be easily monitored. Flexibility and adapta-

tion may not be strengths of children with intellectual disability. They do best with familiar staff and consistent routines (Clinical Judgment 30–3 and see [thePoint](#), Care Path: Care of the Child With a Developmental Disorder Who Is Hospitalized).

Common interventions for the child with intellectual disability include behavior management, such as teaching life and socialization skills, involving the child in play therapy, and education about human sexuality. Behavior management and play therapy are provided by an advanced practice nurse.

There are no specific medical interventions for intellectual disability. As for any child, provide health maintenance, health promotion, and preventive health-care as recommended. Medications should be provided for any comorbid disorders (e.g., seizures, anxiety, infection) present. The child with an intellectual disability who is healthy is usually no more vulnerable to infections than other children, but may have difficulty communicating symptoms related to an acute illness.

Children with intellectual disability are more likely than others to have seizure disorders, hyperactivity, and alterations in mental health. Alterations in mental health and physical health should receive the same medical and mental health treatment given to any child, but approach the child at the appropriate developmental level rather than chronologic age. He or she may be prone to self injury because of **self-stimulation** behaviors (rhythmic, repetitive actions such as excessively flailing arms, jumping up and down, rocking, head banging, finger tapping, vocalizations in an effort to shut out external stimuli and to calm self). Make safety a priority. Determining when situations or people are dangerous can also be challenging for children with intellectual disabilities. Because many children are very friendly and show inappropriate affection, extra care is needed to protect them from unsafe situations or possible predators. See Nursing Interventions 30–2 for strategies in working with children with an intellectual disability.

CLINICAL JUDGMENT 30–3

Developmentally Appropriate Interventions for a Child with Down Syndrome

Sara is a 4-year-old girl with trisomy 21 (Down syndrome). She is admitted to the hospital to have her tonsils and adenoids removed. This has been determined to be necessary by her doctor because periods of sleep apnea have been noted. Sara is happy and playful in her room. Her mother describes this as her usual behavior.

Questions

1. During your assessment, what information should you ask Sara's mother about the child's development?
2. While you are talking with the mother, what observations about Sara's behavior might be useful in planning her care?
3. Sara's mother states that her daughter does not have intelligible speech, but has learned several sign language terms. Her daughter can walk and run with ease. She cannot feed herself well with a spoon. Do you think these milestones are age appropriate?
4. On the morning of surgery, how would you prepare Sara for the events that will occur?
5. After surgery, Sara refuses to drink and continually cries for her mother, indicating that she wants to be picked up and held. What comfort interventions should you implement?

Answers

1. Assess her speech, hearing, and visual skills. Children with Down syndrome often have speech

delays and hearing or vision problems. Determine how Sara communicates her desires and how she can be best approached to follow instructions. Assess whether she has had prior experiences with surgery or hospitalization.

2. Does she readily make contact with strangers? Does she readily explore her surroundings? How does she respond to hospitalization? Does she appear to be afraid?
3. Sara exhibits speech delays and delays with hand-eye coordination. As a 4-year-old, she should be able to feed herself easily using a fork and spoon, and should have speech that is essentially completely intelligible.
4. Have Sara sit with her mother. Provide an additional opportunity to review the process of preparing for surgery and what occurs afterward, using actual pieces of equipment (e.g., mask and intravenous tubing, cup for drink). Allow Sara to practice using these things on a favorite doll or bear. Have Sara teach the nurse how she says "hurt."
5. Allow Sara to sit on her mother's lap in a well-supported chair. Encourage Sara to drink fluids or eat popsicles in flavors that she likes (not citrus). Encourage saliva production with a lollipop if permitted by the surgeon. Administer pain medication as ordered.

NURSING INTERVENTIONS 30–2

Strategies for Working With Children or Adolescents Who Have an Intellectual Disability

Develop a warm, trusting relationship.
 Identify current skills, level of development.
 Assist child and family in achieving the next growth and development skill.
 Break skill into its component parts.
 Teach each component (one at a time) according to the hierarchy of skills—for example, feeding self:

1. Picking up utensil
2. Dipping utensil into food
3. Scooping food onto utensil
4. Lifting utensil to mouth
5. Putting utensil into mouth and getting food off the spoon into mouth
6. Returning utensil to surface or to food container

Use concrete methods to teach (have the items at hand when teaching, so the child can see and manipulate them).
 Teach skill in location where it will happen routinely.

Practice generalization after skill is thoroughly learned.
 Use pictures or the actual object demonstrated.
 Avoid abstract messages.
 Use simple terms and brief, simple sentences.
 Be patient and reward each success.
 Be consistent in expectations.
 Label feelings for child and redirect activities when inappropriate.
 Give child two or three choices (do not expect child to *tell* you what he or she wants, especially when verbal skills are absent or limited).
 Try tools used with younger children to identify feelings and describe problems, because these tools often work with older children.
 Watch for self-injurious behavior; behavior modification and medications may be needed.
 Provide adequate stimulation, rewards, and play to prevent boredom.
 Individualize intervention strategies.

Interventions to improve academic and adaptive functioning include speech therapy, contingency behavior management techniques, occupational and physical therapy, and special education. Teaching advocacy skills to parents is particularly helpful, because parents frequently need to obtain resources for their child in educational and social systems. Children with intellectual disabilities fall under the Education Advocacy Laws and entitle the child with intellectual disability to a free and appropriate education from birth to age 21 years old (see TIP 30–1). Children with intellectual disabilities must be educated and included in all settings with other children (see Chapters 2 and 12 for further discussion of the Individuals with Disability Education Act).

Families usually follow a cycle of adaptation that includes perceptions of the diagnosis and its effect on the family, available family resources, and past experiences (Finke, 2005). Helping parents to gain an understanding of the child's needs based on developmental status is especially important (see [thePoint](#), Care Path: An Interdisciplinary Plan of Care for Family With a Child with New Diagnosis of Developmental Disorder). Assisting parents to connect with support groups is also appreciated, because the family may become isolated. Even in healthy families, periods of stress and grieving may occur when the child's skills and abilities are slow to develop, or when a younger child or a friend's children reach other developmental milestones or surpass the development of the child with intellectual disability. The nurse can help

identify and evaluate resources needed by the child and family.

ANSWER: Provide written information, including local resources, for a family with a child with Down syndrome. Give the family the contact information for the health department and the state's early intervention program. Down syndrome, like many other conditions, has active local associations with a mission to provide education, resources, and support in partnership with individuals, families, professionals, and the community. Find the local association closest to you and be sure the Currcio family has that name, telephone number, and website.

AUTISTIC DISORDER

Autism is a spectrum of disorders that includes pervasive developmental disorders, autisticlike, autistic, high-functioning autistic, Rhett's disorder, and Asperger's syndrome. Autistic disorder, or autism, is characterized by markedly abnormal or impaired development in social interaction and communication (APA, 2000). **Social impairment** is sustained and includes such things as poor eye contact, not liking to be touched, and preferring solitary activities. Children with autism often do not seem to notice others and in fact seem oblivious to others. They may have impaired speech or little or no use of language. Some children who do have language

may not engage in interaction with others in a conversation. They may insist on certain routines and have a very narrow interest range. Children who are autistic may also have repetitive mannerisms such as hand-wringing, head banging, rocking, or running in circles.

The prevalence of autism spectrum disorders in the United States is approximately 1 in 150 children and is about 3 to 5.5 times more prevalent in boys than in girls (Autism and Developmental Disabilities Monitoring Network Surveillance Year 2002 Principal Investigators [ADDM], 2007). The diagnosis of autism is more likely to be made today than in the past (ADDM, 2007). The reason for the increasing frequency of diagnosis may be related to an increase in the factors that cause autism, or it may be a result of better detection—that is, parents and healthcare providers may be recognizing the symptoms and assigning the diagnosis in larger numbers.

Much public attention has focused on the increased number of children diagnosed with autism in recent years. The search for possible causes of autism has led to heated controversy. Different potential causes of autism have strong proponents. Some of the suggested causes include environmental chemicals, viral infections during infancy, and chemicals in childhood immunizations (Tradition or Science 30–1). Scientific evidence supports the existence of familial patterns; risk among siblings of individuals with the disorder is estimated to be 10% (Constantino et al., 2006). Environmental factors have not been identified but are important, considering that concordance in monozygotic twins is less than 100% and expression of the disorder among siblings, including twins, is variable (Santangelo & Tsatsanis, 2005).

Although individuals do not outgrow or become cured of autism, intensive interventions can decrease inappropriate or harmful behaviors and can increase the ability of the child to function at higher levels. Children with autism, just as many of those with intellectual disability, can be productive adults who live independently and contribute to society.

Assessment

All children should be screened for autism at 18 and 24 months (Johnson, Myers, & Council on Children with Disabilities, 2007). The *DSM-IV-TR* (APA, 2000) lists 12 symptoms, half of which must be present to make the diagnosis of autistic disorder. These symptoms are listed under the major categories of social interaction, communication, and behavior. The symptoms are usually noted before the age of 3 years (Chart 30–1). Table 30–1 lists characteristics of disorders of the autistic spectrum. Absolute indicators for immediate evaluation are (Filipek, Accardo, Ashwal et al., 2000)

- No babbling or pointing or other gesture (e.g., waving bye-bye) by 12 months
- No single words by 16 months
- No spontaneous two-word (not echolalic) phrases by 24 months
- Any loss of language or social skills at any age

TRADITION OR SCIENCE 30–1

Is there a link between the increasing incidence of autism and the administration of the MMR (measles, mumps, rubella) vaccine?

EVIDENCE-BASED PRACTICE

One controversial study involving a small number of children (12) suggested a possible link between MMR vaccination, autism, and bowel disease (Wakefield et al., 1998). This study was retracted a few years later by 10 of the 13 researchers (Murch et al., 2004). MMR vaccination is administered at the age when symptoms of autism are first being noted, and this timing may contribute to the appearance of a link. However, the apparent increase in autism incidence may in fact simply be attributable to better diagnosis of the disorder. Multiple studies have demonstrated no association between the incidence of autism and MMR vaccine administration (DeStano, 2007; DeStefano, et al., 2004; Jefferson, et al., 2003; Parker et al., 2004; Thompson et al., 2007). No change in the trend line of the incidence of autism spectrum disorder was noted after the MMR vaccine was introduced (Taylor et al., 1999), and the incidence continued to increase even when MMR immunizations were not administered (Honda, Shimizu, & Rutter, 2005). Thimerosal, a preservative, has been implicated as causing autism. Further support disclaiming a link between thimerosal and autism is provided by a study demonstrating that cases of autism are increasing despite the elimination of thimerosal from vaccines in 2001 (Schechter & Grether, 2008). The evidence does not support a link between autism and MMR vaccination, and children should continue to be immunized against measles, mumps, and rubella.

Assessment of the child suspected to have autism requires an interdisciplinary team, with the family members as important members of the team. A physical examination should be thorough and include a complete neurologic examination. Obtain a detailed history of the neonatal period and early development. Psychological testing and evaluation of functional ability must be part of the assessment. Specific tools exist to assess for autism (Tradition or Science 30–2). Identification of other disorders such as intellectual disability may contribute to the correct diagnosis. As with other developmental disorders, focus the assessment on the child's functional ability. Assessment is needed to determine the child's functioning in the areas of communication, self-care, social and interpersonal skills, and ability to follow directions. Children with autism have difficulty in expressing their needs and responding to changes in routine or loss of objects to which they are attached. They may experience severe temper tantrums, show extreme distress for no apparent reason, and be unresponsive to usual attempts to soothe.

Also assess the family's coping skills and available resources. Families caring for a child with autism may become exhausted trying to maintain routines and cope

CHART 30-1 SYMPTOMS OF AUTISTIC DISORDER

Social Impairment

- Marked impairment in the use of multiple behaviors such as eye-to-eye contact, facial expressions, body postures, and gestures to regulate social interaction
- Failure to develop appropriate peer relationships
- Lack of spontaneous seeking to share enjoyment, interests, or achievements
- Lack of social or emotional reciprocity

Communication Impairment

- Delay in or lack of spoken language
- If speech is adequate, marked impairment in conversation with others
- Repetitive or idiosyncratic language
- Lack of make-believe play or social imitative play

Behavior Patterns

- Preoccupation with one or more interest
- Inflexible adherence to specific, nonfunctional routines or rituals
- Repetitive motor mannerisms such as hand or finger flapping or twisting, or complex body movements
- Persistent preoccupation with parts of an object

Information from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text rev.). Washington, DC: Author.

with the severe temper tantrums. Because these children demonstrate little empathy for others and do not respond to affection, parents may become discouraged and feel hopeless. Siblings may be at risk for injury from the temper tantrums and lack of concern for others.

Interdisciplinary Interventions

Interventions should be targeted at educational strategies, home-based strategies, and behavior management. The goals for intervention should be aimed at promoting developmental skills, reducing repetitive behavior, eliminating negative behavior such as head banging or temper tantrums, and supporting the family.

When caring for the child with autism, allow the child time to become familiar with the environment and staff. Do not make abrupt, rapid movements and allow the child time to transition between activities.

Medication can be helpful in assisting children with autism spectrum disorders (Myers, Johnson, & Council on Children with Disabilities, 2007). Selective serotonin reuptake inhibitors and atypical antipsychotics (e.g., risperidone) may help treat repetitive behavior and obsessive-compulsive symptoms. Stimulants, alpha 2 agonists (e.g., clonidine), and atypical antipsychotics may be used to treat hyperactivity, impulsivity, and inattention. Aggression and self-injury may be treated with atypical antipsychotics, anticonvulsant mood stabilizers (e.g., levetiracetam), selective serotonin reuptake inhibitors, or beta blockers. Careful observation for side effects of any medication is needed to offset negative or harmful reactions.

Behavior therapies and social skills training, performed by a mental health provider such as an advanced practice psychiatrist nurse, can be beneficial. The earlier the interventions are begun, the more likely it is that they will have an effect. Substantial gains can be achieved in language acquisition and social interaction if treatment is consistent and ongoing. Behaviors that need to be eliminated or changed should be targeted, and their frequency and duration should be measured. These behaviors might include hitting, biting, pinching, spitting, head banging, or crying. Establish a baseline rate of the targeted behavior so that progress can be monitored. It is also important to study the antecedents to the behavior so environmental causes can be prevented (e.g., by avoiding crowds or lack of structure).

TABLE 30-1

Spectrum of Autistic Disorder

Diagnosis	Symptom Differences
Rhett's disorder	Impairment only in females, loss of skills between 5 and 30 months
Asperger's syndrome	No delay in language development
Autistic disorder	Impairment before age 3 in social interaction, communication, and behavior
High-functioning autistic disorder	Normal intelligence and learning abilities
Pervasive developmental disorders	Severe and pervasive impairment in social interaction and impairment in either verbal or nonverbal skills; synonymous with autism
Pervasive developmental disorders not otherwise specified	Autisticlike symptoms but does not meet criteria for high-functioning autistic disorder or Asperger's syndrome

TRADITION OR SCIENCE 30–2

What is the best tool for diagnosing autism?

MORE INQUIRY NEEDED

Several factors must be considered to determine the best tool for assessment, including ease of administration (including need for training to administer), cost, time, and sensitivity (how often a tool accurately identifies a child as having the condition) and specificity (how often a tool accurately identifies a child as not having the condition when they truly do not). Tests such as the ADI-R (Autism Diagnostic Interview-Revised) (Lord et al., 1994), the ADOS-G (Autism Diagnostic Observation Schedule–Generic) (Lord et al., 2002), and the Childhood Autism Rating Scale (CARS) (Schopler, Richter, DeVellis, et al., 1980) are the most widely used diagnostic tools but require lengthy, professional administration. The Gilliam Autism Rating Scale (GARS), which is administered by a parent or teacher, is a tool widely used in schools and clinics for children 3 to 22 years of age. The GARS has been shown to produce a large number of false negatives and to have low sensitivity (Lecavalier, 2005; South et al., 2002); therefore, it will not identify many children, who will miss the opportunity for early intervention.

Many screening tools have had some reliability or validity demonstrated. Some of these are the Autism Spectrum Screening Questionnaire (ASSQ) (Ehlers, Gillberg, & Wing, 1999), the Pervasive Developmental Disorders Screening Test–II Primary Care Screener (Siegel, 2004), the Developmental Behavior Checklist–Autism Screening Algorithm (DBC-ASA) (Brereton et al., 2002), Krug Asperger’s Disorder Index (KADI) (Krug & Arick, 2003), the Social and Communication Disorders Checklist (SCDC) (Skuse, Mandy, & Scourfield, 2005), the Autism Observation Scale for Infants (AOSI) (Bryson et al., 2008), and the Quantitative Checklist for Autism in Toddlers (Q-CHAT) (Allison et al., 2008). The Modified-Checklist for Autism in Toddlers (M-CHAT) (Robins & Dumont-Mathieu, 2006) shows good sensitivity but low specificity (Eaves et al., 2006), meaning that it has a higher chance of identifying children as having autism when they do not. The Autism Screening Questionnaire/Social Communication Questionnaire (SCQ) (formerly Autism Screening Questionnaire [ASQ]) (Berument et al., 1999; Rutter et al., 2003) seems to be an acceptable screening tool for older children but does not have as good sensitivity and specificity with younger preschoolers (Allen et al., 2007). The Developmental Behaviour Checklist: Early Screen (DBC-ES) has good sensitivity but low specificity (Gray, Tonge, Sweeney, et al., 2008). The Screening Tool for Autism in Two-Year-Olds (STAT) demonstrates high sensitivity and specificity (Stone et al., 2004), but requires training to administer. More research is indicated to support the psychometric properties of these tools before widespread clinical use; but, given the importance of not overlooking the diagnosis, tools with good sensitivity but lower specificity may be selected as screening tools.

Any tool that requests parents to act as objective observers of their own children incorporates the parents’ biases and lack of professional training. Tools are only as good as the persons trained to use them; test scores should not override clinical judgment. A comprehensive diagnostic assessment must go beyond informant-based rating scales and requires a trained professional.

Controlling a child’s environment to eliminate changes or interruptions is difficult if not impossible, so teaching the child to use strategies to cope with changes is more effective. The tools could be objects, photos, calendars, labels, color codes, and so on. These tools help the child to manage change. For example, help the child to organize the things that he or she can control. Color coding helps the child find things, even if the order or usual routine changes. Calendars list what will happen that day, even if the order is different; if a day will differ from what the child expects, that difference might be noted on the calendar so the child can anticipate the change and talk to someone about how he or she will still accomplish activities. For example, the note might say, “Instead of the bus dropping you off and you getting an after-school snack, Daddy will pick you up, give you a snack in the car, and take you to the ball game.” Anticipating schedule changes also helps lessen behavior outbursts. Children who do not communicate well may use pictures to indicate activities and rearrange the order if the schedule changes. Pictures can be placed on shelves or storage bins to indicate what is in them. This practice gives the child more control while decreasing the frustration of searching for something or making choices. Pictures, colors, and other cues eliminate the need for a parent to get into power struggles with the child or become frustrated as well when the child cannot express what he or she wants or is trying to explain.

Rewarding positive behavior and ignoring negative behavior is also effective. Of course, ignoring negative behavior is not always easy; it requires support for the family or even the therapist.

KidKare ■ Alternative forms of communication may help a child with autism to communicate.

Sign language or assistive communication devices may help the child to communicate needs or give the child choices (see [thePoint](#)). Organizations: The Family Village website for links to more information about communication devices or aids) (Fig. 30–3). Speech and language therapy may improve communicative abilities (Myers et al., 2007). Encouraging communication and building on strengths may stimulate cooperation. For example, if a child is good at counting or reciting letters of the alphabet, the child can be encouraged to use these activities to decrease anxiety in stressful situations.

FIGURE 30-3. A communication board helps children with autism and Down syndrome express their needs and wants.

Because children with autism can be challenging, families need support and can benefit from social support, such as respite care. Ensure that the family knows what resources are available in the community. Parents and family members also need to be taught interventions and behavior management skills to use at home with the child (Elder, 2001). Teach the family how to use tools such as behavior recording, observation, performance measuring, and reward systems. Parents need to understand that they did not cause the child's autism and that because the child has such major needs, reaching out for help from professionals and the community is necessary.

Educational interventions must include special education and should begin as early as possible. An IEP (see TIP 30-1) should guide the child's educational experience. Special attention should be paid to behavioral management and to auditory and visual tools to assist the child. Children with higher intellectual skills should be educationally stimulated. Children with autism do better in learning situations that have consistent routines and rules; use of simple, clear, unambiguous language; a workstation away from distractions; individual assistance; and immediate feedback.

Children with autism also need to participate in after-school and community activities to practice and improve their social skills. These activities should be something at which the child can succeed. Strategic guidance and structured activities assist children with autism to develop their social skills. Social skills training may be helpful in improving peer relations and decreasing the isolation and stigma associated with manifestations of autism.

Pediatric Emergencies

Case History

Chase Whitworth, Cory Whitworth's older brother, is one of four boys in the family. The summer that Chase was 8 years old, he and his family attended a church social function. Chase became bored and took his drink and cookies outside into the parking lot. He noticed a hornet's nest on the back of one of the handicapped parking signs. Was anything inside? He took the paper cup in his hand, balled it up, and threw it at the nest. Nothing happened. He picked it up and

threw it again. This time, several hornets emerged from the nest. Chase took off running, only to trip over the parking curb. The hornets stung him many times. His shrieks brought a crowd out to the parking lot. As his mother looked him over she noticed that he had many welts on his neck, arms, and ears. His mother said, "How do you feel?" Chase answered, "My tongue is tingling." His mother replied, "I think we need to go to the emergency room."

CHAPTER OBJECTIVES

1. Describe the four components of pediatric emergency triage.
2. Describe the nursing interventions required for the infant or child in cardiopulmonary arrest.
3. Discuss common causes, signs, and symptoms of shock in children.
4. Prioritize the sequence of assessing the multiple-trauma patient.
5. Identify common signs of and management for hypoxia in a child in respiratory distress.
6. Explain the physiologic effects of fever in a child.
7. Describe the nursing interventions for the child who has been bitten or stung.
8. Discuss management of anaphylaxis.
9. Describe the initial nursing intervention for a child with epistaxis.
10. Discuss the nursing interventions for the child with an environmental injury: hypothermia, hyperthermia, or near-drowning.
11. Identify the initial treatment for the child who has ingested an unknown poison.
12. Discuss nursing interventions for a family whose child has died of sudden infant death syndrome (SIDS).
13. Discuss considerations for interfacility transfer.

See [thePoint](#) for a list of Key Terms.

Emergency management of ill or injured children is costly, physically and emotionally, as well as financially.

Many emergencies can be avoided through family education and simple prevention techniques. The nurse's astute assessment, knowledge of signs and symptoms of deterioration, and timely interventions can help decrease negative outcomes.

DEVELOPMENTAL AND BIOLOGIC VARIANCES

In an emergency, children are more vulnerable than adults. They have fewer physiologic reserves; for example, tidal volumes and circulating blood volume are smaller. Also, a disease or injury may alter their status more rapidly. Because a child's ability to verbalize is limited, a disease process may be far advanced before signs and symptoms are noted. Although adolescents may be physically and mentally mature, they commonly participate in risk-taking behavior. This behavior, combined with increased mobility and feelings of omnipotence, can put adolescents more at risk.

