Many parents carefully consider how they will present their child's problem to the healthcare provider, because they want to be sure their complaint is seen as legitimate. One strategy parents often take is to wait until the child's next routine visit to bring up any noted problems. This might be detrimental if the problem, such as new-onset diabetes or acute asthma, is progressing rapidly. Another strategy is to seek help on a different issue that they know will get attention. The parent then asks the healthcare provider to check out the symptoms that have been actually causing them concern. To elicit this information in a way that will help the parents feel comfortable, it might be helpful to ask the following question at each healthcare encounter: What are your concerns or questions today about his [her] development [or body function]?

Some healthcare providers might not explore the parents' concerns and the signs that they describe to determine whether there is any credibility to them, often as a result of time constraints or failure to focus on anything other than the cause of the visit. They might tell the parents that they worry too much and that they, the parents, are just anxious (Clinical Judgment 12–1). The healthcare provider might continue to assure them that all is well with their child, although all nurses and physicians should take every parental concern seriously and be sure to check out all problems noted. Friction might also develop between the parents as one expresses concern and the other sees nothing wrong.

The Time of Diagnosis

QUESTION: Identify the emotions expressed by Tom and Jean upon Lindsay's diagnosis. What could you do? What could you say to help support this family at the time of diagnosis?

Families will often need assistance coping with the process of diagnosing a chronic condition, the diagnosis itself, and the impact of the implications of the diagnosis on the child's future. Waiting for a diagnosis certainly can be very stressful for families. Painful testing; uncertainty about the outcomes; uncertainty about the interruption in work, school, and home schedules; and not knowing how to provide treatment for a child who does not feel well all result in stress responses in parents. For some families, however, receiving a diagnosis is a relief and a validation that their child does, in fact, have a real problem. There might also be relief if parents know that the

problem can be managed with minimum inconvenience and if the condition will not interfere with the child's life span or cognitive functioning.

Who to Tell

Parents might have concerns about sharing their child's diagnosis with family, friends, and others who might have contact with their child for fear that the stigma or label will interfere with their child's future opportunities or will reflect poorly on them as parents. This is especially true for conditions that affect a child's neurologic or mental health status. Help provide the family with information booklets and fact sheets that they can hand out to others to explain the condition and educate them about the child's limitations, if any, or needed accommodations. They can be empowered to request that individuals not use certain pejorative terms around them or their child, such as *retard* or *cripple*. It can be explained that these are the terms that result in handicaps and they do not want their child growing up believing they are handicapped.

Parents are often hesitant to inform the school that their child has a diagnosed chronic condition. Reinforce that without the diagnosis being known to those who need to know in the healthcare community and in the school, multiple resources and services needed by them and their child will be denied them. In other words, "no diagnosis; no service." This will affect the support services they can receive in the care they provide their child as well as the accommodations that might be needed to meet the child's academic needs.

Parental Response

Because individuals handle stress differently, be prepared for parents to respond to their child's diagnosis with a variety of behaviors, including crying, anger, and silence. They might ask: Why did this happen? Why my family? Why this child? They may express anger with comments such as, "I knew something was wrong with him, but nobody believed me." They might express guilt with comments such as, "I should have picked up on the symptoms earlier" or "I should have insisted that those tests were done or insisted that we have a second opinion somewhere else." Reinforce to parents that these are normal reactions to the shock of finding out that their child has a chronic condition. Parents might be in a state of disbelief or denial when told of the diagnosis.

Often, with a diagnosis of a chronic condition, "parents experience the loss of the previously taken-for-granted world and fear the potential loss of their child" (Melnik et al., 2001, p. 549). They mourn the loss of the dreamed-for child and their life as they planned it would be. These initial feelings might be followed by despair, depression, frustration, and confusion (Melnik et al., 2001). Parents might feel like they have not been effective parents, which may affect their self-esteem and their confidence in their parenting skills. Nursing interventions for various emotional responses parents might have after their child is diagnosed with a chronic condition are presented in Nursing Interventions 12–1.

CLINICAL JUDGMENT 12–1

The Child With a Learning Disability

Danyael was diagnosed with specific learning disabilities at age 10 and with inattentive attention deficit hyperactivity disorder as an adolescent. She had mild gastroesophageal reflux as an infant and only had a bowel movement, which was normal, every 5 days. As a toddler, she had no interest in having books read to her. She socialized well but did not appear to be interested in the environment around her. She did not show interest in watching television. She learned to read at grade level, but by fourth grade, it was determined that she did not comprehend most of what she read. Although rote learning, such as spelling, was at grade level, all other subjects were below level. Danyael was repeatedly told she didn't pay enough attention to her studies or to directions; she was kept in from recess to redo work that wasn't considered neat enough.

Danyael was a second child to a mother who knew child development. The mother expressed her concerns repeatedly to the pediatrician and teachers. She sought second opinions without receiving a diagnosis. The mother arranged tutoring twice a week, but Danyael continued to receive failing grades on tests that measured understanding, even though she had repeated the information accurately to the tutor. Finally, without being informed of her rights under IDEA, Danyael's mother took her daughter for a comprehensive psychological assessment. It was this evaluation that resulted in a diagnosis of learning disabilities. However, it was another 2½ years before the elementary school acknowledged the disabilities, because no one relayed the test result to the school psychologist. The school continued to give Danyael failing grades on exams and to tell her mother she worried too much.

As the new nurse at Danyael's high school, you have met Danyael, having seen her a few times in your office for minor maladies. You have been reviewing her file and realize she has not had an individualized education plan (IEP) in more than a year.

Questions

1. What could have been done to assist the parents and the child in the past?
2. How were the repeated failures affecting Danyael's self-esteem?
3. What could have been done to assist Danyael until a diagnosis was made?
4. Who should have been an advocate for this family?
5. How can you, as the pediatric nurse, help the family to differentiate normal alterations in growth and development from pathologic and abnormal conditions?

Answers

1. When the mother first had concerns she should have been encouraged to keep a list of the behaviors that concerned her or a log of her child's behaviors. As her concerns were presented to teachers and school administrators, she should have been provided information on IDEA and have been informed of her right to have her child tested at no cost in the school system.
2. Repeated school failures can further diminish academic performance as the child learns to "give up." The child's self-esteem during school-aged years is greatly tied to mastery of new concepts. When children receive constant negative reinforcement in regard to their learning, self-esteem is bound to suffer.
3. Provide alternative learning strategies and document to see what works and what does not. Identify her strengths and promote them. Learn from the family what measures they implement at home to help her achieve, and incorporate the same techniques in the classroom.
4. If symptoms are identified at age 3 years or younger, advocate for an evaluation by the state's early intervention team. After the child reaches age 3 years, the public school system is obligated to serve as an advocate to ensure the child is provided additional resources to enhance learning when a learning disorder is identified.
5. Provide information on developmental parameters to assist the parents to recognize the ranges of what is considered "normal."

WORLDVIEW: Each family's response is influenced by their cultural background. Some might be very verbal about feelings, whereas others may not be willing to discuss feelings with those outside the family. In some families, the father might assume the dominant role as decision maker. If only the mother is seen in the healthcare setting, there might be a need to verify that essential information is communicated to the

father so that decisions can be made supported by the existing family structure. This requires the nurse to ask questions about how the family's culture views a chronic condition (e.g., a curse, a sign from God, a burden, a reason for society to shun them), how the family makes decisions, how they are responding to the diagnosis, and what resources the family has to support them and the care needed by their child.

NURSING INTERVENTIONS 12-1

Supporting the Emotional Responses of Parents

Emotion	Examples	Problematic Examples	Nursing Interventions	Outcomes
Grief	Despair, remorse	Withdrawal; unremitting sadness	Validate feelings Offer support Help parents re-establish structure in life	Parents begin to integrate fact that child has chronic condition into how they view the child in a positive way
Denial	Forgetting Overcompensation Disbelief	Interference with treatment Distrust	Reflect back statements Clarify feelings Offer feedback Help parents recognize that responses are normal	Parents begin to make appropriate plans for future Parents ask questions that show understanding of condition
Guilt	Self-blame	Spousal blame Continual self-recrimination	Give information Explore ideas about why child has condition	Self-blame comments subside Projection of blame onto others decreases Coping with realistic guilt
Anger	Aggression Hostility	Acts helpless Interferes with treatment plan	Include parents when developing treatment plan Remain nondefensive	Parents begin to actively participate in planning care Parents accurately and constructively direct anger
Fear	Anxiety Self-doubt Disoriented	Hypochondriacal Panic attacks Avoidance	Have parents participate in development and implementation of treatment plan Point out parental competence Repeat instructions, if needed	Parent initiates discussion of new treatment approaches Parent carries out needed treatments
Loneliness	Quiet Isolated	Marital discord Job difficulties	Assist in establishing contact with potential support persons/groups Help family re-establish or develop social connections	Family contact support group and goes to meetings Family reports social activities that give them enjoyment

Education and Preparing for Discharge

Provide specific information about a child's chronic condition in a written format at the reading level and in the language of the parents. Be prepared for the parents to ask the same questions over and over as information is

assimilated, and the nurse should allow the parents to vent their feelings, including anger and sadness. It is important to remember that parents usually do not initially comprehend all the information given to them, nor do they react to or cope with the news of their child's diagnosis at the same rate or in the same way (Bugental, 2003) (TIP 12-1).

TIP 12-1 A Teaching Intervention Plan for Parents in the Initial Period After Diagnosis of a Child's Chronic Condition

Nursing Diagnosis and Family Outcomes

- Deficient knowledge: the condition and parents' role in the treatment plan

Outcomes:

Family will be given instruction geared toward their learning style, level of understanding, and knowledge deficits.

Family will be able to implement essential care for the child.

Instructional Interventions

Verify cause of knowledge deficit. For example:

- Excessive anxiety
- Fear of condition
- Illiteracy
- Impaired communication
- Lack of prior teaching
- Language different
- Misinterpretation of information
- Unwillingness to learn

Assess baseline knowledge or experience with the chronic condition.

- What has the parent already been taught?
- Does the parent know anyone else with this condition?
- What have they heard about children with this condition?
- Is there any aspect of the child's care that is of particular concern to them?

Assess family structure, function, and usual patterns as they impact care.

- Who will be providing care to the child?
- Who will be backup for care?
- Where is the child when not with the family?
- What does the parent need to know to care for child safely at home?
- Will any family routines be affected by the presence of the chronic condition?
- What will be the child's involvement in his or her care, based on age and cognitive development?
- What will be the siblings' involvement in the child's care, based on age and cognitive development?
- How are siblings and friends affected by the presence of the child's chronic condition?
- What does the parent want to learn first?

Design teaching plan based on family assessment.

- Involve all caregivers and significant family members.

- Adapt teaching plan to accommodate the usual patterns of family or help the parents change these patterns.
- Begin with essential skills needed for the child's safe care and move on to those needed for long-term care and in-depth understanding of the child's condition and needs.

Present content using standard teaching principles.

- Use language best comprehended by the parent (e.g., English, Spanish, Creole).
- Use vocabulary understood by parent while teaching them to understand medical language that they may hear in future.
- Use a variety of teaching techniques to meet unique learning styles.
 - Discussion
 - Direct demonstration
 - Video/audio tape
 - Books
 - Practice equipment
 - Computer programs
 - Meetings with other parents, children with the condition
- Encourage questions.
- Explore question for possible concerns not evident in questions.
- Be alert for information overload.
- Allow practice and return demonstration of skills.
- Provide source of backup for later questions.
 - Home nursing
 - Phone calls from care provider
 - Support group
 - Written material

Educate for future.

- Expand natural parenting skills to promote development despite presence of chronic condition.
- Learn how the child can continue prior activities or activities can be adapted to accommodate limitations of condition.
- Learn to find new knowledge on own.
 - Support groups
 - Reading
 - Electronic support groups
- Learn to question and collaborate with healthcare providers.
- Learn to evaluate accuracy of information provided.
- Learn to educate staff and other caregivers about child's unique needs.
- Prepare for change in care brought on by progression or improvement of condition, developmental changes of child/caregivers, need for child to increase self-care.

For the infant or child who is hospitalized during the time of diagnosis, it is important for the pediatric nurse to be a role model for parents, showing them how to interact with and care for their child. Continue to educate the parents and the child about both normal child care and the special care needed based on their child's special needs, while serving as a support person as well. It is especially important to point out all the positive attributes of the child and what this child is doing that is perfectly normal for his or her age. Recommending that parents and the child (if appropriate) keep a pad of paper nearby to record their questions as they occur may help parents feel more organized in their thoughts when the medical specialist or others providing care for their child come into the room. This exercise can be continued at home; parents can keep a list of questions and bring them with them when they meet with their healthcare provider.

In addition to answering parent questions, discharge teaching should “prepare the family to deal with a specific health status change at home” (London, 2004, p. 212). Parents should be able to make informed decisions, have enough basic self-care skills to survive until their next teaching or health-related visit, and recognize problems and know how to respond.

When teaching needed skills, be sure to allow the families to do a return demonstration. It is recommended that on the first office visit after discharge that the skill be demonstrated again by the parent to ensure accuracy and to ask questions. This is a prime opportunity for the nurse to praise the parents for what they have learned and for the quality care they are providing to their child. Remind them to focus on the normalcy of their child as well. Be careful not to take over the care from the parents. Sometimes, healthcare professionals can make parents feel inadequate by doing the care quickly and competently, and not including the parents in bedside discussions with other healthcare professionals (Fig. 12–3). This may make some parents more fearful of demonstrating the skill and they may avoid their child more.

FIGURE 12–3. Early after the diagnosis, the parents are often not comfortable participating in assessment and care planning discussions, especially if the healthcare provider makes no effort to include them.

ANSWER: Two emotions stand out in this case study: grief and guilt. Review Nursing Interventions 12–1. One of the most important things you can do is to physically be there; give your presence. Take the time to sit down and be at eye level. Ask the parent, “How are you doing?” Maintain eye contact and really listen. Let them know they are not alone, that most other parents also have these feelings at first but that it does get better. Draw their attention back to Lindsay, who is responding well physically to the management of her blood sugars and accepting this new aspect of who she is. She is tall for her age, she loves animals, and she has diabetes.

The Period of Adjusting to and Coping With the Ongoing Demands of Having a Child With a Chronic Condition

The primary goals for the child's plan of care is to normalize the family's and the child's lives as much as possible, and to promote the optimal health of the child. How a family views their child's chronic condition might dictate how they react to and guide their child's care and development. The child viewed as sick, fragile, and vulnerable might be treated differently than the child viewed and treated as a “normal child who happens to have a chronic condition.” Unfortunately, parents sometimes respond to their child with a chronic condition as if he or she could die at any moment, even though the child might live for decades. This might result in the parents being overprotective of the child (Sallfors & Hallberg, 2003). For instance, parents of children with a chronic condition might not engage in sufficient discipline and might spoil their children by allowing them anything they wish. At the other end of the spectrum, parents might neglect or abuse the child with a chronic condition by failing to keep medical appointments and failing to follow the plan of care (Cowen & Reed, 2002; Telfair et al., 2005). Parents might also give up control altogether and choose to place their child in an institution, which in some cases might be the best option for the family (Tradition or Science 12–2).

Families have reported enormous amounts of stress, emotional turmoil, and sometimes grieving, if full return of function is not achieved. Sometimes, these emotions intensify because they may feel less support at home than in the controlled hospital environment. According to Ray (2002), who studied complex care at home for those with chronic conditions and disability, parents estimated that it took 6 months before the technical aspects of care became the most taken-for-granted part of the child's care. Parents eventually became experts at observing and supervising the technical and interactional competency of professionals.

Multiple stresses have been reported in families caring for children with special health care needs, such as social isolation; financial and employment strains; loss of privacy resulting from the need for many support services and personnel in the home; and strains in spousal

TRADITION OR SCIENCE 12–2

Do healthcare providers have an understanding of the challenges of parenting a child with a chronic condition?

EVIDENCE-BASED PRACTICE

The research literature is rich with studies evaluating parental response to the care and management of children with a chronic condition. One example is a metasynthesis completed by Coffey (2006), which reviewed 11 qualitative studies with a focus on parenting a child with a chronic illness. The studies included data from both mothers and fathers. Parents shared how worry is a bona fide part of everyday life and how often they felt overwhelmed by the care the child requires every day. Mothers have been identified as the primary caregiver, who often experiences exhaustion as they “carry the burden” of caring for their chronically ill child. Parents describe a loss of freedom and a loss of support systems because they are not able to leave their home on a regular basis because of their care obligations. Parents feel their role is that of an advocate for their child. They realize they must take charge, and they want their experience and knowledge of their child’s care recognized.

The need for nurses and other healthcare professionals to provide ongoing support and community resources for parents of chronically ill children is evident. Coffey (2006) suggests that future research needs to focus more on understanding the role of the nurse in support of this group of parents.

relationships sibling responsibilities, and friendships (Allen, 2004a; Ray, 2002; Rehm & Rohr, 2002). Parents describe frustrations with the health, social service, and educational systems; want a system that treats their child as a whole person as opposed to disciplines claiming only a piece, and desire one professional to be the key coordinator in their child’s care (Ray, 2002). Families investigate the Internet, ask for advice from professionals, and seek practical tips from other parents regarding medical management; health promotion and exercise; toilet training strategies; sexuality issues; financial assistance; vocational counseling; sources for dental treatment, respite care, and child daycare; management of behavioral problems and discipline practices; support groups; and so forth. Despite these pressing issues, parents demonstrate unconditional love, an absolute devotion to their children’s care, commitment to their futures, and hopes for good quality of life (Fig. 12–4).

There are four major responsibilities for parents caring for a child with a chronic condition. These include

- Managing the condition
- Identifying, accessing, and coordinating community resources
- Maintaining the family unit
- Maintaining self (Sullivan-Bolyai et al., 2003)

FIGURE 12–4. Jack Freedman, a 10-year-old with spinal muscular atrophy, who enjoys traveling and making family memories. When diagnosed as an infant, his family was told he would not live for more than a year.

The pediatric nurse can play a major role in the first two responsibilities and should be an advocate and a family support for the last two.

Managing the Condition

Managing a child’s chronic condition is often easier for the parents when they feel knowledgeable about the condition, competent in the skills needed to care for the condition, aware of which symptoms indicate problems and which do not, and supported by the healthcare community should they have a problem. Teaching parents about their child’s chronic condition is not something that is done only once; rather, parent and family teaching should be an ongoing process. A home visit might be helpful early during the child’s care. In addition to teaching the needed skills, it is also helpful to assist the family to develop care routines, to coordinate the care in a way that allows for periods without treatments and rest for both the parents and the child, and to determine a method of remembering when to do tasks and in what manner (Sullivan-Bolyai et al., 2004).

However, parents might feel overwhelmed by the technical skill expectations and knowledge needed to manage their child’s chronic condition, especially when equipment fails or does not work properly, their child refuses to participate in the skill, or their child’s condition deteriorates. These situations might make parents feel like they have failed their child in that they are unable to provide for their child’s needs and cure what ails them. There might be times when the stress is too much for the parents and family; stress might result from the physical stress of caring for a growing or technologically dependent child or the psychological stress that accompanies this care. Parents must be supported in being able to acknowledge that they need help.

Parents and caregivers must learn all the basic principles of body mechanics to provide safe care to the child

and to protect themselves from injury. Interventions are especially needed when the child gets too heavy for the parents to handle safely or if they express that the child's behaviors have become too embarrassing for them to go out in public, or too difficult or potentially dangerous to them.

Evaluation is the key to ensuring that home care interventions have been effective. For instance, just because the nurse has made a referral or had the family participate in a teaching session does not mean that the problem has been resolved. One nurse practitioner mother, whose adolescent was finally diagnosed as having Asperger's syndrome at age 13 and who has fought with the school system for years to have her child's needs met, made the following comment, which is a sad commentary on the follow-through of her professional colleagues in education: "Every time I send my child out into the world, the world sends him back."

Identifying, Accessing, and Coordinating Community Resources

Parents might also be overwhelmed by the large number of "others" who are needed to help in the child's care. The interdisciplinary team might include physical therapists, occupational therapists, speech therapists, nutrition therapists, respiratory therapists, pain managers, intravenous (IV) therapists, psychologists, social service members, home care service members, durable equipment suppliers, school personnel, and many others. The pediatric nurse can be instrumental in ensuring that a case manager is assigned to coordinate all these individuals to avoid overlap of services, to ensure consistency in the messages and treatments needed, to limit the number of healthcare visits needed each month by arranging for the family to see multiple specialists at the same time, to limit the number of healthcare providers coming to the home, and to attempt to promote some semblance of normality in the family's life. The case manager can also be responsible for assisting the family in identifying, accessing, and coordinating community resources, especially related to financial assistance and planning for emergencies, such as equipment failure, power failure, and medical emergencies. Knowing that the team is communicating and working together, decreases family stress and lets the family know that the team is focused on what is best for the child and family.

The ongoing assessment of learning needs of the parent and child, even when they appear quite knowledgeable, is a part of each healthcare encounter to ensure parents are properly maintaining their child's treatment plan. It is essential to remember that as the child grows, procedures may have to be performed differently and may have to be retaught to accommodate any necessary changes. An example is percussion and postural drainage. This procedure is often performed one way for a toddler with cystic fibrosis and performed differently as the child enters school and as the child reaches puberty.

Maintaining the Family Unit

QUESTION: What was the impact of the American Diabetes Association precamp weekend on the Jenkins family, particularly the mother?

It can be very stressful for parents and families living with a child who needs continuous health-related interventions. The stress that results often causes parents and families to focus primarily on their child's condition, treatments, and the time involved. For example, parents with a child on a ventilator or tracheostomy tube may fear not hearing their child's need for suctioning; those with a child with type 1 diabetes might become rigid about intake and maintaining tight control of the blood sugar in an attempt to stave off long-term sequelae.

Focusing solely on a child's condition, however, shifts the focus away from the fact that the child also has normal developmental needs. Ensure that every health-related visit and hospitalization promotes what is normal for age about the child and the progress that the child has made toward achieving developmental tasks (Chart 12-2).

Accept the family with the reactions and coping mechanisms (both effective and ineffective) they bring to the situation. A coping mechanism should not be judged as good or bad based on the nurse's personal value system. Do not presume that a family will be at a particular point in their response to coping with their child's chronic

CHART 12-2 PARENTAL INTERVIEW QUESTIONS ON IMPACT OF CONDITION ON CHILD AND FAMILY

- How do you think your child's condition has affected him/her and your family?
- Tell me about your child and school. Explore:
 - Transportation concerns
 - Academic achievement
 - Reactions of classmates and teachers
 - Participation in field trips and other special activities
- Describe your child's ability to dress and toilet him/her. Explore:
 - Concerns about appearance
 - Detail regarding self-care abilities
- Tell me about disciplining your child. How does this compare with discipline for your other children?
- Tell me about your child's friendships. Explore:
 - Rejections by previous friends
 - Having friends over
- What does your child do for fun? Explore:
 - Previous favorite pastimes
 - Group activities
- What are concerns you have about your child as you think about the future?

condition simply because the child's problem was just diagnosed or has been present for years. Multiple research studies have supported that "family's factors are more predictive of the psychosocial adjustment of children with disabilities than the condition parameters themselves" (Witt, Riley, & Coiro, 2003, p. 693).

Although it is common for healthcare providers to ask families how they are coping in the months after diagnosis, they often forget to do so 1, 5, and 10 years later. Ask parents and families how they are coping, especially as the child enters different stages of development. It may be one thing to cope with a toddler with Down syndrome, but it is completely different for the family to cope with an adolescent with Down syndrome. Needs change and the challenges they present also change. Some of the more common nursing diagnoses and outcomes for families of a child with a chronic condition are in Nursing Plan of Care 12-1.

ANSWER: Even though the American Diabetes Association precamp experience was stressful for the parents, it changed the way they viewed Lindsay. They learned that in the right situation she could do all the things other children her age do. They learned that trained "others" can care competently for Lindsay, and they had their first glimpse of a future in which Lindsay did not depend on them.

Maintaining Self

It is not uncommon for caregivers to neglect their own physical needs in their love and dedication to the child. Help families recognize their physical needs and find realistic ways to have those needs met. Encourage parents to accept offers of help from friends or family members to watch siblings, bring meals, or assist in providing care to the child. Suggest that home caregivers nap or rest when the child is resting. Ensure that the care needs of the child can be met by more than one competent individual in the household, thereby allowing caregivers time to pursue their own activities and interest. If needed, families may choose to pursue respite care services (discussed later in the chapter) as a means to allow the caregivers an opportunity to take a trip or have a weekend away from the ill child.

Impact on the Marriage

Because each parent copes with a child's chronic condition in his or her own way, some parents might find it difficult to share their feelings with their spouse, especially when one spouse is not yet ready to deal with the issues. The increased isolation from one's support system may cause stress on the relationship, especially if one spouse goes to work each day and stays away from home for longer periods of time. Isolation may also occur when frequent hospitalizations of the child occur, thus requiring a parent to remain with the child, away from the spouse, in the hospital setting. Parent support groups might prove helpful. It is important for the couple to find time for themselves.

Impact on Grandparents and Significant Others

Parents who have been informed that their child has a chronic condition generally expect that they will be supported and assisted by their parents, the child's grandparents. For many, this is the case. However, this is not always the case for others. Some grandparents live too far away or are unable to assist their children for physical or psychological reasons; others express fear in the required knowledge and skills, and may avoid caring for the child. They might feed into the guilt felt by the parents by relating the condition to something the parent did during their adolescence or their pregnancy. Occasionally, grandparents will blame the condition on their child's spouse, especially if they had never approved of the marriage. In addition to losing emotional support, the parent might be losing a source of respite care. This is also true when close friends or family of the parents begin to shy away from visiting because of fears of what to say and how to help.

Birth of Subsequent Children

The birth of subsequent children can cause anxiety for parents until it can be determined whether the newest child has the same chronic condition as an older child. Parents might need additional assurances that the subsequent child is healthy, even if there are no signs of a problem. Some have all their children born before the first one is diagnosed, and then they find that others have the same condition. Parents will then need additional support. Remember that each child is an individual and no two children present with the same condition in the exact same way. Parents who have more than one child with a particular condition need to be provided with this information so that the subsequent children are not compared with the sibling.

There might be moments of discomfort for parents when the younger children surpass the older child with a chronic condition in motor or academic skills. This is an ideal time to discuss the limitations of the older child with the younger child and to promote sensitivity in not making fun of or causing embarrassment because of the differences that may exist.

Impact on Siblings

An increasing amount of research has been done on the healthy siblings of children with chronic conditions (Murray, 2002). The degree of adjustment difficulty in healthy siblings appears to be related to the degree of disruption of family life that occurs because of the affected child's condition as well as the family's resources to cope with the effects of the disruption (Murray, 2002). Coping difficulties were seen in the healthy siblings' sleeping and eating patterns.

Healthy siblings need information regarding their sibling's condition; this information needs to be age appropriate and presented frequently during the healthy child's life span. Healthy siblings can also be encouraged to participate in the care provided to their sibling with a chronic condition (Fig. 12-5). In addition, healthy

NURSING PLAN OF CARE 12–1: FOR THE FAMILY MEMBERS AND CAREGIVERS OF A CHILD WITH A CHRONIC CONDITION

Nursing Diagnosis: Deficient knowledge: new and complex treatment regimen and/or home care needs

Interventions/Rationale

- Assess family's knowledge of child's condition and care needs.

Assists in focusing teaching to family's needs.

- Teach parents to manage child's condition (e.g., treatments and symptoms to report to healthcare provider).

Appropriate management facilitates optimal outcomes.

- Use developmentally appropriate methods to teach child and family about the condition.

Knowledge facilitates appropriate management of condition and enhances the transition successfully to home management.

- Provide multiple sources of parent/child education including videos, reading material, and hands-on demonstration.

Providing multiple methods of teaching is the best way to present new material to adult learners.

- Demonstrate required care; provide opportunity for return demonstration.

Helps the child and parents master care needs

- Teach child/family to identify and report symptoms that indicate a change in the child's condition and/or a deleterious side effect of medication or other treatments.

Allows for prevention or early detection of problems and early intervention.

- Provide opportunities to room-in whenever possible.

Rooming-in gives the parents a chance to be the primary care providers for their child to work with the actual equipment they will have in the home and to give the medications. The care is provided with support as needed from the nursing staff.

Expected Outcomes

- Parent/caregiver identifies and demonstrates all home care treatment skills.

Nursing Diagnosis: Ineffective therapeutic regimen management related to lack of education, support, or physical ability to carry out plan of care; complexity, cost, side effects; knowledge deficit about how to implement regimen; failure to accept seriousness of problem or benefits of regimen; fear of being different

Interventions/Rationale

- Assess family's knowledge of child's condition and care needs.

Assists in focusing teaching based on family needs.

- Instruct family members about signs of infection and changes from expected response. Stress the need to contact the physician if these occur.

Child/parents cannot manage program if a knowledge deficit exists.

- Provide family with information regarding medications child is receiving. Discuss which of these may be continued upon discharge or when exacerbation of condition has passed.

Ensures family has accurate knowledge to manage child's condition.