Types of emergencies experienced by children of different ages can be attributed to structural and functional changes related to developmental stage (Fig. 31–1). Young children have a greater ratio of surface area to body mass than adults, placing children at higher risk for hypothermia. This risk must be considered in prehospital care or during resuscitation, because hypothermia increases metabolic demands, increases pulmonary vascular resistance, and contributes to acidosis. A child's airway is more difficult to stabilize and manage than an adult's because the larynx is more cephalad and anterior, making the vocal cords more difficult to visualize during intubation. Also, the airway diameter in a child is narrower, resulting in greater airway loss with only small amounts of edema.

In children, the cricoid is the narrowest portion of the airway; cuffed endotracheal tubes are not recommended in children younger than age 8.

In tachypneic children, decreased respiratory rate is not necessarily a sign of improvement; it may mean the child is tiring.

Total blood volume is smaller than that in adults, so small blood losses lead to greater hypovolemia and impaired perfusion and oxygenation.

Respiratory arrest is more common in children than in adults; if it progresses to cardiopulmonary arrest, children have a poorer prognosis than adults.

Infants and young children are more prone to head trauma because the head is proportionally larger to the body than in older children and adults.

Previously healthy children in shock will maintain adequate blood pressure in acute fluid volume loss until more than 25% of their blood volume is lost. Tachycardia and delayed capillary refill are early signs of shock; decreased blood pressure is a late sign.

Prepubescent children are most susceptible to abdominal trauma because their organs are not deeply seated in the pelvis and not as well protected by the thorax as those of adolescents and adults.

Infants and young children are not cognitively or physically capable of protecting themselves from environmental hazards.

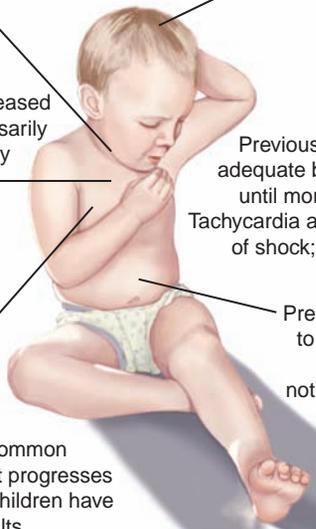

FIGURE 31–1. Developmental and biologic variances: emergencies.

DEVELOPMENTAL CONSIDERATIONS 31–1

Common Emergencies Based on Age

Age Group	Common Medical Emergencies	Common Traumatic Events
Infancy	SIDS Apnea Sepsis Bronchiolitis Seizures	Shaken baby syndrome Falls (off furniture, down stairs in baby walkers) Motor vehicle accident Foreign body aspiration Suffocation Drowning
Early Childhood	Croup Asthma Vomiting and/or dehydration Seizures Appendicitis	Foreign body aspiration Poisoning Falls Drowning Motor vehicle accident Burns Child abuse
Middle Childhood	Asthma Appendicitis Seizures Gastrointestinal disturbances	Motor vehicle accident Bicycle injury Sports injury
Adolescence	Colitis Urinary tract infection Pelvic inflammatory disease	Motor vehicle accident (adolescent as driver) Sports injury Firearm injury Drug and alcohol ingestions (accidental and intentional)

Variances are seen among age groups in the etiology of the situation: medical pathology or traumatic injury (Developmental Considerations 31–1). Young children, in particular, frequently present to the emergency department (ED) with fever, not eating, or a change in sleep patterns. It is then that the underlying pathology is detected.

3. Performing a brief history and physical assessment
4. Making the triage decision

ASSESSMENT OF THE CHILD WITH AN EMERGENCY CONDITION

Assessment of the child in an emergency situation must proceed rapidly. The nurse does not have time to perform a methodical, in-depth assessment, but must obtain information rapidly and make decisions promptly, in a process called *triage*.

The French word **triage** means “to pick or sort.” The goals of triage are to rapidly identify the seriously ill or injured patient, prioritize all patients using the ED, and initiate therapeutic measures for the patient. Triage for children, as for adults, has four components:

1. Performing an across-the-room assessment
2. Determining the chief complaint

Across-the-Room Assessment

QUESTION: How would you document your across-the-room assessment of Chase?

The triage assessment generally starts with a quick across-the-room visual assessment as soon as the child presents to the ED or clinic. Observe the child’s general appearance, work of breathing, and color to determine whether immediate care is required.

Alert! Obvious respiratory distress, cyanosis, positioning to maintain an open airway, seizures, unconsciousness, and profuse bleeding are signs that the nurse should interrupt the triage process and proceed to the emergency care area for immediate intervention.

FOCUSED HEALTH HISTORY 31–1

Pediatric Emergencies*

Current history	<p>What brought you to seek care today? When symptoms started, duration and nature of symptoms, precipitating factors Mechanism of injury Any treatments initiated Mode of arrival (e.g., parent, ambulance) Change in level of consciousness or behavior (e.g., lethargy, irritability, weakness) Recent change in intake of food and fluid Time of last void Is anyone else in the family ill?</p>
Past medical history	<p>Prenatal/Neonatal History Indicated in infants: gestational age at birth, presence of complications Previous Health Challenges Previous hospitalizations, serious illness, injury, or surgeries and child's response History of child abuse Child's baseline condition Presence of allergies Immunization status and date of last tetanus booster Medications: prescription, over the counter, or home remedies; name, amount, and frequency Does the child have a primary healthcare provider? If so, what is the provider's name and phone number?</p>
Family medical history	History of same illness in other family members or peers (describe symptoms)
Social and environmental history	<p>Child care issues: Who cares for child and where (e.g., child care center, home)? Is child exposed to other children? Cultural practices that may overheat infants (e.g., wrapping in blankets even in hot temperatures); administration of home remedies that may be toxic</p>

*This history is focused on pediatric emergencies. See Chapter 8 for a comprehensive format.

ANSWER: Chase is alert and oriented, well perfused, with no signs of trauma. He has red papules on his face and neck and noticeable facial edema.

Chief Complaint

The chief complaint is the reason that the child or parent gives for seeking care. Note the chief complaint using the words of the child or parent, rather than a medical term, to avoid diagnosing a patient before obtaining all objective signs and symptoms and the history. If the chief complaint described by the patient or caregivers does not match presenting signs and symptoms, document this discrepancy.

If the child is unconscious and the parent is not available, the chief complaint is the condition in which the patient presents—for example, “altered level of consciousness.”

Brief History and Physical Assessment

QUESTION: Given that Chase's chief complaint is hornet stings followed by subjective complaints of “tingling” in his mouth, describe the critical elements of a focused physical assessment for Chase.

The second step in the triage process combines obtaining a brief history from the child, parent, or both with performing a brief physical assessment. Obtaining a triage history can be difficult if the child is young, if the parent or primary caregiver is not present, or if a communication barrier exists (Focused Health History 31–1). During triage, use the AMPLE mnemonic to help remember the key components of the history interview (Chart 31–1).

During the physical assessment, perform a rapid evaluation of the child (Focused Physical Assessment 31–1).

CHART 31-1 AMPLÉ MNEMONIC FOR BRIEF HISTORY OF PEDIATRIC EMERGENCY

- **A**llergies
- **M**edications
- **P**ast medical history
- **L**ast meal
- **E**vents surrounding incident

Remember to move from assessment of vital functions to examination of less critical areas.

ANSWER: The critical elements of your physical assessment focus on Chase’s airway and include respiratory rate, respiratory effort, and breath sounds.

Triage Decision

QUESTION: In which triage classification would you place Chase after the multiple hornet stings?

The triage decision involves assigning a triage classification by severity of illness to the patient. This classification

regulates the child’s movement through the ED and determines the best site of care (Clinical Judgment 31-1). Various triage classification systems are in use. The Emergency Severity Index system specifies the following five levels (Gilboy, Tanabe, Travers, et al., 2005):

1. *Resuscitation*: Patients who have unstable vital functions and require maximum resource use
2. *Emergent*: Patients with potential threat to life or limb, who require high resource use and need medical care within 10 minutes
3. *Urgent*: Patients with stable vital functions, who require medium resource use and need medical care within 30 to 60 minutes
4. *Semiurgent*: Patients with stable vital functions and low resource needs, who require care within 1 to 2 hours
5. *Nonurgent*: Patients with stable vital functions and no resource needs, who require care within 2 to 3 hours

ANSWER: Chase would be classified in the emergent category. The urgency of immediate treatment can be deceptive in children with airway swelling because the children are alert, oriented, and with no obvious trauma. However, sufficient swelling to obstruct their airways may occur very rapidly. It is critical that they receive treatment before their airway is obstructed.

FOCUSED PHYSICAL ASSESSMENT 31-1

Triage Assessment From A to I

Airway	Make sure that the airway is open.
Breathing	Check for breathing; begin bag-and-mask ventilation if needed.
Circulation	Check for a pulse; begin chest compressions if needed.
Disability	Assess level of consciousness by performing a rapid mental status assessment (use AVPU mnemonic): A: Is the child alert? V: Does the child respond to verbal stimuli? P: Does the child respond to painful stimuli? U: Is the child unresponsive?
Exposure	Remove clothing and diaper to assess for underlying signs of illness or injury.
Full vital signs	Obtain a full set of vital signs, including temperature, pulse, respiratory rate, blood pressure, and weight in kilograms. Initiate measures to keep the child warm.
Family presence	Facilitate family presence
Give comfort	Manage pain, provide emotional support.
Head-to-toe assessment	Perform a brief head-to-toe assessment, focusing on the systems affected by the chief complaint.
Inspect	Inspect the back for injuries.
Isolate	Isolate the child as necessary for communicable illness or if the child is immunosuppressed.

CLINICAL JUDGMENT 31–1

Triage

Sol is a 4-year-old boy who is carried into the ED by his father, who says, “My son says he’s not feeling too good.” Sol is leaning against his father, holding his head erect with his chin jutting out slightly, alert but not interacting with his environment. He has a respiratory rate of about 40 bpm, his lips are blue, and he presents with nasal flaring.

Questions

1. What is Sol’s most obvious problem?
2. On what factors did you base your assessment?
3. In what triage category should the nurse classify him?
4. Based on the triage decision, what needs to be done now?
5. Sol’s respiratory distress is worsening; what needs to be done?

Answers

1. Respiratory distress.
2. Cyanosis, nasal flaring, positioning to maintain open airway, tachypnea (normal respiratory rate

for a 4-year-old is in the 20s), developmentally incongruent behavior: Sol is 4 years old but was carried in, and he is not interested in his surroundings.

3. Emergent.
4. Sol needs to be taken to the treatment area for immediate intervention. Because Sol still seems to be compensating and maintaining his airway, let him maintain his position of comfort. Do not lay him down; leave him in his father’s lap. Administer oxygen, and perform a brief physical examination (A–I) while obtaining a brief history (AMPLE).
5. Ensure that someone skilled in bag-and-mask ventilation and advanced pediatric life support is monitoring him. Have the physician or nurse practitioner evaluate for treatment of an underlying disorder.

DIAGNOSTIC CRITERIA FOR EVALUATING PEDIATRIC EMERGENCIES

Diagnostic procedures used in emergency situations vary depending on the child’s pathology or injury and presenting symptoms (Tests and Procedures 31–1). Other tests may be performed depending on the mechanism of injury (e.g., a child with iron ingestion has serum iron levels evaluated) or pathology (e.g., if the child has signs of meningitis, a lumbar puncture is done). When head or neck injuries are known or suspected, cervical spine precautions must be maintained until spinal cord injury is evaluated.

In an emergency, procedures often must be performed rapidly. The healthcare provider must always provide age-appropriate support and preparation, even if explanations are given as the procedure is being done. Monitor the child’s status during the procedure. The additional stress to an already compromised child may precipitate further deterioration.

TREATMENT MODALITIES

The best treatment for pediatric emergencies is, of course, prevention. Children, parents, family members,

and caregivers should be familiar with safe practices and child safety techniques, such as using protective equipment when engaging in sports and childproofing the home (see Chapters 4–7), and first-aid procedures.

Pediatric Cardiopulmonary Resuscitation

QUESTION: If Chase’s laryngeal edema progresses to obstruct his airway, what do you anticipate the sequence of interventions will be?

In adults, the most common causes of cardiopulmonary arrest are lethal arrhythmias secondary to heart disease. Cardiopulmonary arrest in infants and children typically results from disorders that lead to respiratory failure and shock. Outcomes of cardiopulmonary arrest in children are usually poor, with high morbidity and mortality rates (Donoghue, Nadkarni, Elliott et al., 2006).

The nurse must understand and be able to recognize the signs of shock, respiratory failure, or both in children (see Tables 31–2 and 31–4 later in this chapter). Signs of impending failure may be subtle, because children are equipped to compensate physiologically for illness or injury for a relatively long period of time. For example, the hypovolemic child compensates by an increase in

Tests and Procedures 31-1 For Evaluating Pediatric Emergencies

Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
Complete blood count with differential	Detects infection or lack of immune response	Elevated white blood cell count with shift to the left may indicate infection; in neonates, may see neutropenia with infection.	Obtain blood, check results, intervene on the basis of results.
	Detects blood loss	↓ Red blood cells ↓ Hemoglobin	
Type and cross-match	Determines child's blood type and compatibility of blood to transfuse		Obtain blood, check results, intervene on the basis of results. May give O-negative blood in emergency before type and cross-match results are obtained.
Serum electrolytes (including glucose)	Detects electrolyte imbalance	Values outside normal reference ranges for age of child	Obtain blood, check results, intervene on the basis of results.
Radiographs chest Abdomen	Detects abnormalities in heart, lung, or ribs Detects obstruction, perforation, structural abnormalities in abdominal organs	Heart failure, pneumothorax, pneumonia, broken ribs. Dilated intestine proximal to obstruction; free air with perforation	Maintain c-spine precautions until cleared. Protect child's genitals with lead shield.
Bones	Detects fractures	Crack, malalignment of bone Tenderness on palpation	Position the child.
Computed tomography	Detects bleeding or masses	Abnormalities visualized include tumors, cancer, lesions, abscesses, fluid collection, and inflammation	Closely monitor cardiorespiratory status. Implement conscious sedation protocol if child is sedated.

heart rate to maintain cardiac output. Rapid recognition of the conditions that precede arrest and prompt intervention to prevent arrest are the keys to successful management of the critically ill child. Cardiac arrest in children is most commonly preceded by respiratory failure. Initially, the child compensates with an increased heart rate to maintain the blood pressure and cardiac output. Bradycardia ensues as the child becomes increasingly hypoxic. Without intervention, cardiopulmonary arrest follows (see [thePoint](#), Procedure: Cardiopulmonary Resuscitation).

The treatment of the child in cardiopulmonary arrest begins with assessment of the ABCs (airway, breathing, circulation) and beginning basic life support, or cardiopulmonary resuscitation (CPR). The child requiring CPR should be transported to a facility that can provide pediatric advanced life support measures and definitive treatment (Fig. 31-2).

ANSWER: Chase's situation is one example in which respiratory arrest in a child would precede cardiopulmonary arrest. Chase will compensate for an ever-narrowing airway by increasing his respiratory rate and respiratory effort until he can no longer move air. This change can occur very rapidly. Measures to secure his airway must be taken before the edema completely obstructs the airway. If his airway becomes obstructed, then the focus of advanced life support is to create a patent airway. Chase has no cardiovascular pathology; therefore, the ability to prevent cardiopulmonary arrest is dependent on the presence of an airway. Vascular access is the next priority. Because of this potential risk, an intravenous (IV) line was placed upon admission to the ED in his right antecubital vein. In the event of airway obstruction, epinephrine will be given via the IV to stimulate the sympathetic nervous system.

FIGURE 31–2. Cardiopulmonary resuscitation in a child varies from the adult, as seen here with cardiac compressions on an infant. Follow American Heart Association guidelines when performing CPR.

Advanced Life Support

Advanced life support includes

- Assistance with breathing, such as manual positive-pressure ventilations with a bag-and-mask device and 100% oxygen
- Circulatory support, such as obtaining vascular access and administration of fluids and emergency medications

The **length-based resuscitation tape** is a tool that is used during emergencies to provide a rapid estimate of the child's length to extrapolate dosages of emergency medications. Use of this tool by prehospital care providers is considered a standard of care. Many EDs also use the length-based resuscitation tape when a child requires emergent resuscitation and there is no time to weigh the child (Fig. 31–3).

Vascular Access

Vascular access is a high priority in pediatric advanced life support, because the child in cardiopulmonary arrest is often hypovolemic. The catheter used should be the largest gauge that can be rapidly and reliably inserted. Secure two IV sites to provide optimal routes for fluid resuscitation. During resuscitation, the easiest peripheral IV sites to access are the antecubital fossa, the dorsa of the hands, and the saphenous veins (see Chapter 17).

NURSING INTERVENTIONS 31–1

Tracheal Tube Intubation

Assess for Indications for Tracheal Tube Intubation

- Respiratory insufficiency
- Hypoxemia
- Respiratory arrest
- Glasgow Coma Scale score less than 8 points

Prepare the Equipment

- Proper size tracheal tube. Do not choose a cuffed tube for a child younger than 8 years because it can damage the trachea. The smallest portion of the pediatric airway is the cricoid ring; using the correct size tracheal tube creates a natural cuff.
- Laryngoscope with
 - Functioning light and charged battery
 - Proper size straight or curved blade
- Resuscitation bag with 100% oxygen source
- Suction source
- Rigid tonsil suction
- Tape
- Stethoscope

Assist With Intubation

- Provide several positive-pressure bag-and-mask breaths before the intubation attempt.

- Monitor the heart rate throughout procedure.
- Anticipate the need for resuscitation equipment, and have it immediately available.

Provide Care Immediately After Tracheal Tube Placement

- Resume bag-and-mask ventilations immediately.
- Hold the tube securely until placement is confirmed and the tube is taped securely in place.
- Auscultate breath sounds bilaterally.
 - If no breath sounds are heard,* pull the tracheal tube immediately and resume bag-and-mask ventilations. After several positive-pressure breaths, repeat attempt to intubate.
 - If breath sounds are heard only on the right side,* the tracheal tube may have been inserted down the right mainstem bronchus. Pull the tracheal tube out slightly until bilateral breath sounds are heard.
- Secure the tube. Prepare the taping site with tincture of benzoin to help secure the tape and tracheal tube; this decreases the need for frequent retaping of the tube.
- Record the tube centimeter markings at the upper gum.

FIGURE 31–3. The length-based resuscitation tape is used to select appropriate-sized resuscitation equipment to use and medication dosages to administer.

No more than three attempts should be made within 90 seconds to obtain peripheral vascular access. If peripheral IV access is not achieved, attempt access via the intraosseous (IO) route. Access is achieved using a specially made IO cannula or bone marrow aspiration needle. The IO cannula is placed in the medial surface of the tibia, approximately one finger breadth below the tibial tuberosity (see Fig. 17–8). The cannula is placed properly if resistance to insertion decreases (indicating that the cannula has entered the marrow), the needle remains upright without support, and fluids can be pushed freely into the cannula. Aspirating bone marrow after the IO needle is in place may not be possible. However, if any marrow is aspirated, it can be used for bedside blood glucose testing and other laboratory testing.

If the attempt to place the IO cannula is unsuccessful, select another site for further IO attempts. Do not use the same extremity, because the bone may have been punctured during the unsuccessful attempt, and any fluids or medications infused into the new site may leak back out the first site, causing extravasation. Other options for vascular access include central venous access and a venous cutdown. Both of these procedures require a skilled practitioner, and they are more time-intensive than using the peripheral or IO route.

Fluid Administration

When vascular access is obtained, the priorities are to administer fluids to restore volume and emergency medications to assist cardiac function. Blood is the fluid of choice for the pediatric trauma victim. However, isotonic crystalloid solutions such as normal saline or Ringer's lactate, more readily available and less expensive than blood, are effective volume expanders for the hypovolemic patient. If crystalloids are used, three to four times the deficit volume may have to be administered, because these solutions expand the intravascular compartment only transiently.

Medication Administration

Emergency or resuscitation medications can be delivered by the IV, IO, or, in some cases, the tracheal route (Nursing Interventions 31–2). Anything that can be given intravenously can be given the IO route (Table 31–1).

caREminder

Unlike adult dosages, pediatric dosages of all resuscitation medications are based on the child's weight in kilograms.

Be familiar with the various drugs, their indications, dosages, and administration techniques. Prepared drug sheets listing drug dosages according to weight are helpful in eliminating drug calculation anxiety and errors during an intense resuscitation.

Volume replacement is the first-line treatment for poor perfusion and hypotension. However, after multiple fluid boluses, the child may develop deteriorating lung compliance and pulmonary edema. Thus, after spontaneous circulation returns, the child may require medications to maintain or achieve adequate blood pressure and systemic perfusion. The three most common inotropic agents used after an arrest are epinephrine, dopamine, and dobutamine. Epinephrine is the drug of choice for children during and immediately after resuscitation.

NURSING INTERVENTIONS 31–2

Administering Medications by Tracheal Tube

- Ensure that the drug is appropriate for tracheal tube administration. To do this think of the mnemonic LEAN:
 - Lidocaine: The endotracheal dose is the same as the IV dose.
 - Epinephrine: Use 0.1 mg/kg (0.1 mL/kg) 1:1,000 solution. The tracheal tube dose of epinephrine is 10 times greater than the IV dose, except in neonates.
 - Atropine: The tracheal tube dose is increased two to three times the IV dose (0.02 mg/kg, with a minimum dose of 0.1 mg).
 - Naloxone: The tracheal tube dose is the same as the IV dose.
- Instill the drug as prescribed directly into the tracheal tube.
- Flush drug with 3 to 5 mL normal saline.
- Provide several positive-pressure ventilations to disperse the medication into the pulmonary vasculature.

TABLE 31-1

Pediatric Emergency Medications

Drug	Indications	Dose*	Interventions
Oxygen From tank or wall-mounted delivery device	Seriously ill or injured child with respiratory insufficiency, trauma, shock, even if measured arterial oxygen is high	100% oxygen during initial stabilization	Place mask on child's face; if child fights this, hold or have parent hold oxygen mask or tubing close to child's nose and mouth. Monitor oxygen saturation via pulse oximetry, interpret results, considering patient status. Anemia or vasoconstriction may result in inaccurate readings.
Fluid Crystalloid Lactated Ringer's Normal saline Colloid 5% Albumin Synthetic colloid solutions: Hetastarch Dextran Blood Fresh-frozen plasma	Hypovolemia	20 mL/kg per dose Repeat as necessary. Some children need up to 80 mL/kg within first hour.	Infuse as rapid bolus. Evaluate perfusion after every fluid bolus and frequently. Give blood to pediatric trauma victims who continue to show signs of hypovolemic shock after two boluses of crystalloid.
Epinephrine	Cardiac arrest, symptomatic bradycardia unresponsive to oxygen and ventilation, nonvolume-related hypotension	For symptomatic bradycardia and cardiac arrest: IV or IO 0.01 mg/kg (0.1 mL/kg 1:10,000 solution), repeat dose every 3 to 5 minutes as needed using same concentration. Intratracheal dose is 0.1 mg/kg 1:1,000 solution.	Give via tracheal tube until vascular access can be obtained. Evaluate child's response.
Atropine	Symptomatic bradycardia unresponsive to ventilation and oxygenation	0.02 mg/kg Minimum single dose: 0.1 mg Maximum single dose: 0.5 mg for child, 1.0 mg for adolescent May repeat in 5 minutes for a maximum total dose of 1.0 mg for child, 2.0 mg for adolescent.	Ensure adequate ventilation and oxygenation.
Sodium bicarbonate	Documented metabolic acidosis	1 mEq/kg Repeat every 10 minutes on the basis of arterial blood gas analysis.	Ensure adequate ventilation and oxygenation of child before giving sodium bicarbonate. Ensure adequate ventilation during administration (the drug's buffering action produces carbon dioxide). Flush IV line before and after drug administration with normal saline (precipitates in presence of catecholamines or calcium).
Naloxone	Reverse effects of opioids	Total reversal dose: 0.1 mg/kg IV/IO/IM/SQ every	Monitor child carefully for recurrence of opioid effects; naloxone has a shorter half-life than

TABLE 31-1
Pediatric Emergency Medications (Continued)

Drug	Indications	Dose*	Interventions
		2 minutes as needed (maximum, 2 mg) Total reversal not required: 1 to 5 µg/kg IV/IO/IM/SQ (titrate to effect)	opioids and may need to be repeated. These doses usually achieve total opioid reversal; use smaller doses if partial reversal desired.
Glucose	Documented hypoglycemia or if the child fails to respond to standard resuscitation measures	0.5 to 1.0 g/kg Use a maximum concentration of 25% glucose to administer peripherally; glucose is supplied as D-50, so dilute 1:1 with sterile water and give 2 to 4 mL/kg, or use D10W at 5 to 10 mL/kg.	Perform bedside glucose testing as soon as possible. Monitor IV closely (D-25 is hyperosmolar and may sclerose peripheral veins).
Calcium chloride	Documented or suspected hypocalcemia, hyperkalemia, hypermagnesemia, and calcium channel blocker overdose	20 mg/kg/dose Repeat <i>only</i> if measured calcium deficiency is present.	Do not administer routinely during resuscitation (may contribute to cellular injury). Administer <i>slowly</i> (no faster than 100 mg/minute); may induce bradycardia or asystole. Monitor IV closely; irritating to veins and causes chemical burns if infiltrates surrounding tissue. Do not mix with sodium bicarbonate.

*Recommended doses are for children older than 1 month. IM, intramuscular, SQ, subcutaneous.

These medications are given by continuous IV or IO infusion and are titrated to maintain adequate blood pressure and perfusion.

Psychosocial Support

 **QUESTION:** What strategies would you use to provide support to Chase and his family?

Critical illness or injury is a stressor. The onset is usually acute and unexpected, the environment and treatments are unfamiliar and painful, and the outcome is uncertain. Usual coping mechanisms used by the child and family may not be adequate in an emergency situation. While addressing the child’s physiologic needs, the healthcare team must place a high priority on providing emotional support to the child and family during this stressful time.

The atmosphere during an emergency can be chaotic and overstimulating. Keep the parents or other family with the child whenever possible. Involve the parents in the child’s care; tell the parents in concrete terms what they can do to support the child (e.g., hold the child’s hand and talk quietly to him or her). Attempt to talk

quietly and soothingly, and provide comfort measures (Fig. 31-4). When time permits, prepare the child and family before performing procedures. Otherwise, explain what is being done in developmentally appropriate terms, as it is performed, even if it seems that the child cannot hear.

FIGURE 31-4. Emotional security can be promoted by letting the child hold on to a favorite toy or security object from home or one from the ED stock.

TRADITION OR SCIENCE 31–1

Should family members be present during resuscitation or invasive procedures?

EVIDENCE-BASED PRACTICE

Family members should be present during these events, but many healthcare providers are uncomfortable with family presence at these times because of concerns about legal liability, family presence negatively affecting the staff's ability to perform procedures, the atmosphere during a resuscitation, and the family's response to the process (Fein, Ganesh, & Alpern, 2004). Other research indicates that healthcare providers believe that family members have a right to be present (Kuzin et al., 2007), support this (Fullbrook, Latour & Albarran, 2007a), and that presence during CPR does not increase liability concerns, but families rarely request to be present during CPR or invasive procedures (Kuzin et al., 2007). When allowed, parental presence during invasive procedures did not negatively affect care (Mangurten et al., 2006) or procedure performance (O'Connell et al., 2007) and, although parental presence did not seem to reduce the child's pain, parents were less anxious (Bauchner, Vinci, Bak, et al., 1996). Being present during the resuscitation may help the family through the grieving process if the child dies, because the parents know that everything possible was done to save their child (Meyers et al., 2004).

The family should be given the option to be present in the room during invasive procedures or while a child is being resuscitated (Tradition or Science 31–1). Many professional organizations (American Heart Association, 2005a; Emergency Nurses Association, 2005; Fullbrook, Latour, Albarran et al., 2007b) support this practice. A protocol for family presence should be in place, and a member of the healthcare team (e.g., chaplain or social worker) should attend to family members to provide support and explanations, and to help interpret events and place them in context (see NIC 11–1).

Nurses and other healthcare providers must provide emotional support to the child and family, and offer timely information with frequent updates about the child's condition. Parents want honest, complete information delivered in a caring manner using language they can understand (Meert, Eggly, Pollack, et al., 2008). Give initial information within 30 minutes. Direct-care providers are usually busy attending to the physiologic needs of the child. Having a social worker or chaplain immediately accessible to support the family is extremely helpful. The social worker or chaplain can keep the family updated on the child's condition, provide resources, and help the family deal with information, make decisions, and mobilize their own resources.

ANSWER: Keeping one of Chase's parents with him and keeping the family informed throughout the ED experience will enhance the family's sense of control during an unnerving experience.

NURSING PLAN OF CARE FOR THE CHILD WITH AN EMERGENT CONDITION

Identification of nursing diagnoses is driven by assessment findings. Diagnosis and implementation of interventions occur almost simultaneously in an emergent situation. Many pertinent nursing diagnoses are specific to the child's chief complaint. Others are common to most or all emergencies (Nursing Plan of Care 31–1). Disease-specific nursing diagnoses are addressed under the specific disease processes.

SPECIFIC PEDIATRIC EMERGENCIES

Emergencies, by their nature, are unpredictable, but some are encountered more frequently than others. This chapter covers the common pediatric emergencies of shock, trauma, respiratory emergencies, fever, bites and stings, anaphylaxis, epistaxis, environmental exposure injuries, poisoning, and SIDS.

SHOCK

QUESTION: Is Chase at risk for shock?

Shock is a sustained and progressive circulatory dysfunction that results in inadequate delivery of oxygen and other substances needed to meet metabolic demands. There are four types of shock: hypovolemic, cardiogenic, distributive (includes septic), and obstructive. Each type has a distinct etiology. Assessment findings and nursing interventions may vary, depending on the etiology (Table 31–2).

The most common cause of shock in children is hypovolemia. In the United States, hypovolemia is most often caused by bleeding as a result of trauma. Worldwide, diarrhea is one of the principal causes of morbidity and mortality in children (Forsberg, Petzold, Tomson, et al., 2007). A major consequence of the fluid and electrolyte losses associated with diarrhea is hypovolemic shock.

Morbidity and mortality associated with shock depend on its etiology and the healthcare provider's ability to recognize the signs promptly and intervene appropriately before shock becomes irreversible. Mortality associated with septic shock depends on the initial site of infection, causative organism, presence of multiple-organ dysfunction syndrome, and the timeliness and appropriateness of therapy. Severe sepsis and septic shock affects millions annually, mortality is more than one in four (Dellinger, Levy, Carlet, et al., 2008).

NURSING PLAN OF CARE 31–1 THE CHILD WITH AN EMERGENT CONDITION

Nursing diagnosis: Ineffective tissue perfusion (specify type: renal, cerebral, cardiopulmonary, gastrointestinal, peripheral) related to disease or injury

Interventions/Rationale

- Monitor for signs of ineffective tissue perfusion:
 - Renal, decreased urine output evidenced by
 - Urine output less than 1 mL/kg/hour
 - High specific gravity (1.030)
 - Cerebral
 - Irritability
 - Decreased level of consciousness
 - Sluggish pupillary response
 - Cardiopulmonary
 - Prolonged capillary refill time more than 2 seconds
 - Weak and/or thready pulses
 - Systolic blood pressure less than $70 + 2$ times the child's age in years
 - Gastrointestinal
 - Signs of ileus
 - Decreased bowel sounds
 - Nausea and/or vomiting
 - Peripheral
 - Pallor
 - Cool, clammy skin
 - Mottled skin pattern
 - Dusky skin

Symptoms vary based on the system affected. Early detection facilitates prompt intervention and reduces likelihood of negative sequelae.

- Notify physician or advanced practice nurse immediately if signs of ineffective tissue perfusion are noted.

Prolonged ineffective tissue perfusion leads to anaerobic metabolism, lactic acidosis, organ ischemia, and ultimately multiorgan system failure.

Expected Outcomes

- Child's signs of altered tissue perfusion will be recognized and treatment implemented promptly.
- Child will maintain tissue perfusion.

Nursing diagnosis: Acute pain related to symptoms of chief complaint or diagnostic procedures

Interventions/Rationale

- Assess the intensity, character, onset, and duration of pain, and the factors that aggravate and relieve it.

Accurate assessment facilitates effective management of pain.
- Provide sedation or analgesia for diagnostic procedures as ordered.

Keeps child comfortable, provides humane care, aids in efficient completion of procedure and optimizing outcomes, and may reduce fear with subsequent procedures.

- Provide ongoing pain assessment and management before pain escalates. Assume that pain is present and treat accordingly in a child who has a condition or is undergoing a procedure or treatment that would be painful to an adult.

Preemptively managed pain is easier to control than pain that is of longer duration, and it requires less medication and produces fewer deleterious side effects. Children may be developmentally or cognitively unable to verbalize pain or unwilling to do so because of their perception of the pain or fear of shots.

Expected Outcomes

- Child's pain will be managed adequately.

Nursing diagnosis: Anxiety related to unknown situation and outcome

Interventions/Rationale

- Explain the child's condition, situation, and interventions that are being implemented, even if the explanation occurs simultaneously with the intervention, as may be mandated by the child's emergent condition.

Providing information can reduce anxiety related to the unknown.

- Avoid excessive reassurance.

Honesty promotes trust.
- Recognize the child's and parent's defenses. Do not take negative outbursts personally; do not confront, argue, or react with anger.

Defenses help one cope in stressful situations, but responding negatively may escalate the situation.

Expected Outcomes

- Child will be told, in age-appropriate terms, what is being done. Parents will be with child as much as possible.
- Family will be kept informed about child's condition and what is being done for the child.

Nursing diagnosis: Anticipatory grieving related to unknown and potentially fatal outcome

Interventions/Rationale

- Encourage family members to stay with the child, if they desire. Provide support personnel to stay with the family when the child is undergoing procedures or resuscitation.

Family presence helps both the child and family cope with the situation. Support personnel can help the

NURSING PLAN OF CARE 31–1 THE CHILD WITH AN EMERGENT CONDITION (CONTINUED)

family interpret the situation more accurately and process their reactions. Family presence during resuscitation, if they desire, has been shown to help the family cope with the situation.

- Keep family members informed about the child's condition.

Not knowing increases the family's anxiety; even if no new information emerges, the family can recognize that the health team is caring.

- Provide support for family from facility chaplain, social worker, or family's own support systems.

Medical staff can focus on care of the child, and the family is supported in coping with the situation.

- Use open-ended questions to elicit child and parent's thoughts and fears.

Can more accurately assess the issues at hand.

Expected Outcomes

- Child and family will be kept informed of child's condition.
- Child and family will be given an opportunity to verbalize feelings.
- Child and family will mobilize own support systems (e.g., spiritual, community).

ANSWER: If Chase's airway is not stabilized, he will become increasingly hypoxic, his heart tissue will not receive enough oxygen, and he will progress into shock.

Assessment

Shock may be classified as compensated or decompensated. In compensated shock, the child becomes tachycardic in an effort to increase cardiac output. The blood pressure remains normal, capillary refill time may be prolonged (>2 seconds), and the child may become irritable because of increasing hypoxia. In decompensated shock, the child displays decreased blood pressure and level of consciousness (stupor or coma), and tachypnea or signs of respiratory failure.

Without treatment, compensatory mechanisms can sustain cellular function only temporarily. As shock progresses, cellular metabolic changes result in further tissue injury and, ultimately, cell death.

Alert! Hypotension is a late sign of hypovolemic shock in children. It may represent a 25% loss of circulating blood volume.

Nursing Diagnoses and Outcomes

Nursing diagnoses and outcomes for the child in an emergency situation are presented in Nursing Plan of Care 31–1. In addition, the following diagnoses and outcomes apply to the child in shock:

Decreased cardiac output related to effects of hypovolemia, sepsis, obstruction

Outcome: Child's signs of decreased cardiac output will be recognized promptly and interventions instituted immediately.

Outcome: Child's cardiac output will remain adequate, as evidenced by vital signs within normal ranges and adequate perfusion.

Deficient fluid volume related to effects of disease process or injury

Outcome: Child's signs of fluid volume deficit will be recognized promptly, vascular access obtained, and fluid administered until the child shows no signs of hypovolemia.

Outcome: Child's fluid volume will remain balanced, as evidenced by child's urine output being 1 to 2 mL/kg/hour.

Excess fluid volume related to effects of myocardial dysfunction

Outcome: Child's signs of fluid volume excess will be recognized promptly and interventions instituted to optimize oxygenation and reduce fluid volume.

Outcome: Child's fluid volume will remain balanced, as evidenced by child's urine output being 1 to 2 mL/kg/hour.

Interdisciplinary Interventions

Shock states result in the failure of cellular oxygenation. The goal of treating shock is to restore circulating blood volume and maintain adequate tissue perfusion and cardiovascular stability. The nurse, physician, and respiratory therapist must work as a team to implement interventions that optimize volume and oxygenation. Obtain vascular access as soon as possible to administer fluid and vasoactive drugs as needed. Monitor electrolyte and glucose levels and correct as indicated. Administer 100% oxygen, and ventilate and intubate as needed. Minimize stress to the child, which further increases metabolic, and thus oxygen, demands. Maintain a normothermic environment; temperature extremes also increase metabolic demands. Reassess the child's status frequently, at least after every intervention.

TRAUMA

Injury is the leading cause of death of children 1 to 19 years of age, accounting for about 42% of deaths (Martin et al., 2008). Traumatic brain injury is the leading cause

TABLE 31-2**Types of Shock: Assessment and Interventions**

Type of Shock	Etiology	Assessment Findings	Interdisciplinary Interventions
Hypovolemic	Caused by inadequate volume relative to the vascular space; primarily caused by dehydration or traumatic hemorrhage	Tachycardia Prolonged capillary refill (>2 seconds) Weak, thready, or absent peripheral pulses Cool extremities	Administer IV fluids: 20 mL/kg bolus of 0.9% normal saline or Ringer's lactate; repeat as necessary. If signs of inadequate tissue perfusion are present, after two or three boluses of crystalloid fluid, administer 10 mL/kg packed red blood cells (type specific or O negative). Control bleeding by applying direct pressure to external sites of bleeding with sterile gauze.
Cardiogenic	Caused by impairment of myocardial function	Tachycardia Tachypnea Narrow pulse pressure Cool, mottled skin Capillary refill longer than 2 seconds Weak peripheral pulses Decreased urine output Hepatomegaly Neck vein distention (older child) Rales Edema	Administer oxygen. Administer IV fluid: 20-mL/kg bolus. Carefully assess child's response to fluid bolus; children in heart failure may be fluid overloaded. Administer inotropes to improve cardiac contractility (dopamine, dobutamine). Administer diuretics to improve preload. Correct acid-base, electrolyte imbalances.
Distributive	Septic shock is discussed here; for anaphylaxis, see Chart 31-2. Caused by inappropriate distribution of blood flow and increased capillary permeability. Is the most common type of shock in the newborn. Most commonly results from gram-negative organisms.	History of infection History of poor feeding Tachycardia Fever Tachypnea Altered mental status Petechiae and/or purpura Poor peripheral perfusion (capillary refill >2 seconds)	Isolate the child as necessary. Administer IV fluid in volumes of as much as 80 mL/kg (in boluses of 20 mL/kg) to restore circulating volume. Administer inotropic agents as needed. Draw blood samples for cultures immediately. Administer wide-spectrum antibiotics; do not postpone antibiotic therapy until culture results are available. Administer IV glucose as needed to treat hypoglycemia.
Obstructive	Caused by inability of normal heart to produce adequate cardiac output despite normal intravascular volume because of mechanical obstruction (e.g., tension pneumothorax, cardiac tamponade, pulmonary embolism)	See Table 31-3 on traumatic chest injuries.	See Table 31-3 on traumatic chest injuries. Relieve obstruction.

of death in childhood (Salorio, Slomine, Guerguerian, et al., 2008). Head injuries are mostly the result of falls and motor vehicle accidents.

The causes of other traumatic injuries are diverse. The most common are motor vehicle accidents (including

automobile-pedestrian and automobile-bicycle accidents), drowning, burns, falls, and firearm injuries. Blunt injuries are more common in children than penetrating ones. Boys have higher injury rates than girls (Flavin, Dostaler, Simpson, et al., 2006). Mortality rates

for children with injuries have declined steadily during the past decade, in part because of injury prevention programs.

Trauma care is provided through a team effort. Standardized policies and procedures should identify the roles and responsibilities of all the trauma team members. Pediatric victims of multisystem trauma or those with a high mortality risk should be transported to a trauma center with pediatric expertise (American Academy of Pediatrics [AAP] Section on Orthopaedics, et al., 2008). When treating trauma patients, the risk of exposure to blood and other body fluids is high. Therefore, before initiating care, don personal protective equipment (i.e., gloves, goggles, mask, and gown) to minimize this risk.

Assessment

The commonly used mnemonic “A through I” represents the steps of the primary and secondary assessments (see Focused Physical Assessment 31–1) (Emergency Nurses Association, 2007). These steps prioritize assessments of the trauma patient and identify lifesaving interventions that may be necessary.

Primary Assessment and Care

Begin the primary assessment by assessing the ABCs. As in CPR, remember not to continue to the next step until the previous step has been stabilized.

Open the airway and assess it for patency. Suction any blood, vomitus, or debris in the oropharynx. Check for any displaced or loose teeth. For the child with a suspected head or spine injury, use the combined jaw thrust–spinal stabilization maneuver to open the airway and manually hold the head in a neutral position. After the airway is opened, stabilize the cervical spine (c-spine) to prevent cervical motion, using a semirigid extrication collar of the appropriate size (Fig. 31–5). The collar must fit perfectly. If it is too large, it may allow cervical movement, which may convert an incomplete spinal cord injury to a complete one.

FIGURE 31–5. For a trauma victim, the cervical spine must be immobilized while the airway is opened. This is done using a combined jaw thrust and spinal stabilization maneuver.

Alert! For the child with a head injury, ensure that the neck remains in a neutral position, not hyperextended. One team member should hold the neck in position while another performs the intubation. Also take c-spine precautions with a near-drowning victim. The child may have hit his or her head during the drowning or when falling into a pool.

Assess for breathing next. Remember that blunt and penetrating traumatic injuries to the chest can severely compromise breathing. Unless these injuries are aggressively assessed, recognized, and rapidly treated, they can kill the patient (Table 31–3). For all trauma patients, administer oxygen by a nonrebreather mask in the highest concentration available until the oxygenation and perfusion status is completely assessed. Oxygen should be given because the child may have as yet unrecognized respiratory failure and shock, both of which contribute to tissue hypoxia. The goal is to stabilize the effects of hypoxia before irreversible damage occurs. If necessary, assist with ventilations, using a bag-and-mask device supplied with 100% oxygen, and prepare for intubation. Place a nasogastric tube (or orogastric tube in the child with a suspected basilar skull fracture) to decompress the stomach.

Assess the child’s circulatory status. Begin chest compressions on the patient without a pulse, and initiate further advanced life support measures.

Obtain vascular access without delay by placing two large-bore (22 gauge or larger) IV lines peripherally. Because leg injuries are more common in children, the arms are the sites of choice for IV access. Do not attempt vascular access in a fractured or severely injured extremity, because vascular compromise is a concern. If vascular access remains unsuccessful, IO access should be attempted next, before considering central line insertion such as percutaneous access of the femoral or subclavian vein or cutdown of the saphenous vein. If signs of hypovolemic shock occur, treat aggressively with fluid replacement.

After the ABCs have been stabilized, assess **D** (disability) by performing a brief neurologic examination, including level of consciousness and pupillary response to light. This assessment determines neurologic status and establishes a baseline from which to evaluate change. Test the child for hypoglycemia. If hypoglycemia is present, treat with 25% dextrose. If opioid overdose is suspected, administer naloxone (Narcan).

E (Expose) the child by removing all clothing and inspect for any obvious signs of injury or illness. Prevent hypothermia by covering the child with a blanket or, optimally, by using an overhead warmer, which allows continued, full visual examination of the child.

Secondary Assessment and Care

Secondary assessment focuses on the “F through I” component of the mnemonic. Obtain **F**, a full set of vital signs, including pulse, respiratory rate, blood pressure, and rectal temperature. Rectal temperatures are the standard of care. Oral temperatures are not appropriate

TABLE 31-3

Types of Traumatic Chest Injuries: Assessment and Intervention

Injury Type	Definition	Assessment Findings	Nursing Interventions
Pulmonary contusion	Bruise on the lung tissue; most common type of chest injury	No initial symptoms may be evident Increased difficulty breathing Hemoptysis Tachycardia Rales	Restrict fluid (unless patient in shock). Elevate the head of the bed (if no c-spine injury). Assist with intubation if the child has severe respiratory distress. Administer ordered antibiotics for pneumonia prophylaxis.
Tension pneumothorax	A tear in the lung lining, which results in air accumulation in the pleural space that compresses the lungs; the amount of air trapped increases with each breath because the air cannot escape	Unstable vital signs Respiratory distress Tracheal deviation Decreased breath sounds over the affected lung Cyanosis Decreased cardiac output	Assist with needle thoracostomy (insertion of a 19-gauge needle into the left second intercostal space, midclavicular line). Prepare for chest tube insertion.
Open pneumothorax	Open chest wound that may be sucking or not sucking	Unstable vital signs Anxious, restless Irritable Cyanosis Decreased breath sounds over affected lung Asymmetry of chest wall movement Subcutaneous emphysema	Apply three-sided occlusive, nonporous dressing; leave one side open to allow air escape. Prepare for chest tube insertion.
Hemothorax	Blood accumulation in the chest cavity as a result of blunt or penetrating trauma	Unstable vital signs Decreased or absent breath sounds Dullness to percussion over affected area Hypovolemic shock resulting from hemorrhage	Prepare for chest tube insertion. Administer fluids for aggressive volume replacement. Monitor chest drainage.
Cardiac tamponade	Blood accumulation in the pericardial sac as a result of blunt or penetrating trauma	Muffled heart sounds Decreased blood pressure Distended neck veins	Assist with immediate pericardiocentesis. Perform fluid resuscitation.

for young children, those with an altered level of consciousness, or those requiring assistance maintaining their airway. Axillary temperatures take too long to obtain, and vasoconstriction or dilation may result in inaccurate readings. Facilitate family presence.