- Complete a nutritional assessment. Develop a plan to modify the family diet if needed to meet the child's current health needs.

Ensures family has accurate knowledge to manage child's condition.

- Help parents/caregivers learn new care activities.

Throughout the course of the child's life, the family will need to make adjustments in the plan of care for the child to account for developmental changes and changes in the child's condition.

- Evaluate the need for education of others who will be in contact with child (e.g., baby-sitters, school teachers, neighbors). Assist parents in providing information as needed.

Support systems are important to give the parents relief time to build on their strengths.

- Verify that modifications in the home environment have been made. Confirm that home care is referral complete (e.g., equipment delivered to home, family knows how to use it, and it is appropriate to that home).

Equipment to manage the child's care and modifications to the home environment may be suggested that improve quality of care for the child and make care processes easier for the family.

- Provide parents with access to supplies as necessary. Provide them with information on available support/financial resources (e.g., local public health department, regional centers).

Access to support systems/resources may help the family manage the care for the child.

- Teach parents to manage the child's condition.

Appropriate management facilitates optimal outcomes.

Expected Outcomes

- Family will successfully manage the child's care needs and will identify sources of support to help in managing the child's condition.

Nursing Diagnosis: Powerlessness related to lack of ability to control progression of condition; inability to communicate with health care provider.

Interventions/Rationale

- Assess the family's stress levels, coping mechanisms, and support systems.
Knowledge of stressors and support can be used to assist the family build on their strengths.
- Encourage family discussion of feelings and acknowledge their normalcy.
Venting of feelings may help decrease anxiety and feelings of powerlessness, and may validate that what the family is feeling is a normal part of coping and adaptation.
- Involve the family in caring for their child.
Helps the parent maintain control and reinforces the parent's ability to provide adequate care
- Support parent's competence in assessing their child's behavioral cues and responses.
Reinforces parental role and the parent's ability to meet their child's needs.

Expected Outcomes

- Family will verbalize feelings of powerlessness and the impact it has on the family.
- Family will identify positive coping strategies to deal with child's chronic condition.

Nursing Diagnosis: Risk for caregiver role strain related to multiple care needs of child; no other caregivers

Interventions/Rationale

- Provide ongoing access to all members of interdisciplinary team for diagnosis and treatment of condition. Use these contact opportunities to evaluate caregiver's coping experiences.
The goal of the interdisciplinary team is to support the family as they manage the child's condition and successfully integrate that care into daily family life. Early identification of caregiver role strain can elicit evaluation of the situation and interventions to decrease stress.
- Refer to home care agency/nursing, respite care, and daycare services for continued care of complex problems.
Provides relief and assistance in managing complex care of the child. Provides opportunities for parents to be away from the child to pursue their own interests.
- Collaborate with school health officials to facilitate continued education or return to school.
Both the child and family can benefit from the ongoing interactions the child has in school with peers and other trained educational specialists.
- Determine number, age, sex of all siblings and their usual level of interaction with child/family.
- Explore siblings' knowledge of condition and family's expectations of siblings.
Unrealistic expectations may be placed on siblings to manage home environment and/or care for chronically ill child.
- Discuss past and present coping mechanisms. Assist to identify effective and ineffective coping mechanisms.

- *Identification of coping mechanisms can provide guidance for selection of appropriate methods.*
- Instruct in use of relaxation techniques (e.g., deep breathing, mediation, journaling, hot baths).
Practicing the methods may help in using them when faced with a stressful situation.
- Identify causative or contributing factors to stress.
Identifies the stresses that are exceeding the resources of the parent.
- Allow the parents to discuss their feelings.
Venting one's feelings may help in decreasing frustrations.
- Discuss the effects of the current schedule on self (e.g., physical health, emotional status, and relationships).
Successful coping depends on the ability of identified resources and self-care. Burnout is associated with exhaustion—physical and emotional.
- Initiate referrals and health teaching; assess family resources and support systems.
Referrals can provide respite care and sharing of responsibilities. Provides a view that others can help and are competent.
- Encourage caregiver to participate in support groups.
Support groups can provide mutual support, anticipatory guidance, education.
- Provide positive encouragement to the caregiver.
Being appreciated and encouraged can decrease feelings of strain.

Expected Outcomes

- Parents will identify and use other caregivers for the child.
- Parents will take time away from the child to meet their own needs.
- Caregivers will verbalize their need to maintain social relationships outside of those that focus on the child with a chronic condition.

Nursing Diagnosis: Sexual dysfunction related to fatigue secondary to care of child; lack of privacy secondary to presence of other caregivers in home

Interventions/Rationale

- Encourage sharing of feelings, concerns, and information between couples.
Provides focus on the couple's relationship
- Assist the couple in identifying possible options to overcome situational influences on sexual functioning.
A satisfying sexual relationship is important to couples.

Expected Outcomes

- Parents will identify factors that might interfere with meeting their own needs for intimacy and will deal with them to meet their sexual needs.

NURSING PLAN OF CARE 12–1: FOR THE FAMILY MEMBERS AND CAREGIVERS OF A CHILD WITH A CHRONIC CONDITION (CONTINUED)

Nursing Diagnosis: Disturbed sleep pattern related to physical care needs of child

Interventions/Rationale

- Evaluate parents' ability to get appropriate sleep/rest. Assist in determining whether current sleep/rest patterns meet individual caregiver needs.

Establish baseline data to explore whether this is an ongoing concern or of a temporary nature resulting from exacerbation of the child's condition.

- Develop a plan to provide the caregiver with uninterrupted sleep. This may include use of night care providers, giving parents permission to go home at night from the hospital, and so forth.

Provides strategies for temporary and potential long-term relief of sleeplessness.

Expected Outcomes

- Caregivers will identify own sleep needs and develop strategies to meet them.

Nursing Diagnosis: Readiness for enhanced family processes related to need for family to work together to accomplish tasks and to develop new ways to meet needs of individual members

Interventions/Rationale

- Offer emotional support as child/family go through periods of adjustment/grief/mourning.
A child with a chronic condition poses challenges that require adjustments in the daily life of the whole family. Families can draw upon previous coping strategies and support systems to help them maintain homeostasis.
- Allow parents to be the expert on care of the child; give acknowledgment and positive reinforcement to efforts to provide a stimulating, healthy environment.
Positively affirms parental role.

- Provide time for family members to discuss concerns and problems; find out how long a specific approach has been used, and how the approach works and does not work.
Examines family resources and provide mechanisms to offer alternative coping strategies as needed.

- Support parental competence in assessing their child's needs and in caring for their child.
Reinforces new behavior and bolsters the parents' feelings of competence.
- Encourage participation and cooperation in care, reward all efforts, and give choice and control over situation as appropriate.
Minimizes perception of powerlessness. Maximizes personal responsibility of child/family for daily care.

Expected Outcomes

- The family will cope with demands imposed by the child's chronic condition, develop new coping strategies to manage demands and to promote family functioning, and feel a sense of achievement that they were able to do so.

Nursing Diagnosis: Anticipatory grieving related to anticipated shortened life expectancy of child resulting from chronic condition; change in family life plan as envisioned prior to child's diagnosis

Interventions/Rationale

- Elicit parental and sibling concerns about child's condition and future implications of that condition on child and family.

The fear of death may be present and may arise each time the child experiences a serious exacerbation of clinical signs.

- Identify for the family members feelings they may have at any point; assure them that in most cases those feelings are a normal part of grieving.

Family members will go through grieving process as they adjust to the loss of "the perfect child" and adapt to the impact the child's condition may have on quality and longevity of the child's life.

- Provide strategies to enhance coping (e.g., use of support groups, use of spiritual supports, increase knowledge of child's condition).

Enhances family knowledge base and provides repertoire of strategies to cope as family deals with ongoing demands of child's condition. The child and family may need additional support services to effectively grieve and cope with the child's condition and to learn to manage home care.

- Promote child/family decision making (e.g., include family members in conferences, encourage them to be advocates for child).

Regular updates on the child's status assist parents in the decision-making process.

- Recognize that each family member will cope differently and at his or her own pace. Respect differences in coping strategies, and assist all family members in dealing with differences.

Responses may vary from acceptance to anger, withdrawal, and depression.

Expected Outcomes

- The parents will progress through the grieving process in an adaptive manner.

Nursing Diagnosis: Hopelessness related to failing physiologic condition of child; loss of something valued (wished for child; belief in God)

Interventions/Rationale

- Ask the parent how she or he sees things, whether anything helps him or her feel better, and what might help improve the situation.
Creates a supporting environment and allows for recognition of own strengths.
- Provide accurate and ongoing information related to child's illness, treatments, and care.
Decreases chance of misconceptions and prognosis that may contribute to hopelessness.
- Encourage the parents to set realistic goals and acknowledge all accomplishments.
Setting realistic goals may decrease the frustration of not accomplishing them.
- Facilitate problem solving for identified problems.
Solving problems in small steps will foster confidence and encourage gradual mastery of the situation.
- Identify current coping strategies and help parents learn and effectively use additional strategies.
Past strategies may not work.
- Identify support systems available to the family.
Parents in social isolation find it difficult to change their situation. Support systems can provide assistance to the family.

Expected Outcomes

- The parents will identify positive aspects of the situation and a feeling of hope.

Nursing Diagnosis: Social isolation related to care requirements of the child

Interventions/Rationale

- Collaborate with interdisciplinary team (social worker, physician, school nurse, and so forth) to develop a plan for the child to participate in family, school, and social activities to their maximum capacity.
Provides additional support system for the family to ensure the child's successful adaptation at home and school.

Expected Outcomes

- Caregivers will verbalize need to maintain social relationships outside of those that focus on the child with a chronic condition.
- Caregivers will take time to get away from caregiving situations, with and without the child with a chronic condition, and enjoy social activities.

siblings may be asked to take on additional household responsibilities. Parents should discuss with their children that these added responsibilities should be viewed as a sign of trust and maturity rather than a chore. Parents need to be sure to praise their nonaffected children for their assistance.

Some healthy siblings may be jealous of the attention paid to the affected child and may therefore engage in attention-seeking or acting-out behaviors; some may complain of symptoms that are psychosomatic in nature. Although some children are embarrassed by their sibling with a chronic condition, others readily defend

them from rude remarks and bullying. Because there is a decrease in social activities and family outings in families in which a child is dependent on a great deal of technology, efforts should be made to ensure that the healthy siblings are given special time outside the home, both with significant adults and with peers. Above all, healthy siblings need to feel free to share their feelings, to be provided with education about the sibling's condition, and to be assured that they will not "catch it" or develop it. This education should be ongoing and not just at the time of diagnosis and discharge. In some areas, there are even support groups for healthy siblings of children with chronic conditions. See TIP 12-2 for various interventions for siblings of a child with a chronic condition.

In some cases, siblings have the same condition, especially if they are genetically caused. In one respect, this may enhance the siblings' feelings of normalcy, because they are each undergoing testing and treatments. However, in the case in which one child dies, siblings with the same condition may experience great fear as they approach the age at which their sibling passed away. For example, in one family of four children, all but the oldest had cystic fibrosis. These three siblings assisted each other with percussion and postural drainage, and shared equipment. The oldest child, who was unaffected by cystic fibrosis, required years of psychological support during her adolescence. She felt guilty for not having the condition and felt different from the rest of the family. The healthcare team assisted her in recognizing and dealing with her conflicting emotions (Clinical Judgment 12-2).

FIGURE 12-5. Siblings need to be fully informed about their sibling's care needs and condition, and be allowed to participate in care activities as much as they wish to and is age-appropriate.

TIP 12–2 A Teaching Intervention Plan for the Sibling of a Child With a Chronic Condition

Nursing Diagnosis and Family Outcomes.

- Deficient knowledge: condition and the effect it will have on the affected sibling the family, and themselves

Outcomes

Sibling will understand the reason actions related to the chronic condition are being taken.

Sibling will identify how he or she can participate in the child's care.

Instructional Interventions

Verify baseline knowledge.

- What have they been told by their sibling, their parents, friends of health care providers?
- What questions do they have about the condition, how it affects their sibling, and how it affects themselves?
- Do they know anyone else with this condition?
- What do they most want to learn now?

Assess sibling's involvement with child with chronic condition.

- Do they ever need to help with care?
- What do they wish they could do? What do they wish they did not have to do?
- Are there any activities they would like to participate in which are not allowed because of their sibling's needs?
- How are friendships affected by the presence of the sibling's chronic condition?

Design teaching plan based on sibling assessment.

- Be specific and increase detail as cognitive ability, age, and interest increase. Do not hide facts of the condition.
- Begin teaching items they are most curious and concerned about.

Present content using standard teaching principles.

- Use vocabulary understood by the child while teaching medical language that he or she may hear in the future.
- Adapt teaching approach to accommodate the sibling's cognitive and physical development (more pictures with preschoolers; pamphlets, books, and computer programs for school-aged siblings).
- Encourage questions.
- Explore questions for possible concerns not evident in questions.
- Provide source of backup for later questions.
- Encourage friendship and communications between siblings and other members of support group.

Sibling support group

- Provide sibling support group.
- Encourage friendship and communications between siblings and other members of support group.

The Time of Exacerbation or Deterioration Requiring Hospitalization

Having to hospitalize a child because of an exacerbation or deterioration of a condition, especially if these visits are frequent, results in added stressors for families of children with chronic conditions. For example, there is the commute between home and hospital or home and work, and there are decisions that have to be made regarding time off from work and care of the other children in the family. Many parents want to be with their child each and every time they are hospitalized (Fig. 12–6). Other parents may not feel the need to be present as much as when the child was first diagnosed or as much as the parents whose child is experiencing their first hospital admission for an acute condition. Some parents may feel a loss of parental control “as they increasingly must adapt to the hospital staff, and they may begin to lose their feeling of competence” (Lewis & Vitulano, 2003, p. 391). A significant number of hospital visits during the first

5 years of a child's life may impair the attachment between child and parent (Lewis & Vitulano, 2003). Although some parents express a significant desire to be with their child and to provide as much care as possible, just as they do at home, others see the hospitalization as a period of respite, and take the time to tend to their own needs. Be careful not to misinterpret this behavior as uncaring. Rather, see it as a sign that the family trusts the nursing staff to provide quality care to their child in their absence.

Staff who see children frequently in the acute care setting might become very attached to them and to their families. Regardless of how many times a child has been hospitalized, never assume that they do not need the same amount of education, support, and clarification of what is going to occur as other patients. They might experience great sadness as they see children start to deteriorate who have been in and out of the hospital for years. Those children and adolescents who are in school might miss being with their peers. Encourage the school to keep the student included, even during hospitalizations.

CLINICAL JUDGMENT 12–2

Sibling of a Child With a Chronic Condition

Lili and Nica are 3½-year-old twins. Lili has spastic diplegia cerebral palsy (CP); which has necessitated her wearing braces, using a walker, and receiving assistance getting on and off the toilet. Nica has no health problems. Their parents report that sometimes Lili says she wishes that she “had legs like Nica’s,” but more often Nica says, “I wish I had cerebral palsy.” Their parents report the following story during a routine health assessment for Lili and ask for your guidance in handling the situation.

One day, a piano tuner came over to check the family piano. Lili and Nica were sitting on the couch and were introduced. Lili piped up. “I have cerebral palsy, my legs aren’t strong like Nica’s, and I can’t run to the potty myself. I wear braces because I have cerebral palsy, but I’m getting stronger, and I can walk in my walker.” The piano tuner said to her, “Well, I’m sure there are lots of people to help you to the potty and to walk.” To which Lili replied, seriously “Yes, that’s right.” Nica looked sad that she didn’t have something special to tell the piano tuner. She put down the picture she had been enthusiastically working on for the last half hour and went out of the room.

Questions

1. What additional information would you try to elicit from the twins’ parents before addressing their concerns? What would you look for in the twins’ interactions if they were both present?
2. What are the signs that Nica may be having difficulty adapting to having a sibling with a chronic condition?
3. Do you think Nica is having a problem because her sister has a chronic condition?
4. What steps could the family take to assist and support Nica?
5. What outcomes would indicate that the twins are developing as expected?

Answers

1. Is this common behavior or does it occur only occasionally? Are there times when Nica is the one who is boasting rather than Lili? What other indications of expected sibling rivalry are present? Are there any times when it seems to occur more or less often? If Lili and Nica are both present, how do they interact with each other? Does Lili dominate the interaction, or does Nica appear to be on an even par with her sister?
2. Her comments about her sister and her failure to engage in the common sibling exchange in which each tries to best the other in achievements and for attention. The fact that she did not show off her drawing.
3. Without repeated observations it is impossible to answer this question. Although the behaviors indicated that she is having difficulties and may be depressed, the practitioner would need to verify this as part of a pattern.
4. Fully inform both girls of all events in the family, including facts about Lili’s condition. Reassess their interaction to see whether they are focusing more than is needed on Lili and her accomplishments and problems to the exclusion of Nica. Work with family to develop a plan to have times at which Nica is the center of attention to balance the time Lili must be. If Nica’s behavior remains negative or if she begins to actively withdraw or stop engaging in activities, refer to a family counselor.
5. Both girls continue to develop a relationship as sisters; each has opportunities to develop personal interests. Each sister may still want something that the other sister has, while still being happy for who she is.

IMPACT OF A CHRONIC CONDITION ON A CHILD/ADOLESCENT

It is often not until preschool that young children born with chronic conditions begin to perceive differences between themselves and their peers. It is during this time that they recognize there is a difference between male and female, and differences in skin color. This is also when they might become aware of differences of what they can and cannot do that their peers do. To help young children cope with these differences, it is impor-

tant both to acknowledge these differences and to treat them as normal. Children with chronic conditions will often perceive themselves as normal when they see that they are being treated just like other children.

The first task when working with older children and adolescents with chronic conditions is to find out what the condition means to them. What is their concept of the chronic condition and how do they think it affects their life? A nursing plan of care for the child with a chronic condition identifies interventions to support the child as he or she adjusts to the impact the condition has on his or her life (Nursing Plan of Care 12–2).

FIGURE 12–6. Encouraging parents to stay in the hospital room with their child allows them to gradually take on responsibility for the care needs of a child requiring complex physical care when they are home.

Impact on Physical Development

Consistently promote physical development for a child with a chronic condition and ensure that the child is receiving enough nutrients to support growth. This may be especially true for children who are unable to feed themselves or who are fed through alternative means, as well as children and adolescents with conditions such as spastic cerebral palsy in which a great deal of motor activity requires additional nutrients. Children with neurologic and orthopedic conditions often have decreased physical activity. They might be slow to crawl and walk, or they may be confined to a wheelchair. Decreased physical activity, especially disuse, often leads to osteoporosis and osteopenia, which could later put them at risk for bone fractures. Rehabilitative services such as physical therapy and occupational therapy can assist in developing goals and daily exercises for the child.

caREminder

Not all children who are below targeted growth parameters have impaired growth. It is important to evaluate whether a child is following his or her own growth curve. A child in the 10th percentile at birth who remains between the 10th and 15th percentiles throughout the first years of life may be doing well, although he or she is clearly smaller than most children of the same age. Other children have conditions that make use of the growth charts inappropriate. In a child with idiopathic scoliosis or scoliosis secondary to myelomeningocele, height may indicate very little about the child's actual development, although it can be used as part of the evaluation of the progression of the vertebral defect.

Impact on Achieving Developmental Milestones

Parents of children with chronic conditions are often acutely aware of the developmental milestones typically achieved at their child's age. Although the developmental

tasks are the same for children with chronic conditions, the rate of accomplishing them and the methods by which they are achieved may be different. For example, toddlers learn to say single words. However, a nonverbal child with Down syndrome may learn to use sign language to express certain words. Both of these examples demonstrate cognitive and social development, and should be applauded. The same is true for the child or adolescent who learns to use eye signals and computers to communicate.

Children who spend a significant amount of time in the hospital are also often slower in their physical and emotional development. They might have had less nurturing by a consistent caregiver and less love provided, because the focus is on the physical skills needed. Children who are frequently admitted to the hospital and those who are dependent on technology are not as free to explore the environment and to view nature (Fig. 12–7). They interact with adults much more than with children their own age. Adolescents have less opportunity for social events, which are so important for this age group. Adolescents with chronic conditions are often treated like younger children and are not afforded adult responsibilities and independence. They should be encouraged to begin taking responsibility for their care and for knowing their health history, because this will make it easier to transition into adult healthcare services.

Parents might often feel discouraged that their child has not achieved a particular developmental milestone and think, “If my child didn’t have _____, they would be able to do _____.” Many parents experience recurrent and/or chronic sorrow as they watch their children struggle to achieve developmentally appropriate tasks, especially as they become more acutely aware of differences and delays between their children and healthy peers (Melnik et al., 2001, p. 549). This chronic sorrow is not continuous, but rather occurs sporadically throughout the child’s young life (see Chapter 13 for more discussion on chronic sorrow). Although the parents might adapt functionally, in that they do all that is needed to keep the child moving forward, they might not internally accept the situation. Encourage parents of children with chronic conditions to recognize the milestones that their children do reach. If the first milestone is 6 months late, help the family to expect all milestones to be at least that late. If they come earlier, the family may be pleased.

Impact on Psychological Development

QUESTION: Discuss the impact diabetes has on Lindsay. What aspects of her development are affected by her chronic illness?

Although most children and adolescents are successful in coping with the needs associated with their chronic condition, it has been noted that children with chronic conditions are at increased risk for psychological adjustment problems (Taylor, Gibson, & Franck, 2008; Wallander

NURSING PLAN OF CARE 12–2: THE CHILD WITH A CHRONIC CONDITION

Nursing Diagnosis: Anxiety related to uncertain prognosis; actual or perceived loss of body integrity; threat to self-concept

Interventions/Rationale

- Inform the child about his or her condition and treatment in developmentally appropriate language, use age-appropriate techniques to discuss situations (e.g., drawing, telling a story, situation completion), and allow the child to cry.
Not knowing increases the child's anxiety, even if no new information emerges. The child can recognize that the healthcare team is caring.
- Provide the child/family support from the facility chaplain, social worker, or the child's own support system.
The medical staff can focus on the care of the child and the family if they are supported in coping with the situation.
- Use open-ended questions to elicit the child's and parents' thoughts and fears.
This approach can more accurately answer the issues at hand.
- Maintain routine and consistent staff if possible.
Predictable routines promotes security.
- Instruct in use of relaxation techniques (e.g., deep breathing, mediation, journaling). Role-play adaptive coping skills, and support and reinforce use.
Practicing the methods may help in using them when faced with a stressful situation.

Expected Outcomes

- The child will verbalize feelings of anxiety.
- The child will identify and use methods to reduce feelings of anxiety.

Nursing Diagnosis: Delayed growth and development related to physical effects of the chronic condition or its treatment; decreased access to usual socialization experiences

Interventions/Rationale

- Complete a baseline developmental assessment appropriate to the child's physical and cognitive abilities. Compare with prior assessments, if available.
Provides comparative data to determine whether delays are perceived or actual in nature. Provides data about delays that can be used as focus for future interventions.
- Discuss and promote the concept of "normalizing" experiences to promote self-sufficiency, adjustment, and mental growth.
Promotes self-sufficiency; adjustment, and mental growth.
- Permit the child to express feelings, but at the same time do not allow unacceptable behavior

(e.g., temper tantrums); reinforce appropriate behavior.

Promotes self-efficiency.

- Provide toys, games, equipment, educational supplies, and teaching that will enable the child to increase cognitive, social, and motor skills.
Tailored activities facilitate the child's ability to participate and achieve milestones.
- Communicate and interact with the child in an age-appropriate fashion; maintain dignity in all interactions with the child.
Simplifying communication may help the child process information.
- Allow and encourage family members, siblings, and nondisabled peers to visit and interact with the child.
Consistent interaction with family diminishes normal separation anxiety and increases the child's ability to cope; may limit regressive responses.
- Foster self-worth, provide personal space so the child's belongings are accessible, and encourage the child to care for the physical environment if appropriate.
Fosters self-efficacy, self-worth, autonomy, and responsibility.
- Arrange for the school-aged child to have normal educational experiences through hospital-based teachers or teachers from the local school system.
Provides opportunities for growth and development.
- Encourage peer visitation if not contraindicated.
Peers can help occupy the child's time and will decrease social isolation. Peers are important to adolescents, and interactions help them meet developmental milestones.
- Assist the family in evaluating the child's regressive responses to the illness or chronic health condition. Explain the effects of acute illness or chronic condition on a child.
Children typically regress when ill. A chronic condition may impose restrictions that limit the child's energy or ability to engage in age-appropriate activities. Parents who understand their child's responses are better able to support the child and assist the child in achieving his or her potential.
- Assist the parents to plan age-appropriate developmental activities for the child based on the child's capabilities.
Will help the child master skills to achieve developmental potential.

Expected Outcomes

- The child will have growth along his or her own growth curve, optimized within the restrictions imposed by the chronic condition.

NURSING PLAN OF CARE 12–2: THE CHILD WITH A CHRONIC CONDITION (CONTINUED)

- The child will participate in developmentally appropriate socialization experiences.

Nursing Diagnosis: Disturbed body image related to being different than peers; perceiving self as sick

Interventions/Rationale

- Explore the child's perception of body image and concerns of health status. Encourage discussion concerning misconceptions, fears, the reality of public discrimination, and social stigma.

Lack of knowledge or inaccurate perceptions may increase anxiety and result in activities that undermine the treatment plan. Knowing the child's perception enables teaching the child to address inaccurate beliefs or modification of the treatment plan to accommodate concerns.

- Actively listen while engaging in dialogue regarding feeling about self and personal appearance.
May reveal self-perceptions and allow discussion of reality versus perception. Child may be embarrassed and feel insecure and resentful about condition and ability to participate in activities considered normal for age. Expression/discussion of feelings may help coping and acceptance of new appearance.
- Encourage and reinforce positive self-statements. Discuss ways to highlight good feelings about self (e.g., improving grooming, hygiene).
Reducing negative thoughts can help increase positive body image.
- Assist child to find methods to enhance physical appearance, personal comfort, and daily management of disease process.
Promotes active adaptation to condition, with a variety of coping strategies to enhance self-esteem and promote normalization in daily life.
- Inform parents of the importance of treating their child as any other child.
Helps the child to feel normal and may avoid behavioral problems from lack of limits.
- Prepare the child to assume self-care responsibilities.
Will help the child achieve developmental potential.

Expected Outcomes

- The child will verbalize a positive body image.

Nursing Diagnosis: Social isolation related to lack of social skills; embarrassment, limited mobility, or energy secondary to specific condition; communication barrier

Interventions/Rationale

- Determine impact of chronic condition on child's ability to participate in school activities.
Provides evaluation of current situation to determine whether further interventions are needed.

- Contact school nurse/teacher to discuss any needed modifications in the child's activities.

Collaboration with school officials will provide a supportive environment for the child to ensure social isolation is minimized.

- Model and role-play appropriate social interactions.
Observing appropriate response and productive interactions may help the child to develop a repertoire of positive responses.
- Convey that you have time to spend with the child, actively listen, and observe verbal and nonverbal communication. Verify communication.
Can convey caring and may increase the child's trust and comfort with you.
- Collaborate with the interdisciplinary team (e.g., social worker, physician, school nurse, and so forth) to develop a plan for the child to participate in family, school, and social activities to their maximum capacity.
Provides an additional support system for the family to ensure child's successful adaptation at home and school.
- Promote coping methods that deal with changes in the child's appearance (e.g., select flattering clothes, improve personal grooming and hygiene).
Learning methods to compensate for changes in appearance can help improve child's self-esteem and improve social activity.

Expected Outcomes

- The child will participate in developmentally appropriate social activities.

Nursing Diagnosis: Sexual dysfunction related to specific effect of condition or its treatment on libido or sexual maturation; nonavailability of partners

Interventions/Rationale

- Discuss the relationship between sexual functioning and the disease process of the adolescent. Teach the importance of adhering to the medical treatment plan designed to reduce or control disease symptoms.
Misinformation and lack of knowledge may affect adolescent's concerns and desires to seek intimate relationships.
- Provide an atmosphere of openness, understanding, and acceptance.
Encourages the adolescent to share his or her feelings and concerns about these very sensitive issues.

Expected Outcomes

- The adolescent will verbalize acceptance of and satisfaction with sexual functioning.

Nursing Diagnosis: Dysfunctional grieving related to inability to adopt to the chronic condition; failure to restructure life after diagnosis of chronic condition

Interventions/Rationale

- Encourage the child to identify/express (e.g., verbally, through drawings, play) feelings and concerns about disease. Be an empathic listener.
Encouraging open expression of feelings may help the child mobilize his/her emotions and validate their concerns.
- Identify the actual, perceived, or potential loss.
Identification of the loss may help the child begin to grieve effectively.
- Identify the stress level of the child.
Stress may inhibit the ability to resolve emotional issues. A therapeutic approach can be taken if there is understanding of the stress level.
- Assess coping strategies in stressful situations. Help build on previously successful coping strategies. Assist the child/parent to look at alternative solutions, but avoid choosing the answer for them.
Identifies child's/family's usual style in confronting emotional pain/loss. Adaptive coping strategies may provide some relief for the overwhelming grief.
- Provide realistic assessment of the event or situation.
False reassurances are not helpful and may encourage dysfunctional coping strategies.
- Explain to the child/family that emotional responses to loss are appropriate and commonly experienced.
Acknowledging the loss is not a sign of weakness or loss of control. Grief is a universal experience.
- Make referrals to other professional (e.g., social workers, religious leaders) and community resources as appropriate.
Support systems can help in the process of grieving.

Expected Outcomes

- The child will successfully work through the grieving process and create a new definition of self and life goals.

Nursing Diagnosis: Hopelessness related to failing physiologic condition; prolonged pain; prolonged activity restriction; loss of something valued (ability to socialize, perform in school, belief in God)

Interventions/Rationale

- Ask the child how he or she sees things, whether anything helps him or her feel better, and what might improve the situation.
Hopelessness characterizes depression and may result in passivity and despondency.
- Use play therapy/role-playing to assist the child in gaining mastery over the issues of concern.
Provides a mechanism for the child to express self in a nonthreatening manner.
- Allow the child to make decisions concerning care. Keep decisions simple. Restrict choices so as not to overwhelm the child.
Provides the child opportunity to have some control over his or her life.
- Engage the child in activities that match or are slightly below his or her developmental level. Provide opportunities for success; avoid activities that set the child up for failure.
Providing positive opportunities may help the child experience the ability to solve problems. Encourage further engagement in problem solving.
- Advance to increasingly higher level tasks, and praise and reinforce accomplishments.
Allows/encourages the child to demonstrate age-appropriate behaviors and developmental tasks.
- Allow the child to make decisions concerning care (e.g., when to brush teeth, comb hair) if appropriate. Keep decisions simple. Restrict choices so as not to overwhelm child.
Allows the child to make simple decisions regarding care.

Expected Outcomes

- The child will express feelings in age-appropriate ways.
- The child will verbalize a sense of control and a positive outlook on life.

et al., 2003). The Ontario Child Health Study found that “children with chronic conditions and major disability were 3 times more likely to have a psychiatric disorder than their healthy counterparts, controlling for age- and sex-specific risks for psychiatric problems” (Witt, Riley, & Coiro, 2003, p. 687). Children with learning and communication impairments were at a higher risk for having psychosocial adjustment problems. Also at risk were those whose mother had poor physical or mental health, and those who were raised in the presence of poverty (Witt et al., 2003).

Children and adolescents might have specific concerns related to their condition. For example, the adolescent with seizures may have anxiety about losing conscious-

ness and losing control, especially in front of peers. Bowel problems might result in discomfort in being with others as a result of the odor or possible loss of control. The stress of having a chronic condition can also be cumulative. “Cumulative risk may arise from such stresses as loss of autonomy, relative immobilization, impaired function, and disfigurement” (Lewis & Vitulano, 2003, p. 391). However, young people might also learn to use their condition and symptoms; the child with asthma might learn to use wheezing as a means of getting out of household responsibilities or activities.

How a child and family cope with the child’s chronic condition can affect the child’s body image and self-esteem. Children with chronic conditions should *not* be

FIGURE 12–7. The presence of a chronic condition does not necessarily prevent the child from engaging in age-appropriate activities.

treated as if they are sick (except during exacerbations) or different. Promote a “you can do it” attitude. Remember that a child should *not* be defined as his or her condition. The fact that a child has a chronic condition should just be another component of the child’s personality. A nursing goal should be to assist them to compensate for their disabilities (Developmental Considerations 12–1).

Children with chronic conditions often begin to feel different from their peers and, perhaps, “abnormal” when others stress the child’s differences and the significant accommodations that have to be made regarding these differences. When the home is set up like a mini intensive care unit (ICU), for example, it gives the message that the child is sick. The focus is on the illness component and the goal becomes getting the child well. Home medical equipment should be as inconspicuous as possible, with the room resembling a typical child’s room. However, children who are dependent on technology, especially those on ventilators, often have a decreased opportunity to explore their environment, to play hide-and-seek, to catch lightning bugs, and to interact with others their age (Selekman & Gamel-McCormick, 2006). They often have a loss of privacy. Families should be encouraged to provide age-appropriate activities (Fig. 12–8). For adolescents dependent on technology, in-style clothing should be modified to accommodate the equipment, yet also make the child feel similar to their peers.

Continue to educate the child about his or her chronic condition when the child moves to new developmental stages or activities (e.g., begins school and travels on the school bus), the condition takes on a new dimension (e.g., blood sugar becomes more difficult to control through the growth spurt of puberty and adolescence), or the family changes (e.g., divorce, remarriage, birth of a child, departure of a sibling for college). As the child develops cognitively and emotionally, the need and ability to learn about his or her condition also evolve. In addition, the impact of the condition on the child, as perceived by the child, will also change. By empowering self-responsibility, the child or adolescent should feel pride in his or her accomplishments, knowledge base (that often can be used to impress one’s peers), skill set, and ability to overcome

obstacles. If presented in a positive way, the child’s self-esteem should increase.

Specialty camps during the summer are specifically geared to children with specific chronic conditions. There are camps for those with cancer, diabetes, cognitive and neuromuscular deficits, and obesity, where the goal is to allow children to be children and to be with others who have the same condition, so that the stigma is erased. Conventions for those who are deaf or of short stature also promote self-esteem and normalcy. The Special Olympics provides a forum for individuals with disabilities to compete and for which they can train during the year and receive recognition. All these forums promote self-esteem and self-respect for both the children and their families.

ANSWER: Lindsay’s ability to spend time with her peers and away from her parents is affected by her diabetes. Sleeping over at a friend’s house becomes much more problematic. Attending summer day camps and overnight camps are often not possible for a child with diabetes, except for the camps for children with diabetes.

REHABILITATION AND HABILITATION

Children and adolescents with orthopedic and neurologic chronic conditions are often engaged in long-term rehabilitation. **Rehabilitation** entails trained and committed health professionals who perform a wide range of services and provide care to the patient to improve or assist with *restoring* function lost through injury or illness. The process includes patient and family support and education to help them adjust to an altered level of functional capacity and possibly altered lifestyle. Principal goals of rehabilitation are to help persons learn lifelong management of their condition or disability, institute health maintenance and preventive strategies, return to work, and become contributing members of society. Pediatric rehabilitation focuses on improving the lives of children with disabilities by *relearning* previous skills and abilities and *returning* to the community (Selekman, 1991; Selekman & Gamel-McCormick, 2006).

Habilitation is similar to rehabilitation because it involves the same professionals who provide services to the child and family; however, the focus is on helping the child with acquired and developmental disabilities *learn* new skills and first-time abilities to achieve his or her maximum potential (Adsit & Hertzberg, 2000). Learning developmental tasks the first time are challenging enough; yet, for the child affected by a disabling condition since birth or early childhood, the skills can be even more difficult. To acquire these developmental tasks, the disabled child might require the implementation of therapeutic interventions with the assistance of healthcare professionals. The terms *rehabilitation* and *habilitation* are often used interchangeably, and both focuses can occur simultaneously. For instance, the infant who is a victim of

DEVELOPMENTAL CONSIDERATIONS 12–1

Potential Effects of Chronic Conditions on Development

Stage	Expected Developmental Achievements	Potential Barriers to Developmental Achievements	Strategies to Promote Development
Infancy	Sense of trust and security Sensorimotor skills Gross motor control	Parental grief Altered feeding experiences Restriction of movement Hospitalization(s) Painful procedures Chronic discomfort Multiple caregivers Inconsistent routines Lack of consistent response to infant cues	Provide consistent care from a limited number of caregivers Establish reciprocity—caregiver responds to infant's cues and infant is given opportunity to respond to caregiver's cues Expose infant to normal range of environmental stimuli while ensuring periods without stimuli Assist parents in the development of attachment and caregiving/parenting roles Enroll in early intervention program if appropriate
Early Childhood	Autonomy and self-control Increasing gross and fine motor skills Independent activity Development of speech Cognitive and social growth Initial development of ego centric thought Normal negativism, confrontations over everyday activities, especially feeding and discipline	Negative response to anything that is restrictive Parents desire to control all activities Limited interaction with other children and adults beyond family Parental conflict between need to discipline and need to complete life-sustaining care Decreased quality and quantity of play opportunities	Teach and support development of usual parenting skills Encourage active interactions with environment (e.g., mobility devices as needed; playing on floor; going out in neighborhood, to mall, to see family and friends) Encourage full range of play activities to develop social, fine and gross motor ability, and cognitive skills Set limits as usual Support parents as child becomes more active and less under their complete control
Middle Childhood: Preschool	Initiative Egocentrism increases Beginning to understand internal body, but thought processes still preoperational Still understands events only through his or her own experience with them Varying understanding of body function and illness	Medication requirements Dietary restriction Mobility restriction or inability to be mobile without assistance Need for adult supervision but need to be with peers Repeated separations from family Caregiver difficulty with limit setting	Promote active involvement with environment Enroll in activities (pre-school, daycare) that allow interaction with other children Identify and correct incorrect associations between events and causes Begin education about condition

Potential Effects of Chronic Conditions on Development (*Continued*)

Stage	Expected Developmental Achievements	Potential Barriers to Developmental Achievements	Strategies to Promote Development
Middle Childhood: School-age	<ul style="list-style-type: none"> Industry Sense of accomplishment/mastery from activities undertaken Begin development of independence from family Develop relationships with peers, school, play groups Refine gross and fine motor, cognitive, and social skills 	<ul style="list-style-type: none"> Differences from peers Dependence on medical care Restriction on independence Requirements for adult monitoring Medication, dietary, activity requirements/restriction School absences Inability to fully participate in desired activities 	<ul style="list-style-type: none"> Allow and encourage participation in self-care activities Promote full participation in school Explore ways to increase stamina and decrease exhaustion Help parents deal with fears related to vulnerability of child Identify barriers to achievement and develop plan to overcome or bypass them Educate about normal changes caused by conditions Encourage increasing self-care Encourage child to develop strategies to deal with negative aspects of condition
Adolescence	<ul style="list-style-type: none"> Sense of identity Increased independence from family Develop problem-solving skills, abstract thought Fuller understanding of body function and condition Accept changes in body image: rapid physical growth, sexual maturation Prepare for life as an adult; choice of vocation Reluctance to accept own vulnerability, leading to increased risk-taking activities 	<ul style="list-style-type: none"> Altered body image Decreased growth Visible deformity Need for adult supervision and/or assistance with daily activities Medication and dietary requirements Possible vocational limitation Development of sexuality Need to explain condition to others 	<ul style="list-style-type: none"> Educate about normal changes of adolescence Explore questions related to sexuality Prepare for transition to adult caregivers Explore sources of social problems Continue education about condition, care of condition Encourage active participation in decisions about own care Re-evaluate level of participation in own care and increase if appropriate Integrate care requirements into daily activities

shaken baby sudden impact syndrome might be admitted to a rehabilitation unit to relearn feeding skills, yet therapists will also focus on new developmental tasks, such as rolling or sitting up (if the child had not yet attained that skill before his or her injury).

Rehabilitation and habilitation services for children have dramatically expanded during the past half century as a result of ongoing advances in technology and medical science, a substantial decrease in child mortality rates, and children with chronic conditions living longer, often into

FIGURE 12–8. The adolescent with disabilities benefits from social interaction.

adulthood (Pastor, Makuc, Reuben, and Xia, 2002). The expansion of rehabilitation and habilitation services for children has also been influenced by the changing nature of hospital reimbursement, decreased lengths of hospital stays, the belief that outpatient and home care services reduce costs, patient preferences, the belief that children should live and thrive better in a natural homelike environment, and legislation that has supported the rights of individuals with disabilities (American Academy of Pediatrics, 2005; Mentro, 2003; Wang & Barnard, 2004).

Unique Features of Pediatric Rehabilitation and Habilitation

Rehabilitation of children differs from that of adults in several ways (Developmental Considerations 12–2). The primary difference between children and adults that forms the basis for understanding all variations in rehabilitative and habilitative services is that adults have reached a level of physical and mental maturity that children have not. Children are in the midst of their growth and development, learning new skills and tasks. The child's cognitive level continues to change, as do his or her emotional, psychosocial, and sexual areas of development. Pediatric physicians, nurses, and therapists need to apply knowledge of developmental theories and age-appropriate strategies to the treatment plan (see [thePoint](#) for Supplemental Information for additional information about members of the rehabilitation healthcare team). For example, the rehabilitation team working with a 15-month-old child would focus on mobility, play, and communication skills (Fig. 12–9). Toileting and dressing would not be focal points because most toddlers would not have mastered these skills yet. The child's learning process is affected by cognitive and developmental factors that may not have an influence on the adult's ability to learn. For example, toddlers and preschoolers learn through exploration, by discovering their world. If a child's environment is limited to the length of an oxygen or ventilator tube, or if experiences

are limited by physical immobility, the focus of rehabilitative care would be on assisting the child to compensate for this limitation. For instance, the family would be instructed to use extra lengths of oxygen tubing and/or a small oxygen tank that could be easily moved from room to room to broaden the world of the oxygen-dependent child. Or perhaps the young child with limited physical mobility would be encouraged to explore his or her environment in a power wheelchair. Unlike an adult, the child may not be aware that there is a world full of exciting adventures and experiences beyond the scope of what can be immediately seen and touched.

The adult in rehabilitation often has a repertoire of past knowledge and experiences from which to build new adaptive skills and to learn to compensate for what he or she has lost as a result of illness or injury. However, the child may not have such a strong experiential basis on which to build. For example, a kindergartner who experiences disfiguring burns on the arms and upper chest must learn, all over again, how to hold a spoon and a drinking cup, as well as how to acquire the new ability of writing.

caREminder

Rehabilitation and habilitation programs are designed for the child to achieve greater mental, physical, and social development. Thus the child must be rehabilitated to his or her current developmental stage and habilitated to acquire new developmental tasks that the child would be acquiring had the injury not occurred.

The adult's rehabilitation goals are to improve function, gain independence, and return to work. Many of the therapy sessions are directed with these goals in mind. Therapies can be difficult, with a grueling repetitive nature to the exercises, yet the adult can usually stay motivated by comprehending the ultimate goals. Children, on the other hand, have a different focus. The work of a child is play and learning in school. Therapists and nurses often have to incorporate fun and creative play into the therapies or treatment sessions to keep the child motivated and involved (Fig. 12–10). The center of pediatric habilitation or rehabilitation is school entry or reentry, respectively; therefore, general education (ABCs, reading, writing, and arithmetic) should also be incorporated into treatment sessions and the overall plan.

Adults most often require rehabilitation because of a sudden disability resulting from a stroke, illness, or injury. In contrast, children most commonly need rehabilitation because of a disability resulting from a chronic condition. Although conditions requiring rehabilitative and habilitative services vary widely, they often share many challenges and commonalities in the functional limitations that can affect the child. These include neurodevelopmental challenges, physical disabilities, conditions caused by genetic disorders, chronic conditions, and complex medical conditions. More complete discussions of specific disease processes can be found in Chapters 14 through 31 of this text, in which alterations in specific body systems are presented.

DEVELOPMENTAL CONSIDERATIONS 12–2

Differences Between Rehabilitation of the Adult and of the Child

In Adult Rehabilitation

The focus is on reintegrating or compensating for what is lost.

The needs for rehabilitation involve suddenly acquired conditions such as trauma, stroke, and heart disease or debilitating conditions such as diabetes, arthritis, and pulmonary disease.

Physical development is complete for the most part. Emotional development and cognitive development have also reached a plateau, with growth continuing, but with less variance than in the pediatric population.

The family is important as a source of support and as an adjunct to treatment.

The goal is to teach the adult to care for himself or herself.

The focus is on vocational rehabilitation, teaching skills and knowledge so that the adult can perform or resume an occupation.

The necessity for rehabilitation is a new concept. Before the condition that brought him or her to the point of requiring rehabilitation, the adult was able to care for himself or herself and to complete daily activities.

Experiencing chronic pain, discomfort, or the need for treatment as a result of the condition and undergoing rehabilitation may be relatively new experiences.

In Pediatric Rehabilitation

The focus is on helping the child to attain skills and abilities at a level that may have been previously unknown to the child.

The needs for habilitation involve some form of chronic illness, congenital anomaly, or disabling condition acquired as a result of medical interventions that have sustained the child's life.

The child continues to experience a tremendous amount of physical, emotional, sexual, social, and cognitive development.

The family must simultaneously learn to care for the child and foster the child's development as well as learn to manage their own individual and family needs.

The goal is to teach the child to care for himself or herself as appropriate for age and capabilities.

The focus is on educational rehabilitation, reaching the highest academic level possible, while teaching the child life skills that would be accomplished by any child, such as ordering food in a restaurant, receiving change from a purchase, and using public transportation. Therapeutic support services also assist in developing skills such as walking, building a block tower, combing one's hair, and learning to color.

The child's disability is the norm. The child has a known dependence and, depending on the age at onset, is likely not to have known a life without his or her chronic condition.

The experience of chronic pain or discomfort or the need for treatment may not be new to the child. The child with a disability or a chronic condition may already have spent many years with these experiences as a result of the condition.

Information adapted from Selekmán, J. (1991). Pediatric rehabilitation: From concepts to practice. *Pediatric Nursing*, 17, 11–14, 33.

Levels and Settings of Rehabilitative and Habilitative Care

Rehabilitative and habilitative services for children fall along a continuum of healthcare. The choice of setting for an individual child is determined by the child's level of medical acuity, the family's insurance, and the availability of specialty pediatric rehabilitation services in the community. *Level of care* can be defined as the intensity of

rehab involved. The different levels can be grouped as inpatient services and outpatient services.

Inpatient Services

Acute rehabilitation refers to the phase of rehabilitative services provided immediately after an injury, illness, or surgical procedure. Ideally, rehabilitation services such as proper positioning, bowel and bladder programs, range-of-motion exercises, and family education should start as

FIGURE 12–9. Pediatric rehabilitation and habilitation services help the child regain and learn new skills that are appropriate to his or her developmental age.

early as feasible. Some children begin therapies while in the pediatric or neonatal intensive care units. Early rehabilitative services can prevent secondary complications such as pressure ulcers, muscle contractures, and constipation or urinary tract infections. After the child is medically stable, therapeutic services are delivered through an inpatient (hospital setting) pediatric rehabilitation program or a center providing coordinated and integrated services with physician oversight and around-the-clock nursing care.

The pediatric **subacute rehabilitation** program focuses on rehab services to medically fragile children, oftentimes those with technologic needs. These children transferred to subacute care generally do not require the medical intensity of acute care, but are still not well enough to go home. They are admitted and receive continuous care in a subacute inpatient care fa-

FIGURE 12–10. Play is the young child's motivation for participation in rehabilitation therapies.

cility. Concerns exist about the exact role of subacute care because of duplication of similar services in other care settings (American Rehabilitation Association, 1996). Continued patient and family teaching is emphasized, with a goal of reentry to the child's home, school, and community.

Outpatient Services

Outpatient rehabilitation provides services to children who no longer require hospitalization. Outpatient rehab can consist of comprehensive programs (day rehab, where children receive intensive interdisciplinary coordinated services during the day, but go home with their families at night), single service or multiple services (not program based or coordinated, yet receiving one or multiple types of therapies usually weekly), and community-based services (home or school setting). Many children with congenital or special developmental healthcare needs never require hospitalization for rehabilitation services. Instead, these children receive periodic evaluation by a pediatric physiatrist (a physician who specializes in physical medicine and rehabilitation) or primary care provider who may prescribe therapies. Therapy services should be prescribed to meet specific goals and focus on reinforcement of adaptive techniques to optimize functional ability and independence.

Community-based rehabilitation delivers therapy services in the child's natural environment (e.g., home, school, early childhood education program, child care setting). Treatment plans are formulated by the family and community care providers, typically as part of the individualized family service plan or the child's individualized education plan (IEP). Therapeutic services generally focus on education of the family, optimizing academic achievement and the function of the child in the school setting and the community.

Children can also live in residential settings (long-term facilities) instead of with their families. Many of these institutions have incorporated rehab or habilitation programs. These institutionalized settings were much more common in the past, but are still necessary today as an alternative setting for caring for children with long-term physical healthcare needs. Some parents have described the emotional strain involved when forced to make the difficult choice of institutionalizing their child, yet claim inadequacies of the system (primarily, lack of financial and caregiver assistance) as the reason for placing their child. Many families stay involved with their children, often accompanying them to doctor's appointments and caring for them at home on weekends or holidays.

Some of these settings might also provide respite care or short-term care in the absence of the regular caregiver (parent or guardian) to provide a rest or break for the family. Occasionally, coordinated relief of caregiver responsibilities is needed in times of crisis or undue emotional or physical stress. The major emphasis during this time is on psychosocial support for the family.

Assessment of the Child With Rehabilitative and Habilitative Needs

Regardless of level of care or setting, assessment of the child with a long-term disability requires the use of standardized measurement tools and ongoing assessment information gathered by members of the rehabilitation or habilitative team (Focused Health History 12–1). Measurement tools in rehabilitative and habilitative care provide an objective measure of the child’s functional abilities. They also provide information regarding the needs of the child and the family, the effectiveness of interventions, and the success of a specific rehabilitative or habilitative program. Few tests, however, are available that specifically address all the special needs of children and their families. As such, the measurement tools should not be used in isolation, because no single tool provides a complete picture of a child’s needs. Rehabilitation and habilitation teams generally find it useful to adopt two or more pediatric measurement tools, tailoring aspects of each to capture the specific needs of a particular patient population. The WeeFIM and Pedi are the most common functional outcome tools used in pediatric rehabilitation (see [thePoint](#) for Diagnostic Tools: Measurement Tools Used in Pediatric Rehabilitation for a review of the outcome tools that can be used by the pediatric rehabilitation team).

Management of Functional Limitations

The focus of care for the child dealing with the effects of a sudden illness, injury, or a chronic condition is to enable the child to lead a life as independent and age appropriate as possible. Achieving that goal requires that all of the child’s growth and development needs, in addition to the impact of disability, be considered and addressed by the healthcare team. First, a focused and comprehensive health history and assessment of the child with rehabilitation or habilitation needs is performed (see Focused Health History 12–1). In addition to the child’s condition, the family’s ability to care for the child identifies areas requiring special attention. Then, appropriate goals can be identified with the child and family to direct the plan of care (see [thePoint](#) for Nursing Plan of Care for the Child in Rehabilitation/Habilitation). The plan of care in rehabilitation differs from that when managing a child with an acute condition. In rehabilitative services, the plan of care is for the interdisciplinary team, and interventions are communicated as goals (both short and long term) for the child and family to achieve.

As with all children, the approach to care should be guided by the child’s understanding of and ability to cope with a given situation. For example, an 8-year-old with a developmental disability undergoing orthopedic surgery may not benefit from a coloring book depicting the operating room and recovery room. If his or her cognitive ability is at a 4-year-old level, it may be more beneficial to have the child handle equipment such as the face mask used by the anesthetist, trying it on a doll’s face and then on his or her own face. Likewise, placing a bandage

“cast” on a doll’s leg helps prepare the child for what he or she will find after surgery. The child with physical impairments, regardless of his or her level of intelligence, should be afforded every opportunity to participate in self-care activities that will foster independence.

Focal Areas of Treatment Program

Regardless of the reason for rehabilitative and habilitative services, the basic components of the treatment program need to identify and address the child’s functional limitations in the following areas: ambulation and mobility, dressing, personal hygiene, bladder and bowel management, grooming, language and communication, eating, and acquiring vocational skills.

Ambulation and Mobility

Ambulation depends on an ability to perceive one’s position in space (proprioception), to maintain a sense of balance, and to support the body while shifting weight to move the feet in sequence. Children with hemiplegia or diplegia may learn to walk if spasticity and impaired control are not too severe. These children might be at a modified independent level requiring a device, a cane, crutches, walker, or long- or short-leg braces for stability. Children with quadriplegia, depending on the severity and type, may walk only with the assistance of a helper and a supporting device, usually for limited or short distances. Wheelchair mobility requires a good seating system for stability and the strength either in the upper extremities to be able to reach the wheels and move them with the hands or in the lower extremity to be able to touch the floor and move the wheelchair with the feet. A power wheelchair might be considered if strength, balance, and endurance are a problem, although the controls may require adaptation. Proper seating is essential and is a particular challenge with growing children. An ill-fitting wheelchair exaggerates abnormal movement. Individuals with cognitive issues or perceptual deficits may have difficulty steering properly and safely. Therefore, safety factors to be considered include the child’s level of development and judgment. The rehab nurse is always aware of how the child moves about the environment as he or she supervises and assists as necessary.

Transfers are essential in many activities of daily living (getting on and off the toilet or in and out of a tub, for example). Some children with disabilities have balance issues, poor muscle control, or visual problems that impair their ability to maneuver and perform these skills. Generally, children with spastic diplegia with upper extremity function can use a slide board or pivot independently. Moderately affected children who are able to support their weight on their lower extremities and maintain balance can also pivot transfer with assistance. When an injury to the spinal cord is involved, the transferring situations are usually from one seated surface to another (e.g., bed to wheelchair, wheelchair to toilet or shower chair). Children who are more disabled may require a two-person or mechanical lift transfer. Pediatric nurses working in rehabilitation must know the type of transfer, the assistance required, and how to incorporate body

FOCUSED HEALTH HISTORY 12–1

The Child With Rehabilitation and Habilitation Needs*

Current history	<p>Primary diagnosis and associated disorders, sensory deficits, cognitive/communicative issues, motor impairments, functional limitations, safety precautions, services, and treatments</p> <p>Current Medications</p> <p><i>Symptoms and treatment program</i></p> <ul style="list-style-type: none"> • <i>Neurologic</i>: Decreased responsiveness to stimuli, irritability, lethargy, decreased strength, persistence of primitive reflexes (thumb/fist posturing, symmetric tonic neck reflex, asymmetric tonic neck reflex, Moro), asymmetry, dystonic or abnormal movements, hypotonia, hypertonia, spasticity, or seizures may reflect the child's typical level of functioning. Changes from the child's normative level may indicate changing condition. • <i>Specific neurologic support strategies</i>: Environmental stimulation strategies, monitoring, positioning, and range of motion (ROM) • <i>Additional system assessment based on child's condition (e.g., respiratory, elimination, musculoskeletal, skin)</i>: Determine typical manifestation of child's specific condition. Changes from the child's normative manifestations may indicate changing condition. • <i>Specific support strategies: Respiratory</i>: Ventilator care, artificial airway management, apnea monitor, bilevel positive airway pressure (BIPAP), suctioning/respiratory care procedures, oxygen, nebulizer treatments • <i>Specific support strategies: Elimination</i>: Toileting program, catheterization schedule, devices used for incontinence management, bowel program • <i>Specific support strategies: Musculoskeletal</i>: ROM exercises, positioning use of splints and devices • <i>Specific support strategies: Skin integrity</i>: Dressing changes, sitting and turning tolerances, pressure relief methods, specialty equipment (cushions/mattresses)
Past medical history	<p><i>Prenatal history</i>: Maternal conditions (e.g., placental abruption, toxemia, coagulation disorders, Rh incompatibility, trauma) or maternal infections (e.g., rubella, cytomegalovirus, toxoplasmosis) and/or multiple pregnancies are associated with cerebral palsy (CP); complications of delivery</p> <p><i>Neonatal history</i>: Infant's gestational age in weeks and birth weight (prematurity and low birth weight associated with CP), spontaneous breathing at birth, meconium staining, Apgar scores (5-minute Apgar score less than 7 points may be associated with asphyxia, traumatic delivery, hemorrhage, nuchal cord), neonatal intensive care unit admission and length of stay, need for assisted ventilation or oxygen, jaundice/need for bilirubin lights, seizures, drug exposure (type/presence of withdrawal), infections (bacterial meningitis, viral encephalitis associated with CP), hypoglycemic events (may be associated with neurologic insult)</p> <p><i>Previous health challenges</i>: Past surgeries: gastrointestinal procedures such as fundoplication, gonomy tube, or button (swallowing problems); orthopedic procedures such as tendon releases or bone surgeries (CP, brain injury, muscular dystrophy, arthritic conditions); neurosurgical procedures such as rhizotomy, baclofen pump placement (CP); urinary diversion procedures such as spina bifida, muscular dystrophy.</p> <p>Pain issues (related to scoliosis, hip dislocation, spasticity, contractures)</p>
Nutritional assessment	<p>Growth patterns plotted on growth curves (head circumference, height, weight and body mass index), food allergies</p> <p><i>Feeding patterns</i>: Poor suck, difficulty swallowing, episodes of coughing, pocketing or choking during meals, increased time to eat meals, poor intake are signs of feeding difficulties</p> <p><i>Specific feeding strategies</i>: Type, consistency, texture, formula type, amount and frequency of feedings, and supplements</p>

mechanics in every transfer performed for the patient and their own safety.