G (Give) comfort measures such as reassurance, including touching and providing age-appropriate diversional activities. This may also include splinting of extremity injuries, dressing wounds, and providing pain control. Perform **H**, a head-to-toe examination, and obtain a history, using the AMPLE mnemonic (see Chart 31-1). The head-to-toe examination may reveal signs and symptoms of internal hemorrhage, such as abdominal pain, guarding, rigidity, or tenderness. The abdomen may be distended and have signs of obvious abdominal trauma such as a positive seat belt sign (bruising that correlates with the position of the seat belt).

Shock that persists despite aggressive fluid replacement may indicate internal hemorrhage and requires immediate surgery.

Finally, **I** (inspect) the patient's back. To do this, roll the child over, maintaining c-spine precautions (logrolling). Then check for penetrating objects, bleeding, bruising, abrasions, or lacerations.

Nursing Diagnoses and Outcomes

Nursing diagnoses and outcomes applicable to the child and family when the child is experiencing a medical emergency are discussed in Nursing Plan of Care 31-1. The nursing diagnoses and outcomes identified for the child in shock also are frequently relevant to the child who has suffered a traumatic injury. Additional ones include the following:

Impaired spontaneous ventilation related to effects of injury

Outcome: Child's ventilation, spontaneous or assisted, will be adequate.

Ineffective airway clearance related to effects of injury

Outcome: Child's signs of ineffective airway clearance will be recognized immediately, and interventions to clear the airway will be implemented promptly.

Acute pain related to effects of injury

Outcome: Child will be assessed for baseline neurologic and cardiovascular status, and pain will be adequately managed.

Hypothermia related to exposure from injury or treatment

Outcome: Child's body temperature will be maintained within the normal range while the child is exposed adequately during inspection for injuries and treatment.

Risk for infection related to effects of injuries, invasive treatments, and stress decreasing immune response

Outcome: Child will not acquire injury-related infection.

Imbalanced nutrition: Less than body requirements related to injury increasing metabolic demands or decreasing ability to ingest nutrients

Outcome: Child's intake of nutrients will be sufficient to meet metabolic needs and support healing and growth.

Interdisciplinary Interventions

Upon completing the primary and secondary assessments, additional interventions may be identified. Insert an indwelling urinary catheter to monitor urine output (contraindicated if blood is present at the urethral meatus). Do not remove an impaled object; stabilize it for later removal in surgery.

Assess the child's pain level and administer pain medications as ordered. Before administering a pain medication to a child with a traumatic injury, ensure that a thorough neurologic and cardiovascular examination has been performed. Administer pain medications in small doses and titrate to achieve adequate pain control. Larger bolus doses of pain medication may make it difficult to evaluate accurately whether a change in level of consciousness is drug induced or the result of pathology. Pain medications may also cause vasodilation, causing a precipitous drop in blood pressure in a child with hypovolemia or unstable cardiovascular status. Until definitive treatment is achieved, splint, elevate, and ice any extremity fracture. Apply sterile dressings to any open soft-tissue injuries such as lacerations or abrasions. Determine the child's tetanus immunization status, and administer a booster if necessary.

If bruising is noted around the eyes (raccoon eyes) or behind the ears, or if hemotympanum is present, the child may have a basilar skull fracture. This type of fracture places the child at risk for intracranial hemorrhage, respiratory depression, respiratory arrest, and cerebral edema. Such a child may require intubation and mechanical ventilation to maintain a normal PaCO₂ of 35 to

45 mm Hg. Prophylactic hyperventilation is not recommended with head trauma because of its vasoconstricting effect on cerebral arteries and subsequent risk for brain ischemia (Brain Trauma Foundation et al., 2007). Hyperventilation, as a means of preventing impending herniation of the brain, is reserved for treatment of intracranial hypertension that is refractory to other treatments (Adelson, Bratton, & Carney, 2003). Measure PaCO₂ by serial arterial blood gas measurements or with an end-tidal carbon dioxide monitor. Cerebral blood flow or brain tissue oxygen monitoring is recommended (Adelson et al., 2003). Administer hyperosmolar therapy (e.g., mannitol) as ordered, to decrease intracranial pressure. Continually evaluate therapy effectiveness and monitor for signs of severely increased intracranial pressure, including asymmetric or fixed, dilated pupils; bradycardia; posturing; and nonresponsiveness. Prepare the child for computed tomography—the diagnostic study of choice to evaluate the intracranial space.

COMMON RESPIRATORY EMERGENCIES

QUESTION: How does the laryngeal edema that Chase is experiencing compare with these respiratory emergencies?

Respiratory emergencies are a major cause of morbidity and mortality in the pediatric population. Rapid assessment, recognition of distress or failure, and immediate intervention are the keys to successful management. Causes of respiratory emergencies include epiglottitis, foreign body aspiration, bronchiolitis, croup, and asthma (Table 31–4). See Chapter 16 for an in-depth review.

Assessment

Approach the child in a calm, gentle manner to minimize fear, which increases metabolic demands. While approaching, obtain a general assessment of the child's status. Note the child's position of comfort. Older children assume a position that optimizes airway patency and minimizes the work of breathing. Assess level of consciousness. Hypoxia may be manifested as anxiety or irritability; hypercapnia, as lethargic or obtunded behavior. Evaluate the child's color. Cyanosis is a late sign of respiratory distress, unless the child has chronic pulmonary or cardiovascular pathology.

Assess the rate and effort of breathing. Tachypnea in children is often the first sign of respiratory distress.

Alert! It is an ominous sign if a child who was tachypneic has a slowed respiratory rate. This may indicate that the child is tiring and respiratory failure is imminent.

Increased effort of breathing may be manifested by stridor, wheezing, grunting, retractions, use of accessory muscles, and nasal flaring. Note chest movement for

TABLE 31-4

Common Respiratory Emergencies: Assessment and Interventions

Disease	Assessment Findings	Interdisciplinary Interventions
Foreign body aspiration/obstruction	History of running while eating or of playing with a small toy Acute onset of respiratory distress	If the child can breathe spontaneously or has coughing, wheezing, or stridor, do not attempt to dislodge the object. Perform basic life support measures to dislodge foreign body. If basic life support techniques do not dislodge foreign body, then physician should perform direct visualization and manual removal as needed. If apnea persists and manual bag-and-mask ventilations cannot bypass the obstruction, emergency intubation, tracheostomy, or needle cricothyrotomy is necessary to establish a patent airway and to enable CPR to be effective.
Croup	History of viral infection, especially parainfluenza virus Onset during late fall or winter (most common) Mild to moderate illness (compared with toxic appearance of child with epiglottitis) Prodrome of upper airway infection that progresses to <ul style="list-style-type: none"> • Fever • Barking cough • Inspiratory stridor • Tachycardia • Tachypnea • Suprasternal and/or subcostal retractions • Altered breath sounds (from stridor alone to rhonchi and/or wheezing) 	Base treatment on severity of illness. Administer corticosteroids such as dexamethasone as ordered. Improvement can be expected within 2 to 3 hours. Administer nebulized racemic epinephrine as ordered to reverse airway obstruction quickly; requires cardiopulmonary monitoring. Duration of effect lasts for 2 hours. Monitor child for rebound airway obstruction for at least 2 to 3 hours after the last racemic epinephrine treatment before considering discharge.
Epiglottitis	Inflammation and swelling of the epiglottis and surrounding structures Age, 2 to 6 years (most common) Rapid onset of symptoms (e.g., child appears healthy 2 hours previously) Tripod positioning (neck stretched forward with jaw up to obtain a “sniffing” position, in an attempt to achieve the best airway) High temperature (>104 °F [40 °C]) Inability to eat or drink Excessive drooling Choking Muffled voice Difficulty breathing “Stridorous” cough possible	Observe the child in a controlled medical environment (e.g., ED, intensive care unit); never leave the child unattended. Immediately gather appropriate equipment for emergency intubation and/or tracheostomy. Allow the child to maintain the position of comfort; avoid invasive or disturbing procedures because any agitation or attempts to lay the child down may result in laryngospasm and complete obstruction of the child’s airway. Administer antibiotics to treat <i>Haemophilus influenzae</i> , <i>Streptococcus pneumoniae</i> , or <i>Staphylococcus</i> infection.
Asthma	Tripod positioning Profound respiratory distress Anxious, restless Cyanotic, pale Tachycardia Tachypnea Retractions, use of accessory muscles Decreased or unequal breath sounds Expiratory wheezing, inspiratory wheezing with a prolonged inspiratory phase; the absence of	Allow the child to maintain position of comfort. Administer nebulized bronchodilator/albuterol as ordered. Administer supplemental oxygen. Consider nebulized terbutaline or atropine for children who do not respond to albuterol. Administer epinephrine (1:1000 solution) subcutaneously as ordered immediately if the child cannot generate a peak flow measurement or has a decreased level of

(Continued)

TABLE 31-4

Common Respiratory Emergencies: Assessment and Interventions (Continued)

Disease	Assessment Findings	Interdisciplinary Interventions
	wheezing with signs of respiratory distress is an ominous sign Decreased peak expiratory flow rate	consciousness. Reassess the child's vital signs, respiratory effort, and breath sounds after each treatment. Early treatment with a dose of steroids may prevent asthma exacerbation. Consider hospital admission if child does not respond to three albuterol treatments; has retractions, tachypnea, pallor, and/or cyanosis that continues without wheezing; or has a peak expiratory flow that does not improve to at least 65% of normal; or when parental adherence to therapy is questionable.
Bronchiolitis	History of acute viral infection of the lower respiratory tract Onset in winter (most common) Upper respiratory infection for 3 to 5 days Worsening cough Audible wheezing Low-grade fever Poor feeding (common)	Bronchodilator therapy and corticosteroids are commonly prescribed; however, little scientific evidence exists regarding the usefulness of these therapies. Supportive care (such as oxygen to maintain oxygen saturation more than 94% or during feeding to prevent oxygen desaturation) and IV hydration for those infants who are unable to maintain adequate oral intake are the mainstays of therapy.

symmetric expansion. Auscultate breath sounds for location and quality.

Interdisciplinary Interventions

Assessment findings indicate the level of respiratory support needed by the child. General support includes attending to the ABCs and optimizing oxygenation and ventilation. More specific interventions depend on pathology.

For any child showing respiratory distress or desaturation on pulse oximetry, administer oxygen, using a method tolerated by the child, to keep the oxygen saturation level above 94%. Administer oxygen cautiously to those with a history of chronic pulmonary disease. Instruct the parent how to hold oxygen tubing to provide blow-by oxygen, which may be better tolerated by the child (Fig. 31-6).

KidKare ■ Create a nonthreatening mask by cutting a hole in the bottom of a Styrofoam cup. Then place the oxygen tubing through the hole and place the cup over the child's mouth. Monitor the child to prevent him or her from chewing on the cup.

For children who require nebulizer treatments and are too young to hold a nebulizer mouthpiece in the mouth, have the parent hold a face mask in place.

Allow the child to maintain a position of comfort, either sitting or remaining in the parent's arms. Support infants with the head in a neutral position.

Check arterial blood gas measurements for any child with severe respiratory distress. A PaCO₂ more than

FIGURE 31-6. Young children offer less resistance if oxygen is delivered unobtrusively.

50 mm Hg may indicate that the child requires intubation and mechanical ventilation. Do not feed children who are experiencing respiratory distress. Limit disturbances to essential interventions to prevent further distress.

ANSWER: There are many similarities between the laryngeal edema that Chase is experiencing and these respiratory emergencies. For Chase and any child presenting with respiratory emergencies, the assessment will focus on the effectiveness of their breathing. Although the treatments may vary according to the etiology of the respiratory distress, all respiratory emergencies in children have the potential for very rapid changes in status and are potentially life threatening.

FEVER

Fever is one of the most common reasons that parents seek care for their infant or child in the emergency department. Fever is an elevation of body temperature to at least 100.4 °F (38 °C) rectally. It occurs when toxic substances or abnormalities in the brain reset the thermoregulatory set point of the body to a higher than normal value. Fever itself is not a disease; rather, it is a sign of an underlying disease that has activated an immune response.

Although exceptions occur, children with invasive bacterial disease often appear ill and are easy to identify as requiring treatment. With occult bacteremia, the source of the fever may not be evident despite a careful history and physical examination. The incidence of bacteremia has declined significantly in children younger than 3 years of age since the introduction of the pneumococcal conjugate vaccine (Antonyrajah & Mukundan, 2008). Currently, urinary tract infection is the most common cause of fever in children 3 to 36 months of age (Carstairs, Tanen, Johnson, et al., 2007).

Another concern with fever is the possibility of triggering a **febrile seizure**. These seizures occur most commonly in children between 6 months and 5 years of age with a frequency of 2% to 5% (AAP, 2008). Infants younger than 1 year of age have an approximately 50% chance of experiencing recurrent febrile seizures. Children older than 1 year experiencing their first febrile seizure have about a 30% chance of recurrence (AAP, 2008) before they outgrow them. Most febrile seizures last 1 to 2 minutes. Febrile seizures that last longer than 15 minutes are considered complex febrile seizures.

There is no evidence that febrile seizures cause a decline in IQ, academic performance, behavioral abnormalities, or neurocognitive inattention (AAP, 2008). Simple febrile seizures are associated with the same risk of developing epilepsy as the general population. However, the risk of epilepsy is higher in children who are younger than 1 year of age when experiencing their first febrile seizure, have multiple simple febrile seizures, and have a family history of epilepsy; most likely as a result of genetic predisposition (AAP, 2008).

Assessment

Fever increases the basal metabolic rate, resulting in tachycardia, tachypnea, and increased oxygen demand. With each degree Celsius increase, the febrile child's caloric requirements are increased by 12%.

Perform a complete physical examination in a child with fever, specifically noting level of hydration, skin lesions (petechiae, which usually appear first on the chest, may indicate a serious bacterial infection), and neurologic status, which includes palpating the fontanel in infants younger than 18 months. A bulging fontanel may indicate meningitis; a sunken fontanel, dehydration. The child may be irritable and lethargic. The child who appears "toxic" may be cyanotic, have an altered level of consciousness, and have poor perfusion manifested as mottled skin color, capillary refill time longer than 2 seconds, cool extremities, and weak pulses.

Febrile seizures are usually manifested as sudden unresponsiveness, generalized rhythmic jerking, and tonic posturing lasting less than 15 minutes, usually less than 90 seconds. A determination must be made whether the fever caused the seizure or the seizure is a sign of underlying pathology that also caused the fever (e.g., meningitis, encephalitis) or is coincidental with the fever (e.g., toxic ingestion, hypoglycemia, hemorrhage, neurocutaneous disorder). Children who experience febrile seizures appear neurologically well within a few hours.

A complete "septic" workup may be indicated for infants younger than 3 months who present with a rectal temperature of 100.4 °F (38 °C) or higher, and for children 3 to 36 months of age who present with a rectal temperature of 102 °F (38.9 °C) or higher and who appear toxic. A complete septic workup includes a complete blood count, blood culture, urinalysis, urine culture, lumbar puncture, and chest radiograph. Obtain all culture specimens before initiating antibiotic therapy.

caREminder

Do not wait for laboratory results before starting antibiotics. Antibiotic therapy should be initiated within 1 hour, especially if the child appears toxic.

Interdisciplinary Interventions

The nurse plays a pivotal role in managing the child with fever and in educating parents about home management (TIP 31–1). Treatment for fever includes antipyretics, fluids, and cooling measures. Managing fever in the acute care setting does not differ markedly from managing it in the home (see [thePoint](#) Procedure: Cooling Measures).

Protocols are usually in place in emergency departments for antipyretic administration. Although alternating ibuprofen and acetaminophen has been shown to be more effective than monotherapy in reducing fever (Nabulsi et al., 2006; Sarrell, Wielunsky, & Cohen, 2006), more research is needed because of study limitations. Alternating medications can increase confusion about dosing and

TIP 3 1–1 A Teaching Intervention Plan for the Child With a Fever

Nursing diagnoses and outcomes

Deficient knowledge

- Home management of fever

Outcome

- Caregivers and child, if appropriate, will implement appropriate fever management interventions.
- Caregivers and child, if appropriate, will notify healthcare provider appropriately of negative changes in the child's condition.
- **Risk for deficient fluid volume related to effects of increased metabolic demands**

Outcome

- Child will have sufficient fluid intake to prevent dehydration.
- **Hyperthermia related to effects of disease process**

Outcome

- Child will have fever controlled as needed to decrease risk for febrile seizure, decrease metabolic demands, and promote comfort.
- **Risk for injury related to potential for febrile seizures**

Outcome

- Child will not sustain injury if seizure occurs.

Teach the child/family

Knowledge of Fever

- Fever in itself is not harmful; it may be beneficial in fighting pathogens.
- Make certain parents know how to take the child's temperature:
 - Use method appropriate for child's age and condition.
 - Read thermometer accurately.

Cooling Measures

- Manipulate environment to cool child:
 - Unbundle child. May cover with light blanket if shivering occurs.
 - Decrease room temperature.
- Administer antipyretics as needed for temperature more than 102 °F (38.9 °C) and, if your child is uncomfortable, administer

- Acetaminophen at 15 mg/kg orally or rectally every 4 hours (drug of choice)
- Ibuprofen at 10 mg/kg orally every 6 to 8 hours
- *Do not alternate use of acetaminophen and ibuprofen*, because of the risk of overmedication.
- *Do not give aspirin* because of its association with Reye syndrome.
- It will take 30 to 60 minutes for these medications to have an effect on the temperature.
- Sponge with tepid water (85–90 °F [29.4–32.2 °C]):
 - Sponge immediately if your child has a febrile seizure or temperature more than 106 °F (41.1 °C); otherwise, wait until after the antipyretic has taken effect, the temperature remains more than 104 °F (40 °C), and your child is uncomfortable.
 - If sponging is done, water should be lukewarm (85–90 °F [29.4–32.2 °C]). *Do not use ice water*, which will bring your child's temperature down too rapidly and cause shivering. Avoid shivering, because it raises the temperature as the body attempts to produce heat.
 - *Do not use alcohol* for sponge baths, because alcohol intoxication can result from inhalation of fumes and skin absorption.
 - Stop sponging when your child's temperature starts to decrease to avoid having the child become too cold.

Hydration Status

- Increase child's fluid intake. Offer frequent, small sips of fluid or popsicles.
- Monitor child's hydration status, including urine output (count wet diapers or check color of urine), moistness of mucous membranes, and presence of tears.

Contact the Healthcare Provider if:

- Child's fever persists longer than 2 to 3 days
- Child's condition worsens (e.g., seizure, purple spots on skin, increased lethargy or irritability, stiff neck, vomiting, decreased oral intake, signs of dehydration [<8 wet diapers/24 hours or urine is dark and voiding small amounts, dry mucous membranes, no tears with crying after the neonatal period])

thus the risk of toxicity. Replace fluid deficits orally or intravenously, depending on the child's level of consciousness and cooperation.

Sponging as a cooling measure is controversial, because fever may be beneficial in helping fight the infection. Sponging does not add to sustained fever reduction and only increases the discomfort of children with non-life-threatening fever (Alves, Almeida, & Almeida, 2008). Never sponge a shivering child, because shivering will increase the body temperature. Sponging should be done only

- In a child with a neurologic disorder, because many have abnormal temperature control mechanisms that do not respond well to antipyretics
- When the increase in metabolic demands resulting from the fever may be deleterious to the child (e.g., a child with cardiac or pulmonary disease, a pregnant adolescent)
- In a child with liver disease, for whom the use of antipyretics is contraindicated
- For heat-related illness (discussed later in this chapter)

All febrile infants younger than 28 days and any toxic-appearing infant or child should be hospitalized and treated with parenteral antibiotics (see **thePoint**). An Interdisciplinary Plan of Care for the Neonate With Sepsis). For older infants and children with fever and nontoxic appearance, outpatient management based on laboratory tests and clinical signs and symptoms, and implemented by reliable caregivers is appropriate. Antibiotics should not be given routinely for fever alone, but based on clinical findings and laboratory tests.

If the child does have a febrile seizure, protect the child from injury while stabilizing the ABCs (see Chapter 21). Place the child in a side-lying position to prevent airway obstruction or aspiration. For prolonged seizures, a benzodiazepine should be administered intravenously in appropriate doses to stop the seizure (Millar, 2006).

Alert! Administer IV sedatives slowly and closely monitor the child for ability to maintain a patent airway and spontaneous ventilations.

Educate the family about febrile seizures and how to manage them. Reassure them that febrile seizures cause no long-term sequelae. Explain the risk of recurrence. Instruct them that antipyretics can be administered when fever occurs but that seizures often occur as the temperature is increasing, before it is noticed by the parent, so they may not be prevented. Also, teach the parents first-aid measures to take if a seizure occurs.

BITES AND STINGS

Thousands of children are treated yearly for various types of bites and stings. In 2006, more than 27,300 bites and envenomations among children younger than the age of 19 years were reported to poison control centers in the United States (Bronstein, Spyker, Cantilena, et al., 2007). The actual numbers are likely much higher, because this

total does not include nonparticipating poison centers or unreported incidents.

Mammal and Human Bites

The most common bites seen in emergency departments are from dog, cats, and humans (Conlon, 2007). Children predictably suffer more serious injuries than adults. Dog bites to children younger than 6 years, often from the family dog, typically affect the head, face, and neck (Dwyer, Douglas, & van As, 2007). These bites can be disfiguring because the lips, nose, eyes, and ears are often involved. Dog bites to children older than 6 years are often to the perineum, buttocks, legs, or feet from dogs outside the home (Dwyer et al., 2007). Other common bites are inflicted by snakes, cats, rodents, Hymenoptera, scorpions, spiders, and humans. Wound infections are the most common complication, with bites inflicted by cats and humans having the highest infection rates (Taplitz, 2004).

Assessment

Obtain the history of the circumstances surrounding the bite, including who, or what, bit the child. If the bite is from an animal, include the type of animal (species and whether wild or domestic). Also determine the amount of time since the injury and the child's immunization status.

Manifestations depend on the type of wound. Human and dog bites often cause lacerations and crush injuries. Cat bites usually cause puncture wounds. Rodent bites tend to be superficial. Physical examination should evaluate the type, size, and depth of the injury; the presence of foreign material in the wound; and the status of underlying structures. Fractures may occur; evaluate for skull fractures in young children who have dog bites to the head and face.

Nursing Diagnoses and Outcomes

Nursing diagnoses common to the child experiencing an emergency, as listed in Nursing Plan of Care 31-1, apply to the child suffering from a bite. In addition, the following diagnoses and outcomes may apply to a child after a bite injury:

Impaired tissue integrity related to presence of bite wound

Outcome: Child's wound will be appropriately cleansed and closed as soon as possible after the injury to minimize further tissue damage.

Risk for infection related to effects of bite wound

Outcome: Child will not develop wound infection.

Acute pain related to effects of bite wound or treatment

Outcome: Child's pain will be adequately managed; child will verbalize minimal level of pain and demonstrate few pain behaviors.

Deficient knowledge: Home management of wound

Outcomes: Parents, and the child as appropriate, will state reasons for antibiotic prophylaxis and the importance of completing a full course of therapy.

Parents and the child as appropriate, will demonstrate prescribed techniques of wound management.

Parents, and the child as appropriate, will list signs of wound infection and state when to notify healthcare provider.