Dressing

Dressing is a developmental milestone and a basic activity of daily living. When a child has physical limitations, the caregiver frequently fosters dependence without intending to do so. The functional abilities necessary for independence in dressing include cognitive recognition of the garments that are appropriate for the weather conditions, motor planning or sequencing of the task (underwear before pants and shoes), the ability to access clothing from storage areas, the strength to shift weight and maintain balance in a sitting or standing position while negotiating limbs into the garment; the flexibility to reach parts of the body, eye–hand coordination, and the manual dexterity to maneuver the garments and/or assistive devices. Children with disabilities benefit from rehab nurses who know their assistance level requirements and can assist them to foster independence in this area.

Personal Hygiene

Personal hygiene, like dressing, is an activity of daily living that in our culture generally commands respectful privacy. Personal hygiene includes activities related to bathing, washing, and toileting. These activities require accessibility of bathroom fixtures. Safety in performing

these activities is also a concern. Children with a mild disability may need only initial assistance in preparation and supervision, especially in areas of safety (e.g., monitoring the water temperature, placement of bath mat, and level of water in the tub or the sink). Children with a moderate disability require physical assistance in performing parts of the care. Children who have more severe functional limitations may be completely dependent or able to assist the caregiver only partially in these areas. Generally, the more dependent a child is, the more the responsibility of privacy falls on the caregiver. Rehab nurses can be pivotal educators by ensuring privacy, and by teaching modesty and sexuality when the opportunity arises during bathing or toileting an individual.

Bladder and Bowel Management

Bladder and bowel management refers to the control of urine and bowel movements. The functional skill of continence is one of the most important developmental milestones a child achieves. If not met, a child may be left behind or may have limited participation in activities—for instance, not going to preschool if continence is a prerequisite. The timing, strategies, and expectations of toilet-training practices differ widely. For children with disabilities who have physiologic, environmental, and social challenges, a team approach to their bladder and bowel management might be necessary, and generally the

nurse takes the lead. Bladder and bowel control might require the use of equipment (e.g., urinal within reach for the mobility challenged or supportive toilet seat for the child with trunk weakness), medications (e.g., laxatives, anticholinergics), or assistance (e.g., cueing the child with a brain injury to toilet before and after therapy). Another example is the child with spina bifida who needs to compensate for the loss of these functions. A clean intermittent catheterization program (ICP) might need to be performed by a caregiver initially, but can be performed independently by the child upon reaching school age. The goal is to be independent and dry between catheterizations, because an unregulated ICP with urinary accidents interferes with socialization. A bowel program (such as a daily suppository, which is necessary to prevent fecal incontinence and embarrassment for the school-aged child) may continue to be administered by the caregiver for a longer period of time, although ultimately will become the child or adolescent's responsibility.

Grooming

Grooming activities include hair brushing and oral hygiene, as well as shaving or makeup application in adolescence and adulthood. Although perhaps not considered as critical as dressing and personal hygiene, these activities of daily living are vitally important to the child's self-esteem. Generally, these activities require upper extremity strength, manual dexterity, and visual acuity with eye-hand coordination. The rehab nurse's contribution might be to ensure that the child perform these skills as able on a daily basis.

Language and Communication

Language and communication are essential functional components. Language development involves the ability to hear, to interpret, and to understand situations encountered in the environment. It also involves the ability to formulate thoughts and to interact with the environment and with other persons in it. Communication skills are essential to interacting with others. Making one's needs known in a manner that is understood by others is a basic function of all humans. Compromise of this process can be related to several conditions: cognitive deficits, sensory impairment (e.g., vision, hearing), motor impairment (e.g., dysarthria, or difficulty forming words with the structures of the mouth), or an alteration in physical structures (e.g., tracheostomy). Rehab nurses working with a child who has a communication impairment assists the team in developing a reliable yes/no system and helps the child use signs, gestures, verbal language, or an alternative communication device. Augmentative or alternate communication systems provide a means to interact and facilitate meeting the child's needs. Some are very simple (picture and word boards) and others are quite sophisticated (alphabet board or technologic talking systems). Rehab nurses require patience, a familiarity of the device used by the child, and knowledge of strategies used to facilitate language or communication skills.

Eating

Eating problems may include poor control of the lips, the tongue, and the airway protective mechanisms; slow eating; and poor chewing and swallowing ability. Visual-motor problems interfere with the coordination of motions for scooping and carrying the food to the mouth. Feeding problems may also be related to a variety of other clinical problems, such as: hypotonia, a weak suck, poor coordination of swallow, tonic bite reflex, hyperactive gag reflex, exaggerated tongue thrust, drooling, aspiration, gastroesophageal reflux, and the child's inability to communicate hunger. Constipation can also affect the child's appetite. Pediatric rehab nurses are attuned to feeding and developmental issues as they provide for a safe eating environment, assist children with this skill, use alternative (nasogastric or gastric) feedings, and continuously monitor for problems.

Acquiring Vocational Skills

Vocation and employment options are a key aspect of function and development. The law, IDEA, requires that IEPs include the adolescent's specific vocational goals (also see Chapters 2). The adolescent, parents, vocational counselor, educators, therapists, physician, and nurse all participate in the planning process and play a role in guiding the teen and family with idealistic and realistic objectives. Cognitive deficits and mobility limitations are the greatest factors in determining the vocational possibilities for an individual with a disability. The young adult may achieve development of skills and hopefully enter the workforce in competitive employment, supported employment, or even a sheltered workshop where they can be productive and develop a positive self-esteem. The astute rehab nurse, who is knowledgeable about vocational rehabilitation, may play a vital role in this process. The nurse can help create opportunities to learn new skills in the home, school, and community; investigate adaptive hobbies; and foster talents. The nurse should also keep an open mind and ask the child with a disability, "What do you want to be when you grow up?" If the child answers, "I want to be a veterinarian," suggest that the child visit and volunteer at the local humane society, which can foster her idea of caring for animals. If the child says, "I want to be a baseball player," explain that a professional athlete needs to be physically fit to achieve this goal. Propose that the child get involved in "buddy ball" or adaptive sports now, and begin incorporating a fitness program in his daily routine. Generally, children's goals are supercilious; however, with participation in the activity and time they will usually gain a more realistic perspective and oftentimes even formulate different ideas. The most important point is to raise the question to the child with disability, which bestows an impression that they should be productive and work later in life.

When determining life skills and adaptation, it is also important to consider the child's ability to socialize with peers and to experience success. Recreational activities for children with disabilities may be as therapeutic in facilitating physical function as they are in teaching them

FIGURE 12–11. Therapeutic riding and adapted sports are rehabilitative activities that provide socialization and an opportunity to achieve.

alternative ways to participate in activities (Fig. 12–11). Each experience brings an opportunity for the child to achieve and obtain mastery of age-appropriate developmental skills and abilities. In addition, children with disabilities can participate in athletics at a variety of levels that use leisure time, can be fun, and may promote fitness and self-esteem.

Adaptive and Assistive Devices

To maximize the child’s independence and to support the child’s recovery from an injury or illness, the rehab nurse needs to know what **adaptive devices** and **assistive devices** the child uses. Adaptive and assistive devices are equipment or tools used to alter the environment and enhance functional abilities. The use of positioning devices that maintain alignment is essential in rehab. In addition, positioning the child in relation to his or her external environment can positively foster the child’s function. For example, speaking to a child from above his or her line of sight fosters poor muscular alignment; speaking at eye level promotes positive alignment. Positioning a child in bed who favors his or her right side with toys on the right side of the bed fosters continued preference and possible contracture development. Contractures may develop when muscles consistently have increased tone and remain in shortened positions for prolonged periods. Therefore, positioning the child with items of interest to the left side enhances the child’s desire to turn in this direction and fosters elongation of the trunk muscles and extremities.

The use of “siders” and corner seats for infants and young children promotes flexion and appropriate positioning for play and functional activities. Supportive orthotics or braces also work to reduce spasticity, maintain range of motion, prevent contractures, and promote function. Orthoses may be used to maintain a group of muscles in a lengthened state so that function of the joint is improved.

One of the most commonly prescribed orthotics is a short leg brace called an *ankle-foot orthosis* (Fig. 12–12). This type of brace serves to correct foot-drop and might further

increases muscle tone in the hips, providing a more stable sitting or standing position. Correcting the child’s atypical foot position may alter the position of the hips and knees when the child stands, thereby improving gait.

A variety of splints may be used to improve hand function. A common one is the resting hand splint. In this splint, the thumb is held in an abducted position with the wrist in a neutral or slightly extended position. This maintains the hand in an open position to prevent deformity and maintain function. Even with loss of fine motor control of the hand and fingers, a functional grasp with fingers and opposing thumb is tremendously advantageous. The loss of this level of function significantly affects the child’s degree of independence.

Other devices include the prone stander, which promotes skeletal alignment, preserves bone mineralization, and allows the child to participate in activities (Fig. 12–13). Stander also provide an opportunity to see the world from a different viewpoint, gaining a new perspective of life (similar to a small child who can finally see over the countertop and discover new terrain).

FIGURE 12–12. Ankle-foot orthotics provide the support needed for independent or assisted walking.

FIGURE 12–13. The use of a mobile prone walker helps the child to better participate in daily activities at school and at home.

Scoters, tricycles, and wheelchairs provide a means of moving independently within the environment, which increases opportunities to explore, learn, have fun, and participate in social interactions. The variety of wheelchair adaptations is incredible. There are accommodating features such as headrests, custom-molded seating systems, lateral supports, and extremity supports (arm rests and leg rests) (Fig. 12–14). An array of controls for power mobility exist (e.g., sip and puff control, chin control, and joystick). Children with disabilities often enjoy the freedom of power mobility, which may allow them to leave their parent’s side at the mall, keep up with their peers in the school hallways, and participate in new community activities when the environment is accessible.

It is virtually impossible to describe all the adaptive and assistive devices available, for the list is endless and continuously growing as technology advances. There are low-tech feeding tools (e.g., built-up utensils, plate adaptations, and variable cup holders) for independent eating, and aids for dressing and bathing. Electronic aids and adaptive switch toys allow for play and leisure, voice activation devices and environmental controls are high-tech devices used for emergency call systems, and school aids (e.g., books on tape, large-print textbooks, page turners, and voice-activated computer programs) might enhance the child’s independence and ability to learn. All these devices change the environment so the child can perform at his or her best.

COMMUNITY REENTRY AND ONGOING HEALTHCARE NEEDS

Preparing the child for discharge from the inpatient unit or rehabilitation setting to the home and community

FIGURE 12–14. This custom-molded seating system properly positions the child so she can use the laptop computer.

begins even before admission. Determination of goals set during the preadmission phase guide the discharge process. Typically, the home is the primary outcome identified. Every member of the team maintains this focus during the assessment of the child and integrates it into the development of the child’s plan of care. In addition to identifying the child’s health status and functional ability, key assessments include the level of coping and adaptation, skill in performing the care required, and compatibility with the home environment and lifestyle. Of primary importance is whether the physical environment can accommodate the needs of the child. The team investigates potential issues during initial interviews. Parents are asked to describe their home environment: type of community, transportation available, type of dwelling, number of stairs or rails, location and description of principal rooms in the house, and specifics regarding the supply of utility services as necessary. Services in the community are explored throughout admission. Depending on the needs of the child, a home or school visit by key rehabilitation or home care team members might be conducted before discharge. In this manner, potential obstacles to the success of community care home care or rehabilitation program can be identified.

Prior to discharge, arrangements are made for family members to provide all the child’s care, for a specified period of time (generally 24 hours) without assistance from nursing staff. In this way, unforeseen problems or obstacles identified can be discussed and comprehensively addressed with the team prior to discharge. Pediatric nurses provide a therapeutic environment for

learning to help prepare the child and family for life outside the inpatient unit. Nurses must make a conscientious effort to incorporate teaching into daily tasks; therefore, they utilize teachable moments as they provide care and support. For instance, when putting anti-embolism stockings on an adolescent patient, the perceptive nurse informs the patient of risk for deep vein thrombosis (DVT) resulting from puberty and from being immobile, reviews the importance of prevention (ambulation and use of medications), discusses assessment techniques, and describes the management of a DVT complication. This educational focus is paramount in daily rehabilitative care.

Another useful educational technique to help patients prepare for life in the community is to ask what-if questions. For instance, in the hospital setting it is common to catheterize every 4 hours around the clock, and patient's and families get into the routine. However, question the teen about how he will manage his catheterization schedule if he was asked to go to an eight-o'clock movie. Should he just skip the catheterization or decline the invite? Or is the safer solution to catheterize early, before going to the movies? These discussions regarding all aspects of care help patients and families with problem-solving and life skills.

Home Care

Most children with chronic conditions do not need home care services. Parents might have to administer medications and perform procedures (e.g., catheterization, percussion and postural drainage) (Fig. 12–15). For some, however, home care might require both the need for visiting nurses and aides as well as the need for large pieces of equipment and medical supplies (Community Care 12–1). Referral to community services, although initiated as early as possible, requires having a firm sense of the child's anticipated needs. Home care agencies and community providers are notified and supplied with essential information by the nurse, care manager, or social worker

FIGURE 12–15. Encourage parents to assist the young child to manage his or her care at home, thereby helping to prevent the need for hospitalization.

COMMUNITY CARE 12–1

Questions for Families to Ask Home Care Agency

- Does the nurse who will be caring for my child have pediatric experience?
- Has the agency handled children with this condition before?
- If we have any problems of questions will there be a nurse on call 24 hours a day?
- What are my options if I do not like or agree with the nurse who come to my home?
- Does your agency provide other services such as case management and therapy?
- (Private duty) How often does your agency not have enough nurses to cover the number of cases? What can we do if a nurse is not available to care for our child?
- Will the nurse call and make an appointment with us for her visits or just show up?
- How will the billing be handled? Do you work directly with the insurance company?
- Will your agency arrange for the equipment that we need?
- Who do we call if there is a problem with the equipment and/or it needs to be repaired or replaced?
- Will your agency arrange for the medical supplies that we may need? Who reorders them?

before discharge. At times, members of the home care and equipment companies meet with the child and the family during the inpatient stay (especially in cases of the medically fragile child or technology-dependent child in whom care is complex). The home care nurses are invited to the healthcare facility to learn the child needs and to participate in the transfer process. When this is not possible, creating a videotape of the child's care may be a useful alternative. Patients and families are active participants in learning and should be fully informed regarding the child's ongoing care needs for a coordinated and safe discharge home. At this time, summaries of the child's progress, continued goals, and care needs are provided to the parent or primary caregiver, as well as forwarded to the community rehab care provider, primary care physician, and referrer to facilitate continuation of care across the continuum.

caREminder

When visiting the home to provide services, remember the principles of public health nursing: You are a guest in the home and the parent is the one who is ultimately responsible for the child's care needs.

The rules surrounding treatment in the home need to be flexible to accommodate the family's needs. For example, many procedures that are done under sterile conditions in the hospital are often done using clean protocols in the home and school.

Equipment and Supplies for the Home

All equipment, supplies, and medications the child will require after discharge are delivered to the child's hospital room and should be used by the family members prior to discharge. Frequently, families will need two pieces of equipment, in case one breaks (e.g., ventilators). They might need oxygen tanks, suction machines, dialysis equipment, or freezer space for clotting factors, and they might often need to find child-safe areas for needles and sharps containers. It is essential for families with children who require large amounts of equipment to do a home assessment. This includes ensuring that there is enough electrical power, clean running water, and cleanliness to accommodate the child's condition (Nursing Interventions 12–2).

Primary Care

Too often, children with chronic conditions do not see their primary care provider enough because they see their various specialists on a routine basis. It is essential, however, for all children and adolescents with chronic conditions to receive a physical at least every year and to ensure that their immunizations and other preventive health care initiatives are addressed by their medical home (see Chapter 1). This includes dental care and an assessment of their growth and development.

Respite Care

Having a child who requires highly technical care as well as one who requires constant assistance can drain the family of its energy and can increase family stress. In addition, this situation makes it very difficult for the family to find child care providers/baby-sitters so that they can “go out” as a family or couple, or take the other children to normal activities of childhood. Sometimes, parents might need to quit their jobs to provide the care their child needs, which can further isolate parents from peers and social support, and from meeting their own life goals. This increasing stress and isolation are thought to be related to the increase in child maltreatment in some.

To allow parents a break from this constancy of care, the pediatric nurse can encourage respite care. Respite care is a way to give families a break by providing temporary child care, support, and referral services. Respite care involves either having qualified providers provide care for the child in the child's home so that the parents and other family members can have a vacation, or provide these services in an inpatient setting, so that family members can have a break from the constant care and, instead, care for themselves.

Respite care might be arranged by social services or the hospital. The pediatric nurse can be an advocate for the family to get these services, although in many areas of the country, there are very few resources available for respite care. For some families, just having a good night's sleep is a respite. Occasionally, children with chronic conditions are admitted to the hospital for a checkup. Staff should not be judgmental if the parents are absent for periods of time, because this may be as close to respite care as they get.

Transportation Issues

Transporting equipment necessary in treating a chronic condition, such as oxygen or a wheelchair, takes strength and physical dexterity, as well as a vehicle that can accommodate this equipment. This is essential to get to school, healthcare visits, and family outings. Without appropriate transportation, the family is restricted to the home, thus increasing the isolation and stress on the family. Social services might need to be contacted to ensure that the family has the appropriate gear to safely transport their child and all necessary equipment to healthcare visits. If the family relies on public transportation, they should be provided with the contact number for local services to transport them and their child.

Pain Management

Some individuals with chronic conditions experience a great deal of pain. There is no research that studies the long-term impact of chronic pain in children as they move toward adulthood. Multiple finger sticks to test for blood sugar, rheumatoid arthritis, percussion and postural drainage, and the pain from vaso-occlusive crises in sickle cell disease or from the treatments for cancer are examples of the discomfort experienced by children. Parents need to be able to act as advocates for their child at times when the assessment or treatment of the condition causes the child pain or discomfort.

Help the family identify ways to minimize the pain as much as possible. One teen found that if she played the piano the first thing in the morning, it helped allay the stiffness in her arthritic fingers; another used EMLA before having any blood draws for her cancer.

Financial Constraints

QUESTION: What are the costs associated with having a child with diabetes?

The economics of providing healthcare for children with chronic conditions has a significant impact on the availability of services for children with chronic conditions, or the lack of these services. It is estimated that approximately 13% of those with special healthcare needs were responsible for 45% of the pediatric healthcare expenditures (Centers for Disease Control and Prevention, National Center for Health Statistics, 2003). There does

NURSING INTERVENTIONS 12–2

Family and Home Assessment

Expected Outcome	Intervention
Family caregivers will have adequate training and preparation to care for the child at home.	<p>Before discharge or at the first visit identify the family members who will actually be providing the care.</p> <p>Review all written instructions with the caregivers.</p> <p>Observe the caregivers' demonstrations of any medically related task they will be completing independently.</p> <p>Leave booklets with pictures and/or videos that can be used as references with the caregivers in the home.</p> <p>Review the care path with caregivers and make changes needed to meet the child's and the family's needs.</p>
Family caregivers will respond appropriately to situations that indicate potential medical problems.	<p>Provide the family with written lists of signs and symptoms that signal potential variances from what is considered the baseline for the child.</p> <p>Review steps to be taken should a medical problem arise.</p> <p>Alert emergency services in the community to the presence of a child in the home who may need their assistance.</p> <p>Post important phone numbers in a prominent location in the home.</p>
Telephone service will be available to the family.	<p>Identify a local business or neighbor who will allow the family to use their phone in an emergency.</p> <p>If no phone is in the home, a cell phone can be rented through many home care companies or through local fire departments.</p>
Basic utilities will be available to the family.	<p>Assist the family to secure the basic utilities needed to provide for the child's needs.</p> <ul style="list-style-type: none"> • Bottled water can be used if there is no running water. • Electrical generators can be rented from local utility companies. If equipment required for the child's care and electricity are not available use battery-powered equipment. • Many local governments assist with heating costs in an emergency. Many churches stock blankets and warm clothing for families in need. • If electricity is available to the family, alert the local utility company, and place the family on a priority service list. • If refrigeration is required and there is none, dry ice can be obtained from any food marker at little of no cost. If dry ice is used, care must be taken not to touch it directly and not to store the medication directly on it.
The home will be a safe environment.	<p>Assess the home safety,</p> <ul style="list-style-type: none"> • If electrical equipment use a three pronged grounded plug should be used. Avoid extension cord use.

Expected Outcome

The home will be a safe environment (continued).

Intervention

- To avoid overheating and the risk of fire, place plywood or other wood under the electrical equipment rather than having it rest directly on carpet.
- Cover knobs and buttons on all equipment with clear tape. This enables them to be checked while lessening the risk of accidentally changing the setting.
- Store medications, needles, syringes, sharps, and sharps container in a locked container.
- Attach a list of all medications and their dosages to a list of emergency phone numbers.
- Properly store all medications.
- Unplug all equipment when not in use.
- Avoid throw rugs to lessen the possibility of tripping on them.

not appear to be sufficient resources to fund all the needed interventions for children with chronic conditions. This is certainly one reason why these families need many advocates to help them through the insurance maze to access the services their child needs without depriving their families of their needs. In addition, all children with special healthcare needs should receive regular, ongoing comprehensive care within a medical home (Health Resources and Services Administration, 2001). Chapter 1 discusses the concept of medical home, an environment in which healthcare to children is accessible, continuous, comprehensive, family centered, coordinated, compassionate, and culturally effective.

For those families in which income precludes them from receiving Medicaid but who do not make enough to purchase private insurance, there is the State Children's Health Insurance Program (or SCHIP). See Chapter 2 for a more complete discussion on funding options for children with chronic conditions.

ANSWER: Prior to having the insulin pump, the costs include insulin, insulin syringes, a glucometer and associated supplies, and emergency glucagons.

Participation in the Educational Process in the Schools

QUESTION: Jean and Tom discovered quickly that they needed to be strong advocates for their daughter in the school system. After discharge from the hospital, Lindsay could not attend school until the proper forms were completed. What personnel in the school environment should be informed about Lindsay's condition?

School is an important component in the lives of all children and adolescents, not only for the academic learning that occurs, but also because of the social and emotional components as well. At school, children learn rules and values that build on the ones learned at home; they learn to interact with others, and they have expectations placed on them and are held to the same standards as their peers (Fig. 12–16).

School teachers and staff are often uneducated about most of the conditions experienced by children in their

FIGURE 12–16. School attendance allows the child with a chronic condition to develop both socially and cognitively.

classrooms and how these conditions affect the student. They also are usually unaware of the laws that provide these students with rights to an appropriate education with the needed accommodations. Typically, it is the school nurse who becomes the coordinator of the student's care while in the school setting. The school nurse interacts with the healthcare provider to ensure continuity of care; interacts with the parents to ensure that medications and equipment are available in the school to meet the child's needs; and teaches the faculty, administrators, and other staff (e.g., maintenance staff, bus drivers, cafeteria staff) about the child's condition on a need-to-know basis to prevent problems and provide emergency care if needed. Yet, all agree that children with chronic conditions should attend school (Rehm & Rohr, 2002).

The school nurse will develop an individualized healthcare plan (IHP), which is very similar to care plans developed in hospitals, except that they are specific to the needs of students in schools. The school nurse will also develop an emergency action plan that will be distributed to those school personnel who have contact with the student. This plan will instruct school staff what to avoid, what symptoms indicate a problem, and what to do, including administering glucagon. The school nurse will work with all these individuals to educate them to the degree needed to increase their comfort level and to provide a safe environment for the student.

Although children with chronic conditions can reap many benefits in the school environment, some problems such as an increased incidence of teasing and bullying, as well as difficulty making friends, might exist. These challenges are often exacerbated by the child's differences. Intervention approaches include having the child present information to the class about the condition, assigning buddies to assist the affected student, and making school policies that do not tolerate teasing of others.

Children in the school whose condition relies on technology are often dependent on others for their care and, in some cases, rely on others to speak for them. Their needs most commonly are respiratory (requiring ventilators, tracheostomies, oxygen), nutritional support (requiring gastrostomy or nasogastric tubes, IV nutritional support), mobility (requiring wheelchairs, braces, crutches), and urinary (requiring catheterization) (Rehm & Rohr, 2002). This requires school personnel to be familiar with the importance of the equipment, designate appropriate space to store the equipment and provide the services, and be knowledgeable about the use of these devices and how to troubleshoot them when problems arise.

School staff might be fearful that children with special needs are more fragile than other children. They may be concerned about possible exposure to pathogens both from the child with a chronic condition to the class and vice versa, and they also may be concerned about the child's safety. Parents may express frustration that teachers have lower expectations for their children and that their children's education will suffer (Rehm & Rohr, 2002). It is up to the school nurse to eliminate barriers and to make the integration process go smoothly. The overall goal should certainly be **normalization**, but the specific goals written

into the IEP should be to assist the student to achieve integration to as high a level as possible (Community Care 12–2). Normalization involves establishing a normal pattern of living, with daily routines and participation in age-appropriate activities, including school attendance. Chapter 2 provides more information about IEPs.

Some children with chronic conditions qualify for special education through their local school districts. IDEA (2004) mandates a free and appropriate public education in the least restrictive environment from the age of 3 to 21. The goal is to educate all children, regardless of their disability. The least restrictive environment means that most of these children are included in regular classrooms. More than 5.6 million children with disabilities in the United States receive special education services in the schools (U.S. Department of Education, Office of Special Education Programs, 2004). IDEA also mandates that all children who are referred to determine their eligibility to receive special education services will receive an evaluation that is bias free. If eligible, students must receive the medical support and services necessary to stay in the school setting. This might mean tracheostomy care, insulin administration, catheterizations, tube feedings, alternative communication devices, or accessibility for a wheelchair. It might also include the additional academic services needed so that the student can be as successful as possible.

An essential component of IDEA is the development of an IEP for the student. This is developed by an interdisciplinary team that includes the school nurse and the parents. It looks like a nursing care plan with objectives, an intervention plan, and how and when the student will be evaluated to ensure that the plan is working toward meeting the objectives. One of the main objectives is **mainstreaming** the child into the regular classroom setting, which means they are integrated into the class with their peers for as much of the school day as is possible.

“Children who have disabilities are nearly three times as likely to repeat at least one grade as are children who have no disabilities” (Byrd, 2005, p. 233). It is estimated that one in five children who repeat a grade has a disability. This might be the result of issues such as increased absences because of the condition, failure of the school to carry out the IEP, or family problems. Advocacy is needed to ensure that the student does not begin a downward spiral of school failure and low self-esteem.

For those students who do not qualify for special education under IDEA, but who need accommodations to fully participate in the school environment, the Rehabilitation Act of 1973 provides the legal basis for the development of a plan. Section 504 of the Rehabilitation Act states that no otherwise qualified individual with a disability shall be excluded from participation nor be denied the benefits of or be subjected to discrimination simply because of the disability (Clay, 2004). This section of the act is referred to as a *504 accommodation plan*. These accommodations might simply be an allowance for the student to carry his or her asthma inhaler or specialized seating in the classroom, or it might include the need for wheelchair access ramps, use of

COMMUNITY CARE 12-2

Interdisciplinary School-Based Care for the Child With a Chronic Condition

Actions for the School Nurse

- Maintain individualized health care plan (IHP) for every student who may need treatment at school. Include information on medications, dosages, triggers, and emergency procedures.
- Alert staff members about students with a history of condition likely to manifest themselves in the classroom.
- Assist with the administration of medication in accordance with school policy.
- Monitor response to treatment using criteria appropriate to condition.
- Communicate with parents about problems at school and the student's general progress in controlling his or her condition at school.
- Conduct inservice training on chronic conditions as needed.
- Consult with staff to help develop appropriate school activities for student with specific conditions.
- Collaborate with the Parent-Teacher Association to offer family education programs in school if numerous children have similar conditions or children with multiple chronic conditions have common needs.
- Collaborate with community-based treatment and support groups.

Actions for the Guidance Counselor

- Recognize that learning to cope with any chronic illness can be difficult. Teachers may notice low self-esteem, withdrawal from activities, discouragement over the steps needed to control the condition, or difficulty making up schoolwork.
- Offer special counseling with the faculty, student, and/or parents to help the student handle problems more effectively.

Actions for the Principal

- Involve staff in the IHP, which should be a cooperative effort involving the student, parents, teachers, school staff, and physicians.
- Develop a clear policy on taking medication during school hours.
- Designate one person on the school staff to be responsible for maintaining each student's IHP.
- Provide opportunities for staff to learn about the chronic conditions.
- Establish a resource file for the staff to get additional information available to students as well.

- Support and encourage communication with parents to improve school health services.

Actions for the Physical Education Instructor and Coach

- Encourage exercise and participation in sports for students with chronic conditions that impact their ability to engage in usual physical education programs.
- Support the student's IHP if it requires premedication before exercise.
- Understand what to do if an acute episode occurs during exercise. Have the child's IHP available.
- Encourage students with chronic conditions to participate actively in sports, but also recognize and respect their limits. Permit less strenuous activities if a recent illness precludes full participation.
- Refer your questions about a student's ability to fully participate in physical education to the parents and school nurse.

Actions for the Classroom Teacher

- Know the early warning signs of problems for specific chronic conditions (e.g., wheezing with asthma, irritability with hypoglycemia).
- Have a copy of the child's IHP in the classroom. Review it with the student and parents. Know what steps to take in case of a problem.
- Develop a clear procedure with the student and parent for handling schoolwork missed.
- Understand that students with some chronic conditions may feel drowsy or tired, different from the other kids, anxious about access to medication, embarrassed about the disruption to school activities that their condition causes, and/or withdrawn.
- Help the student feel more comfortable by recognizing these feelings. Try to maintain confidentiality. Work with the student and plan education of classmates about the child's condition.
- Know the possible side effects of the child's medications and how they may impact the student's performance in the classroom. Refer any problem to the school nurse and parent(s).
- Encourage the student with a chronic condition to participate fully in physical activities.
- Allow a student to engage in quiet activity if recovery from an acute episode precludes full participation.

the school nurse's office for specialized bathroom needs, or altering the class schedule to allow for student rest and to optimize learning.

ANSWER: Although all of this communication is guided by HIPAA laws (Health Insurance Portability and Accountability Act), parents are often willing to have information about their child's condition shared with those who need to know. For example, Lindsay may experience a seizure from low blood sugar at school. Her bus driver and her teachers need to know the signs of hypoglycemia and how to administer glucagon. Lindsay's parents have granted permission to notify the parents of her classmates that Lindsay has diabetes. Consider how many elementary school events are celebrated with sugar!

AGING WITH A CHRONIC CONDITION

With advances in healthcare, it is estimated that 95% of children with chronic conditions reach adulthood (Bittles et al., 2002). This is a relatively new development, because 30 years ago, this was not the case and many of these children died in childhood. What has been discovered is that as the body adapts to certain conditions, other conditions result. For example, youths in their late teens and early adulthood who have cystic fibrosis are at risk for developing diabetes because of the chronic involvement of the pancreas. This type of diabetes appears to be a cross between type 1 and type 2. Individuals who have been treated for cancer are developing conditions years after the initial treatment and "cure." These "late effects" (see Chapter 22) might be the development of other types of cancers in other locations or conditions such as learning disabilities. Another example includes fractures that might occur in individuals who are wheelchair dependent and unable to use their lower limbs as a result of the osteopenia that has developed.

Rather than a cure then, the focus for children with chronic conditions is on the adjustments that need to be made throughout their lives in order for them to be as healthy and functional as is possible. Their care needs to have a coordinated, collaborative approach that involves the family.

Transitioning to Adult Services

One of the mandates under IDEA is to assist the adolescent to transition to further education or employment and independent living. This includes transitioning from pediatric healthcare to adult healthcare services. Regardless of whether the adolescent qualifies for special education, all pediatric nurses should be assisting children and their families to prepare for eventual responsibility for their personal healthcare. Transitioning actually begins from the moment the child is diagnosed and/or moves

from one developmental stage to another. As early as they are cognitively and physically able, children with chronic conditions should learn to perform the skills needed for their care. They should be able to record needed information (e.g., blood sugars, peak flow readings) and relate these to the healthcare provider (Fig. 12–17).

As children transition into preschool, initial adjustments will be needed. Parents and the children themselves should be able to identify what works and what does not. In this way, when they enter the school environment, they will be able to assist in the development of an IEP or an IHP. IDEA mandates that the process of adult transitioning needs to begin at age 14 with career exploration activities. A transition plan must be written into their IEP by age 16, including the services needed to assist these students as they transition out of high school and into the adult world.

The Department of Health and Human Services developed a consensus statement regarding healthcare transitions for teenagers. "*Healthy People 2010* established the goal that all young people with special health care needs will receive the services needed to make necessary transitions to all aspects of adult life, including health care work, and independent living" (Blum, 2002, p. 1305). Some specialty centers have arrangements with specialty centers that cater to adults with specific conditions, such as cystic fibrosis. They might actually set up appointments for the adult healthcare provider to come to the pediatric setting or for the advance practice nurse to accompany the teen to the adult center for their first appointment. Teens need to know what to expect and how it will differ from the "pediatric" focus of care.

Reiss and Gibson (2002) have identified the following factors as some of the components for successful transitioning: "1) the family, young adult, and provider have a future orientation; 2) transition is started early; 3) family members and health care providers foster personal and medical independence; 4) planning occurs for the future; 5) the young adult verbalizes the desire to function in the adult medical world; and 6) reimbursement for services is not interrupted" (p. 1312). Some parents have difficulty

FIGURE 12–17. The child with a chronic condition should be encouraged to become more and more responsible for managing his or her own treatment and medications.

relinquishing control of their child's care in order for the child to become more independent. This might require the healthcare team to remind families of the normalcy of "letting go" and the fact that their child is reaching a new stage of development. Even when the young adult is not capable of self-care, parents need to recognize that they are also aging and this may be a good time to begin making plans for the future care of their child.

Transition services are not just limited to health care. They also include job planning and resources, vocational rehabilitation, health insurance coverage, family planning, and whether the condition warrants Social Security benefits (Lewis-Gary, 2001). In addition, most of the organizations that cater to young people with chronic conditions have materials that will assist in the transition. "Transition is a process, not an event—it occurs over time There needs to be a commitment on the part of both the leaders and members of adult and pediatric teams to the concept of transition and to excellence in care" (Lewis-Gary, 2001, p. 524).

Palliative Care

Case History

Remember Ashley Tran (Chapter 7), George Tran (Chapter 10), and their parents Loan and Tung? George has osteogenic sarcoma (the assessment, diagnosis, and treatment are discussed in Chapter 22). At the time of diagnosis, George's cancer had already metastasized to his lungs. He received chemotherapy before the amputation of his leg and again afterward, but the cancer has continued to spread. George spent time in the hospital at the time of his amputation and received his chemotherapy as an outpatient. It has been 8 months since George was diagnosed; he is now 15. He is noticeably thinner and weaker. He has progressive disease with significant respiratory involvement.

Initially, George tried to return to school. He found it very difficult, both physically and emotionally. Some days he did not have the strength to get around the school on crutches, and getting the wheelchair around the school was difficult as well. He discovered that the state university has an online independent-study high school program, and he began taking classes online. George has a few very good friends who share his interest in computers and video games. They come over several times a week to visit George and play video games, but George does not go out very often.

A home care nurse visits George once a week and performs the skilled nursing care that is needed. George's mother, Loan, does not work outside the home. She has been providing much of his day-to-day care, although George insists on doing as much for himself as he can. George's older sister moved back home at the time of George's diagnosis. She

spends time after school every day with George going over schoolwork or playing video games. Loan has two sisters in the area. Her youngest sister, Aunt Ha, who Ashley lived with for a time, is able to come and help often. Loan's brother died of "leg cancer" in Vietnam. Loan was only 5 years old when he died, but she remembers his funeral and she is certain he died at home.

George's condition is deteriorating. He has profound dyspnea and circumoral cyanosis with exertion. Even at rest, he has some shortness of breath, and he has a constant nonproductive cough. He is extremely thin and cannot eat much. The family faces the choice of admitting George to the hospital or trying to keep him home. Since his amputation, George is insistent that he will not go back to the hospital. The amputation was understandably traumatic for George, and he is quite adamant that he is staying home. It upsets his parents, but he tells them, "I know that I am dying and I want to die here. I am not going back to the hospital." It is George's father, Tung, who wants George to go to the hospital and still talks about George "getting well."

Osteogenic sarcoma is a disease that affects primarily adolescents and young adults. George's oncologist sees both adolescents and adults and has a working relationship with a hospice service. It is not a pediatric hospice service, but because George is not a young child, the service is confident they could work with the Tran family. The Tran family comes to the decision to keep George home and work with the hospice service.

CHAPTER OBJECTIVES

1. Relate the sociopolitical influences on the development of palliative care services for children.
2. State the core definitions and principles of palliative care.
3. Describe models used to guide palliative care services.
4. Delineate barriers to implementation of pediatric palliative care.
5. Select strategies that enhance communication during the provision of palliative care.
6. Identify interdisciplinary measures to promote quality of life at end of life.
7. Describe interdisciplinary care interventions at the time death occurs.
8. Examine the process of grief and bereavement in the family coping with the death of a child.
9. Describe bereavement responses of children when a loved one dies.
10. Explain support measures that healthcare providers can implement as they grieve the loss of a pediatric patient.

See [thePoint](#) for a list of Key Terms

The death of a child at any age is difficult for the parents and family, which may include siblings, grandparents, aunts, uncles, and cousins. The loss can also be hard for the friends, nurses, and other healthcare professionals who care for the child and the child's family. An important part of the nursing management of the child with a life-threatening condition involves providing interventions to support the effects of the physical illness, as well as provide for the psychosocial, spiritual, and social aspects of care related to the end of life. This chapter discusses the provision of palliative care for a child with a life-threatening condition and his or her family. Palliative care definitions and concepts are presented. Barriers to palliative care are discussed and interdisciplinary interventions to promote palliative care are shared. When children have a terminal condition, the child and family will experience loss, grief, and eventually bereavement. These concepts and their impact on the child, the family, and the healthcare provider are reviewed. Strategies to assist the child and family cope with impending death are also reviewed.

HISTORICAL PERSPECTIVES OF PEDIATRIC PALLIATIVE CARE

Throughout the 19th century, the focus of healthcare was to treat symptoms and provide comfort. Pharmaceutical preparations were inadequate, and most medications were derived from locally grown herbs and plants. Healthcare practices were steeped in religion, mythology, and superstition. There were a limited number of physicians who had received any formal education or training, and even fewer trained nurses. Medical care was frequently

provided by women in the community who developed expertise in assisting to relieve symptoms (Kalisch & Kalisch, 2003). Consequently, patients either recovered or died within a short time. Illnesses that are considered minor or insignificant today were common causes of death.

The early 20th century brought about a change in the approach to general living standards as well as healthcare. Pioneers in medicine and nursing, such as Lister, Pasteur, and Nightingale, had recognized the importance of sanitation and its impact on illness more than 50 years earlier, but their theories were only starting to be widely acknowledged and practiced. As the 20th century progressed, with technologic and scientific advances including the development of a variety of medications from insulin to antibiotics, the focus began changing from treatment of symptoms and comfort care to attempts of cure (Super, 2001).

These advances in healthcare have had a ripple effect. Improved sanitation and immunizations drastically reduced the deaths from common childhood illnesses, resulting in a decrease in infant and child mortality. In underdeveloped countries, some illnesses such as immunization-preventable infections, diarrhea, and dehydration remain frequent causes of death in children. In developed countries, the improvements in sanitation and medical care have resulted in childhood death becoming a rare occurrence for a family. In the mid 20th century, the ability to revive some people by the use of cardiopulmonary resuscitation (CPR) drastically changed attitudes related to death (Corr, 1999). By the 1970s, it became standard practice that, unless previously determined otherwise, attempts to resuscitate would be performed on all patients within the acute care setting, regardless of diagnosis or potential quality of life. This has led to a blending of expectations between curable and incurable illness, such that in medical and societal views, death is considered both a personal and medical failure (Saunders, 1999).

Thus, the death of a child has become an unusual experience. The trajectory of death has also changed. In previous centuries, when a child became ill, he or she either recovered within a short time or died within days or weeks of the onset of illness. Death usually occurred in the home environment with the child cared for by family and friends (Field & Cassel, 1997). In today's healthcare environment, many children with illnesses and traumas now live for months to years with the illness prior to succumbing to death (Martinson, 1995). Children survive longer because of advances in early diagnosis and treatment of life-threatening conditions.

Reports indicate that approximately 7% to 10% of children in the United States have a chronic or debilitating illness (Levetown, 2000; Perrin, Bloom, & Gortmaker, 2007). There are approximately 55,000 deaths per year in children, with half of these deaths occurring during the neonatal period (Field & Behrman, 2003). Two thirds of all infants die in the intensive care unit and, overall, 75% to 85% of childhood deaths occur in the acute care setting. In addition, there are approximately 900,000 birth tragedies (defined as in utero death or stillbirths) each year. Of the remaining childhood deaths, accidents are the leading cause of death in all age groups

greater than 1 year of age; cancer is almost always the leading cause of death by disease in all age groups (Field & Behrman, 2003; Hendrickson and McCorkle, 2008). It is estimated that 15,000 infants, children, adolescents, and young adults (up to age 24) die annually from the complications of a complex chronic condition. On any given day, it is estimated that 5,000 of these patients are living within the last 6 months of their lives (Feudtner et al. 2001). One survey revealed that although there are about 2,500 U.S.-based hospice programs aimed at adults, only 247 were geared toward children. Fragmentation of services for children with life-limiting conditions remains an international problem (Pfund, 1998). See [thePoint](#) for Supplemental Information: Factors Influencing Dying Patterns Within the United States.

Although palliative care concepts have traditionally been applied to children with cancer, the importance of developing services for children with other life-threatening conditions has become evident. In particular, the need for palliative care arises among children with the following conditions:

- Life-threatening conditions for which treatment is available but may fail
- Conditions in which premature death is expected, but long periods of intensive treatment to prolong good quality of life are anticipated (cystic fibrosis, HIV)
- Progressive conditions that may extend over many years and for which no curative treatment is available (mucopolysaccharidosis)
- Conditions with severe disability that, although not progressive, lead to extreme vulnerability and in which premature death is likely (cerebral palsy)
- Neonatal conditions in which the diagnosis of a terminal condition may be made prenatally or is evident at birth (Chaffee, 2001; Goldman, 2001; Liben & Goldman, 1998).

DEFINITION AND APPROACHES TO PEDIATRIC PALLIATIVE CARE

A simplistic definition of **palliative care** is “actions to relieve symptoms.” The World Health Organization (WHO) (1998) defined palliative care as an approach that improves quality of life in patients and families facing life-threatening illnesses. The WHO definition also includes the need to provide relief of pain and other distressing symptoms as well as the need to affirm life. WHO further defines death as a normal process, which integrates physical, psychological, emotional, and spiritual needs as part of routine care. They also suggest that palliative care can be provided across any setting and be initiated early within the course of an illness. Based on these definitions, it is clear that palliative care is a component of all healthcare and is not just provided as part of the dying process. Figure 13–1 presents a diagram that depicts the need to address palliative care at the time of diagnosis regardless of cure potential. As the individual’s condition deteriorates and the curative focus diminishes,

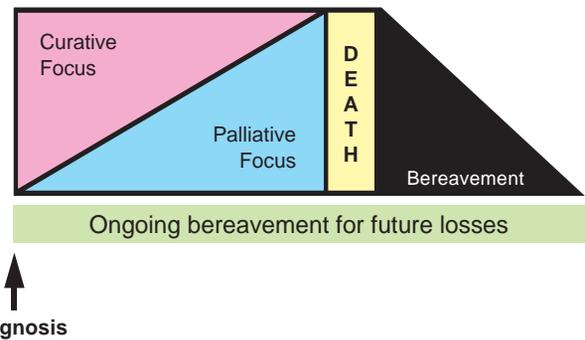

FIGURE 13–1. The progression of palliative care interventions. Adapted from American Association of Colleges of Nursing & City of Hope (2007).

the diagram illustrates the need to have an increasing emphasis on palliative care interventions. If death is the outcome, palliative care continues for surviving family members as part of bereavement care (American Association of Colleges of Nursing and City of Hope, 2007).

When care changes from curative intent to palliation, the focus becomes management of symptoms and promoting comfort (Ferrell & Coyle, 2002), which requires family-centered care (FCC) at its foundation (Fochtman, 2002) (see Chapter 1 for more info on FCC). It is important to remember that the child’s family may comprise biologic and nonbiologic members. In family-centered palliative care, all aspects of the child’s life, including physical care, symptom management, cultural components, and spiritual components are interlinked with the interdisciplinary team, which may encompass grandparents, siblings, friends, church members, community members, and healthcare team partners. Pediatric palliative care adheres to a family-centered model that addresses the emotional needs of the child and family, and demonstrates respect, clarifies goals, acknowledges their preferences and choices, and enhances open communication and shared decision making with the healthcare team related to their psychosocial and medical care (Last Acts Palliative Care Task Force, 2002).

Most recently, the care of individuals facing the end of life has received renewed attention by both healthcare providers and the public. Pediatric interest groups have been focusing on pediatric palliative care, resulting in the development of recommendations to improve pediatric palliative care. In addition, concepts associated with provision of palliative care to children and a variety of care models have been developed. The discussion that follows presents the interdisciplinary work that has been pursued to identify aspects of palliative care unique to the pediatric population.

Institute of Medicine: When Children Die

QUESTION: Which of the unique concerns of palliative care for children identified in Chart 13–1 apply to George and the Tran family?

The Institute of Medicine (IOM) is a nonprofit organization associated with the National Academy of Science. The organization provides science-based advice on matters of biomedical science, medicine, and health. Three IOM reports have been instrumental in examining the state of end-of-life healthcare. These reports are *Approaching Death: Improving Care at the End of Life* (Field & Casel, 1997), *Improving Palliative Care for Cancer*, (Foley & Gelband, 2002), and *When Children Die: Improving Palliative and End-of-Life Care for Children and Their Families* (Field & Behrman, 2003).

When Children Die provides a summary of the “state of the science” of pediatric end-of-life care. From this report and the research conducted about pediatric palliative care, it is recognized that certain palliative care concerns are unique to or particularly evident with children (Chart 13–1). The report made major recommendations that provide clear directions to improve the quality of care to children and their families with respect to ensuring a family-centered approach; managing financial concerns; educating healthcare professionals; and broadening the research base for pediatric palliative, end-of-life, and bereavement care (Field & Behrman, 2003) (see [thePoint](#) for Evidence-Based Practice Guidelines). The IOM report clearly established that much more needs to be done to address and support the unique challenges of caring for children with life-threatening medical conditions (Carter et al., 2004).

ANSWER: Each of the following concepts is applicable to the Tran family. First, the wishes of George, a 15-year-old, are counter to those of his father, an adult. The healthcare team will have to wrestle with the issue of who makes the decisions regarding his care—George or his father. Nurses advocate respecting the autonomy of the patient. If the family cannot come to an agreement, the healthcare team is faced with the ethical dilemma of respecting the autonomy of the patient or the parent. Formal advanced directives signed by a minor, in most cases, are not recognized as binding documents. In most situations, parents have absolute authority over making healthcare decisions that affect the child.

Second, Ashley has suffered from clinical depression as an adolescent (see Chapter 29). She has expressed the wish that she should be the one with cancer; she should be the one to die, not her brother. Nurses will need to continue to monitor her well-being as her brother’s health declines. Siblings must be considered in the care management of the pediatric patient, with special attention given by the healthcare team to the siblings’ developmental needs.

Finally, the Tran family is Vietnamese American. The mother, Loan, does not speak fluent English; thus, there are language and cultural variances. The educational needs of the child and family pose considerable challenges for the healthcare team. Language and cultural variances, cognitive development, and family dynamics must all be considered.

Last Acts: Precepts of Pediatric Palliative Care

Last Acts, a former national program, was developed and supported by a grant from the Robert Wood Johnson

CHART 13–1 PALLIATIVE CARE ISSUES UNIQUE TO CHILDREN

- Children are not small adults. Developmental differences must be taken into account when dealing with the spectrum of pediatric patients, which ranges from neonates to adolescents. Additionally, care management of the child must change over time as the child changes developmentally (e.g., cognitively, emotionally, physically).
- A smaller number of children die compared with adults.
- A heterogeneity of illnesses affect the pediatric population. Many conditions are rare, making diagnosis, prognosis, and medical management difficult and uncertain.
- Many illnesses affecting children are familial in nature, thus more than one family member may have the same condition.
- Formal advanced directives signed by a minor are, in most cases, not recognized as binding documents. In most situations, parents have absolute authority over making healthcare decisions that affect the child.
- The time continuum for managing a pediatric condition can be extremely variable, with the need for palliative care extending over days, months, or even years.
- Many children lack any type of public or private health insurance.
- Siblings must be considered in the care management of the pediatric patient, with special attention given by the healthcare team to the siblings’ developmental needs.
- The educational needs of the child and the family pose considerable challenges for the healthcare team.

Foundation for the purpose of establishing guidelines leading to the improvement of care and caring near the end of life for infants, children, adolescents, and their families. Representatives from the IOM as well as many pediatric nursing organizations, including the Association of Pediatric Oncology Nurses (now the Association of Pediatric Hematology/Oncology Nurses), the National Association of Neonatal Nurses, and the Society of Pediatric Nurses, were members of this task force. The work by this group was published in 2002 as the *Precepts of Palliative Care for Children, Adolescents and Their Families* (Last Acts Palliative Care Task Force, 2002). These precepts acknowledge that comprehensive management of physical, psychological, social, spiritual, and existential needs are essential in providing care for children who are born with serious medical conditions and those who develop such illnesses during a later stage of childhood or adolescence.

Last Acts further identified the core principals from which palliative care must be integrated throughout the trajectory of a child’s illness. These principals include

- Respecting patient goals, preferences and choices
- Providing comprehensive care
- Using the strength of interdisciplinary resources
- Acknowledging and addressing caregiver concerns
- Building systems that support responsible palliative care policies and regulations (see [thePoint](#) for Supplemental Information: Principals Promoted in the Last Acts Precepts of Palliative Care)

Integrated Palliative Care Model

The American Academy of Pediatrics and others developed and support a care model in which cure-directed treatment and palliative care are integrated, allowing children to benefit from both philosophies of care (American Academy of Pediatrics, Committee on Bioethics and Hospital Care, 2000). This model is based on the belief that traditional definitions of palliative care are too narrow and rigid, and may hinder children from access to palliative care services when the focus is providing those services only to those children actively dying. The integrated care model accommodates children with recurrent malignancy for whom death is a certainty as well as children with cystic fibrosis, for whom premature death is often a certainty but one that is many years away. Chaffee (2001) further discusses this model in terms of developing an appropriate collaborative plan of palliative care for a child with a life-limiting illness (see [thePoint](#) for Supplemental Information to view the collaborative care model). Members of the collaborative team include the family, primary care group, tertiary care group, palliative care group, community, school, and resource group. Successful collaboration depends on reciprocal communication among all groups as well as maintaining pertinence and applicability to the family circumstances. Frequent reassessment of the plan is needed as the child's illness progresses to ensure the plan is practical and is meeting the needs of the child and family.

Kane, Barber, Jordan, Tichenor, and Camp (2000) share that palliative care “involves a gradual transition from a posture of hope for a cure to a state in which patient and family embrace the possibility of death and hope for other things of importance to them, such as peace and understanding, control of pain, enriching relationships, a meaningful death, and divine concern with the fate of their loved one” (p. 168). From a biopsychosocial–spiritual model of patient care, it is asserted that the introduction of palliative and supportive care services *early during the course of a severe illness* “may serve as a bridge between a scientific, disease-oriented approach to diagnosis and treatment, and a humanistic, person-oriented form of care” (Kane et al., 2000, p. 171).

Four Cornerstones of Clinical Practice in Pediatric Palliative Care

QUESTION: What is one example of nursing care with the Tran family in which one of the cornerstones of clinical practice is reflected?

Empiric studies and anecdotal feedback from parents and families have consistently demonstrated that they are seeking a quality of care, connection to, and genuineness from practitioners that is all too often missing. The Initiative for Pediatric Palliative Care is an example of an interdisciplinary group that identified four cornerstones of clinical practice in pediatric palliative care:

1. Responding to the ethical claim of the child/family
2. Adopting a collaborative relational stance
3. Cultivating cultural humility
4. Developing reflective practice

Responding to the Ethical Claim of the Child and Family

Development of these cornerstones began with the premise that the foundation for clinical practice should be grounded in what children and their families have said is important to them (Browning, 2003a). The first cornerstone presents the concept that the extreme vulnerability of the dying child and the family imposes an ethical claim on the healthcare providers. This is a claim that practitioners are not free to opt in or opt out of; rather, practitioners, by the nature of their caregiving role, must accept an ethical obligation to the child and their family.

Adopting a Collaborative Relational Stance

The second cornerstone asserts that clinical practice in pediatric palliative care is fundamentally relational, involving a “two-way” relationship with the child and the family. In this relationship, engaged practitioners must move fluidly between the position of “expert” and the position of “learner.” In this relationship, children and their families are regarded as experts with regard to their own experiences.

Cultivating Cultural Humility

Cultivating cultural humility, the third premise, expresses the need to reflect on one's own culture as well as the culture of the child and the family. This requires the capacity for awareness and self-critique regarding one's own culture and beliefs. Additionally, this entails efforts to understand the world from the viewpoint of the patient. This cornerstone demonstrates a commitment to understanding similarities and differences between professional values, goals, and priorities, and those of the child and their family. In application of this cornerstone, practitioners must also recognize and understand biomedicine as a culture—one that is all too often new and foreign to the child and family.

Developing Reflective Practice

Developing reflective practice examines the question: What do I do in practice, and how do I do it? Reflective practice embodies the concepts of self-awareness (values, thoughts, feelings, assumptions), practice-based learning (learning by doing), and tacit knowledge (knowing in action). As a cornerstone, this concept reflects the importance of constant evaluation of one's beliefs and

how those beliefs are translated into palliative care practices.

ANSWER: There are many right answers. Examples that show the collaborative relationship between nurses and the family are a good fit. Likewise, examples that explore the ability to see this experience through the family's eyes also model one of the cornerstones.

NURSING CARE OF GRIEVING FAMILIES

To plan interventions appropriate for the child and family, a baseline assessment is completed (Focused Health History 13–1). The healthcare provider's attitudes, strengths, and limitations in working with children and families who have experienced loss influence the relationship with the grieving family. A structured assessment is completed in a private area, conveying an unhurried, nonjudgmental attitude. All interactions with the child and family provide opportunity for informal data collection regarding the family's grief and loss. Listen astutely to the family and answer their questions honestly.

The staff can help the family by establishing a relationship, by being present both physically and emotionally,

and by continuing to focus on the family as a system (Nursing Plan of Care 13–1). Educate the family about normal grieving and encourage them to talk about the death, their reaction to it, and their feelings. Assist siblings to receive education, attention, and support. When necessary, refer the family for counseling. Often, the staff nurse caring for the dying child is in an excellent position to initiate the bereavement support process.

A recent study by Wolfe et al. (2008) indicates that parents are reporting better preparedness for the end-of-life course and decreased suffering in their children, as well as substantial improvements in advance care planning. This is thought to be attributed to the increased focus during the past decade in educating healthcare professionals on the issues of palliative care and hospice. Caring for dying children and their bereaved families is one of the most challenging components for a nurse. Here, more than anywhere in our practice, we must be especially aware of how we deliver care and communicate to patients and their families, because the messages we provide can either hinder or facilitate their choices. If we keep in mind that the ultimate outcome when caring for a child with a life-threatening or terminal condition is to add life to the child's years, not simply add years to the child's life (American Academy of Pediatrics, Committee on Bioethics and Hospital Care, 2000), we will be able to do a great service as advocates to the children and families under our care.

FOCUSED HEALTH HISTORY 13–1

The Grieving Family*

Current history	Type of loss (e.g., death, disfigurement, material possession) Circumstances surrounding the loss
Past medical history	Stage of acute grief or bereavement; period of time since loss History of other significant losses (persons, pets, objects) and responses to them Usual patterns of coping Measures that have been used previously to comfort family members
Nutritional assessment	Changes in eating patterns
Family medical history	Review of deaths in the family, including cause, age at time of death and unusual circumstances surrounding the death
Social history	Changes in sleeping patterns Changes in activity level Changes in interactions with friends and family members Usual support systems (family, spiritual, community) and the availability of these support systems in the current situation
Growth and development and psychological assessment	Behavioral manifestations of grieving (aggressiveness, anger, anxiety, sadness, depression, withdrawal, attention-seeking behaviors) Child's cognitive level and understanding of the concept of death Understanding of the grieving and bereavement process Sense of control in the current situation and how this affects the ability to deal with the loss

* This is a history focused on the needs related to a family experiencing grieving (see Chapter 8 for a comprehensive formal history and see Chapters 14 through 30 for the focused health history of specific body systems).

NURSING PLAN OF CARE 13–1: FOR THE GRIEVING FAMILY AFTER A LOSS

Nursing Diagnosis: Grieving related to reaction of death of a loved one

Interventions/Rationale

- Encourage the family members to talk about feelings of anger, sadness, guilt, and frustration.

The grief and bereavement process is the process of coping with and adapting to the loss.

- Observe for reactions to loss that may indicate dysfunction: delayed grieving, inhibited grieving, bereaved displays various physical conditions, and no demonstration of grief.

Responses to loss vary from person to person; however, each has the potential to respond in a fashion that indicates grieving is being suppressed. Suppression of grief can lead to physical maladies and changes in relationships with other family members.

- Provide environment that supports expression of grieving behaviors (e.g., crying, anger).
Reinforces appropriateness of expressing grief.
- Discuss responses to grief and tell what to expect during the grieving process. Repeat over time with family as needed.

The experience of grief may make it difficult for the family to take in and retain information; thus, discussions of the grief responses may need to be repeated over time.

- Help the client identify his or her own strengths for managing the loss.
Reinforces positive, adapting grieving behaviors.
- Help parents and siblings work through their grief for the lost child, encouraging individual expression and coping patterns.

Individuals grieve and show grief differently. It is essential to affirm that grief responses will vary and to encourage family members to be supportive of these differences.