Disturbed body image related to presence of disfiguring wound

Outcome: Child will verbalize a positive body image if wound is disfiguring.

Interdisciplinary Interventions

Parents often seek treatment for their child's bite because of concern about rabies, a fatal viral infection of the central nervous system. However, the incidence of rabies is extremely low in the United States. The decision to initiate prophylactic treatment for rabies is based on the species of animal (dogs and cats are typically low risk; bats, skunks, coyotes, raccoons, and foxes are higher risk), the animal's condition, and the prevalence of rabies in the region. Rabies prophylaxis consists of passive immunization with rabies immune globulin and active immunization with human diploid cell vaccine, rhesus diploid cells (rabies vaccine adsorbed), or purified chick embryo cell vaccine. After thoroughly cleansing the wound, give the rabies immune globulin dosage as ordered, if anatomically possible, by local subcutaneous infiltration of the site. Active immunization should be given intramuscularly in the deltoid or anterolateral aspect of the thigh on days 0, 3, 7, 14, and 28 (Centers for Disease Control and Prevention [CDC], 2008).

Prompt care of the wound is the key to successful healing. Inspect the bite wound for teeth, clean the site with a 1% povidone-iodine solution, and irrigate the wound forcibly with normal saline. Closure of the wound depends on the affected site. If the wound is considered at high risk for infection, it should not be sutured. High-risk wounds include puncture wounds, minor hand or foot wounds, cat or human bites, bite wounds not treated within 12 hours, and wounds in the immunocompromised patient.

Antibiotic prophylaxis may be indicated depending on the wound site (hand or face) and severity (deep wounds, ones that cannot be adequately debrided), whether the wound was not sutured, and all high-risk wounds (Taplitz, 2004). Generally, a combination of antibiotics is given over a course of 3 to 5 days. Consider tetanus prophylaxis for all bite victims. Most bite wounds in children should be rechecked for signs of infection in 24 to 48 hours. Some children with severe injuries require hospitalization for adequate management, including operative repair, treatment of extensive local infection, or correcting poor adherence to therapeutic regimen. Offer psychological support and refer if needed, because violent dog attacks are associated with risk of posttraumatic stress disorder (Peters, Sottiaux, Appelboom et al., 2004).

Teach the parents how to assess for signs and symptoms of wound infection and when to notify the healthcare provider. Discuss potential fears and behavioral problems of the child and how parents might manage them. Teach children to avoid stray and wild animals, and not to provoke animals.

Arthropod Stings and Bites

QUESTION: How common a childhood problem is an allergic reaction to an insect sting or bite?

Animals in the Arachnida (spiders, scorpions, ticks, mites) and the Insecta (lice, fleas, bedbugs, flies, bees, ants) classes are probably accountable for more morbidity and mortality worldwide than any other group of venomous creatures (Steen, Carbonaro, & Schwartz, 2004). Hymenoptera (bees, wasps, hornets, yellow jackets, and ants) are responsible for 50% of human deaths from venomous bites and stings. Allergic reactions are the most common result of these stings.

ANSWER: Most children are stung or bitten during their childhood, and according to the National Institutes of Health, approximately 4 in 1,000 will have an allergic experience.

Assessment

Reactions to insect stings and bites can vary from mild (slight swelling, erythema, and pain at the site) to moderate (generalized pruritus and urticaria) to severe (wheezing, nausea and vomiting, laryngedema, hypotension, and shock). A bee's stinger is barbed and remains in the victim's skin.

Interdisciplinary Interventions

Treatment of stings is based on the severity of the reaction. Most respond to treatment at home (Community Care 31-1). Treatment for severe anaphylactic reactions is discussed in the following section.

ANAPHYLAXIS

QUESTION: Is Chase exhibiting signs of an anaphylactic reaction?

Anaphylaxis, or anaphylactic shock, is a life-threatening emergency caused by an acute systemic allergic or hypersensitivity reaction to an antigen. Anaphylaxis usually occurs immediately, although it can occur 30 to 60 minutes after a repeated exposure to the antigen. Almost any foreign substance is capable of eliciting anaphylaxis. The most common causes are foods (seafood, nuts, eggs), drugs (aspirin, penicillin, cephalosporins, chemotherapy), insect venom, and biologic agents (allergen extracts, iodinated radiocontrast media, latex). Incidence of anaphylaxis in the United States is estimated at 1% to 2% of the population and seems to be increasing (Lieberman, 2008). A sharp increase in the incidence of hospitalizations for anaphylaxis from food in children

COMMUNITY CARE 31-1

Treatment for Insect Stings and Bites

Teach parents, school personnel, and other caregivers to

- Remove stinger if present. Take care to remove the stinger by flicking or scraping. Do not squeeze or pull with tweezers; these actions inject any remaining venom into the wound.
- Rub the area for 15 minutes using a cotton ball soaked in a solution of meat tenderizer with a few drops of water, which may help reduce inflammation.
- Apply cold compresses to reduce site swelling and pain.
- For itching, administer diphenhydramine hydrochloride (Benadryl), 4 to 5 mg/kg/day (to a total of 200 mg/day) divided into four doses.
- Call a healthcare provider immediately if the child has:
 - Breathing or swallowing difficulty
 - Hives
 - Ten or more stings
 - A sting in the mouth
- Call a healthcare provider later if:
 - The stinger cannot be removed
 - The swelling continues to spread after 24 hours
 - Swelling of the hand (or foot) spreads past the wrist (or ankle)

younger than 5 years of age has been noted (Lieberman, 2008).

Severe anaphylactic reactions can result in death. Prompt diagnosis and immediate intervention with appropriate therapy are necessary to avert this outcome.

Initial exposure to the antigen causes the formation of antibodies, usually of the immunoglobulin E class. Upon repeated exposure to the same antigen, symptoms develop and the hypersensitivity reaction may occur. The antibody-antigen reaction causes a massive release of chemical mediators (such as histamine) from mast cells and basophils throughout the body.

Assessment

The common manifestations of anaphylaxis include urticaria, angioedema (a condition characterized by development of urticaria and edematous areas of skin, mucous membranes, or viscera), bronchospasm, laryngeal edema, hypotension, hyperperistalsis, and cardiac arrhythmias.

The degree of the sensitivity reaction depends on the antigen's nature and the child's degree of **atopy**. Atopy

is the inherited tendency to form immunoglobulin E antibodies. Often, a strong family history exists for allergies or hypersensitivity reactions to particular drugs, insects, or foods. Take the family history seriously; it indicates a need for the child to avoid certain drugs or foods.

ANSWER: Chase has facial edema and laryngeal edema, both of which are signs of an anaphylactic reaction.

Nursing Diagnoses and Outcomes

QUESTION: Which nursing diagnosis is appropriate for Chase?

Nursing diagnoses and outcomes for the child experiencing an emergency are discussed in Nursing Plan of Care 31-1. In addition, the following diagnoses and outcomes apply for the child experiencing an anaphylactic reaction:

Ineffective airway clearance related to effects of laryngoedema

Outcome: Child will have interventions immediately implemented to reduce laryngoedema and optimize airway patency.

Decreased cardiac output related to effects of vasodilation

Outcome: Child's signs of decreased cardiac output will be recognized promptly and interventions will be initiated immediately.

Ineffective breathing pattern related to effects of bronchospasm

Outcome: Child will generate an effective breathing pattern or will have interventions implemented to support an effective breathing pattern to optimize gas exchange.

ANSWER: Potential for ineffective breathing pattern related to laryngeal edema would be an appropriate nursing diagnosis for Chase.

Interdisciplinary Interventions

QUESTION: Did Chase's family respond appropriately? What medications do you anticipate Chase receiving? Develop a teaching plan for Chase's family after this emergency.

As with all allergic disorders, avoidance or preventive measures for patients at high risk are the primary treatment. However, most serious anaphylactic reactions are unanticipated. Therefore, immediate recognition and treatment of

CHART 31-2 INTERDISCIPLINARY INTERVENTIONS: MANAGING ANAPHYLAXIS

- Administer epinephrine intramuscularly or intravenously to reverse histamine release and hypotension.
- Rapidly assess ABCs and intervene as necessary.
- Maintain patent airway.
- Administer oxygen.
- Start IV.
- Stop antigen release or slow absorption. If the antigen responsible for the anaphylaxis has been injected or is infusing intravenously, discontinue immediately.
- Administer albuterol aerosols to reverse bronchospasm.
- Administer antihistamines such as H₁ or H₂ antagonists (e.g., diphenhydramine or ranitidine) to counteract histamine release.
- Administer fluids if hypotension is not responsive to epinephrine and H₁ and H₂ antagonists.
- Administer corticosteroids (e.g., methylprednisolone) after initial treatment to prevent recurrence of anaphylaxis.
- Continually monitor ABCs, vital signs, and response to treatment. Observe for late-phase symptoms.

anaphylaxis are critical to prevent death resulting from upper airway obstruction, shock, or both (Chart 31-2).

Children who have experienced an anaphylactic reaction should be hospitalized for observation, because there may be a biphasic reaction in which symptoms recur (as late as 28 hours) after initially resolving in response to therapy. After the causative antigens have been identified, teach the child and family how to prevent anaphylaxis (Community Care 31-2).

ANSWER: By seeking medical treatment immediately, Chase's family responded appropriately to his signs of an anaphylactic reaction. You can anticipate that Chase will receive epinephrine as well as an antihistamine such as diphenhydramine (Benadryl) in the emergency room (see Chart 31-2 for more details). Your teaching plan for the Whitworth family would include strategies to avoid hornets and the use of an EpiPen.

EPISTAXIS

The nose is highly vascular and is susceptible to bleeding. Common causes of **epistaxis** (nosebleed) include trauma, frequent nose picking, infection, inflammation, low environmental humidity, and foreign bodies. Children are more susceptible during respiratory infections and during the winter, when dry air irritates the nasal mucosa. Epistaxis is rare in infants and common in children, with the incidence decreasing after puberty. In

COMMUNITY CARE 31-2

Preventing Anaphylaxis

Teach parents and child to:

- Notify caregivers and school personnel of known allergies
- Have child wear a medical alert bracelet, as appropriate
- Reduce the risk of exposure as appropriate to the situation (e.g., a child allergic to bees should wear shoes when outside, wear clothing that covers extremities, not walk through flower beds, and not wear perfume or brightly colored clothing)
- Take allergy medications before unavoidable exposure to known allergens
- Keep a kit with him or her at all times that contains self-injectable epinephrine and an oral antihistamine if the child has had an anaphylactic reaction. Teach parents, and the child as appropriate, and school or daycare personnel how to use the EpiPen appropriately.
- Notify an adult at the first signs of anaphylaxis; instruct adults to call an ambulance and get the child to the nearest ED

adolescent females, epistaxis may be associated with pregnancy.

Epistaxis is usually mild and responds to home management, but occasionally bleeding is severe enough to require transfusion. Epistaxis may also signal an underlying pathology such as Osler-Weber-Rendu disease (hereditary hemorrhagic telangiectasia) or juvenile angiofibroma, usually found in adolescent males.

Assessment

Epistaxis often occurs without warning, with blood flowing from one or both nostrils. Evaluate vital signs for indicators of hemodynamic instability (increased heart and respiratory rates, decreased blood pressure, or orthostatic changes). Examine the skin and mucous membranes for petechiae and ecchymosis, which may indicate coagulopathy. Inspect the nasopharynx and oropharynx for masses and blood dripping from a posterior bleeding site. Examine the nares visually and attempt to identify the site of bleeding (Fig. 31-7). Most commonly, the anterior nasal septum is the site of origin in epistaxis (Douglas & Wormald, 2007).

Laboratory workup is warranted when the child with epistaxis has a family history of a bleeding disorder, spontaneous bleeding of other areas in the body, continued bleeding lasting longer than 20 minutes despite direct pressure, or onset of recurrent epistaxis before 2 years of

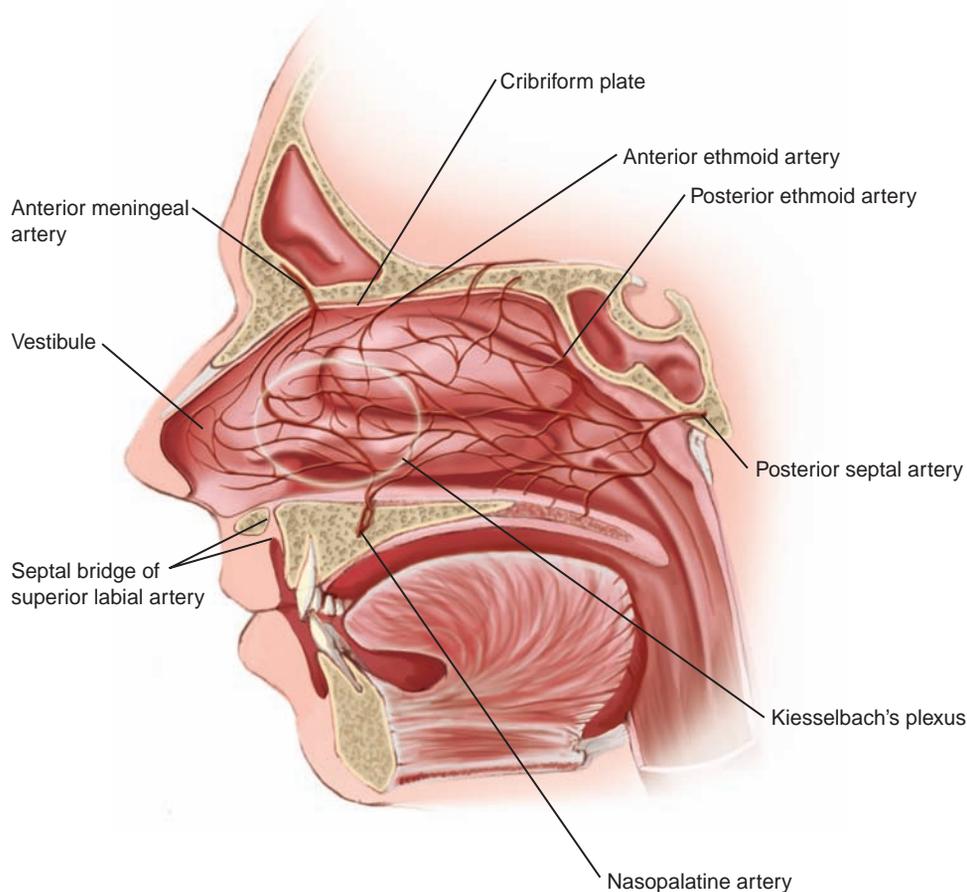

FIGURE 31–7. Most nosebleeds arise from the anteroinferior portion of the nasal septum, an area called Kiesselbach's plexus.

age or when the hematocrit level decreases substantially secondary to epistaxis.

Interdisciplinary Interventions

Most nosebleeds can be managed effectively outside the acute care setting. Teach parents and children techniques that may prevent nosebleeds. Also teach school and day-care personnel immediate management of nosebleeds (TIP 31–2). Petroleum jelly and antiseptic cream may be effective, but studies have methodologic limitations and more research is needed to determine optimal treatment (Burton & Doree, 2004). A healthcare provider might need to provide more intensive intervention for bleeding that does not stop with home management. Maintain the child in a sitting position with the head tilted forward to avoid blood dripping into the posterior pharynx. If the anterior nasal septum is the site, apply direct pressure on the bleeding site by compressing the external nares for 10 minutes (Fig. 31–8). If this measure does not stop the bleeding, cauterization, either chemical (silver nitrate) or electrical, of the site by trained personnel may be required for definitive control of bleeding from the anterior nasal septum (Douglas & Wormald, 2007). Cauterization is not indicated for epistaxis in children with bleeding

disorders because of the likelihood of multiple bleeding sites and the risk of severely damaging and perforating the nasal mucosa in the attempt to control bleeding from the various sites.

For active bleeding that is not controlled by pressure and cauterization, spray phenylephrine (Neo-Synephrine), 0.25% to 0.5%, into the nares. If phenylephrine does not control the bleeding, insert a cotton pledget soaked in 2% lidocaine (Xylocaine) or tetracaine phenylephrine, Neo-Synephrine, or epinephrine, 0.25% to 0.5%, tightly into the affected nares. Leave the pledget in place for 10 minutes while applying pressure, then reassess the nares for continued active bleeding. If necessary, insert another pledget, soaked with a vasoconstrictor, and leave it in place for an additional 10 minutes.

If the bleeding site is anterior and not controlled by pressure, vasoconstrictors, or cauterization, then anterior packing by a physician may be performed. Anterior packing is contraindicated in the child with nasal trauma or when a cerebrospinal fluid leak is suspected. Anterior packing impregnated with antibiotics remains in place 2 to 3 days. Antifibrinolytic agents delivered via gel are also effective and better tolerated than packing, but use has not been widely adopted (Douglas & Wormald, 2007).

TIP 31–2 A Teaching Intervention Plan for Preventing and Managing Epistaxis

Nursing diagnoses and outcomes

- Risk for aspiration related to presence of blood in oropharynx

Outcome

- Child will not aspirate blood into bronchial tree.
- Child will maintain patent airway.
- **Deficient fluid volume related to effects of bleeding**

Outcome

- Child will be brought to healthcare facility before fluid volume deficit exerts a negative affect on hemodynamic stability.
- **Anxiety related to bleeding**

Outcome

- Child will be calm and able to follow directions as age appropriate.
- **Deficient knowledge: Community management of epistaxis**

Outcome

- Caregivers and child, if appropriate, will implement appropriate interventions to control nosebleed.

Teach the child/family

Preventing Epistaxis

- Increase the humidity in the home or the child's bedroom by using a humidifier.

- Instill saline nose drops before having the child blow nose.
- Have the child avoid picking nose.

Managing Epistaxis

- Position the child erect, sitting with head tilted forward to avoid blood dripping posteriorly into the pharynx.
- Pinch the nose.
 - Tightly pinch the soft parts of the nose against the center wall for 10 minutes; this should be timed by a clock, not estimated.
 - Do not release the pressure for 10 minutes.
 - Encourage child to remain calm and quiet, and to breathe through the mouth.
- If bleeding continues,
 - Soak gauze in phenylephrine hydrochloride (Neo-Synephrine) or petroleum jelly and insert it into the nostril.
 - Pinch the nose with gauze in place for another 10 minutes.
 - Be aware that swallowed blood may irritate the stomach and cause vomiting.

Contact the Healthcare Provider if:

- Bleeding does not stop within 20 minutes
- Child feels dizzy or faint

Alert! Keep emergency resuscitation equipment readily available when using anesthetic packing. The anesthetized airway may cause the child to lose protective reflexes.

FIGURE 31–8. Compression of the nasal alae controls most epistaxis, which commonly occurs in Kiesselbach's plexus (Little's area).

Sinusitis is a complication of nasal packing, and oral antibiotics should be administered prophylactically. Antibiotics to cover for coagulase-positive *Staphylococcus* (e.g., first-generation cephalosporins) should be used, because *S. aureus*, which may cause toxic shock syndrome, is often present in the nares. Administer pain medication to children who need nasal packing. Nursing care includes maintaining a patent airway, watching for signs of hypoxia or respiratory distress, monitoring fluid balance, and reducing anxiety in the child and family. The amount of blood often seems quite large, which is frightening to the child and family. A child with packing in place is unable to breathe through the nose, which also causes anxiety.

ENVIRONMENTAL EXPOSURE INJURIES

Various environmental exposures can injure an infant or child. Most often, injury occurs because the infant or child physically cannot remove or protect himself or herself from the source of injury. The environmental exposure injuries discussed here include prolonged exposures to heat (hyperthermia) or cold (hypothermia), smoke

inhalation, and near-drowning. See Chapter 25 for discussion of sunburn.

Heat Illnesses

Prolonged exposure to heat without protective equipment can cause hyperthermia. Hyperthermia occurs when the thermoregulatory set point of the body remains normal but heat gain exceeds heat loss despite the body's efforts to return to the set point. Heatstroke is a condition caused by failure of the body's thermoregulatory system during prolonged exposure to heat and high relative humidity. Heatstroke is marked by body temperature more than 105 °F (40.6 °C), headache, and confusion. Sweating is often absent, which if untreated can progress to delirium and coma (Grunbenhoff, du Ford, & Roosevelt, 2007). Severe heat illness may increase core temperature to the level at which cellular injury occurs as a result of dysfunction of enzymatic processes and the related cellular proteins (Grunbenhoff et al., 2007). Without treatment, individuals with heat stroke die. Even with treatment, heatstroke can be fatal or result in long-term neurologic sequelae.

Hyperthermia is a preventable illness that is manifested by heat cramps, exhaustion, or stroke. Heat illness is most commonly seen in the tropical regions of the world, but heat is responsible for the deaths of more than 3,400 people per year in the United States; 7% of these deaths are in children younger than 15 years (Grunbenhoff et al., 2007). The elderly population is most vulnerable, but children are at risk as well, especially young athletes, infants left in automobiles on hot days, children with cystic fibrosis, and those with anhidrosis. For more information on heat illnesses, see Table 31–5.

Prevention is the best treatment for heat illnesses. Teach children and parents measures to prevent overheating in hot environments. Children should be dressed in lightweight clothes and hats or visors. Keep children well hydrated by providing and offering cool drinks every 15 to 30 minutes, even if the child is not thirsty. Water is a good choice, because children sweat less than adults and thus lose less salt. Activity level should be regulated on the basis of environmental conditions and should be restricted when temperature or humidity is high. Scheduled rest periods in the shade should be enforced to promote heat dissipation. Athletes are at particular risk for heat illnesses. They should be specifically instructed to avoid both water deprivation and wearing excessive clothing that reduces evaporation of sweat.

Hypothermia

Hypothermia is defined as a core body temperature less than 95 °F (35 °C). In the United States, moderate (temperature, 82.5–90 °F [28–32.2 °C]) to severe hypothermia (temperature <82.5 °F [28 °C]) causes almost 700 deaths per year (CDC, 2005). All ages are affected, although infants and children are at particular risk because of their greater ratio of surface area to body weight, thin skin, limited amount of subcutaneous fat, and immature

thermoregulatory system. The causes of hypothermia include immersion in icy water, prolonged exposure to cold temperatures, and exposure for an extended time during a medical evaluation. Hypothermia is also common in patients with sepsis and shock (see Chapter 25 for discussion of frostbite).

Alert! Hypothermia can lead to prolonged bleeding, metabolic acidosis, decreased respiratory rate, bradycardia, and cardiopulmonary arrest.

Assessment

Mental status may remain normal in mild hypothermia. Central nervous system function becomes progressively impaired as the temperature decreases. Increasing lethargy, incoordination, apathy, confusion, clumsiness, irritability, hallucinations, and bradycardia are seen. A decreasing level of consciousness is seen in moderate hypothermia, and coma occurs with severe hypothermia. At a temperature of 77 °F (25 °C), profound respiratory depression occurs, followed by ventricular fibrillation or asystole, and usually results in death.

Hypothermia can mimic death, with the child demonstrating dilated pupils, muscular rigidity, faint or absent pulse, and an unobtainable blood pressure. However, life can be sustained for long periods, despite cessation of cardiac function, because of the marked decrease in oxygen consumption.

Nursing Diagnoses and Outcomes

Nursing diagnoses and outcomes for the child experiencing an emergency are discussed in Nursing Plan of Care 31–1. In addition, the following diagnoses and outcomes are appropriate for the hypothermic child:

Impaired spontaneous ventilation related to effects of decreased body temperature

Outcome: Child will maintain spontaneous ventilation or have adequate ventilatory support provided.