Expected Outcomes

- Family will verbalize feelings and will work through bereavement tasks.
- Family will have dysfunctional responses recognized early and will be offered psychosocial and spiritual counseling.
- Family members will go through the stages of grief in their own manner and reach resolution.

Nursing Diagnosis: Interrupted family processes related to changes in relationships and roles in the family secondary to death of a family member

Interventions/Rationale

- Assist family to openly discuss changes in the family since loss of the loved one.

Provides recognition of how each individual perceives changes in the family dynamics.

- Assist family to develop strategies to adapt to changes in family roles and functions.

As an open system, the family should strive to seek to adapt to the enforced changes in their family structure and all cooperate in developing meaningful ways to reestablish family cohesion and adaptation.

Expected Outcomes

- Family will remain supportive of all members.
- Family will incorporate changes in power alliances, assigned tasks, decision making, and communication patterns to accommodate for loss of family member.

Nursing Diagnosis: Spiritual distress related to crisis of the illness, suffering, or death of a child

Interventions/Rationale

- Assess for expressions of spiritual distress (e.g., lack of hope, meaning, and purpose; acceptance; love; forgiveness of self; inability to express previous state of creativity; inability to pray or participate in religious activities; refusal to interact with spiritual leaders).

Indicate inability to integrate meaning of life and purpose in life through connecting with self, others, and creative outlets.

- Provide a list of community resources and support for emotional and spiritual needs.
Assists family members to seek internal and external support to manage the current crisis.

Expected Outcomes

- Family will verbalize distress and will have spiritual counselors available for support.
- Family will articulate ability to find strength from spiritual support systems.

Nursing Diagnosis: Impaired social interaction related to gradual withdrawal from friends and community resources after loss of child.

Interventions/Rationale

- Observe family members' interactions and potential discomfort in social situations. Assess for report of change of style or pattern of social interactions.

Anger that others were spared the pain of the death of a child can lead to self-imposed social isolation.

- Involve family members in support groups or in social/recreational activities with families who have experienced similar loss.

Provides support system to family in comfort of environment with others to have had a similar experience.

- Promote the sibling's participation in activities with friends and in school.

Encourages ongoing, daily interactions with peers.

NURSING PLAN OF CARE 13–1: FOR THE GRIEVING FAMILY AFTER A LOSS (CONTINUED)

Expected Outcomes

- Family members will maintain social relationships with other family members, friends, and neighbors.
- Family members will utilize community resources appropriately.

Nursing Diagnosis: Chronic sorrow related to ongoing and pervasive sense of loss since death of child

Interventions/Rationale

- Determine events that may trigger recurring and pervasive sadness experienced by the parent or siblings.

Missed birthdays, family celebrations, and school-related events may enhance feelings of continual loss.

- Assist family members to develop strategies to manage feelings of depression, sadness, lethargy, and malaise.

Chronic sorrow may intensify over time and may interfere with the person's ability to reach a high level of personal and social well-being. A repertoire of interventions to manage the feelings associated with chronic sorrow will assist the individual in the coping process.

Expected Outcomes

- Family members will establish a plan to manage trigger events that lead to chronic sorrow.
- Family members will successfully manage grief and come to resolution.

BARRIERS TO PEDIATRIC PALLIATIVE CARE

There is often disparity between the way children die and the way they want to be cared for when dying. This multifactorial issue is related to barriers within the healthcare system concerning acceptance of the realities of life-limiting disease, access to palliative care services and hospice, communication with the family, and the understanding of death.

Failure to Accept Realities of Life-Limiting Disease

QUESTION: Is there a family member who is struggling to admit that George is dying?

Most healthcare professionals report that they did not receive any specific education or training related to end-of-life care within their schooling and have learned by role models and trial and error. Many report that they have a great deal of discomfort in communicating bad news and prognoses with children and their families. They claim they have little formal training to assist them in decision making regarding the discussion of ending curative treatments; providing supportive care and pain management; or in addressing the psychological, social, and spiritual aspects of care (Hilden et al., 2001).

A child's death affects a family and community much differently than the death of an older person. We do not consider it natural for a child to die before the parents, and families find it hard to adjust to role changes that affect the family structure. It is difficult to ask families to abruptly switch from curative-intent therapy to comfort care. This transition could be eased if healthcare profes-

sionals explain early within the illness that death is a possible outcome, and thus offer curative and palliative care simultaneously (Levetown, 2001). During the past several decades, a failure to acknowledge the limitations of medicine has led to a significant increase in the initiating and maintaining of futile interventions. Inappropriate use of aggressive curative treatments can prolong the dying process and contribute to physical, emotional, and spiritual distress (Wolfe et al., 2000b). Often, a parent's decision making is based on limited comprehension of the actual situation, because of inadequate or poor communication from the healthcare provider. Because many healthcare professionals are uncomfortable communicating bad news, the full array of options are often not made available or understood by the family (Levetown & American Academy of Pediatrics Committee on Bioethics, 2008; Sine, Sumner, Gracy, & von Gunten, 2001).

ANSWER: George's father, Tung, is struggling to accept that George is dying.

Access to Palliative Care Services and Hospice

QUESTION: What are some of the influences that have affected the Tran family's decision to care for George at home?

Integrating palliative care services into care of children with life-threatening conditions can be challenging, because often healthcare providers, patients, and families view this as "giving up" or only a viable option if all other measures have failed (Rushton, 2004; Solomon et al., 2005). Many do not realize that palliative care can coexist

with interventions aimed at cure or stabilization of disease and prolongation of life (Last Acts Palliative Care Task Force, 2002). Not all patients who are critically ill go on to die of their disease, but they can benefit from palliative care services even if they are not near the end of life (Ferrell & Coyle, 2002). If more health professionals as well as patients and families understood the purpose and goals of palliative care and hospice services, usage probably would be higher. Since the 1970s in the United States, a grassroots effort has facilitated the development of hospice programs in many communities. In essence, **hospice** is a form of healthcare that provides palliative care services across a variety of settings, based on the philosophy that death is a natural part of the life cycle. Hospice care provides an interdisciplinary team to work with a patient and family to support them physically, emotionally, and spiritually through the latter phases of illness and the dying process by promoting a “living until you die” philosophy; the care then continues to support the family through bereavement (American Association of Colleges of Nursing and City of Hope, 2007). According to Children’s Hospice International, fewer than 1% of children in the United States who could benefit from hospice services receive it (Children’s Hospice International, 2003).

The few children who receive palliative care and hospice services are usually referred late within the illness, when there is limited time to reap the full benefits of the programs. Typically, services are not fully understood by the healthcare provider, there is a hesitancy to acknowledge that there is no chance for cure, or there may not be accessibility to a pediatric hospice within the child’s community or palliative care services within the acute care setting. Thus, acute interventions are prolonged, even when it is evident the child is in the final stages of death. Other common barriers may include institutional regulations that have restrictive visiting hours, inadequate policies for pain and symptom management, and limited FCC. Regulations related to insurance and third-party payment often do not provide for adequate financial compensation for palliative care and hospice. They may not pay for them at all within an inpatient setting and only have limited reimbursement for outpatient services, although it is speculated that appropriate palliative care and hospice interventions would actually decrease overall medical costs. A statement frequently uttered by healthcare providers is that “it is too early to refer to hospice.” Early identification of patients for palliative care and hospice services allows time for the child and family to set and achieve goals (Super, 2001), to develop relationships with the palliative healthcare team, and to benefit from supportive care services (Tradition or Science 13–1).

ANSWER: One factor affecting the Tran family’s decision is George’s determination to stay home. His family will do their best to respect his desires. Another family characteristic is the fact that Loan remembers her older brother’s death from the same disease. She is having an easier time accepting the outcome of this disease because she has a previous experience with it, even though she was quite young.

Yet another factor is the oncologist’s experience with a hospice service. The oncologist’s willingness to coordinate George’s care through a hospice service affects the family’s ability to care for George at home.

Communication With the Family

When nurses were asked what they wish they were taught in nursing school regarding care for the terminally ill, the number one response was “how to talk with patients/families about dying” (Coyne, 1999). Effective communication imparts medical information, dispels myths or preconceived notions about the disease and treatment, and helps the patient and family to make informed decisions about care. An essential component of communication is to realize that it is a dynamic, ongoing process and that too much information can be delivered at one time. It is important to ask what the family knows, what they are ready to hear, and to be prepared to repeat the information over the course of time. In times of crisis or stress, concentration and understanding may be impaired as a result of overwhelming feelings of loss and helplessness. Elicit understanding by repeating what the person has said or by asking for clarification. Do not assume that what you are saying and what the patient and family are hearing is the same message (Browning, 2003b).

When caring for children who are dying, or for the family members after the child’s death, it is important to remember that the words and actions used can have an impact on the patient’s and family’s entire experience of the illness and dying process in either a negative or positive manner. Sitting down to talk and maintaining eye contact with the family helps to establish that you care about what is happening to them. Say things clearly and simply, and provide definitions to medical terminology. Try to “listen with the patient’s or parents’ ears.” If you were in their situation, what words would be helpful to you to hear and how would you say them so there is a clear understanding of the intent?

Semantics are often crucial in effective communication. Telling a family that “there is nothing more that we can do for your child” is a callous and unnecessary way to tell a family that there is no more effective treatment that will cure their child. Instead, say to them, “We do not have treatment that will stop the progression of the disease [injury]. During this time, prior to death, we will focus on providing types of therapy to keep your child as comfortable as possible to enhance his [her] remaining life.” A healthcare provider might say, “A miracle could keep your child from expiring,” instead of saying, “Despite all our efforts, the disease is not responding to the treatment, and it is clear that your child is dying as evidenced by the inability of the organs, such as the kidneys and heart, to work properly.” The first statement gives false hope, and many people in our multicultural society, for whom English is often a second language, do not realize that the word “expire” is commonly used within the context of death. The second statement definitely informs the parents that death is the expected outcome. The expansion of that

TRADITION OR SCIENCE 13–1

Do dying children receive unnecessary interventions at the end of life?

EVIDENCE-BASED PRACTICE

Carter et al. (2004) were interested in determining what care interventions were provided to children during the last days and hours of their life. A retrospective chart review of 105 children who died at their institution revealed the following:

- Comfort care services were provided to 55% of children and pain medications were given to 90% during the last 72 hours of life.
- Intubation and ventilation was done on 98% of the children, although 63% of them had that support withdrawn within the last 48 hours of life.
- Nutritional support was initiated in 96% of the children and withdrawn during the last 48 hours for 23% of them.
- Almost all the children (96%) had at least one laboratory or diagnostic test, or radiographs done within the last 48 hours of life.

Carter et al. (2004) found that discussions of a life-threatening situation were documented in only 23% of the children, and only 42% of children had a do-not-resuscitate order written; only one child was actually referred to hospice. The authors concluded that more care interventions initiated toward comfort or palliation might reduce unnecessary, nonbeneficial, and potentially burdensome tests for children at the end of life. Pierucci et al. (2001) demonstrated that when ill newborns were referred to a palliative care consultation service, there was a significant enhancement of end-of-life care as evidenced by fewer days in the intensive care unit; less invasive procedures such as intubation and mechanical ventilation, radiographs, blood draws, central lines, and feeding tubes; decreased use of vasopressor and paralytic agents; and limited use of CPR. In addition families were more frequently referred to social service and hospital chaplains for support than families who were not referred to the palliative care service. Both these studies (Carter et al., 2004; Pierucci et al., 2001) demonstrate the impact on human suffering as well as healthcare costs in relation to how illnesses are managed during the last days of life. This type of information will help to educate healthcare providers regarding the value of early access and implementation of palliative care services.

statement is then, “What we can do now is concentrate on administering treatment that offers comfort.” The focus of hope then becomes a proactive form of therapy that provides, as a goal, a dying process that enhances remaining life. The end result provides an atmosphere of care, which places the child and family in an environment that respects their relationship, promotes safety, and relieves suffering (American Association of Colleges of Nursing & City of Hope, 2007) (Nursing Interventions 13–1).

Body language and tone of voice should provide comfort and support. Whenever talking to patients and fami-

lies about distressful news, it is important not to appear rushed; sit down with them and allow time for answering questions (Mack & Grier, 2004). Another important part of communication is being able to listen. Allow children and their families to share their stories, their sadness, and their joys. Part of listening is also observing the nonverbal cues being exhibited by the patient and family. Children of all ages commonly express their most important feelings through play and nonverbal methods. These simple measures can make a huge difference in how a family views their child’s illness and last days of life.

The Child’s Understanding of Death

QUESTION: What is George’s understanding of death based on his developmental level and the case study?

Another barrier to palliative care is the child’s own understanding of his or her condition, its potential outcomes, and the issues surrounding death and dying. Parents and healthcare providers might wish to protect the child from the realities of the situation, but in doing so present a barrier to the implementation of palliative care services by not communicating fully or openly with the child about the child’s condition. When children’s concerns and questions about their condition and about death are not addressed, their fears will magnify (Ethier, 2005).

Communication becomes the key in helping to meet the psychological needs of the dying child. Addressing and working through unresolved issues, hidden fears, and the need for the child to make plans might decrease suffering and facilitate a more peaceful death (American Association of Colleges of Nursing & City of Hope, 2004). Dying children are usually aware of their illness and the fact that they are dying. Remain alert to the child’s desire to talk about death and the child’s condition. This might be expressed by behavioral changes or questions about other topics, because death is rarely expressed directly.

If their impending death is not discussed, children do not always initiate the discussion because they sense that doing so will make their parents sad. Children can feel guilty that they caused their parents’ sadness and then they might try to protect their parents by not talking about the things that concern them the most. Parents and other family members must be helped to understand that the child often knows that he or she is very sick and dying. Not talking about these issues actually adds to the child’s burdens, because he or she must then expend energy to leave this very important topic out of conversations.

caREminder

Parents know their child best and, if they feel strongly that their child should not be told of his or her impending death, the nurse should elicit their reasons. Respect parents’ wishes, although it is not appropriate to lie to or deceive the child.

NURSING INTERVENTIONS 13–1

Unclear or Distressful Versus Helpful Communication

Unclear or Distressful	Helpful
Referring to the child as “the patient” “It’s time to pull back.”	Referring to the child by name “Let’s discontinue treatments that are not providing benefit.”
“Your child is stable today.”	“There has been no improvement in your child’s condition.”
“Do you want us to do everything for your child?”	“Everything is being done to care for your child and to keep him [her] comfortable.”
“There is nothing more we can do.”	“We should change the goals of care.”
“A miracle may turn things around.”	“In my experience, I have not seen a child in this situation survive.”
Avoidance “You have other children to comfort you” or “You are young and can still have other children.”	Frequent contact and communication “Each child you have is a unique and special individual to you. Your other children may be a comfort for you, but they do not replace the loss of this child.”
“I know how you feel.”	“I am sorry that this is happening to your child and family.”
“This will make you a better/stronger person.”	“Would you like me to talk with other family members, or be with you when you talk with them?”
Standing in the doorway or at the foot of the bed and avoiding eye contact	Sitting and facing the patient or family, in the conference room if available, and maintaining eye contact
Appearing vague or helpless “If the disease would have been found earlier and treatment had started sooner, maybe things would be different.”	Letting your genuine concern and caring show “You have done a wonderful job taking care of your child throughout his [her] life and this illness. You should be proud of what you have been able to provide your child.”
“Do you want us to do CPR?”	“CPR is a method of trying to keep your child alive with machinery to keep them breathing, and/or medications to keep the heart beating and kidneys working. In your child’s situation, it will not save their life for possibly more than a few hours or days, they will not be aware of their surroundings and they will still die from this disease. By not doing CPR, your child will be able to be in your arms at the time of his [her] death and will be surrounded by loved ones.”

It is important to understand that a child’s perception of death, its finality, irreversibility, causality, and the cessation of body function are based on developmental stage and cognitive level. It is unknown how preverbal children, such as infants and toddlers, perceive death. Behavioral changes associated with death are primarily thought to be a response to the parents’ physical and emotional state (Ethier, 2005). Preschoolers to early school-aged children interpret death as a sleep state or as a temporary trip. Their magical thinking can lead them to believe that their behavior led to someone becoming ill or leaving (dying). It is not until children reach school age that they understand that death is permanent and irreversible. Older school-aged children also begin to appreciate that death is not

only inevitable, but that it is universal and that all body functions cease when death occurs. Adolescents perceive death similarly to adults; they ask about death, have concerns related to spirituality and the afterlife, and search for the meaning of why it happens (Fochtman, 2002). Developmental Considerations 13–1 depicts children’s concepts of death related to developmental stage, potential behaviors, and communication strategies they might invoke or methods an adult might use in discussing death with them.

Even if the facts of the illness are discussed openly, the child often needs help in expressing feelings such as fear of the unknown about dying or sadness about not being able to play with friends. Self-expression in writing, play, and art can facilitate the manifestations of a child’s

DEVELOPMENTAL CONSIDERATIONS 13–1

Children's Perceptions of Death and Associated Behaviors

Concept of Death	Behavior	Communication Issues
Infancy		
No known concept Death viewed as separation	May be clingy or irritable	Related to infant's perception of separation anxiety Need comfort from persons important to them
Early Childhood		
Does not have comprehension of death Aware someone is missing Aware of other people being "sad"	Altered sleep patterns Irritable Clingy	Similar to infants as related to separation anxiety Needs reassurance
Middle Childhood		
Knows the word <i>death</i> or <i>Dead</i> , but has little understanding of the meaning Sees death as temporary or reversible May feel ambivalent about absent person May develop "magical thinking," viewing themselves as the cause	Withdrawal Regression Irritable May feel confused or guilty Concerned about whether the person who has died has food, clothing, and so forth Uses imaginative play Anticipates return Has imaginary conversations with the dead	Children may parrot what they have heard others say They may be very curious and ask uninhibited or frank questions Bereaved siblings may feel that their thoughts or actions caused the death Therapeutic play is often an effective intervention to address feelings and anxieties May still have fears related to separation and need family to be close They need the opportunity to express concerns, fears, and curiosity
Middle Childhood		
Begins to understand death as irreversible Sees death as natural May begin to realize they or others might die Associates death with fear, violence, or destruction May be uncomfortable in expressing feelings May have anxiety related to mutilation fears	Asks specific questions about death and death-related rituals, such as funerals, burials Curious about how the body feels after death Needs burial and closure rituals if a pet dies May use play to cope with feelings Often denies death May "act out" at school or with family	Needs to express fears about potential loss of a parent A dying child may try to "protect" parents and family by withdrawing May choose favorite nurse as confidante May seem outwardly uncaring, although inwardly upset Siblings of ill, dying, or dead sibling may need more specific information about cause of illness or death Bereaved or dying children may have feelings of guilt related to blaming themselves for causing the illness or death
Adolescence		
Accepts finality of death Over time, develops mature understanding of death	May feel or express sadness, loneliness, or anger May have reckless demeanor or tough, uncaring attitude	Needs questions answered openly and in a nonjudgmental manner, especially when related to morbid curiosity

Concept of Death	Behavior	Communication Issues
Has fears that he or she may die	Tries to act adultlike, but may develop regressive behavior	Needs more detailed explanations of illness and potential causes of death
May have “morbid curiosity” related to gruesome or violent death	Often wants to touch the body after death	Requires discussion about reckless behavior and consequences
Becomes concerned about practical matters associated with death	May use rituals to decrease anxiety	Wants opportunity to voice fears and concerns
Denies own mortality by risk-taking behaviors	Often develops regressive behavior with staff or family	Dying adolescents have the need to discuss value of life and concerns related to dying, but may find it difficult to initiate these conversations
Incorporates cultural rituals and attitudes to death and is interested in exploring issues related to afterlife	May use creative outlets such as writing, music, or art	Siblings of ill or dying child may act sad or depressed, or may seem oblivious to situation and become angry if their plans or activities or disrupted; often want to be at school or with friends and not at home or the hospital, yet have difficulty in voicing concerns
	Peer support may seem more important than family	
	May be very concerned about body image	
	Ill child may want to be involved with funeral planning and “putting their affairs in order”	

Sources: American Association of Colleges of Nursing & City of Hope (2007); Brown-Hellsten, Hockenberry-Eaton, Lamb, Chordas, Kline, & Bottomley (2000); Ethier (2005); Fochtman (2002).

feelings. They can also present a nonthreatening method to initiate open communication with family and friends (Ethier, 2005). By examining these creative efforts and discussing them with the child, the parent and nurse can help the child understand what is happening, and develop needed and effective coping techniques.

KidKare ■ As children deal with their impending death, they may designate who they want their treasured belongings to be given to after they die. This is a method of coping. Do not discourage such actions on the part of the child.

ANSWER: As an adolescent, George has an understanding of death that is similar to an adult’s understanding. His statement in the case study, “I know I am dying and I want to die here” is evidence that George understands and accepts his impending death.

ACHIEVING QUALITY OF LIFE

QUESTION: As you read through this section, what are some aspects of George’s care that must be addressed to maintain a quality of life for him as his disease progresses?

Dying is a personal experience. What one person defines as **quality of life** in the stages of his or her illness and the final phase of death may differ significantly from the next person. Ferrell and Grant (2000) developed a model depicting the multiple dimensions of care as physical well-being and symptoms, psychological well-being, social well-being, and spiritual well-being. These aspects of care must be addressed to achieve quality of life for all individuals. In the situation of a child with a serious illness, the application of the model must incorporate both the child and the family caregiver’s point of view, because the child’s quality of life is directly interwoven with the family’s perspective (Field & Behrman, 2003). Although children may not be able to understand the term *quality of life*, they are able to tell you what they like and what is important to them in making their life comfortable and meaningful. Unfortunately, they are rarely asked, and their care is typically defined by those (parents and healthcare providers) who speak for them, often resulting in the child’s desires and goals being overlooked (Fig. 13–2).

Environment of Care

The physical environment of the child receiving palliative care includes the actual bed or chair where the child spends time. Both should be comfortable and able to support the child physically. Make the child’s environment amenable to the child’s activities, such as sleeping, reading, playing games, or visiting with friends.

FIGURE 13–2. Focusing on quality of life includes providing diversional activities that consider the child’s level of fatigue, ability to concentrate, and personal interests.

The child must be able to move within the environment to spend time with people, to spend time alone, or to spend time sleeping. What works well early during the terminal phase might not work as the disease progresses and the child’s physical condition deteriorates, so make adjustments to facilitate both physical and emotional comfort. At times, especially when a child is primarily confined to bed, the bed might be placed in a common room such as the dining room or family room to decrease isolation from the family. This might also require placing a commode in a private place near the bed if the bathroom is not easily accessible. Evaluate the environment repeatedly to ensure that it remains appropriate for the child and the family.

Physical Care and Symptom Management

Acute, chronic, or debilitating illnesses lead to multiple symptoms as the course of the disease progresses. These symptoms may cause metabolic and organic changes that affect the physical well-being of the child. Assessing and managing symptoms encompasses those services aimed at developing and implementing a plan of management for all symptoms related to the child’s changing condition over time. This includes the use of formal assessment tools that are age specific for evaluating pain and other symptoms. Specific problems that need to be managed include pain, feeding, nausea and vomiting, neurologic problems, depression, anxiety, and sleep disorders (Belasco, Danz, Drill, Schmid, & Burkey, 2000; Collins, Stevens, & Cousens, 1998; Lambert, 2003). The nurse plays a predominant role in managing the physical symptoms of the dying child. Nursing Interventions 13–2 summarizes physical symptoms of the dying child and specific interventions that can be used by the nurse to comfort the child. The interventions are directed toward meeting physical needs and symptom management (Tradition or Science 13–2).

Pain Control

Pain or fear of pain is often the most significant concern for a patient and family, and one of the most challenging to manage by healthcare providers (see Chapter 10 for a full review of pain pathophysiology and management). Physiologic tolerance to the narcotics, dealing with side effects, and determining the best route of administration must all be considered when the pain control program is developed and continually reevaluated. Fears and concerns related to side effects and addiction frequently inhibit healthcare providers in administering appropriate medication, and patients and family members often need to be reassured about the realities of addiction. Explain and reinforce the difference between physiologic dependence and drug addiction with drug-seeking activity. Some parents may fear specific drugs and may prefer alternatives to opioids. In almost all cases, the goal is to maximize the child’s comfort and quality of life. Side effects of opioids are common, and anticipatory management is essential. Patient and family education regarding the use of opioids and the expected side effects and management is a critical component of nursing care. Also, it is important to reassure patients and families that it is always possible to administer appropriate doses of medications to manage pain.

caREminder

Children who require long-term pain control often need to have opioid dosages increased periodically, possibly by 30% to 50% at a time, to maintain comfort. Meperidine (Demerol) is never used for such long-term pain control because of the resultant accumulation of a toxic metabolite (normeperidine) after as few as 3 days of treatment.

Other Symptoms Associated With the End of Life

Nursing Interventions 13–2 provides a comprehensive discussion of symptoms that a child may experience at the end of life (American Association of Colleges of Nursing & City of Hope, 2007). Symptoms associated with the end of life vary in severity and may wax and wane as the disease and dying process progresses. As death approaches, some symptoms become more prominent, especially those related to anorexia, somnolence, and changes in breathing patterns. Individual children need help dealing with symptoms of their particular terminal illness with interventions by members of the healthcare team, so that the cause of each symptom may be determined to deliver the correct treatment. For example, administering larger doses of opioids will not help abdominal pain from constipation; the only effective treatment is eliminating constipation with the use of stool softeners and laxatives. Consider treatment of specific physical problems in the dying child as part of the child’s long-term care. For example, constipation commonly occurs in the child receiving opioid pain management, and generally continues until the child dies. Thus, laxatives, normally given on an as-needed basis, must be

administered routinely whenever someone is receiving opioids. The presence of a daily bowel movement is an indication that the medication is working, not that it is time to stop giving the laxative.

Keep the child clean, dry, well hydrated, and physically comfortable. Excretions and secretions must be removed to prevent skin breakdown. Loss of urinary and bowel control might occur, and steps to prevent this or to clean the child are immediately used. Encourage a child who is hungry, thirsty, and capable of swallowing to eat and drink. If the child is receiving parenteral or enteral fluids, a volume sufficient to maintain full hydration is given to help make the child comfortable. Oral care is especially important when the child is not drinking or cannot brush his or her teeth.

KidKare ■ Even if the child does not appear to be conscious, talk to the child during care and explain what is happening and why. Talk about the weather, television programs, and other interests of the child. Post pictures from home or school around the bedside if the family desires.

Initiate provisions to prevent or eliminate symptoms whenever possible while providing for comfort. Some symptoms, such as anorexia, cause no discomfort for the patient, but they do cause a great deal of distress to the caregivers as they often focus on the lack of food and drink ingested by the child. It is important for them to understand that terminal dehydration and anorexia do not cause suffering in the individual who has no desire for food and water (Fochtman, 2002). When a child has reached the stage of terminal dehydration and anorexia, it is not appropriate to initiate enteral or parenteral feedings, because they do not promote comfort at this point and will not sustain life. Education to families is crucial to help them understand that these are common and natural components of the dying process.

The nurse, as an expert in providing physical care to the ill, is the essential member of the team to guide the patient and family through this stage of the dying process. The use of both pharmacologic and biobehavioral interventions is critical in the management of the patient, but the biobehavioral intercessions, in particular, offer family members an excellent opportunity to take an active role in providing comfort measures (see Chapter 10 for an extensive discussion of nonpharmacologic comfort measures). Successful use of one or more of these methods often gives the family a sense of mastery and accomplishment while enhancing the child's comfort and security.

Psychological Support

Children with a life-threatening condition continue at some level to have the same emotional and developmental needs as their healthy peers. They need to have a

degree of independence and some control in day-to-day decision making. For a young child, it might be as simple as what cup to drink out of, whereas an older child may elect to attend school, even if only for a few hours a day, to maintain some sense of normalcy. These measures are only small ways in which a child can preserve some form of dignity and control of how and with whom they spend the last days of their lives (Fochtman, 2002).

As the child's condition worsens, emotional responses to the realization that life is ending may include anxiety, sadness, grief, fear, depression, hopelessness, denial, guilt, and anger. In addition, the child might feel loneliness and isolation, especially if he or she is hospitalized or removed from family members and peers. Commonly, children might not express true emotions in an effort to protect friends and family or when this type of openness is outside the family norm. School-aged children and adolescents need to be involved in purposeful activity and spend time with peers. Adolescents, with their more comprehensive understanding of death and dying, often express concerns about their individuality and body image as well as concerns about the future. They expect and need honesty from adults.

An interdisciplinary team of professionals, laypersons, family members, and friends can best provide these components of care for the dying child. The role of each member of this team changes over time, especially as the focus of the care becomes the support of a peaceful death rather than the promotion of continued life. For the dying child, the preservation of relationships with family members, friends, and trusted healthcare providers, and the maintenance of personal dignity can be of utmost importance.