Hypothermia related to environmental exposure

Outcome: Child will regain normal body temperature and will suffer no long-term effects from hypothermia.

Interdisciplinary Interventions

Prevention is the best treatment. Educate families about the increased risk of hypothermia in young children. Children have higher metabolic rates than adults. They generate more heat, so children may not feel the effects of exposure. Parents should dress children appropriately for the weather and monitor their activities so that they are not exposed for long periods.

Nursing interventions for a child with hypothermia are discussed in [thePoint](#). Procedures: Use of Warming Devices. Support cardiorespiratory function as needed. If the child develops lethal dysrhythmias, defibrillation is often ineffective until the core temperature reaches 86 °F (30 °C). Drug therapy is rarely effective at low temperatures and can lead to toxicity, because hepatic and renal metabolisms are decreased.

TABLE 31-5

Heat Illnesses: Assessment and Interventions

Illness	Etiology	Assessment Findings	Interdisciplinary Interventions
Heat cramps	Prolonged or extensive exercise in a hot environment with high humidity Electrolyte depletion secondary to profuse sweating and fluid replacement with salt-poor fluids	Sudden onset of intermittent, excruciating cramps in the skeletal muscles Usually occurs after exercise, during the cool-down period	Have child stop exertion and rest in a cool, shaded area. For mild cramps, administer oral salt solution (1 tsp salt in 500 mL water). Give over 1 to 2 hours. For severe cramps, administer 0.9% normal saline (NS) (20 mL/kg) IV over 1 to 2 hours.
Heat exhaustion (heat prostration)	Prolonged or extensive exercise in a hot environment, with high humidity and inadequate fluid replacement Most common heat illness Without treatment, can progress to heat stroke	Onset over 30 minutes, but may have a more acute onset, such as the “parade ground faint” Headache Intense thirst Inability to work or play Tachycardia Orthostatic hypotension Nausea and vomiting Lethargy Central nervous system dysfunction, such as hyperventilation, agitation, incoordination, paresthesia, psychosis Intractable seizures and muscle cramps (in severe cases) Normal body temperature or body temperature as high as 102.2 °F (39 °C) with high ambient temperatures or exercise Hemoconcentration Hyper- or hyponatremia (depends on type of fluids ingested) Hyperchloremia Respiratory alkalosis (resulting from hyperventilation)	Provide the child with a cool, well-ventilated place to rest. Remove some clothing, spray with water, and fan the child. Replace fluids orally (or IV if the child is weak or has an impaired level of consciousness); liquids should be cool with unrestricted dietary sodium. If IV fluids are required, administer bolus of 0.9% NS, 20 mL/kg given over 20 minutes. Repeat boluses to correct electrolyte balance and to restore blood pressure. Treat severe cases with an initial IV of 5 mL/kg of 3% NS over 20 minutes followed by a second dose of 5 mL/kg over 4 to 6 hours.
Heat stroke (a true medical emergency)	Thermoregulatory failure after prolonged exposure to high environmental temperatures and humidity	Hyperpyrexia (≥ 105 °F or 40.6 °C) Hot, dry skin, typically with anhidrosis (absence of sweating) Moderate central nervous system disturbances such as headache, dizziness, faintness, and confusion Severe central nervous system disturbances such as stupor, seizures, coma, and sudden loss of consciousness (more common when treatment is delayed) Tachycardia and an increased pulse pressure initially Ashen cyanosis and a thin, rapid pulse later	Remove the child from the source of heat. Maintain patent airway and cardiovascular support. If comatose, may require intubation to secure airway. Remove clothing and actively cool the child. Monitor temperature closely with a rectal probe. Be aware that antipyretics such as acetaminophen are not useful. Perform active cooling measures such as sprinkling the child with water, directing fans toward child, applying a cooling blanket, giving an ice bath (although

TABLE 31-5

Heat Illnesses: Assessment and Interventions (Continued)

Illness	Etiology	Assessment Findings	Interdisciplinary Interventions
			this makes other monitoring mechanisms difficult). Discontinue active cooling measures when the core temperature decreases to 102.2 °F (39 °C). Avoid shivering, because this increases heat production. Carefully monitor electrocardiogram, central venous pressure, arterial blood pressure, and urine output in a patient with signs of failing cardiac output (ashen skin, tachycardia, hypotension); such a patient is in danger of imminent death.

Alert! External rewarming techniques may result in early warming of the skin and extremities and peripheral vasodilation, and worsen hypotension and shock. This phenomenon, called *afterdrop*, is characterized by a decrease in the core temperature as it receives cold blood from the periphery.

Active rewarming can be accomplished through external or core rewarming techniques (Nursing Interventions 31-3). Core rewarming is the most appropriate choice when the temperature is 86 °F (30 °C) or less with cardiopulmonary arrest. Survival of severely hypothermic patients after prolonged periods of nonperfusing cardiac

rhythm has been reported (Kempainen & Brunette, 2004). Clinical judgment should be used to determine when resuscitative efforts should cease (American Heart Association, 2005b). Often the child is rewarmed to 95 °F (35 °C) prior to stopping resuscitation.

Smoke Inhalation

Smoke inhalation usually results from a fire, which may also cause burns (for a discussion of burn injuries see Chapter 25). Exposure to fire, smoke, or both causes substantial damage to the child’s pulmonary tree. In fact, most fatalities resulting from fires are the result of inhalation of toxic gas (e.g., carbon monoxide and cyanide) rather than burns (Mlcak, Suman, & Herndon, 2007). Inhalation injuries are the primary cause of death in burn patients within the first 24 hours.

Several factors place children at high risk for inhalation injuries. Their higher respiratory rate leads to increased intake of toxic gases and contributes to insensible fluid losses from the pulmonary tree. They have a small airway diameter and increased proportion of soft tissue, and the diameter may become even smaller because of inhalation of hot air and irritants, which causes edema. Progressive airway edema may ultimately lead to airway obstruction.

Alert! Suspect smoke inhalation and upper airway burns in a child with facial burns.

Assessment

Clinically, the child may have singed eyebrows, carbonaceous sputum, tachypnea, and other signs of respiratory distress such as wheezing, rhonchi, rales, or stridor. However, symptoms of an inhalation injury may not be manifest for up to 24 hours after exposure. Therefore, close

NURSING INTERVENTIONS 31-3

Core Rewarming Methods

The nurse may assist in administering the following methods:

- Heated, humidified oxygen
- Warmed IV fluids
- Heated (104–111 °F [40–44 °C]) lavage of Bladder
Stomach
Colon
Peritoneum (1.5% dialysate, short dwell time)
- Left hemithorax (pleural lavage)
- Open thoracotomy with mediastinal irrigation
- Venovenous or arteriovenous circuits with heating element
- Extracorporeal circulation (heart–lung pump)

observation of respiratory status is necessary during this time. Because the carbon monoxide molecule has a 250-fold higher affinity for hemoglobin than oxygen, tissue hypoxia occurs as carbon monoxide binds to hemoglobin, reducing its oxygen carrying capacity and decreasing oxygen saturation. Without prompt treatment, serum carboxyhemoglobin levels more than 50% can cause irreversible central nervous system damage. Central nervous system signs of carbon monoxide poisoning range from slight dyspnea, decreased visual acuity, irritability, nausea, and fatigue to confusion, ataxia, and coma.

caREminder

Do not rely on pulse oximetry to measure oxygen saturation. Pulse oximetry does not distinguish between oxyhemoglobin and carboxyhemoglobin, so the actual oxygen saturation is less than the pulse oximeter reflects.

Nursing Diagnoses and Outcomes

Nursing Plan of Care 31–1 lists nursing diagnoses and outcomes applicable to the child experiencing an emergency. The following diagnoses and outcomes may also be appropriate for the child after smoke inhalation:

Ineffective airway clearance related to effects of edema and inhaled toxins causing mucosal sloughing

Outcome: Child will be intubated early, if indicated, and child's airway will remain patent.

Impaired gas exchange related to effects of cellular damage, carboxyhemoglobin replacing oxyhemoglobin, pulmonary edema, and smoke exposure causing decreased surfactant resulting in atelectasis

Outcome: Child will maintain adequate cellular oxygenation.

Risk for deficient fluid volume related to effects of tachypnea, cellular damage, and increased fluid demands

Outcome: Child will receive adequate fluids to prevent dehydration, will have accurate intake and output monitored, and will not develop pulmonary edema because of overhydration.

Interdisciplinary Interventions

Administer 100% oxygen via a snug-fitting, nonre-breather mask to all children with smoke inhalation. The usual 4-hour half-life of carboxyhemoglobin can be reduced to less than 1 hour by administering 100% oxygen (Mlcak et al., 2007). Children with severe laryngeal edema, hypoxemia, and audible stridor require intubation to maintain a secure and patent airway. Obtain baseline arterial blood gases, pH, and carboxyhemoglobin levels, and monitor them periodically.

Maintain a neutral thermal environment. The child is susceptible to hypothermia because of associated burn injuries and exposure for treatment of injuries. Hypothermia and alkalosis decrease the dissociation of carbon monoxide from hemoglobin. Hyperbaric oxygen therapy may be considered.

Encourage the child to cough and breathe deeply to promote airway clearance and to help prevent subsequent pneumonia and respiratory distress syndrome. Suctioning, chest physiotherapy, and medications (e.g., bronchodilators, mucolytics) help clear secretions (Mlcak et al., 2007). Also promote early ambulation out of bed, even in the child who is ventilated.

Monitor the child for hypoxia, respiratory distress, and pulmonary edema. Even if not seriously injured or intubated, children who have been in fires should be hospitalized for observation for at least 24 hours.

Near-Drowning

Globally, drowning is the principal cause of unintentional injury deaths in children age birth to 4 years, with a mortality rate of 7.4 in 100,000 (Hyder, Borse, Blum, et al., 2008). Males, children younger than age 4, males 15 to 18 years of age, and those who have a seizure disorder are at particular risk (Somers, Chiasson, & Smith, 2005).

Drowning is defined as death resulting from suffocation by submersion in a liquid. Near-drowning is defined as survival, although sometimes temporary, for at least 24 hours after a submersion episode.

Children can drown whenever unsupervised around any body of water, including bathtubs, toilets, and buckets of water. Most drownings occur because of lack of adequate barriers to prevent access to a swimming pool. Precipitating factors include trauma (including child abuse), intoxication (plays a significant role in adolescent drownings), seizure disorders, and exhaustion. Whether in fresh- or saltwater, the end result of near-drowning is the same: pulmonary compliance decreases, airway resistance increases, pulmonary arterial pressure increases, and pulmonary flow decreases. These changes result in hypoxemia, which leads to cardiac arrest and ischemia.

Although all organs are susceptible to ischemic injury, the central nervous system is most vulnerable, and prognosis depends on the degree of central nervous system injury (see Chapter 21 for discussion of increased intracranial pressure). The degree of brain injury depends on the submersion time (which is often underestimated), the water temperature, and the speed with which resuscitative measures are initiated. The longer the submersion, the poorer the prognosis (Suominen et al., 2002). Irreversible cerebral injury from hypoxia begins to occur after about 3 to 5 minutes of submersion. Submersion in cold water occasionally may be compatible with recovery after longer periods (Modell et al., 2004); cold water may increase the likelihood of survival by decreasing the cerebral metabolic rate.

Assessment

Initially, the clinical problems of children after a near-drowning episode involve the pulmonary and neurologic systems. The child may present with varying degrees of neurologic insult, from alert with minimal injury to full cardiopulmonary arrest. Cerebral edema may develop later, with irritability, confusion, and lethargy leading to seizures and coma. Respiratory symptoms range from

cough, dyspnea, tachypnea, adventitious breath sounds, and expectoration of pink frothy sputum to apnea.

Initial arterial blood gas measurements often indicate hypoxemia and metabolic acidosis. Chest radiograph results vary, but should be obtained to provide a baseline against which to compare later radiograph. Electrolyte abnormalities may be seen. Renal damage resulting from hypoperfusion, hypoxia, and ischemia is revealed by oliguria, proteinuria, and elevated blood urea nitrogen and creatinine.

Nursing Diagnoses and Outcomes

In addition to the nursing diagnoses discussed in Nursing Plan of Care 31–1, nursing diagnoses and outcomes applicable to the child after near-drowning are the following:

Impaired gas exchange related to effects of aspiration, hypoxia, pulmonary edema

Outcome: Child will demonstrate adequate oxygenation and no signs of respiratory distress.

Ineffective airway clearance related to effects of aspiration of water and foreign material, accumulated secretions, and artificial airway

Outcome: Child will maintain a patent airway, and secretions will be adequately cleared to maintain gas exchange.

Ineffective breathing pattern related to effects of cerebral hypoxia

Outcome: Child will be supported in maintaining a breathing pattern that maintains adequate gas exchange.

Ineffective tissue perfusion: Cardiopulmonary related to effects of dysrhythmias, hypovolemia

Outcome: Child will maintain adequate cardiopulmonary perfusion, as evidenced by normal sinus rhythm, strong bilateral peripheral pulses, and urine output of at least 1 mL/kg/hour.

Ineffective tissue perfusion: Cerebral related to effects of hypoxia, cerebral edema, and increased intracranial pressure

Outcome: Child will maintain adequate cerebral perfusion; signs of decreased perfusion will be recognized immediately and interventions implemented.

Excess fluid volume related to fluid resuscitation, renal damage from hypoxia

Outcome: Child will maintain fluid balance, evidenced by absence of edema, urine output of at least 1 mL/kg/hour, and electrolytes and urine specific gravity within normal ranges.

Deficient knowledge: Water safety

Outcomes: Family will discuss and implement water safety measures.

Family will not experience future near-drowning events.

Interdisciplinary Interventions

Manage the child near-drowning victim in the same fashion as the trauma patient. Initially, focus on assessing the ABCs and correcting hypoxemia.

Continue to monitor and support pulmonary, cardiac, and neurologic function. Assess airway patency, breath sounds, color, and respiratory effort, and assist with ventilation as indicated. Cardiac assessment includes heart

COMMUNITY CARE 31–3

Water Safety

Instruct parents and other care providers to

- Supervise children *constantly* around *any* body of water, including bathtubs
- Designate one person to watch the child, especially when many adults are present and each assumes the others are watching the child
- Fence any pool or hot tub and equip it with self-closing gates
- Empty pails and buckets of fluid immediately after use
- Keep toilet lids closed and secured, especially around young children whose heads are relatively large and heavy and, when they fall in head first, they cannot extricate themselves
- Allow children with a seizure disorder to swim or take a bath only with supervision, regardless of age
- Discuss with adolescents the dangers of combining drugs or alcohol with swimming or water sports

rate and rhythm, blood pressure, capillary refill, and pulses. Monitor intake and output to assess fluid balance and renal function. Catheters may be placed to monitor arterial, central venous, and/or pulmonary artery pressure. Assessment of neurologic functioning includes level of consciousness, pupillary response, reflexes, and presence of posturing or seizure activity. As with all pediatric emergencies, provide family support. If the child survives, or if other children live in the house, instruct the family in water safety measures (Community Care 31–3).

POISONING

A poison is a substance that causes harmful effects upon exposure. Globally, poisoning is the fifth leading cause of death in children younger than 5 years (Kendrick, Smith, Sutton et al., 2008). Children younger than age 2 years are poisoned more frequently from household products than from medications; the reverse is seen in children older than 2 years (Kendrick et al.). More than 1.5 million calls are made to poison centers annually with questions concerning children (Bronstein et al., 2007). Children younger than 3 years of age were involved in 38% of poisoning cases, and 51% occurred in children younger than 6 years (Bronstein et al.). More than 90% of these events occur at home, with the majority being managed at home (Bronstein et al.).

Poisoning ingestions in infants are often the result of therapeutic overdosing. Ingestions are most common in children 1 to 6 years old. Children are naturally curious and often explore by tasting. They also imitate adult behavior. If they

witness a parent take medication, they may try some themselves or may feed the medication to a younger sibling.

KidKare ■ Never tell a child that medicine is candy, which may increase the child's desire to obtain it. Tell the child it is medicine and is taken for a specific reason.

Young children usually ingest only a single substance and, because they are generally closely watched, the time from ingestion to discovery and treatment is brief. Children younger than 6 years most frequently ingest substances such as cosmetics and personal care products, cleaning substances, analgesics, foreign bodies, topical agents, and cough and cold preparations (Bronstein et al., 2007). Such agents may not be the most toxic, but are the most readily accessible to children.

Adolescents may be affected by drug experimentation or suicide attempts. Therefore, poisoning in adolescents often involves multiple substances, with a delay between when exposure occurs and when medical treatment is obtained.

Assessment

The child may have a wide range of symptoms, from none to coma. Obtaining an accurate history is paramount to successful treatment. Be sure to determine the following information:

- What was ingested
- How much was ingested (one swallow of liquid approximately equals a volume of 5 mL)
- When it occurred
- What, if any, therapy was initiated before arrival in the ED

WORLDVIEW: Folk remedies may contain toxic agents, so use of such remedies should be included in the history. For example, Hispanic and other cultures use mint tea to treat colic and minor ailments. Most mint teas are not toxic, but mint leaves that contain pennyroyal oil can be lethal.

Recommended tests include serum glucose, electrolytes, serum osmolarity, and anion gap. Quantifying drug levels whenever possible is also helpful in determining further interventions and administration of antidotes. An elevated anion gap value is characteristic of the acidosis seen in poisonings. The formula to calculate the anion gap and common etiologies for increased anion gap values are listed in Chart 31–3.

Nursing Diagnoses and Outcomes

Nursing diagnoses and outcomes for the child experiencing an emergency are discussed in Nursing Plan of Care 31–1. Nursing diagnoses applicable to the poisoned child depend on the specific poison and symptoms the child displays (e.g., risk for aspiration applies to the child who has a depressed level of consciousness resulting from the

CHART 31–3 COMMON CAUSES FOR INCREASED ANION GAP VALUES*

Utilizing the mnemonic AT MUD PILES (Woolf, 1993):

Alcohol
Toluene
Methanol
Uremia
Diabetic ketoacidosis
Paraldehyde
Iron
Lactic acidosis
Ethylene glycol
Salicylates

*Anion gap is calculated using the formula: $\text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-)$. The normal value is less than 16 mEq/L.

poison). An additional nursing diagnosis and outcomes are as follows:

Deficient knowledge: Poisoning

Outcomes: Family will discuss poison prevention techniques and how these techniques change as the child grows and develops.

Family will describe first-aid measures appropriate for poisoning, including having the local poison control center phone number readily accessible.

Interdisciplinary Interventions

Obviously, preventing poisoning is the key (see Chapters 4–7). Teach parents to keep medications in their original, childproof containers, and lock them out of children's reach. Advise them to store cleaning solutions, cosmetics, and hydrocarbons (e.g., gasoline, solvents and thinners, polishes) in high, locked cabinets (Fig. 31–9). Advise them to make the child's environment free of lead-based paints and poisonous plants (Community Care 31–4).

Perform a rapid assessment and implement immediate interventions to ensure that the ABCs are managed. Secure IV access and obtain a serum glucose level, because hypoglycemia is a common manifestation of acute poisoning. Treat shock with fluids and vasopressors as necessary. To reduce the absorption of potentially toxic substances, gastric decontamination may be required (Table 31–6). Depending on the severity of the ingestion, it may occur immediately after the airway is secured, during resuscitation. An **antidote** (a substance that neutralizes the poison or its effects) may also be administered. Some metallic poisons (Table 31–7) can be countered with **chelation** therapy, a process during which certain compounds are used to bind the toxin, making it inactive or less injurious.

FIGURE 31–9. This frustrated child cannot reach the tempting, but potentially dangerous, poisons and cleaning supplies stored safely out of her reach.

caREminder

Treat the child, not the poison. Specific treatment depends on the type and amount of toxin, time since exposure, and the child's symptoms. Many children do not need treatment.

Iron

Iron overdose is one of the most common causes of poisoning death in children (Madiwale & Liebelt, 2006). Iron-containing compounds are readily available as brightly colored, sugar-coated tablets and often are viewed by parents as a harmless vitamin. Prenatal iron preparations are often the source. Moderate to severe toxicity occurs after ingestion of 20 to 60 mg/kg; a dose of iron of more than 200 mg/kg is potentially lethal (Baranwal & Singhi, 2003). The number of pills ingested may be useful in determining whether the dose was toxic. Monitoring serum iron levels is critical in the management of the patient. See Table 31–7 for clinical effects of iron ingestion.

Management includes assessing and monitoring the ABCs, gastric decontamination, and chelation therapy (administering something that binds with iron, such as deferoxamine). Activated charcoal (see Table 31–6) does not bind with iron and so is not useful for iron poisoning.

Lead

Lead poisoning can occur after a child ingests substances that contain lead (Community Care 31–5). Lead exposure is most commonly chronic, although occasionally a child ingests a large quantity of lead at one time.

COMMUNITY CARE 31–4

Plant Poisonings

Educate parents and caregivers about which common plants are poisonous and to limit the child's access to them (not an inclusive list):

Azalea
 Castor bean
 Cherry (pits)
 Deadly nightshade
 Dumb cane (*Dieffenbachia*)
 English ivy
 Holly
 Jimsonweed
 Lily of the valley
 Mistletoe (berries)
 Mushrooms (certain species)
 Oleander
 Potatoes (sprouts)
 Rosary pea
 Rhododendron
 Rhubarb (leaves)

Water hemlock
 Yew

Tell parents and caregivers to do the following if the child ingests a poisonous plant:

- Stay calm.
- Call the regional poison control center or the national number (800) 222-1222.
- Describe symptoms (if any) and name of plant if known.
- Follow instructions from poison control center.
- Take plant with you when seeking treatment.

Teach parents and caregivers the following poison prevention tips:

- Supervise the child's activities.
- Place household plants out of reach.
- Teach children not to eat any plant without permission.

TABLE 31-6

Gastric Decontamination

Decontamination Method	Method of Action	Indications and Dosage	Contraindications and Considerations
Activated charcoal	Absorbs substances in stomach and gastrointestinal tract	<p>Indications: ingestion of most drugs, including acetaminophen, arsenic, barbiturates, camphor, chlorpromazine, cocaine, digitalis, iodine, lead, mercury salts, muscarine, nicotine, opioids, oxalates, parathion, penicillin, petroleum distillates, phenol, phenolphthalein, quinine, salicylates, strychnine, tricyclic antidepressants</p> <p>Dosage: <1 Year: 1 g/kg every 4 to 6 hours as needed 1–12 Years: 1 to 2 g/kg every 2 to 6 hours as needed A single dose of a cathartic such as sorbitol is often mixed with the first dose of charcoal. Do not give repeated doses of sorbitol; may lead to fluid and electrolyte imbalance.</p>	<p>Method of choice in reducing drug absorption.</p> <p>Activated charcoal is not effective in the following ingestions: cyanide, mineral acids, caustic alkalis, organic solvents, iron, ethanol, methanol, or lithium.</p> <p>Do not use activated charcoal with sorbitol in patients with fructose intolerance.</p> <p>Use with gastric emptying (gastric lavage) only if within 1 hour of ingestion and child has central nervous system depression.</p> <p>Can be given orally or via nasogastric (NG) tube; cover cup to increase palatability.</p> <p>If giving via NG, prime NG tube with mineral oil and dilute activated charcoal with water to ease administration.</p>
Gastric lavage	Dilutes and removes substances from stomach	<p>Indications: child with depressed loss of consciousness or airway compromise; <i>perform tracheal intubation before lavage</i> to protect airway</p> <p>Ingestion of drugs that decrease gastric motility or are not adsorbed by charcoal</p> <p>Dosage: large-bore NG or orogastric (OG) tube inserted and the stomach lavaged with normal saline</p> <p>Amount of normal saline (NS) to instill: ≤age 12 years: 10 to 15 mL/kg (maximum, 100–150 mL/exchange); >12 years: 300 mL</p>	<p>Perform only if a life-threatening ingestion has occurred or within 1 hour of ingestion. After 1 hour of ingestion, risks outweigh benefits.</p> <p>Use large-bore (36–40-Fr) OG tube, possibly smaller in children, but tube should be bigger than pill fragments to be extracted.</p> <p>Do not perform gastric lavage when caustic substances have been ingested, because insertion of the NG or OG tube may induce vomiting and cause more burns to the esophagus and oropharynx, and may increase the risk for aspiration.</p> <p>NS is instilled and then aspirated to remove poisons, pills, and pill fragments from stomach.</p>
Whole-bowel irrigation	Used to flush toxin from entire gastrointestinal tract	<p>Indications: not well established in children; use for iron poisoning and other agents not bound by activated charcoal</p> <p>Dosage: administer a balanced polyethylene glycol solution (e.g., GoLYTELY, Colyte) orally or via NG over 4 to 6 hours until rectal effluent is clear; ≤5 years: 20 mL/kg/hour; >5 years: 0.5 to 2 L/hour</p>	<p>May also be useful to eliminate contraband that was placed in bags or condoms and swallowed.</p> <p>Solution is isosmotic and thus is not associated with fluid and electrolyte imbalance.</p> <p>The large fluid volumes used may cause nausea, vomiting, bloating, cramping, and abdominal distention.</p>

TABLE 31-7

Assessment and Management of Commonly Ingested Substances

Substance	Clinical Effects	Pharmacologic Management
Iron	<p><i>Phase 1:</i> within the first 6 hours after ingestion Symptoms range from gastrointestinal (GI) complaints (nausea, vomiting, and GI blood loss) to hypovolemic shock and coma.</p> <p><i>Phase 2:</i> 6 to 24 hours after ingestion Symptoms improve with treatment for hypovolemia (improvement may only be transitory).</p> <p><i>Phase 3:</i> may follow phase 2 or may occur rapidly after ingestion Metabolic acidosis and cyanosis; possibly coma, seizures, and shock. May result from hepatocellular injury.</p> <p><i>Phase 4:</i> 1 to 2 months after ingestion Pyloric stenosis secondary to gastric scarring; consequent obstruction, bowel stricture, and cirrhosis</p>	<p>Chelation Dose of deferoxamine depends on severity of ingestion. If initiated, IV deferoxamine at a rate not to exceed 15 mg/kg/hour (total maximum, 6 g/day) is administered.</p> <p>After deferoxamine is administered, the child's urine turns a reddish (vin rosé) color, indicating that the iron is binding with the antidote.</p>
Lead	<p><i>Acute lead poisoning</i> Burning sensation in the mouth and throat, GI disturbance (e.g., diarrhea, constipation), paralysis of the extremities, seizures, and coma</p> <p><i>Chronic lead poisoning</i> Irritability, anorexia, anemia; may progress to the acute form Even low lead levels can negatively affect neurobehavioral functioning and can result in slight decreases in IQ. Severe cases of lead poisoning can cause seizures, muscular collapse, and lead encephalopathy (delirium, seizures, mania, cortical blindness, coma).</p>	<p>Chelation dimercaptosuccinic acid (DMSA, succimer), calcium disodium edetate (CaNa_2EDTA), or dimercaprol (British antilewisite [BAL]).</p> <p>Advantages of DMSA, an analogue of BAL, over other chelating agents include the following: less toxic, can be administered orally, does not eliminate iron, copper, or zinc from the body.</p> <p>Lead concentrations of 44 to 70 $\mu\text{g}/\text{dL}$ are treated with DMSA.</p> <p>Lead concentrations of more than 70 $\mu\text{g}/\text{dL}$, without evidence of encephalopathy, are treated with a two-drug regimen of CaNa_2EDTA in combination with DMSA or BAL.</p> <p>Lead concentrations of more than 70 $\mu\text{g}/\text{dL}$, with encephalopathy, are treated with CaNa_2EDTA and BAL.</p>
Acetaminophen	<p><i>Phase 1:</i> within first 24 hours after ingestion Nausea, vomiting, pallor, and diaphoresis</p> <p><i>Phase 2:</i> 24 to 72 hours after ingestion Child appears better, but bilirubin, prothrombin time, and hepatic enzymes are elevated; right upper quadrant tenderness may appear; hepatomegaly, tachycardia, hypotension</p> <p><i>Phase 3:</i> 72 to 96 hours after ingestion Liver function abnormalities peak; right upper quadrant tenderness, jaundice, hypoglycemia, coagulopathy, and encephalopathy</p> <p><i>Phase 4:</i> 7 to 8 days after ingestion Hepatic dysfunction resolves or child develops hepatic failure or dies.</p>	<p><i>N</i>-acetylcysteine orally (Mucomyst) or IV (Acetadote).</p> <p><i>N</i>-acetylcysteine smells like rotten eggs. If administered orally, place the antidote in juice or a carbonated beverage in a covered cup to mask the smell and make it more palatable. It may have to be administered via a nasogastric tube. If the child vomits within 1 hour of administration, repeat the dose.</p>

WORLDVIEW: Folk remedies to treat digestive problems, fever, or rash, such as *azarcon* and *greta* (Mexico), *bint al dhahabor* or “daughter of gold” (Oman, United Arab Emirates), and *paylooh* (Southeast Asia), may contain lead and poison the child. Many Chinese, Indian, and Arabic traditional remedies contain lead and other harmful substances (Ernst, 2003).

No safe blood lead level has been identified. Blood lead levels less than 10 $\mu\text{g}/\text{dL}$ can negatively affect the physical and mental development of children (AAP, 2007). Blood lead levels more than 10 $\mu\text{g}/\text{dL}$ are considered toxic. Children with blood lead levels between 10 and 19 $\mu\text{g}/\text{dL}$ are typically asymptomatic, but may exhibit some impairment

COMMUNITY CARE 31–5

Preventing Lead Poisoning

Teach parents and other caregivers to remove sources of lead from the child's environment:

- A common source of lead is lead-based paint present in old homes; lead content in paint for new residences has been limited since 1978.
- Children may ingest paint chips or inhale dust from peeling paint.
- Keep children from playing near old homes being renovated, where the lead-based paint may have contaminated the dirt surrounding the home.
- Check lead levels in tap water, which may pick up lead if lead solder was used in the plumbing.
- If lead level exceeds drinking water standard, use bottled water or run cold water until it gets no colder before using for drinking or cooking.
- Do not use lead-glazed ceramic dinnerware or decorative pottery to serve food; citrus juices, in particular, leach lead from the pottery.
- Do not store food or drink in lead crystal.
- Discuss folk remedies used by the family that may contain lead.
- Parental occupation (e.g., construction or factory worker where lead-based substances are used) or hobbies (e.g., using leaded solder in stained glass, making leaded fishing weights) may increase the child's lead exposure; parents should wash their hands and change clothes and shower, if possible, before entering the home.
- Have child wash hands before eating.

Advise parents to ensure that the child has adequate nutritional intake, which decreases lead absorption by the body. Screen the child for lead levels per facility policy. The CDC recommends universal lead screening for children between the ages 6 months and 6 years. Question parents of young children about potential lead exposure and risk factors.

in cognition, fine motor skills, and growth (Erickson & Thompson, 2005; Yeoh, Woolfenden, Wheeler et al., 2008). Increased motor impairment and lethargy are seen in blood lead levels of 20 to 44 $\mu\text{g}/\text{dL}$. At blood lead levels of 45 to 69 $\mu\text{g}/\text{dL}$, irritability, intermittent lethargy, anorexia, vomiting, and abdominal pain are seen. Symptoms of blood lead levels more than 70 $\mu\text{g}/\text{dL}$ are persistent vomiting, loss of developmental skills, seizures, ataxia, cranial nerve palsy, altered sensorium, and coma. Blood lead levels more than 70 $\mu\text{g}/\text{dL}$ require emergency treatment to treat the encephalopathy and to preserve health and cognitive functioning (Erickson & Thompson, 2005). Treatment for lead poisoning includes terminating exposure, ensuring adequate dietary intake, and chelation for high lead levels (AAP, 2006). Lead and essential minerals compete for binding sites, so it is important to correct dietary deficiencies, particularly calcium (ensuring adequate vitamin D intake) and iron. Chelating agents form a compound with lead that is excreted through the kidneys.

caREminder

The carrier for British anti-Lewisite (BAL), a chelating agent, is peanut oil. Children with peanut allergies should not receive BAL.

Nursing care focuses on managing fluid, administering medications in a manner that minimizes pain, dealing with psychosocial issues, and providing education. Adequate urine output must be maintained, but overhydration should be prevented, especially in the presence of

central nervous system symptoms, because children with lead encephalopathy have the potential to develop cerebral edema. Ethylenediaminetetraacetic acid and BAL administered intramuscularly is extremely painful. The drug should be mixed with procaine and administered by the deep intramuscular route. Teach parents and caregivers about healthy dietary guidelines, including sources of calcium and iron, and how to prevent future exposure to lead (see Community Care 31–5).

Acetaminophen

Acetaminophen is an analgesic and antipyretic, commonly found in over-the-counter medications, that is metabolized in the liver. It accounts for a significant proportion of unintentional and intentional toxic ingestions in children (White & Liebelt, 2006). Acetaminophen is the most common cause of acute liver failure in children (Squires, Shneider, Bucuvalas et al., 2006).

Ingesting more than 150 mg/kg acetaminophen is potentially toxic (Bartlett, 2004). Ingesting large amounts of the drug is known to cause substantial hepatic damage, hepatic failure, and death. To allow for full absorption of the drug, severity of overdose is most accurately predicted from acetaminophen serum levels drawn 4 hours after the ingestion.

Treatment may include gastric decontamination by gastric lavage, if performed within 60 minutes of ingestion, and administration of activated charcoal (Clinical Judgment 31–2). Depending on the serum level of

CLINICAL JUDGMENT 31–2

Child With a Potentially Toxic Ingestion

Mrs. Denali calls to find out what to do about her son, Jamal, a 4-year-old who has ingested acetaminophen capsules, thinking they were candy. Jamal weighs 20 kg.

Questions

1. What further questions would you ask Mrs. Denali?
2. What factors indicate a potentially toxic ingestion?
3. Does Mrs. Denali need to do anything further? If so, what?
4. What interventions will be implemented when Jamal gets to the ED?
5. Jamal does not develop toxic serum levels of acetaminophen. What factors probably contributed to this positive outcome? What should the nurse do before sending Jamal home?

Answers

1. When did Jamal ingest the acetaminophen? Can Mrs. Denali estimate how many capsules he may have ingested? How many milligrams are in each capsule? Has any treatment been initiated? Is Jamal acting unusual or doing anything out of the ordinary (e.g., altered level of consciousness, nausea, vomiting, pale, diaphoretic)? She thinks that Jamal may have ingested six capsules, 500 mg each,
2. Jamal may have ingested six capsules of 500 mg each, which totals 3,000 mg acetaminophen. Jamal weighs 20 kg, corresponding to 150 mg/kg ingested, a potentially toxic dose.
3. Mrs. Denali should immediately call the poison control center then proceed to the nearest ED.
4. Activated charcoal will be administered to adsorb the acetaminophen further; it does not adsorb the antidote for acetaminophen, *N*-acetylcysteine. Serum acetaminophen levels will be measured 4 hours after ingestion to determine whether *N*-acetylcysteine should be administered. Liver function studies should be monitored and symptomatic care given.
5. Mrs. Denali discovered the ingestion quickly and took immediate action. The acetaminophen ingestion was treated before absorption of toxic amounts could occur. Jamal is younger than 6 years, when alternative pathways for acetaminophen metabolism may decrease the incidence of hepatotoxicity. The nurse should review poison prevention techniques with Mrs. Denali.

acetaminophen and poison control center recommendations, the antidote *N*-acetylcysteine may be given.

Hydrocarbons

Hydrocarbon or petroleum distillate ingestion can be lethal. Commonly found hydrocarbons include liquid polishes, solvents, and thinners; gasoline; and kerosene. Toxicity depends on the agent ingested and whether it has also been aspirated. The incidence of associated aspiration is high; aspiration can cause respiratory failure. Hepatic failure and central nervous system depression are other serious results.

The child may present with gasping, choking, coughing, chest pain, dyspnea, or cyanosis. Airway management is vital, with frequent reassessment for signs and symptoms of aspiration. Auscultation may reveal rales, rhonchi, wheezing, or decreased breath sounds. Chest radiographs, which commonly show bilateral perihilar and basilar infiltrates and varying degrees of atelectasis, may not be diagnostic until several hours after ingestion. Gastric decontamination depends on the agent and amount ingested; consult the poison control center for recommendations. Activated charcoal is not recommended.

Alert! Do not induce vomiting for hydrocarbon ingestion, because vomiting increases risk for aspiration.

Caustics

Caustic ingestions involve acids or alkalis commonly found in household cleaning products (e.g., Drano, lye). Ingestion of these substances may cause lip or tongue swelling, burning pain in injured areas, dysphagia, drooling, or whitish or red plaques in the mouth or perioral areas. Severe burns of the esophagus and stomach may occur.

Alert! Do not induce vomiting to treat caustic ingestion, because vomiting results in further burning of the mouth and esophagus. Activated charcoal is also contraindicated in treating this type of ingestion.

Do not give the child anything by mouth until the extent of injury is evaluated and ability to swallow fluids is assessed. Endoscopic evaluation is necessary 12 to 24 hours after injury to determine the severity of the

damage. Complications include esophageal perforation, scarring, and stricture formation.

Burns may be present on other parts of the body after exposure to caustics such as strong acids, strong alkalis, or petroleum distillate agents. The child should be fully decontaminated by removing all clothing and flooding affected areas with normal saline or water. Treat exposures to the eyes, skin, and mucous membranes by washing the affected area with a stream of water for 15 to 20 minutes. The water temperature should be comfortable to the child. The healthcare team members should wear gloves, because some toxins can be quickly absorbed through the skin. Poisonous exposure to these substances can occur through contact with the patient's skin, clothing, or vomitus.

SUDDEN INFANT DEATH SYNDROME (SIDS)

SIDS is the third most common cause of death in infants (Kung, Hoyert, Xu, et al., 2008). Approximately 90% of SIDS cases occur by age 6 months (AAP, Hymel, & Committee on Child Abuse and Neglect, National Association of Medical Examiners, 2006). The typical SIDS scenario involves the caregiver finding the normal, healthy infant prone in bed, in full cardiopulmonary arrest. The cause of SIDS is unknown, but may reflect delayed development of arousal, cardiorespiratory control, or cardiovascular control and is associated with other risk factors (Chart 31-4) (AAP et al., 2006). For a discussion of apparent life-threatening events and apnea, see Chapter 16.

Assessment

On presentation to the ED, examine the infant thoroughly to rule out other causes of death, including child abuse. The infant's face may be quite blue because of blood pooling in the dependent prone position. This discoloration may look like bruising. Trauma may also be present as a result of the basic life support measures used. Individual institutions may have specific protocols consisting of multiple laboratory and radiographic studies that aid in differentiating SIDS from child abuse.

caREminder

First-line responders (paramedics, police) and ED personnel must maintain an unbiased demeanor, asking questions in a matter-of-fact, information-gathering manner. Initially, these families may be wrongly accused of child abuse, further traumatizing them during this devastating period.

The history elicited from the family or caregiver helps in differentiating SIDS from abuse. With SIDS, the history is consistent each time it is given, by the same person and between family members; with abuse, the history may vary. A history that is incompatible with the infant's developmental level should also raise suspicion of abuse (e.g., a history of a 5-month-old trying to climb out of the crib and falling).

CHART 31-4 RISK FACTORS ASSOCIATED WITH SIDS

Maternal

- Younger age
- Smoking (antenatal and postnatal)
- Drug use (opiates, cocaine)

Infant

- Premature
- Asphyxia at birth
- Male gender
- Multiple birth
- Sibling who died of SIDS
- Age younger than 6 months (peaks at 2–4 months)
- Black or Native American

Environmental

- Cold-weather season
- Exposure to cigarette smoke
- Lower socioeconomic status
- Bottle-feeding
- Prone sleeping position
- Swaddled too warmly
- Soft sleeping surface

It is uncertain which risk factors are causal and how the risk factors are interrelated.

Nursing Diagnoses and Outcomes

In addition to the nursing diagnoses discussed in Nursing Plan of Care 31-1, nursing diagnoses and outcomes applicable to the family after the death of a child from SIDS include the following:

Compromised family coping: Related to reaction to death of child

Outcomes: Family will verbalize feelings.
Family will list and use sources of support.
Family will perform activities of daily living and maintain supportive interactions with each other.

Spiritual distress related to unexpected death of infant

Outcome: Family will verbalize feelings of spiritual tension and be adequately supported in working through them.

Impaired parenting related to parents dealing with own grief

Outcome: Parents or significant others will provide an environment for siblings that supports growth and development.

Interdisciplinary Interventions

Delivering the news to the family is difficult, because there is no explanation for the death and the ED healthcare team does not have a relationship with the family. Tell the family that the child may have died from SIDS and that an autopsy will be done to confirm this diagnosis.

WORLDVIEW: Deliver the news using the words *dead*, *died*, or *deceased*. Words such as *gone*, *expired*, or *passed away* are often misunderstood. This is especially true in families whose primary language is not English. Translation services should be provided for these families.

The primary nursing responsibility is to support the family in beginning the grieving process. Provide the family with a private, quiet area. Tell them that the exact cause of SIDS is still unknown and that it cannot be predicted or prevented. Use hospital and community resources, such as social workers and clergy members, to provide additional support and comfort to the family. Give the parents an opportunity to hold their baby (see Chapter 13). Prepare them for how the baby will look, explaining the presence of any tubes or resuscitation equipment. A staff member should stay with the family to support them.

The parents may not be emotionally able to understand all the information provided to them (e.g., funeral home lists, when to anticipate autopsy results, support group information). Provide them with written material so they can view it later. Often, one family member (perhaps an aunt or uncle) appears less emotional than the others. Providing this person with the written material and information can also be helpful. Frequently, parents do not return home after the SIDS death of an infant, so be sure to obtain a contact phone number from a friend or family member, in case the parents cannot be reached at home.

Community Care

The nurse can also participate in community education regarding ways to decrease risk factors that contribute to SIDS (see Chart 31–4). Because placing infants on their backs for sleeping (the “Back to Sleep” campaign) has been instrumental in reducing the incidence of SIDS, maternal smoking now has emerged as a significant risk factor for SIDS (Fleming & Blair, 2007).

PREPARATION FOR TRANSFER

QUESTION: Do you anticipate Chase will need to be transferred to a tertiary care facility?

Depending on the healthcare facility in which the child received initial emergency care, the stabilized child may need to be transferred to another facility or another unit. Regardless of where the child is transferred, take appropriate steps to prepare the child for transport.

The extent of preparation for transport of a child must be specific to the child and their condition at the time of transfer. A child who is transferred to a critical care unit will require the same level of monitoring and team ability to manage emergent situations during the transfer as was required in the ED.

For interfacility transfers, the Emergency Medical Treatment and Active Labor Act regulations must be followed. These require that the receiving facility has accepted the patient and that an appropriate, authorized physician has accepted the transfer of care as well. The mode of transfer, whether by ground ambulance, helicopter, or fixed-wing aircraft, must be selected based on the child’s condition, care needs during the transfer, availability of transport modes, and appropriate staff, along with traffic and weather conditions. A complete report between transferring and accepting physicians and nurses must occur prior to the child leaving the transfer facility. Copies of the patient’s chart, radiographs, and diagnostic tests must be sent to the receiving facility. Clear, consistent communication between the referring and receiving facilities is key to a successful transport.

ANSWER: Most likely, Chase would not need to be transferred to a tertiary care facility. Most EDs, even in very small facilities, are able to manage an anaphylactic reaction.

DIRECTIONS FOR ADMINISTRATION

1. Try to get child to smile by smiling, talking or waving. Do not touch him/her.
2. Child must stare at hand several seconds.
3. Parent may help guide toothbrush and put toothpaste on brush.
4. Child does not have to be able to tie shoes or button/zip in the back.
5. Move yarn slowly in an arc from one side to the other, about 8" above child's face.
6. Pass if child grasps rattle when it is touched to the backs or tips of fingers.
7. Pass if child tries to see where yarn went. Yarn should be dropped quickly from sight from tester's hand without arm movement.
8. Child must transfer cube from hand to hand without help of body, mouth, or table.
9. Pass if child picks up raisin with any part of thumb and finger.
10. Line can vary only 30 degrees or less from tester's line. ✓
11. Make a fist with thumb pointing upward and wiggle only the thumb. Pass if child imitates and does not move any fingers other than the thumb.

12. Pass any enclosed form. Fail continuous round motions.

13. Which line is longer? (Not bigger.) Turn paper upside down and repeat. (pass 3 of 3 or 5 of 6)

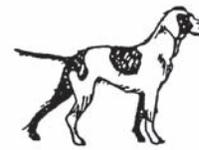

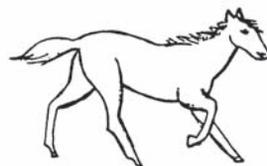

14. Pass any lines crossing near midpoint.

15. Have child copy first. If failed, demonstrate.

When giving items 12, 14, and 15, do not name the forms. Do not demonstrate 12 and 14.

16. When scoring, each pair (2 arms, 2 legs, etc.) counts as one part.
17. Place one cube in cup and shake gently near child's ear, but out of sight. Repeat for other ear.
18. Point to picture and have child name it. (No credit is given for sounds only.)
If less than 4 pictures are named correctly, have child point to picture as each is named by tester.

19. Using doll, tell child: Show me the nose, eyes, ears, mouth, hands, feet, tummy, hair. Pass 6 of 8.
20. Using pictures, ask child: Which one flies?... says meow?... talks?... barks?... gallops? Pass 2 of 5, 4 of 5.
21. Ask child: What do you do when you are cold?... tired?... hungry? Pass 2 of 3, 3 of 3.
22. Ask child: What do you do with a cup? What is a chair used for? What is a pencil used for?
Action words must be included in answers.
23. Pass if child correctly places **and** says how many blocks are on paper. (1, 5)
24. Tell child: Put block **on** table; **under** table; **in front of** me, **behind** me. Pass 4 of 4.
(Do not help child by pointing, moving head or eyes.)
25. Ask child: What is a ball?... lake?... desk?... house?... banana?... curtain?... fence?... ceiling? Pass if defined in terms of use, shape, what it is made of, or general category (such as banana is fruit, not just yellow). Pass 5 of 8, 7 of 8.
26. Ask child: If a horse is big, a mouse is ___? If fire is hot, ice is ___? If the sun shines during the day, the moon shines during the ___? Pass 2 of 3.
27. Child may use wall or rail only, not person. May not crawl.
28. Child must throw ball overhand 3 feet to within arm's reach of tester.
29. Child must perform standing broad jump over width of test sheet (8½ inches).
30. Tell child to walk forward,  heel within 1 inch of toe. Tester may demonstrate.
Child must walk 4 consecutive steps.
31. In the second year, half of normal children are noncompliant.