Social Support

Illness of any type can social structure and integrity of any family. In minor illnesses, the changes are usually temporary, but in catastrophic illnesses and death, roles are irrevocably altered. Relationships at all levels through the family—parent to parent, parent to ill child, parent to well child, and sibling to sibling—are disrupted and may result in chaos, insecurity, and uncertainty. There may be adjustments in interactions with extended family, peers, and community members. Financial burdens resulting from changes in income from loss of work and nonmedical costs of care can drastically alter family lifestyle and activities. Older children might be aware of these changes and feel responsible.

Continuing in School

As the illness of the terminally ill child progresses, a frequent question is whether the child may continue to go to school. The answer is usually yes. School plays a very important part in a child's life. In addition to helping the child acquire knowledge, school activities promote self-esteem and allow the child to be identified as an important member of society (Wood, 2006). At school, the

NURSING INTERVENTIONS 13–2

Management of the Physical Symptoms Associated With the End of Life*

Symptom	Possible Causes	Mediations	Nursing Interventions
<i>Pain that may be either acute or chronic (refer to Chapter 10 for more specific details)</i>			
Restlessness	Disease progression	Opioids and nonopioid analgesics	Slow, gentle movements
Irritability/crying	Metastases	Adjuvant medications such as nonsteroidal anti-inflammatory drugs	Quiet environment
Withdrawal	Trauma	Anticonvulsants	Heat or ice
Refusal to move	Neuropathic Idiopathic	Antidepressants Benzodiazepines Steroids	Massage Parental presence Cuddling/reassurance Distraction Guided imagery, relaxation Art/music therapy
<i>Neurologic</i>			
Seizures	Brain tumor Cerebral bleed Increased intracranial pressure Infection Metabolic disorders Fluid and electrolyte imbalances	Anticonvulsants	Patient safety Oxygen or suctioning Monitoring of anticonvulsant levels and adjusting as indicated Reassurance
Restlessness/agitation	Oxygen deprivation	Assess and improve pain management	Biobehavioral interventions
Delirium/confusion	Pain Medication reaction Metabolic changes Central nervous system insult/bleed Hypoxia Urinary retention or constipation Anxiety/worry/fear Insomnia/nightmares Spiritual distress	Eliminate medications that may be contributing to problem Oxygen Correct electrolyte abnormalities Use antianxiolytics as indicated Add stool softeners and laxatives	Encourage open communication to address fears Use calm, reassuring manner and tone of voice If hospitalized, bring favorite items from home to place in child's room
<i>Pulmonary</i>			
Dyspnea	Anemia Pulmonary disease Pneumonia Pleural effusions Muscle weakness Lung metastases Anxiety	Oxygen Antianxiolytics Morphine Albuterol inhalation Treatment of underlying cause	Cool mist, fans Loose-fitting clothing Elevating head of bed Quiet environment Reassurance
Slowing of respirations	Progression of dying process characterized by moaning and sighing, with pauses between breaths	Oxygen	Very distressing for family
Agonal breathing	May continue for hours to days	Morphine	Quite, calm environment Reassurance Elevate head of bed

Symptom	Possible Causes	Mediations	Nursing Interventions
Cardiovascular/Circulatory			
Irregular heart rate	Anemia	Antipyretics for fevers	Keeping warm or cool, depending on temperature
Fatigue	Decreased oxygenation	Oxygen	Explaining color changes to family
Temperature fluctuations	Shutting down of body as dying process progresses	Packed red blood cell (pRBC) transfusions if anemia impairing quality of life and symptoms will abate when delivered	
Color changes			
Mottling			
Pallor			
Cyanosis			
Gastrointestinal			
Diarrhea	Bowel obstruction	Stool softeners	Small, frequent meals
Constipation	Fluid electrolyte imbalance	Laxatives	Nutritional supplements
Nausea/vomiting	Fecal impaction	Antidiarrheal agents	Aggressive bowel care regimen
Anorexia	Medications	Antiemetics	Perianal skin care
	Opioids		Treating underlying cause as appropriate
	Poor dietary intake		In some situations a nasogastric tube may relieve bowel obstruction or a colostomy may be indicated for palliation
	Underlying disease		
Renal			
Urinary incontinence	Opioids	Treating urinary tract infection with antibiotics if symptomatic	Intermittent or indwelling urinary catheter
Urinary retention	Disease progression		Running water
Anuria	Infection		Warm baths
Oliguria	Renal shutdown as death approaches		Increasing fluid intake
			Privacy for voiding attempts
			Explanations to family that as death approaches, urination decreases
Musculoskeletal			
Weakness	Pain	Possibly appetite stimulant to increase caloric intake, resulting in more energy	Physical therapy
Hemiparesis	Disease progression	Eliminating medications causing fatigue, if possible	Range of motion
Contractures	Fatigue	Sleep aid	Rest periods
	Medication side effects		May need walker or wheelchair
	Inadequate rest		Modify environment to save strength (e.g., bedside commode)
	Prolonged immobilization		
	Metabolic disturbances		
Skin			
Breakdown/irritation	Dehydration	Antifungal agents	Creams or ointments to dry or hydrate skin depending on assessment
Rashes	Malnutrition	Steroid creams	Thorough cleaning and drying
Pressure ulcers	Immobility	Antihistamines for itching	Patting to clean or dry, avoiding rubbing
Pruritus	Incontinence		Barrier ointments for perianal region
	Opioids		Massage
	Medication reactions

NURSING INTERVENTIONS 13–2

Management of the Physical Symptoms Associated With the End of Life* (Continued)

Symptom	Possible Causes	Mediations	Nursing Interventions
<i>Hematologic</i>			
Anemia	Anemia of chronic disease	Blood product transfusions if they will improve quality of life	Pressure to areas of bleeding (nose most common location)
Fatigue	Bone marrow-based disease progression	Treatment of infections	Rest
Thrombocytopenia	Residual effects of cancer treatment	Oxygen	Warm environment
Bleeding	Poor diet		
Neutropenia			
Infection			

*All suggested interventions are recommended only if they will improve quality of life. They may not be appropriate for every patient's situation.

child can continue to gain independence and maintain some degree of control over the environment.

School provides opportunities for socialization. Encourage the child to maintain contact with peers, and help peers to maintain contact with the child. Attendance at school also minimizes exclusion from school activities that are important to the child. Regardless of whether the child goes to classes regularly, the school-aged child needs to maintain academic success. Both the child and teacher must set attainable goals without the child being

relieved of responsibility for learning and completing assignments. Making no academic demands can lead the child to believe that he or she has no value in life or is close to death (Tradition or Science 13–3).

Some parents might be concerned about the child attending school because they see it as a potential site of physical and emotional danger. Other parents want to spend more time with their child, and thus they see school attendance as an impediment. Identify and discuss these issues so that the child may still attend school if he or she desires.

TRADITION OR SCIENCE 13–2

Are parents satisfied that at the end of life, their child's pain and symptom management needs are adequately identified and treated?

MORE INQUIRY NEEDED

Wolfe et al. (2000a) identified that suffering from pain was nearly three times more likely in children whose parents reported that the primary care physician was not actively involved in providing end-of-life care. Treatment alleviated pain for only 27% of children and dyspnea for only 16% of the children. For all children, medical records indicated that parents were significantly more likely to report that the child had symptoms of fatigue, poor appetite, constipation, and diarrhea than did the physicians caring for the child. This suggests that end-of-life symptoms were not recognized, nor therefore treated, by the medical team. Similarly Meyer et al. (2002) found that 25% of the parents in analyzing their child's end-of-life care, felt their child was not comfortable in their final days. Furthermore, they believed they (the parents) had little or no control during their child's final days. More research is needed to ensure children receive adequate pain relief.

TRADITION OR SCIENCE 13–3

Is school attendance valuable for the child with a terminal illness?

EVIDENCE-BASED PRACTICE

A study conducted in France evaluated the educational careers of 30 children with incurable cancer receiving palliative care (Bouffet et al., 1997). Forty percent of the children did not wish to attend school as they approached the last months of their life. Reasons for the nonattendance included disease debilitation (blindness, neurologic damage) that prohibited learning, parent's belief that given the context of their child's disease the attendance was "useless," and child's own fear of attending. However, many children demonstrated a genuine desire to attend school, with increasing disability and fatigue decreasing their motivation over time. The study highlighted the importance of having the child sustain relationships with peers and their teachers. School attendance and terminal disease need not be mutually exclusive, and can offer the child a sense of growth and purpose in the midst of their declining state.

Teachers and school staff members need information and support for themselves (Community Care 13–1). The school nurse works with the child and parents to establish the nature of the material to be discussed and the manner of its presentation. Accurate information and answers help prevent incorrect conclusions. Some children want to present this information to their peers themselves. Others want the teacher, treatment center staff, or school nurse to tell their fellow students about their loss of hair, or need for a wheelchair or other assistive device.

Regardless of what the classmates and the school staff are told, prepare the child for the questions and changes in relationships that arise after returning to school. By practicing responses and role-playing possible situations, the child learns how to answer questions and to understand peer reactions. When working with students, faculty, and staff, stress the need for openness and free communication. Acknowledge and address fears. Few adults and older children are comfortable discussing or facing death, which can make them avoid the affected child. They need to learn that the child knows that he or she is sick and that avoiding opportunities to discuss the illness robs the terminally ill child of needed opportunities to share the experience. The child also wants to participate in life. Continue full and open discussion of day-to-day events.

Cultural and Spiritual Support

As discussed in Chapter 1, *spirituality* refers to a search for meaning in life and a relationship with the universe (Heilferty, 2004); *religious beliefs* are those formed within the context of practices and rituals shared by an organized group to establish or find a connection with a god (Davies, Brenner, Orloff, Sumner, & Worden, 2002). Thus, a child may or may not have a religious link with their spiritual being. A child's spirituality is often what allows them to find hope and meaning in life, and provides the foundation for their beliefs in the afterlife.

A child who has a formal religious faith might intertwine those feelings with the spiritual self. Spirituality frequently provides the foundation of hope related to life. Impending death might challenge or diminish that hope, but with guidance, that hope can be redefined to contribute meaning to the dying process (Ersek, 2001). Instead of attempting to redirect hope, many healthcare professionals try to maintain false hope by continuing to provide curative or life-prolonging treatments even when there is a minimal chance of cure. Unfortunately, what they accomplish often leads to greater suffering, diminished quality of life, isolation from family, increased morbidity, and, at times, a hastening of death (Wolfe et al., 2000b).

COMMUNITY CARE 13–1

Helping Teaching Staff to Cope With Terminally Ill Children in School

Address the staff's personal concerns and attitudes toward terminal illness, death, and dying:

- Evaluate the staff's prior personal experiences with death.
- Discuss with staff the fears of working with a child who is dying.
- Discuss concerns about other students and how they are coping with having a terminally ill peer.
- Evaluate uneasiness or concerns about teacher–pupil ratio.
- Educate the staff about the child's condition and the needs of the terminally ill student.
- Encourage meaningful communication among children and among children and teaching staff.
- Encourage staff to tell the student that he or she is a valuable person and will not be forgotten.
- Work with the child and family to modify the child's instructional program in light of fatigue, absences, and effects of medications.
- Allow rest periods for the child while at school.
- Send work home on the weekend before it is assigned, so work can be done at the student's own pace.
- Hold the student to whatever academic and behavioral standards he or she is able to meet.

Do not isolate the student from activities or peers.

Teach ways to protect the child from injury or illness:

- Teach the child not to share utensils.
- Wash hands after blowing nose, toileting.
- Ask parents to keep children who are sick at home.
- Develop written instructions for emergency care of the specific child.

Develop a plan for after the death of a child:

- Share reactions within the class through discussions and writing.
- Correct misunderstandings about the illness and death or the student's responsibility for it.
- Encourage creative expressions of grief such as letters and memorials.
- Present information about death rituals and funerals.
- Listen to and empathize with the children; hear what they say.
- Refer students (classmates) for additional help/counseling as needed.
- Acknowledge that the bereavement process may last 6 months or more.

When dealing with the grieving child and family, recognize and address cultural and religious concerns (see Table 8–2 for components of a cultural assessment and Table 8–3 for components of a spiritual assessment). Grieving and bereavement are treated differently among cultures, which influences the response of the child and family. When assessing the family, it is important for the nurse to seek out such factors and to take steps to accommodate the family's wishes, even if their requests are unfamiliar. If the nurse is unsure of the family's cultural beliefs or needs, ask the family to share them. It is imperative to be cognizant of differing cultural practices and beliefs and to understand behavior based on these ideas. It is equally important not to expect certain behaviors based on cultural influence.

WORLDVIEW: Nurses often offer support with a pat on the hand or the back. For Native Americans, touching is reserved for family or very close friends; therefore, touching is not an appropriate method of providing support for Native Americans. The subculture of gender may also influence the grieving patterns of Native Americans; women often openly and emotionally express their grief, whereas men may show little emotion and seek no support. These patterns, although common, are not exclusively related to gender (Nishimoto, 1996), and interventions are tailored to the individual response.

Many families draw great strength from their faith, although spiritual beliefs are not always expressed by involvement with a particular church or religion. Concepts such as hope, faith, and a sense of meaning and purpose in life are directly tied to the spiritual domain. Spirituality or religion may or may not be a source of support for the family. Some families hope for religious miracles at the time of their child's diagnosis or death. If desired, encourage parents to seek their minister, priest, rabbi, imam, or members of their church for support, and modify the plan of care to accommodate religious practices (Fig. 13–3).

To assess the family's spiritual beliefs, look for evidence of involvement with a religion, such as religious symbols, medals, statues, books, or music (see Chapter 8 for a discussion of spiritual assessment). These may be used to initiate discussion of spiritual strengths or needs. Many religions have specific death services or rituals; make every effort to allow for them (Chart 13–2). When death occurs, the family may wish to complete special prayers or services and death rites to prepare the body for burial.

Spiritual beliefs and cultural practices often help to define people both as individuals and as a family unit. Respect for and allowing adherence to their values provides comfort and strength that assists with coping during the child's illness and after their death (Taylor, 2006).

ANSWER: Almost all of these aspects of George's will need to be addressed. Physical care and symptom management as well as pain control are typically the focus of nursing care and management. The psychological support, social support, and cultural and spiritual support may be

FIGURE 13–3. A family's religious practices, a source of spiritual support, should be incorporated into care.

areas where nurses do not feel as confident of their skills. Nurses who work in palliative care must develop well-rounded skills to meet the needs of the families in their care.

WHEN DEATH OCCURS

In unexpected death, parents have no time for preplanning and preparation. Often it is in a crisis situation and they have to rapidly make decisions about how they want their child's body cared for within a few minutes to hours after the accident and death. Because there may be limited time to contact family and support persons to help them with decision making, they have to rely on health-care providers who are essentially strangers.

When death is expected, the decisions are related not in what to do to prevent death but what can be done to enhance the dying process by controlling what interventions are necessary to minimize suffering and maximize quality of life for the patient and family. Planning can be done regarding what treatments to continue or halt. These might include such measures as allowing natural death by requesting a do-not-resuscitate (DNR) status, eliminating antibiotics or blood transfusions if they are no longer providing a benefit, withdrawing interventions like ventilator support, as well as having time to make decisions regarding whether death will occur at home or in the acute care setting.

Discontinuing Treatment

A difficult aspect of the care of the terminally ill child is deciding what care to carry out and what to omit. New curative treatments should not be initiated if there is no chance of cure. This is often a requirement for participation

CHART 13-2 DEATH RITUALS OF DIFFERENT RELIGIONS

Muslim

Organ donation or transplants may be opposed. The dead must be buried intact so autopsy is uncommon and cremation is not permitted. Grief is not shown in the dying person's presence, and impending death is hidden from the person. After the death, loud expressive mourning occurs. The body is wrapped in special cloth and buried in the ground.

Hindu

Hindus believe in reincarnation. Death may be seen as God's will, and believers need time for prayer readings from holy Sanskrit books. Strings (to signify a blessing) may be tied around the wrist or neck of the child. Families may want to wash the body after death, and they may not want the body to be touched by non-Hindus. Transfusions, transplants, and autopsies are permissible; cremation is preferred.

Jewish

Burial usually takes place within 24 hours of death. The body must not be mutilated, so autopsies, embalming (which removes blood that is considered a body part), and cremation are forbidden. The body must return to the earth. The body of the deceased is never left unattended until buried.

Christian Scientists

Believers may oppose the use of drugs, blood transfusions, or other treatments. Healing is seen as spiritual renewal, so Christian Scientists may want treatment or support from another Christian Scientist. Autopsy is permitted only in cases of sudden death.

Episcopal or Catholic

Infant baptism is not mandatory, but can be done if the parents desire. If a priest is unavailable, nurses can baptize by pouring a small amount of water over the child's head and saying, "I baptize you in the name of the Father, the Son, and the Holy Spirit." Sacrament of the sick is offered to all seriously ill patients. It is often given to those who are dying and is no longer given only if death is imminent. Donation and transplantation of organs is permitted, and believers do not think that extraordinary artificial means of sustaining life must be used.

in hospice programs. However, some treatments are given for palliative as well as curative reasons. Radiation therapy, usually given to "cure" the tumor, can also reduce its size and reduce pain. Giving antibiotics to cure the constant colonization of an indwelling urinary catheter is probably a futile effort. However, treatment of a urinary tract infection that is causing dysuria, frequency, and pain can improve the child's quality of life. A child may receive oxygen or be suctioned to promote comfort. Providing enteral or parenteral

fluids can be appropriate to maintain hydration if the child is unable to drink and complains of thirst or hunger.

A decision about continuing treatment for the dying child might be necessary when the care being given is causing discomfort with no benefit to the child. Hemodynamic monitoring, insertion of central lines to administer total parenteral nutrition to meet *long-term* nutrition needs, and taking daily weights or laboratory studies are examples of interventions that are futile in most situations. The parents and healthcare team must work together to determine when these interventions should be stopped (Levetown, 2006).

caREminder

As death nears for the child, direct care activities, except for comfort measures, are omitted to allow the environment to be peaceful. Another important decision is determining what, if any, resuscitation measures will be implemented. When it is apparent that the child is close to death, usually no interventions are appropriate. Communicate the resuscitation status of the child to all those involved in the child's care, including ancillary staff.

Time-of-Death Decisions

Decisions made at the time of death often relate to organ donation, autopsy, and funeral arrangements. The nurse plays an instrumental role in the decision-making process with the family by facilitating contact with appropriate personnel, ensuring that the family understands the choices before them, and completing tasks to ensure that family decisions are acted on by the healthcare team.

Organ Donation

As previously discussed, when approaching parents about decisions that must be made at the time of death, the nurse must be sensitive to the family's cultural and ethnic background. Some interventions, such as organ donation, are not permitted in certain cultures. Discuss the subject of organ donation only after the parents have been told that their child is dying and the feasibility of organ donation is confirmed. It is important for the nurse to be familiar with the state and agency's protocol for identification of potential organ donors. Some states do not allow healthcare professionals to approach the family about organ donation and relegate these responsibilities to those identified as part of an organ donation team (generally associated with the organ donation agency).

When discussing organ donation with the parents, be alert for comments that indicate that the parents do not understand the process. The general public often poorly understands the concept of brain death. Parents might not comprehend that the child has been pronounced dead and that equipment, such as a ventilator, is being used to maintain circulation to the organs that will be donated, not to preserve the child's life.

caREminder

Do not let preparation for the donor process interfere with the parent's wishes to be with their child before the ventilatory support is removed. Throughout the process, the child's body is treated with respect.

Autopsy

The decision about an autopsy is often made by the medical examiner's office in unexpected death or when criminal intent is suspected, but in expected death (such as death from progression of a chronic disease) the decision is left up to the parents. Present facts about the autopsy (TIP 13–1) with sensitivity and give the parents enough time to make the decision. Most important, respect is afforded to families who forgo autopsy because of cultural or religious prohibitions. Chart 13–2 discusses some of the cultural and religious beliefs associated with death, including permitting postmortem examination of the child.

Funeral Arrangements

Funereal arrangements need to be made by the parents. This is something few parents are prepared to do. If local mortuaries offer free or low-cost funerals for infants and children, provide such information to the parents. For the parents whose child has just died, talking about a funeral may be very disturbing. A service can be a source of comfort or distress to a family member. There are often different issues for surviving family members based on their relationship to the child as well as their gender. For instance, in many cultures, it is more socially acceptable for the mothers to openly grieve. Many times, a father

may feel like he cannot express his full emotions publicly. A mother is often offered more support than a father, and the father may feel “left out” or that his grief has less value than the mother's. The healthcare team can assist in identifying the individual needs of family members as funeral service arrangements are made. All family members can contribute to the arrangements (e.g., choosing a favorite piece of music, a poem to be read), thereby giving each member a special memory of their final farewell to their loved one.

Care at the Time of Death

Each child's death is a special, albeit sad, moment. The fact that the child will die soon is often known when the child is terminally ill. Allow parents, siblings, and other support persons who the child or parents wish to have present to be with the child if possible.

caREminder

Offer the parents the opportunity to be with their child after the death and before the child receives postmortem care. Ask parents if they want someone to be with them or if they want to be alone with their child. Some parents welcome the option of giving care such as the final bath. Stay with the parents if they request.

It is helpful to prepare families for the physical changes that are going to occur during the last weeks, days, hours, and minutes of life. If the family is prepared for physical symptoms, they are less likely to panic with alterations in appearance, such as mottling and cyanosis or changes in respiratory status when moaning and agonal breathing

TIP 13–1 For the Family Considering an Autopsy

Nursing Diagnosis and Outcome

Deficient Knowledge: Autopsy

Outcome: The family makes an informed decision regarding performance of an autopsy.

Interventions

- Determine any religious or cultural prohibitions against and exceptions for permitting an autopsy.

Teach the following:

- Autopsies are not mandated, unless the cause of death may be a criminal matter. Advise the parents that they have a choice regarding whether an autopsy be performed.
- Health insurance companies may not cover the cost of an autopsy.

- The autopsy may help to clarify the cause of death and/or confirm the diagnosis of the child.
- The autopsy can help the medical team to understand the disease or the impact of the injury and thus help other children.
- Alternatives to a full autopsy can include examination of specific organs only, examination of the cord and placenta, blood or tissue sampling for genetic analysis, radiographic examination, and the possibility of laparoscopic autopsy.
- The child will feel no pain.
- The child's body will be respected and there will be no obvious indication of an autopsy.
- The family will get feedback about the autopsy from their family healthcare provider.

Source: Chichester (2007) and Wright & Lee (2004).

occur. Even when death is anticipated, the reality as it occurs might seem overwhelming, and having systems of support at hand might help to ease the transition from life to death. Making advance preparations regarding which mortuary to contact might help relieve the stress of trying to make a decision after the death.

As previously discussed, during and after the death it is important to honor cultural and religious practices. Encourage families to invite their clergy member, priest, imam, or rabbi to join them. Encouraging and allowing the family to spend as much time as they wish with the child is often one of the memories that sustain them. The child's ability to hear and understand is not always clear to caregivers, but this should not stop efforts to talk to and communicate with the child. Holding the child or assisting in caring for the child's body by bathing and dressing provides a comforting ritual for many families (Fochtman, 2002). The presence of multiple intravenous lines, tubes, and even ventilatory support are not reasons to deny this request (Fig. 13-4).

Allow parents to determine who will attend the final visit with the child—other family members and siblings of the child, religious leader, or friends. In cases of severe injuries, prepare the parents for how the child looks. Prepare the child and room for the parents' visit, but it might be beneficial to leave much of the resuscitation equipment in the room to reinforce the fact that efforts were taken to save the child.

Parents who do not want to see their child after the death can be gently encouraged to do so. Even when the death was the result of severe trauma, parents who see their child have fewer fantasies about the event. Offer the parents the opportunity to hold their child, and allow the length of the final visit to be determined by the needs of the individual family.

Give mementos and personal items of the child to the parents, and initiate the rest of the agency's bereavement protocol or policies. Provide written information about support available for the family over the difficult months ahead.

FIGURE 13-4. Parents' wishes to hold their dying child should be respected and facilitated.

The nurse can act as the gatekeeper who helps the parents find needed privacy and facilitates communication among family members. Suggest ways for parents to discuss the events with their other children. Be prepared for the family to express grief in a variety of ways, including anger and rage, and do not take negative responses personally.

Care of Parents

Often when death is anticipated, parents are reluctant to leave the child's bedside; supplying sleeping couches and meals in the room can be viewed as a tremendous kindness and support to the family. Within the home environment, using a child-monitoring system, such as the readily available baby monitors, can allow a parent to feel comfortable to leave the child's room for short periods because they can remain in contact through sound. Utilizing community resources such as neighbors, friends, and members of their religious community to assist with siblings, provide meals, do household chores, and generally be available for assistance can take some of the burden off of routine activities of daily living needed to keep a household functioning.

Parents are often in a state of shock. Assess parent's decision-making ability carefully. Assistance with driving home or caring for other children might be needed. Caregiver fatigue, sleep deprivation, physical exhaustion, and depression can all affect the caregiver's ability to make decisions and interact with other family members. For many caregivers, the full impact of the child's death might be delayed until they recover from the physical demands of caring for their child. Encouraging parents to rest when the child is sleeping, eating small meals, and drinking fluids can help to sustain them through this time.

Care of Siblings

Siblings of dying and dead children need care also. At times, with good intentions, a parent might try to protect the siblings from the reality of the dying process; however, this can inadvertently increase fears in that the sibling's fantasies may be more detrimental than reality (Fochtman, 2002). Siblings often have been involved in some fashion throughout their sibling's illness; thus, allow siblings to participate in the final process of their brother or sister's life. Many times they may wish to be present at the death, help with the physical care of the body, and plan the funeral. Studies in the 1980s demonstrated that when siblings participated in the care of their dying sibling, they had a more positive adjustment (Lauer, Mulhern, Bohne, & Camitta, 1985; Martinson, Davies, & McClowery, 1987). If they are present in the acute care setting, inform siblings about what is happening and give them an opportunity to express their questions and fears. If children want to see their brother or sister, discuss this issue with the parents. It is generally preferable to honor this request; however, if they do not wish to see their sibling, they should never be forced to do so.

WORLDVIEW: In Japanese culture, there is emphasis on the importance of the family over the individual. Siblings are expected to be patient with the sick or dying child. Research by Saiki, Martinson, and Inano (1994) found that siblings usually did not complain when attention was focused on the dying child, but in some siblings, physical or emotional problems did develop. Japanese mothers are the primary caregivers, and families are not comfortable receiving support from outside the family. Therefore, Japanese families, especially mothers, struggle to provide care on their own at the expense of their own health and the needs of siblings (Saiki et al., 1994). An appropriate intervention would be to remind parents to pay attention to the needs of siblings. Regardless of the child's cultural background, allow siblings of a child who has died to be involved to the degree that they wish to be involved. Freely and openly address their questions and concerns.

If the siblings are not present, advise parents on ways to talk to them about their brother or sister's death. Fantasies and misunderstandings are common, and some children see themselves as responsible for the death. These ideas must be identified and dispelled. However, if the sibling is responsible—for example, after a firearm injury or fatal accident—emergency emotional support for the sibling must be initiated immediately.

Siblings may choose not to attend a funeral service or may not be present based on parental wishes. When a child is at the funeral of a family member, advise parents to have a person sit with the siblings to answer questions or take them out if they feel they need to leave during the service. This person should be a close friend or family member who would be comfortable with the child. Children may feel that they should cry, and they may need permission to do so. Often children feel that they need to “be strong” at the funeral service so as not to further upset their parents. Before the service, bring parents and children together to discuss expressions of grief and to prepare the children for what they may see at the funeral. These discussions will provide family members an opportunity to comfort surviving children and prepare them for the many emotions they may experience over the next days and weeks.

Follow-up Care

The healthcare staff and/or a bereavement coordinator play an important role in follow-up care with the family who has lost a child. Follow-up efforts can include sending a personal letter from the nursing staff to the family followed by a call within 2 weeks of the child's death, at which time additional support can be offered and referral to counseling can be made if needed. The family can be contacted at times that are likely to trigger resurgence of the grief response, such as the child's birthday, major holidays, or the anniversary of the child's death, so that additional support can be provided (Fig. 13–5). A tracking card and check sheet can be used to identify dates for follow-up interventions.

Include extended family members and friends in the bereavement programs as previously described based on their degree of involvement with the person who has died. Persons such as out-of-state grandparents, spouses of the

noncustodial parent, daycare providers, and parents of the child's friends are often not seen and are thus overlooked by the healthcare providers who are caring for the child and family.

Extended family and friends are often unsure of how they can help the grieving family. They fear they will do something wrong when they call or visit, so they do neither. This contributes to the isolation of the grieving family in a time of great need. Provide suggestions of helpful activities to family members (Community Care 13–2).

caREminder

Reassure friends and family that, if they act genuinely and with sincerity when they are with the grieving family, what they do will rarely be wrong.

SPECIAL CONSIDERATIONS RELATED TO THE CAUSE AND PLACE OF DEATH

The cause of death (expected, unexpected, or traumatic) and place where the death occurs affects the choice of healthcare provider interventions and the family's response to the loss. These issues must be considered to meet the needs of the family when delivering care.