The Food Pyramid

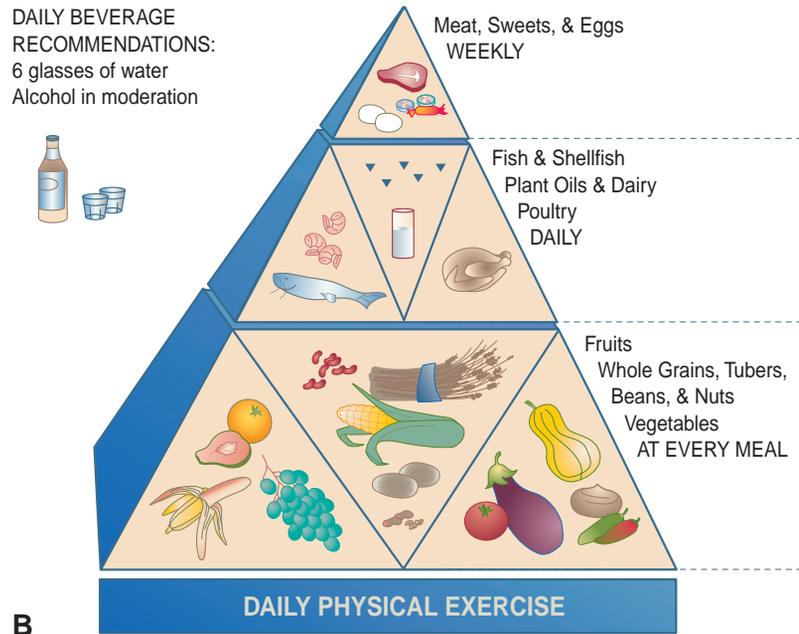

GRAINS	VEGETABLES	FRUITS	MILK	MEAT & BEANS
Make half your grains whole	Vary your veggies	Focus on fruits	Get your calcium-rich foods	Go lean with protein
Eat at least 3 oz. of whole-grain cereals, breads, crackers, rice, or pasta every day 1 oz. is about 1 slice of bread, about 1 cup of breakfast cereal, or 1/2 cup of cooked rice, cereal, or pasta	Eat more dark-green veggies like broccoli, spinach, and other dark leafy greens Eat more orange vegetables like carrots and sweetpotatoes Eat more dry beans and peas like pinto beans, kidney beans, and lentils	Eat a variety of fruit Choose fresh, frozen, canned, or dried fruit Go easy on fruit juices	Go low-fat or fat-free when you choose milk, yogurt, and other milk products If you don't or can't consume milk, choose lactose-free products or other calcium sources such as fortified foods and beverages	Choose low-fat or lean meats and poultry Bake it, broil it, or grill it Vary your protein routine – choose more fish, beans, peas, nuts, and seeds
For a 2,000-calorie diet, you need the amounts below from each food group. To find the amounts that are right for you, go to MyPyramid.gov.				
Eat 6 oz. every day	Eat 2½ cups every day	Eat 2 cups every day	Get 3 cups every day; for kids aged 2 to 8, it's 2	Eat 5½ oz. every day

<p>Find your balance between food and physical activity</p> <ul style="list-style-type: none"> Be sure to stay within your daily calorie needs. Be physically active for at least 30 minutes most days of the week. About 60 minutes a day of physical activity may be needed to prevent weight gain. For sustaining weight loss, at least 60 to 90 minutes a day of physical activity may be required. Children and teenagers should be physically active for 60 minutes every day, or most days. 	<p>Know the limits on fats, sugars, and salt (sodium)</p> <ul style="list-style-type: none"> Make most of your fat sources from fish, nuts, and vegetable oils. Limit solid fats like butter, margarine, shortening, and lard, as well as foods that contain these. Check the Nutrition Facts label to keep saturated fats, <i>trans</i> fats, and sodium low. Choose food and beverages low in added sugars. Added sugars contribute calories with few, if any, nutrients.

Immunization Schedule

Immunizations schedules are updated annually through a collaborative effort by the Centers for Disease Control I (CDC) and the American Academy of Pediatrics.

Below are the official websites where the most current immunization schedules for children, adolescents and catch up schedules can be located. In addition, these sites contain vital information for parent teaching and precautions for healthcare providers concerning administration of vaccines.

A P P E N D I X

F

Reference Ranges for Laboratory Tests

Prefixes Denoting Decimal Factors

Prefix	Symbol
mega	M
kilo	k
hecto	h
deka	da
deci	d
centi	c
milli	m
micro	μ
nano	n
pico	p
femto	f

To conserve space, the following common abbreviations are used.

Abbreviations

Ab	absorbance
Al	angiotensin I
AU	arbitrary unit
cAMP	cyclic adenosine 3', 5' monophosphate
cap	capillary
CH ⁵⁰	dilution required to lyse 50% of indicator RBC; indicates complement activity
CHF	congestive heart failure
CKBB	brain isoenzyme of creatine kinase
CKMB	heart isoenzyme of creatine kinase
CNS	central nervous system
conc.	concentration
Cr.	creatinine
d	diem, day, days
F	female
g	gram
hr	hour, hours
Hb	hemoglobin
HbCO	carboxyhemoglobin
Hgb	hemoglobin
hpf	high-power field
HPLC	high-performance liquid chromatography
IFA	indirect fluorescent antibody

IU	International Unit of hormone activity
L	liter
M	male
MCV	mean corpuscular volume
mEq/L	milliequivalents per liter
min	minute, minutes
mm ³	cubic millimeter; equivalent to microliter (μ L)
mm Hg	millimeters of mercury
mo	month, months
mol	mole
mOsm	milliosmole
MW	relative molecular weight
Na	sodium
nm	nanometer (wavelength)
Pa	pascal
pc	postprandial
RBC	red blood cell(s); erythrocyte(s)
RIA	radioimmunoassay
RID	radial immunodiffusion
SI	Système Internationale

Symbols

>	greater than
\geq	greater than or equal to
<	less than
\leq	less than or equal to
\pm	plus/minus
\approx	approximately equal to

Abbreviations for Specimens

S	serum
P	plasma
(H)	heparin
(LiH)	lithium heparin
(E)	EDTA
(C)	citrate
(O)	oxalate
W	whole blood
U	urine
F	feces
CSF	cerebrospinal fluid
AF	amniotic fluid
(NaC)	sodium citrate
(NH ₄ H)	ammonium heparinate

Abbreviations

RT	room temperature
s	second, seconds

SD	standard deviation
std.	standard
therap.	therapeutic
U	International Unit of enzyme activity
V	volume
WBC	white blood cell(s)
WHO	World Health Organization
wk	week, weeks
yr	year, years

Test	Specimen	Reference Range	Reference Range (SI)	
Activated partial thromboplastin time (APTT)	P(C)	25–35 s	25–35 s	
		Infant: <90 s	Infant: <90 s	
Adrenocorticotrophic hormone (ACTH)	P(H)	Cord blood	130–160 pg/mL	
		1–7 d postnatal	100–140 pg/mL	
		Adult		
		0800 hr	25–100 pg/mL	25–100 mcg/L
		1800 hr	<50 pg/mt	<50 mcg/L
Alanine aminotransferase (ALT, SGPT)	S	0–5 d	6–50 U/L	6–50 U/L
		1–19 yr	5–45 U/L	5–45 U/L
Albumin	P	Premature 1 d	1.8–3.0 g/dL	18–30 g/L
		Full-term <6 d	2.5–3.4 g/dL	25–34 g/L
		<5 yr	3.9–5.0 g/dL	39–50 g/L
	U	5–19 yr	4.0–5.3 g/dL	40–53 g/L
		4–16 yr	3.35–15.3 mg/24 hr/ 1.73 m ²	
Aldosterone	CSF	10–30 mg/dL		100–300 mg/L
	S,P(H,E)	Ad lib Na intake		
		Premature infants, supine		
		26–28 wk	5–635 ng/dL	0.14–17.6 nmol/L
		31–35 wk	19–141 ng/dL	0.53–3.9 nmol/L
		Full-term infants, supine		
		3 d	7–184 ng/dL	0.19–5.1 nmol/L
		1 wk	5–175 ng/dL	0.14–4.8 nmol/L
		1–12 mo	5–90 ng/dL	0.14–2.5 nmol/L
		Children, supine		
		1–2 yr	7–54 ng/dL	0.19–1.5 nmol/L
		2–10 yr	3–35 ng/dL	0.1–0.97 nmol/L
		10–15 yr	2–22 ng/dL	0.1–0.6 nmol/L
		Adults, supine	3–16 ng/dL	0.1–0.4 nmol/L
		Children, upright		
2–10 yr	5–80 ng/dL	0.14–2.2 nmol/L		
10–15 yr	4–48 ng/dL	0.11–1.3 nmol/L		
Adults, upright	7–30 ng/dL	0.19–0.83 nmol/L		
U	Ad lib Na intake			
	Newborn 1–3 d	20–140 mcg/g Cr. 0.5–5 mcg/24 hr	6.28–43.94 nmol/mmol Cr. 1.39–13.88 nmol/d	
	Prepubertal 4–10 yr	4–22 mcg/g Cr. 1–8 mcg/24 hr	1.26–6.91 nmol/mmol Cr. 2.78–22.20 nmol/d	
	Adults	1.5–20 mcg/g Cr.	0.47–6.28 nmol/mmol Cr.	
		3–19 mcg/24 hr	8.32–52.72 nmol/d	

Test	Specimen		Reference Range	Reference Range (SI)		
Ammonia nitrogen	S,P(LiH)	Newborn	90–150 mcg N/dL	64–107 μmol/L		
		0–2 wk	79–129 mcg N/dL	56–92 μmol/L		
		>1 mo	29–70 mcg N/dL	21–50 μmol/L		
		Thereafter	15–45 mcg N/dL	11–32 μmol/L		
		1–90 d	59–202 mcg N/dL	42–144 μmol/L		
		3 mo–3 yr	48–195 mcg N/dL	34–139 μmol/L		
Amylase	U		500–1,200 mg N/24 hr	36–86 mmol/d		
	S	1–19 yr	35–127 U/L	35–127 U/L		
Pancreatic isoenzyme	S,P(H)	Cord blood 8 mo	0–34%	0–0.34 fraction of total		
	Zymes	9 mo–4 yr	5–56%	0.05–0.56 fraction of total		
		5–19 yr	23–59%	0.23–0.59 fraction of total		
Anion gap (Na–(Cl + CO ₂))	P(H)	7–16 mmol/L		7–16 mmol/L		
Antidiuretic hormone (hADH, vasopressin)	P(E)	<i>Plasma Osmolarity</i>	<i>Plasma ADH</i>	<i>Plasma ADH</i>		
		270–280 mOsm/kg	<1.5 pg/mL	<1.5 ng/L		
		280–285 mOsm/kg	<2.5 pg/mL	<2.5 ng/L		
		285–290 mOsm/kg	1–5 pg/mL	1–5 ng/L		
		290–295 mOsm/kg	2–7 pg/mL	2–7 ng/L		
		295–300 mOsm/kg	4–12 pg/mL	4–12 ng/L		
Antistreptolysin-O titer (ASO titer)	S	≤ 166 Todd units				
		170–330 Todd units in School-aged children				
α ₁ -Antitrypsin	S	0–5 d	143–440 mg/dL	1.43–4.40 g/L		
		1–9 yr	147–245 mg/dL	1.47–2.45 g/L		
		9–19 yr	152–317 mg/dL	1.52–3.17 g/L		
	F	<1 yr				
		breast milk	<4.4 mg/g solid			
		formula	<2.9 mg/g solid			
		6 mo–44 yr				
		cow milk, regular diet	<1.7 mg/g solid			
Aspartate aminotransferase (AST, SGOT)	S	0–5 d	35–140 U/L	35–140 U/L		
		1–9 yr	15–55 U/L	15–55 U/L		
		10–19 yr	5–45 U/L	5–45 U/L		
Base excess	W(H)	Newborn	(–10)–(–2) mmol/L	(–10)–(–2) mmol/L		
		Infant	(–7)–(–1) mmol/L	(–7)–(–1) mmol/L		
		Child	(–4)–(+2) mmol/L	(–4)–(+2) mmol/L		
		Thereafter	(–3)–(+3) mmol/L	(–3)–(+3) mmol/L		
Bicarbonate	S,P	Arterial	21–28 mmol/L	21–28 mmol/L		
		Venous	22–29 mmol/L	22–29 mmol/L		
Bile acids, total	S,fasting	0.3–2.3 mcg/mL		0.3–2.3 mg/L		
	S, 2–hr pc	1.8–3.2 mcg/mL		1.8–3.2 mg/L		
	F	120–225 mg/24 hr		120–225 mg/24 hr		
Bilirubin	S, P					
Total	S	<i>Premature</i>	<i>Full-Term</i>	<i>Premature</i>	<i>Full-Term</i>	
		Cord blood	<2.0 mg/dL	<2.0 mg/dL	<34 μmol/L	<34 μmol/L
		0–1 d	<8.0 mg/dL	<6.0 mg/dL	<137 μmol/L	<103 μmol/L
		1–2 d	<12.0 mg/dL	<8.0 mg/dL	<205 μmol/L	<137 μmol/L
		2–5 d	<16.0 mg/dL	<12.0 mg/dL	<274 μmol/L	<205 μmol/L
		>5 d	<2.0 mg/dL	0.2–1.0 mg/dL	<34 μmol/L	3.4–17.1 μmol/L

Recommendations for Preventive Pediatric Health Care

Each child and family is unique; therefore, these **Recommendations for Preventive Pediatric Health Care** are designed for the care of children who are receiving competent parenting, have no manifestations of any important health problems, and are growing and developing in satisfactory fashion. **Additional visits may become necessary** if circumstances suggest variations from normal.

Developmental, psychosocial, and chronic disease issues for children and adolescents may require frequent counseling and treatment visits separate from preventive care visits. These guidelines represent a consensus by the American Academy of Pediatrics (AAP) and Bright Futures. The AAP continues to emphasize the great importance of continuity of care in comprehensive health supervision and the need to avoid fragmentation of care.

The recommendations in this statement do not indicate an exclusive course of treatment or standard of medical care. Variations, taking into account individual circumstances, may be appropriate. Anticipatory guidance ^x	•	•	•	•	•	•	•	•	•	•	•	•	•	•	•	•	•	•	•	•	•	•	•	•	•	•	•	•	•	•	•	•	•	•	•	•	•

^a If a child comes under care for the first time at any point on the schedule, or if any items are not accomplished at the suggested time, the prenatal visit is recommended for parents who are at high risk for first-time parents, and for those who request a conference. The prenatal visit should include anticipatory guidance, pertinent medical history, and a discussion of benefits of breastfeeding and planned method of feeding per AAP statement "Breastfeeding: A Guide for the Modern Parent" (2005) [URL: [http://aappublications.org/cgi/content/full/pediatrics;2005;115\(5\):1025-1035](http://aappublications.org/cgi/content/full/pediatrics;2005;115(5):1025-1035)].
^b Every infant should have a newborn evaluation after birth, breastfeeding encouraged, and instruction and support offered, to include and instruction regarding jaundice in AAP statement "Prevention and the Use of Human Milk" (2005) [URL: [http://aappublications.org/cgi/content/full/pediatrics;2005;115\(2\):496](http://aappublications.org/cgi/content/full/pediatrics;2005;115(2):496)]. For newborns discharged in less than 48 hours after delivery, the infant must be examined within 48 hours of discharge per AAP statement "Hospital Stay for Healthy Term Newborns" (2005) [URL: [http://aappublications.org/cgi/content/full/pediatrics;2005;115\(7\):1197-1202](http://aappublications.org/cgi/content/full/pediatrics;2005;115(7):1197-1202)].
^c Blood pressure measurement in infants and children with specific risk conditions should be performed at visits before age 3 years.
^d If the patient is uncooperative, rescreen within 6 months per AAP statement "Eye Examination and Vision Screening in Children" (2005) [URL: [http://aappublications.org/cgi/content/full/pediatrics;2005;115\(5\):1025-1035](http://aappublications.org/cgi/content/full/pediatrics;2005;115(5):1025-1035)].
^e All newborns should be screened per AAP statement "Year 2000 Position Statement: Principles and Guidelines for Early Hearing Detection and Intervention Programs" (2000) [URL: [http://aappublications.org/cgi/content/full/pediatrics;2000;105\(5\):1025-1035](http://aappublications.org/cgi/content/full/pediatrics;2000;105(5):1025-1035)].
^f For children at risk of lead exposure, consult the AAP statement "Lead Exposure in Children: Prevention, Detection, and Management" (2005) [URL: [http://aappublications.org/cgi/content/full/pediatrics;2005;115\(7\):1197-1202](http://aappublications.org/cgi/content/full/pediatrics;2005;115(7):1197-1202)]. Additionally, screening should be done in accordance with state law where applicable.
^g See AAP Pediatric Nutrition Handbook, 5th Edition (2003) for a discussion of universal and selective screening options. See [http://aappublications.org/cgi/content/full/pediatrics;2003;111\(5\):1025-1035](http://aappublications.org/cgi/content/full/pediatrics;2003;111(5):1025-1035).
^h Schedules per the Committee on Infectious Diseases, published annually in the January issue of Pediatrics. Every visit should be an opportunity to update and complete a child's immunizations.
ⁱ See AAP Pediatric Nutrition Handbook, 5th Edition (2003) for a discussion of universal and selective screening options. See [http://aappublications.org/cgi/content/full/pediatrics;2003;111\(5\):1025-1035](http://aappublications.org/cgi/content/full/pediatrics;2003;111(5):1025-1035).
^j For children at risk of lead exposure, consult the AAP statement "Lead Exposure in Children: Prevention, Detection, and Management" (2005) [URL: [http://aappublications.org/cgi/content/full/pediatrics;2005;115\(7\):1197-1202](http://aappublications.org/cgi/content/full/pediatrics;2005;115(7):1197-1202)]. Additionally, screening should be done in accordance with state law where applicable.
^k Newborn metabolic and hemoglobinopathy screening should be done according to state law. Results should be reviewed at the 2-month visit.
^l These may be modified, depending on entry point into schedule and individual need.
^m Schedule per the Committee on Infectious Diseases, published annually in the January issue of Pediatrics. Every visit should be an opportunity to update and complete a child's immunizations.
ⁿ See AAP Pediatric Nutrition Handbook, 5th Edition (2003) for a discussion of universal and selective screening options. See [http://aappublications.org/cgi/content/full/pediatrics;2003;111\(5\):1025-1035](http://aappublications.org/cgi/content/full/pediatrics;2003;111(5):1025-1035).
^o For children at risk of lead exposure, consult the AAP statement "Lead Exposure in Children: Prevention, Detection, and Management" (2005) [URL: [http://aappublications.org/cgi/content/full/pediatrics;2005;115\(7\):1197-1202](http://aappublications.org/cgi/content/full/pediatrics;2005;115(7):1197-1202)]. Additionally, screening should be done in accordance with state law where applicable.

 description of, 867
 drainage tubes for, 867, 872
 in obstructive uropathy, 898
 stents for, 872
 stomal diversion, 873
 urine output measurements, 904
 Urinary incontinence
 anatomic causes of, 896
 assessment of, 897–898
 behavior modification techniques for, 899
 bladder retraining for, 899
 diagnostic tests for, 898
 dietary manipulation for, 899
 functional, 895–896
 history-taking, 897
 interdisciplinary interventions for, 898–900
 neurogenic, 896–900
 nursing diagnoses and outcomes for, 898
 nursing management of, 900
 pharmacologic management of, 898–899
 physical examination for, 897
 psychosocial factors associated with, 897
 psychotherapy for, 899–900
 surgical management of, 898
 Urinary reconstruction, 873–874
 Urinary tract infections
 antibiotics for, 890, 892
 assessment of, 889
 bacteria associated with, 884
 causes of, 893b
 community care for, 890–892
 constipation and, 890
 cranberry products for, 890b
 cystitis vs., 892
 definition of, 884
 description of, 862
 in early childhood, 889b
 etiology of, 884, 888–889
 fluid intake increases for, 890, 891f
 follow-up management for, 892
 incidence of, 884
 in infant, 889b
 interdisciplinary interventions for, 890
 in middle childhood, 889b
 neural tube defects and, 1056
 in newborn, 889b
 obstructive uropathy and, 902
 pathophysiology of, 889
 prevention of, 1056
 pyelonephritis progression of, 888–890
 risk factors for, 888
 signs and symptoms of, 889b, 893b
 teaching intervention plan for, 893b–894b
 urinary specimens for evaluating, 865, 874b, 874–875
 vesicoureteral reflux and, 888–889, 903
 voiding cystourethrogram for, 871b, 892
 voiding frequency associated with, 890
 Urinary tract obstruction, 901, 901f
 Urination
 by infant, 142, 151
 pain during, 895b
 Urine
 blood in, 869b
 culture and sensitivity of, 870b, 1226b
 fetal production of, 861
 glucose in, 869b
 obstruction of, 862
 osmolality of, 736b
 pH, 736b, 869b
 protein in, 869b
 specific gravity of, 735b–736b, 869b
 specimen of, 399b, 865, 873b–874b
 24-hour collection of, 870b

voiding profile, 865c
 white blood cells in, 870b, 889
 Urine bag, 399b
 Urine catecholamines, 1105b, 1153b
 Urine catheterization
 clean intermittent, 874–875, 876b–877b, 899, 1057
 during hospitalization, 399b
 self-catheterization, 875
 Urine output, 607
 Urodynamic testing of bladder, 872b, 898
 Urolithiasis, 928
 Urticaria, 1341t, 1342–1343, 1343c
 Urushiol, 1337–1338

V

Vaccines
 diphtheria–tetanus–acellular pertussis, 261–262
Haemophilus influenzae type B, 262
 hepatitis A, 264
 hepatitis B, 262–263
 human papillomavirus, 265
 in immunosuppressed patients, 1131
 inactivated poliovirus, 263
 influenza, 264–265
 malignancies treated with, 1116b
 measles–mumps–rubella, 263
 meningococcal, 265
 pneumococcal 7-valent conjugate, 264
 polysaccharide pneumococcal, 264
 research about, 260
 rotavirus, 265
 simultaneous administration of, 265b
 storage of, 265
 varicella-zoster, 263–264, 1131, 1251
 VACTERL, 805, 810, 824
 Vaginitis, 1263
 Vagus nerve
 description of, 298t
 stimulator therapy of, 1047
 Varicella zoster immune globulin, 1251
 Varicella zoster virus
 infection caused by, 1250–1251, 1251f, 1252b
 vaccine for, 263–264, 1131
 Varicocele, 915–916
 Varni-Thompson Pediatric Pain Questionnaire, 336t
 Varus, metatarsus. *see* Metatarsus adductus
 Vascular access, 1594–1595, 1602
 Vascular birthmarks, 1300, 1302
 Vascular endothelial growth factor, 1490