Perinatal Loss

Palliative care services can be integrated into the neonatal intensive care unit (NICU) and the labor and delivery areas. The need for palliative care services in these areas is very real. Thirty-eight percent of all childhood deaths occur during the neonatal period (Carter et al., 2004). In

FIGURE 13–5. On the anniversary of a child's death, family members and friends meet to symbolically send balloons (non-Mylar) up to heaven with messages inside for the deceased child.

COMMUNITY CARE 13–2

Suggestions for Family and Friends After the Death of a Child

- *Be yourself.* Show your concern and sorrow in your own way. You will not be effective without natural and total sincerity.
- *Be there.* Brief telephone calls and visits say “I care and I want to help.”
- *Say “I’m sorry.”* After you have expressed your sorrow, allow the parents or family to respond. Don’t be afraid of silence. Often, your caring presence is enough.
- *Touch.* A hug or a hand to hold can sometimes say more than words.
- *Find helpful activities.* Don’t wait to be asked to do something. Look around for what is needed. Provide a meal, do errands, or baby-sit the other children.
- *Don’t protect.* There are many helpful things to do, but shielding the family from the reality of the situation is not one of them. They need to make their own decisions and work through their grief.
- *Talk about the child.* Don’t be afraid that mentioning the child will remind them of their grief. They haven’t forgotten. They need to talk about their child. When you avoid the subject, it seems that you are saying that the child didn’t exist.
- *Cry with them.* Family members and friends often feel that they must “hold up” to be supportive. This is not necessarily true. Your tears show that you care. However, if your own grief is so overwhelming that you cannot function, it is probably best to wait to interact with the parents or family until you can function.
- *Laugh with them.* It is important to recall humorous incidents and endearing qualities about the child. These memories may bring mutual smiles and laughter. Remember, though, that jokes and trivial discussions are not appropriate at this time.
- *Don’t look for something positive.* There is nothing positive in the situation, and anything you try to point out as positive may be perceived by the parents or family as a lack of understanding for their pain.
- *Avoid stock responses.* Don’t use such cliché phrases as “I know how you feel.” “Be thankful that . . .” “Don’t cry.” “It’s better this way.” “You have other children.” “You can have other children.” “It’s God’s will.”
- *Listen with understanding.*
- *Acknowledge the family’s feelings and questions.* You cannot answer these questions, so don’t try. Just acknowledge their right to be angry.
- *Reassure.* It is common for those who are grieving to feel guilt and to engage in an “if only” type of exercise. Although this is normal, repeated reassurance is necessary.
- *Be patient.* Every person grieves differently and on his or her own timetable. You cannot rush the process.

perinatal loss, a parent can experience a significant grief reaction, even when a pregnancy has been brief. As the pregnancy becomes real to the parents, particularly to the mother, there can be significant investment and bonding, even before the signs of pregnancy are clear to others.

Nurses in many settings care for families experiencing perinatal loss, miscarriage, stillbirth, and neonatal death. This could be in the emergency department (ED); labor and delivery, neonatal care, mother–baby, or women’s units; or primary care settings in the community. The goals of care are to meet the family’s medical needs, validate the loss, and teach about usual responses to the loss. It is thought that to facilitate grief resolution, parents must first attach to, then detach from, their deceased infant (Schlomann & Fister, 1995) (Tradition or Science 13–4).

Regardless of the setting of a perinatal death, offer the parents the option of touching, fondling, or holding the deceased fetus or infant, even if it is grossly malformed (Fig. 13–6). This gives parents a chance to attach to their infant. Lundqvist, Nilstun, and Dykes (2002) found that the behaviors of healthcare professionals were directly related to that of the grieving mothers’ feelings of both empowerment and powerlessness after the death of a baby. When healthcare providers attended to the needs of the

TRADITION OR SCIENCE 13–4

Do physicians agree that DNR orders should be initiated in the delivery room when death is imminent?

MORE INQUIRY NEEDED

Among pediatric care providers, initiating DNR orders remains an ethical challenge. Catlin (2000) found this to be true when examining the perceptions of physicians who made delivery room decisions to resuscitate extremely low-birth-weight infants. Although the physicians did not report being influenced by their own religion or moral philosophy, 96% of the doctors reported that the role expectation of saving lives contributed to viewing resuscitation of these infants as necessary—this, despite known mortality and morbidity statistics. Physicians reported that they did not feel the delivery room was the proper site for decision making about resuscitation, thus resuscitation was initiated with transfer to the NICU, where the facts of the case could be examined in depth. Cost and concerns about the legal system had no effect on the decisions to resuscitate; rather, the role expectations to perform and the subsequent sense of burden this created were the driving factors of the decision-making process.

FIGURE 13–6. A father spends time with his dying infant.

mother by seeing the mother as an individual, seeing the situation “through the mother’s eyes,” and showing empathy for the mother’s feelings, a sense of empowerment was established for the mother. On the other hand, an insistence on following prescriptive rules of the acute care setting rules, of feelings not being taken into account, and a fear of sharing feelings with staff who seemed distant and disconnected all led to a sense of powerlessness by the 16 mothers interviewed in this study.

Parental fantasies about the infant’s appearance are often worse than the reality of the anomalies or condition of the deceased infant. Seeing and holding the infant validates the existence of the infant and makes the reality of the death more clear. Clean and wrap the infant as appropriate for the gestational age in preparation for this visit, and describe the appearance of the baby to the family before the visit. Stay with the family at the beginning of the visit and then offer them time alone with the infant. Decisions about the length of this visit and the individuals who will be present are left up to the family.

Alert! Be cautious about allowing fathers or other family members to decide whether the mother is to see her deceased child. Offer this opportunity to the infant’s mother independent of family input. If the woman is incapable of seeing the child or making the decision at the time of the infant’s death, an option to visit at the morgue can be provided if the baby cannot be taken from the morgue.

Photographs of the child can be taken, with nursing personnel preparing the child in such a way as to offer a peaceful and attractive remembrance of the child. If the family decides not to see the infant, allow the body to be kept on the unit as long as possible, to allow them time to change their minds.

Immediately after the death, activate the perinatal bereavement protocol. Immediately notify bereavement team support persons (e.g., nurses, social workers, physicians, or other parents who have experienced perinatal losses) so they can visit as soon as possible after the death. Resolve Through Sharing is an example of a program that

is used internationally to support families experiencing a perinatal loss. This program trains healthcare providers to serve as counselors who can intervene with families to facilitate coping with their loss.

The bereavement team members can help parents make the many decisions needed during the immediate postdelivery period. Each time parents make a decision, they are able to take control in a very difficult situation. An autopsy may be desired by the parents or required by law. For some infants, the option to donate organs may be viable.

The parents must determine how and where the infant will be buried. Requirements for burial vary from state to state, but it is usually required for all births after 20 weeks’ gestation. Parents may choose to have the institution dispose of the body. If the infant is to be buried, the parents can be asked whether there is a special outfit, blanket, or other object they would like to have buried with the infant. Provide sufficient time without pressure so that a family decision may be made.

When an infant’s death occurs on the perinatal unit, a decision must be made about where the mother will be placed during the immediate postdelivery period. Involve parents in this choice because it is an action that can increase their sense of control. Many agencies attempt to place a woman whose infant has died on a nonobstetric unit. Regardless of the unit where she stays, alert all staff members to her loss. The Resolve Through Sharing program recommends placing a simple card with a photo of a flower on the door to the woman’s room (Fig. 13–7). The photo is a visual reminder to all personnel that a loss has occurred. This prevents inadvertent comments about the infant who has died and reminds caregivers that this woman and her family need more than the usual postpartum care.

When the perinatal death occurs in the ED, take special care to protect the family and to provide them with an opportunity to see and hold the infant. Avoid terms such as *spontaneous abortion* because the term *abortion* is more closely associated with voluntary termination of pregnancy. Be especially careful of where the fetus is placed. Putting the fetus on a cold metal tray can be very disturbing to the parents. Offer a remembrance packet to the parents. This packet may include a photograph of the child and a lock of the child’s hair.

FIGURE 13–7. The Resolve Through Sharing purple rose on the door alerts all staff to the family’s loss.

Referral to a support group and teaching about the normal reactions that follow perinatal death are essential components of the care provided to these families, even if the interactions with the healthcare system are brief. Prepare parents for the intensity of their reactions and for the fact that they will each react differently. The loss of a fetus early during pregnancy is different from the loss of a baby in later pregnancy, and both are different from the loss of an older child or adult. The grief might focus more on what could have been rather than what was.

People's reactions to the couple's loss will also differ. Sometimes a seemingly helpful comment can be dismissive. For example, someone might say, "Don't worry, you'll get pregnant again real soon," or "At least you have two healthy kids at home." These comments diminish the loss of that specific pregnancy. If the loss was early during the pregnancy, other family members might act as if they are ignoring the loss because they are afraid to hurt the couple by talking about it. Offer pamphlets with suggestions for the family and friends to the parents to share with their support persons. If the death occurs during a later stage of pregnancy, when many people know about the expected birth, help the parents to plan how to respond to questions about their new baby. One such response is, "Thank you for asking. I am doing well, but my baby died just after he was born."

Much of the grief work of parents who have experienced a perinatal loss occurs after discharge from the acute care institution. Use of detailed perinatal loss follow-up tools assists primary care providers in community settings to thoroughly address the parents' physical and emotional status, autopsy results, and the parents' support network; and ability to communicate with significant others and to give anticipatory guidance regarding grief reactions and future pregnancies. If symptoms of unresolved grief are present 12 to 18 months after the loss, make a referral for in-depth counseling.

Dying in the Acute Care Setting

Children who die in the acute care setting may be in the general pediatric unit, ED, critical care unit, or an operating room (OR). The principles of care are the same in all locations, but the site of death and the circumstances that bring the child to the unit can have a significant bearing on the needs of the family.

General Pediatric Unit

When a child dies on a general pediatric unit, the child is often at the terminal stage of long-term disease. Care is similar to that described for the emotional and physical care of the dying child. Encourage open visiting. Families who spend a lot of time at the hospital during the child's illness might need healthcare provider support and encouragement to leave the room and the unit to meet their own needs and the needs of their other children. After the child's death, the staff working with the child might also need support. Children on the unit who knew the child frequently need help to address their grief.

Emergency Department or Critical Care Unit

Children who die in an ED or a critical care unit are often the victims of accidental or intentional trauma. Others die because of sudden illness, such as respiratory failure, sudden infant death syndrome, or fulminating meningitis. In addition, children who have been in treatment for a chronic condition and who are admitted to an ED or critical care unit might die because of an acute crisis that does not resolve.

When the death is from trauma, other family members or friends might have been injured or killed. Determine the relationship among all victims and provide support appropriate to the situation. When one or both parents are injured or dead, the emotional support of surviving children is essential. Issues of authority for consent must be clarified. When the affected family members are in different facilities, lines of communication between family members and the healthcare team must be established.

When the child's death is the result of violence, steps to document the injuries, preserve evidence, and notify law enforcement authorities, if they are not already involved, are needed. Nurses must also work with social service, pastoral care, and other support personnel to initiate crisis support care for the parents and other children.

When the death is suspected to be the result of family violence, the nurse must report suspected abuse. Social workers and law enforcement authorities then have a major role in initiating child protection activities for other children and initiating action against the perpetrator. The nursing role is one of assessment, documentation, and parent and family support. The facts of the case are rarely clear when the child is first brought to the ED.

caREminder

A nonjudgmental approach to all family members is taken to avoid the damage that can be caused by the false accusation of an innocent parent.

In other cases, the child's fatal injury might occur because the parent or another person did not use safety precautions to protect the child (Clinical Judgment 13–1). For example, a mother does not clean out the drawers in the bathroom cabinet when she has her first baby. As a result, she does not discard the half-full bottle of antimalarial pills, which poison her 2-year-old girl when she ate them thinking they were candy. Or, an aunt decides to hold her infant nephew in the front seat rather than getting the car seat from her brother's car. Because they were "just going down the block," she never thought they would be hit from behind. The baby dies the next day from a ruptured spleen and liver. Such parents and family members need supportive care and might need referral to a mental health professional to resolve their guilt about their role in the child's accidental death.

When the child is admitted to the ED or critical care unit, the family assessment process must be accelerated. The nurse must determine what the family knows and expects, and then reinforce and clarify that information.

CLINICAL JUDGMENT 13–1

A Child Experiencing the Traumatic Death of a Sibling

Nine-year-old Eric G. and his 4-year-old sister Sara were playing at home while their parents worked in the garden. Eric and Sara had been carefully instructed never to play with the gun that Mr. G. kept in a cabinet over the refrigerator. Around 4 PM, Eric and Sara were searching for snacks to eat before dinner. Eric pulled a chair up to the kitchen counter and began searching the cabinets. He finally found a full bag of chips hidden in the cabinet over the refrigerator, just behind the gun. When he moved the gun, he was fascinated by how it felt and looked and brought it down “just for a minute.” The gun discharged, hitting Sara in the chest. The emergency response team transported Sara to the hospital. After briefly interviewing Eric and his parents, the police helped them get to the hospital. There, Eric tells you that the policeman said he killed his sister.

Questions

1. What other data about Eric and his family should be obtained at the time of their admission?
2. What assessment finding indicates that Eric was misinterpreting comments made to him?
3. What simple tools can be used to help Eric express his feelings?
4. What immediate referrals would you make for Eric’s care?
5. What types of concerns would you have about Eric’s reaction to his sister’s injury and possible death?

Answers

1. Who do the children live with? Which members of Eric’s family provide his greatest support? Has Eric had any prior experience with such an event?
2. Eric says that the policeman said that he killed his sister, but the police officers only remember asking Eric what happened to his sister.
3. Drawing, storytelling, and reading stories that contain the themes that Eric expresses in his comments to staff and family
4. A child life worker, social worker, psychologist, or psychiatrist should see Eric within an hour of his sister’s admission.
5. Eric is likely to react strongly to any comments made in the hours and days after the accident. Even supportive comments of caring adults may be misinterpreted by him. He will feel responsible for her death.

Focus comments on what parents want and need to know. The critically ill or injured child is often fully alert and aware of the surrounding activities despite serious injuries. Answer the child’s questions and give the child opportunities to express concerns and, if age appropriate, participate in care decisions.

The family must be helped to comprehend a rapidly evolving series of events concerning their child’s condition and the multiple decisions they need to make. Parents need rapid preparation for what they will see, feel, and experience. Discuss the possibility of the child’s death as soon as such an outcome seems likely. Encourage questions even when they are repeated multiple times.

Ask parents whether a clergy member, either the hospital chaplain or someone from their place of worship, should be called. Respect their need to carry out specific religious rituals for the time of death. Give parents frequent updates on their child’s condition. Parents unfamiliar with the ED and critical care environments might need permission to approach or touch their child. They may also welcome being asked to help with simple care. This allows them to have a sense that they are caring for and comforting their child even at the time of death. When answering questions, be as direct and complete as possible, and try to not rush the parents as they work to absorb the reality of the impending or actual death of

their child. Review Tradition or Science 13–1 for a discussion of parental presence during resuscitation and invasive procedures.

Operating Room

Another possible place of death for the hospitalized child is the OR. Parents may express a need to be with their child when it becomes clear that the child will die in the OR. Individual institutions have procedures regarding such eventualities, because the decision to grant a parental request to enter the OR, or to ask parents whether they want to enter the OR often must be made quickly.

Designate one member of the OR team as the person who confirms that death is likely. Offer the parents the chance to be with their child in the OR. Other persons who can be with parents, such as the child’s siblings, clergy, extended family, or friends, should be identified. Be careful not to give parents the message (verbally or nonverbally) that they must go into the OR.

If the parents choose to go to the OR suite, prepare them for what they will see and how the child will look. Also, prepare the OR environment and staff for the parents’ visit. Visible blood on the child, the bed, or on surgical instruments should be cleaned or covered up. Have one staff

member, preferably a nurse, support the parents during the visit. If possible, offer the parents a place to sit during the visit. Help the parents approach and touch their child because they may need to receive permission from the healthcare team to do this. Allow parents the opportunity to be present when life support is discontinued.

After the child's death, offer parents additional time to be with their child before, during, or after postmortem care is completed. At this point, movement of the child to the recovery area may be considered.

Dying in the Community

QUESTION: What is one unique and beneficial aspect of selecting hospice care for the Tran family?

More children with complex chronic conditions are dying in the community (Feudtner et al., 2001). These children might be cared for in the home. Hospice and respite care might also be provided.

Home Care

Parents have reported that providing end-of-life care in the home was a valuable and positive experience for the dying child and all family members. Primary benefits include the freedom for family and friends to visit at any time, less disruption to family life, ability to cater to the child's unique needs (e.g., dietary preferences), and allowing more family members to participate in the child's care and be present at the time of death. Challenges that remain when the child is at home are ensuring adequate symptom management; ensuring availability of professional support at all times of the day; watching the child physically decline; and managing the fatigue, loneliness, and fears (Collins et al., 1998; Kopecky, Jacobson, Joshi, et al., 1997; Liben & Goldman, 1998).

Kopecky and colleagues (1997) reviewed a home-based palliative care program for children. The sample consisted of 126 children referred from a variety of clinical areas. Of the 93 children who died, 53% died at home, 18% died in community hospitals, and 29% died in tertiary care centers. Children in the home-based program experienced fewer hospital readmissions, with an average of 80% of the child's surviving days spent at home. Additionally, when adequate support for families was in place, there were few calls and pages initiated by the patient's families. Parental support in the program was offered via home visits, regular telephone calls, and a pager. The authors concluded that the home-based palliative program was effective for many children in providing adequate support to the children and their families by the team of health professionals.

Hospice Care

Another option for children who are approaching death is enrollment in a pediatric hospice program. Hospice programs all subscribe to similar standards and practices.

The child must be in the terminal phase of illness, usually with death expected in the ensuing 4 to 6 months. The child and family must have decided to forgo any further treatments or diagnostic efforts to sustain life. These standards are perceived as a barrier to access to pediatric hospice services. In many cases of children with a chronic condition, it is impossible to determine whether the child is within 4 to 6 months of dying. Furthermore, the child may need ongoing treatments to sustain life even during the dying process. For example, the child with cancer may need chemotherapy or radiation even during the last months of his or her life to decrease the uncomfortable growth of a tumor. Many states are challenging the hospice enrollment standards and are forging ahead with legislation to improve pediatric access to hospice services.

The initial visit of the hospice worker is usually made within 24 hours of the referral because the family's needs are usually acute and the child might be close to death. The essential components of hospice care include assistance with pain and symptom control, support for children and families, and education about the physiologic processes of death. The site where hospice services are delivered and the scope of services provided differ from hospice to hospice and even from family to family.

Most children enrolled in hospice are cared for at home. The hospice staff helps the child and family deal with pain, manage symptoms, and maintain nutrition; they do anything needed to promote the comfort of the child. Emotional support for the entire family is an essential component of hospice care both before and after the child's death. Although nurses are often in the home at the time of the death, many parents choose not to call the nurse until after the death so that the family can be alone with the child. Most hospice programs continue to support the family after the child's death because the acute stage of grief can extend for 2 years after the child's death.

In some cases, the child needs to be admitted to an *inpatient hospice*. Inpatient hospice units meet the needs of families who cannot provide care in the home when the child is not a candidate for admission to an acute care or rehabilitative setting. The inpatient hospice can address the psychological and physical needs of children and their families while providing the excellent nursing and medical care needed.

ANSWER: One of the unique benefits of hospice care is the psychological support offered to families and the extended support for the family after the death of the child.

Respite Care

Although parents are better able to maintain control and life is less disrupted when dying children are cared for at home, the parents and family still experience stress as a result of the illness, the child's care, and their own fatigue. **Respite care** allows the parents and family to leave the child with the assistance of a home health aide or hospice volunteer. Respite care can also be a part of the

hospice program or a separate program offered to the family (Horsburgh, Trenholme, & Huckle, 2002). Care of these children is complex and time-consuming; respite care offers caregivers a specified period of time to seek rest and refreshment. With respite care, parents and other family members can continue to work and participate in activities that the dying child cannot attend.

Such services are provided with different options based on the family's needs. Some families report needing short-term breaks (a few hours or part of a day). Night care also may be needed to provide parents the ability to get sufficient rest. Away-from-home respite care may include nursing and symptom management for periods of several days or a week or more. Such services allow families to have vacations without the sick child. Emergency respite is also needed when a crisis occurs at the home.

GRIEF AND BEREAVEMENT

Grief is the painful, sad, and anguished feeling accompanying loss. Grief is usually thought of as a reaction to the death of a loved one; however, other losses, such as the loss of an object (e.g., long-term home), of a relationship (e.g., divorce), or the loss of anything, tangible or intangible, that is highly valued, can result in a grief reaction. A family eagerly anticipating the birth of their healthy newborn will experience grief and bereavement if the child is premature, stillborn, or born with a congenital abnormality or serious illness. The unanticipated diagnosis of leukemia or diabetes in a previously healthy teenager elicits grief within the family and for the afflicted child. When grief from any type of loss is unresolved, it can reappear during an attempt to resolve the grief associated with a later loss. There are many types of grief that have different characteristics, manifestations, and responses. The nurse should be able to identify the type of grief and implement appropriate interventions based on the exhibited behaviors. Table 13–1 explains the types of grief and characteristics associated with each type.

When a person significant to a family has died, each member of the family is in need of immediate help and assistance. If family members have the needed knowledge and coping mechanisms, then immediate help assists them until their resources can be mobilized. For family members without needed resources, the nurse's role is one of educator and support person as the family is helped to move through the bereavement process to life without the loved one.

Bereavement, often called *mourning*, is the mental work following the loss, which allows adaptation to that loss. The care of the child and family facing death is not simple. Mourning is typically thought of as the outward social expression of the loss and may be dictated by cultural norms and rituals, as well as the individual's personality and life experiences. Anticipatory mourning is the process of emotional preparing that occurs up to and leads to the time of death (Rini & Loriz, 2007). Anticipatory mourning allows family members time to begin grief work prior to the actual death of the loved one.

The death of a child affects not only the individual family members, but also the family unit as a whole. Adults helping children must deal with their own grief and need to mourn while helping the child do the same. The child may be the one who is dying, or the child may be a sibling or friend of a child who has died. The loved one whom the child loses through death can be a grandparent, parent, sibling, other family member, or a friend. For the child, resolution of the experience of the loss of a loved one involves both progression through the bereavement process and achievement of normal developmental milestones. The role of the nurse includes facilitating the grieving process by assessing grief and assisting survivors to acknowledge the loss by expressing grief in their own way (Fig. 13–8).

Grief Responses

QUESTION: What stages of grief are Tung, Loan, Ashley, and George manifesting?

Grief caused by the potential or actual loss of a loved one or by an anticipated outcome results in both physiologic and emotional responses. Physiologic symptoms include waves of physical distress, such as shortness of breath, an empty feeling in the stomach or heart, physical weakness, and a loss of appetite. An inability to concentrate or sleep, a general sense of unreality, and a need to withdraw from others is also common.

Kubler-Ross (1969) described five common reactions to death or approaching death: denial and isolation, anger, bargaining, depression, and acceptance. These stages of death, or reactions to mourning, explain the coping mechanisms people use to deal with losses. Although Kubler-Ross (1969) presented these mechanisms as sequential reactions, they actually occur more randomly, with individuals moving from one reaction to another before achieving full resolution. Not all persons experience all the reactions.

Denial and Isolation

The first reaction is denial and isolation. Denial can be overt, such as when a parent says, "The doctor told us Sammy has a very bad head injury, but with all these new machines, he will be back at school in no time." Signs of denial can be more subtle, such as when the family attempts to go on with life as usual with no adaptation for essential disease care. At times, the denial is in the form of psychological isolation. In this case, the child or parent is able to talk about the illness or the potential or actual death, with no emotion or acknowledgment of what the death will mean.

Denial can be therapeutic if it allows individuals to distance themselves from the trauma of the diagnosis or death itself to activate coping mechanisms or to reach out for help. Prolonged denial, however, can cause missed opportunities for needed emotional care, for actual disease treatment, or for amelioration of negative symptoms.

TABLE 13 – 1

Types of Grief

Type of Grief/Definition	Characteristics
<p>Anticipatory Grief Anticipated and real losses associated with diagnosis, acute and chronic illnesses, and terminal illness Experiencing anticipatory grief might provide time for preparation of loss, acceptance of loss, finish unfinished business, life review, resolve conflicts. For survivors, anticipatory grief provides time for preparing for life without deceased, including preparation for role change, and mastering life skills such as paying bills and learning how to manage a checkbook (Rando, 2000).</p>	<p>With acute illness, chronic illness, accidents, and other changes in health, a patient may experience loss of general health, loss of functionality, loss of independence, loss of role in the family (breadwinner, caregiver), and loss of life-style as a result of dietary or activity restrictions. Loss of a limb or body part (breast, uterus) may cause loss of self-confidence and changes in perception about body image. Family members, significant others will also experience losses when the patient is ill, including loss of role in the family, loss of relationship, loss of finances, loss of security, loss of companionship, loss of relationship, and so forth. AIDS can cause multiple losses over short periods of time, such as loss of a job, material possessions, body image resulting from changes in physical appearance, functionality, privacy (the secret is out), friends, partners, and social acceptance. With diagnosis of terminal illness, additional losses may include loss of control (choice), loss of physical and/or mental function, loss of relationships, loss of body image, loss of future, loss of dignity, loss of life.</p>
<p>Uncomplicated Grief Also known as “normal” grief. Typical feelings, reactions and behaviors to a loss; grief reactions can be physical, psychological, cognitive, behavioral Children mourn or grieve based on their developmental level. (Doka, 1989; Parkes, 1999; Worden, 2001).</p>	<p>Reactions to loss can be physical, psychological and cognitive. Symptoms of grief in younger children:</p> <ul style="list-style-type: none"> • Nervousness • Uncontrollable rages • Frequent sickness • Accident proneness • Antisocial behavior • Rebellious behavior • Hyperactivity • Nightmares • Depression • Compulsive behavior • Memories fading in and out • Excessive anger • Excessive dependency on remaining parent • Recurring dreams: wish filling, denial, disguised <p>Symptoms of grief in older children:</p> <ul style="list-style-type: none"> • Difficulty in concentrating • Forgetfulness • Poor schoolwork • Insomnia or sleeping too much • Reclusiveness or social withdrawal • Antisocial behavior • Resentment of authority • Overdependence, regression • Resistance to discipline • Talk of or attempted suicide • Nightmares, symbolic dreams • Frequent sickness • Accident proneness • Overeating or undereating • Truancy

Anger

The second reaction is anger, which can be quite pronounced. Often, the trigger is the loss of the person who is dying or who has died, but anger can also be triggered by the loss of the expected future. It is not unusual for displaced anger to be directed at persons who have no role or culpability in the death or loss. These persons can be healthcare workers, family members, friends, or anyone with whom the person interacts. The anger can also be self-directed, because of actual or perceived personal failure in preventing the loss from occurring. Anger can be directed at family members whose children are alive and thriving, at healthcare providers, or at a higher power such as God.

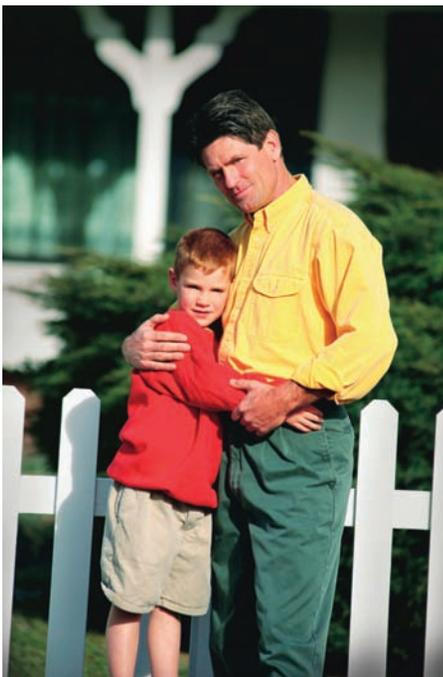

FIGURE 13-8. There is no script for grief and bereavement. Each family member responds to the loss of a loved one in unique way.

caREminder

Do not take the anger of a grieving person personally. Address specific issues and correct patient care concerns if possible. Allow the angry person the time needed to overcome this reaction and to move on in his or her grieving process.

By not overreacting to the angry person, the nurse allows continued development of the therapeutic relationship that the person needs to complete the grieving and bereavement process. To help prevent disruption of family relationships, teach family members that anger is a normal part of the grief reaction.

Bargaining

In bargaining, the grieving person offers some action, perhaps to a higher being, in exchange for a cure or the return of the loved one. Promising good behavior, returning to active participation in religious activities, and offering to support a special cause are all examples of bargaining. A major component of bargaining is the maintenance of hope.

Bargaining can be therapeutic and may actually help the person look to the future, even when that future is not clear. On the other hand, bargaining can cause individuals to seek out alternative but ineffective treatments “just in case” they might work. These can be physically, emotionally, and financially draining on the family and may delay use of traditional, but not so promising, approaches to care.

Depression

Depression can be based on both current and prior losses. Expressing underlying fears and concerns helps the person move beyond the depression. The depressed person prepares for the altered future, which may encompass dealing with a chronic or acute illness in the family, coping with the person’s own death and the loss of all that is associated with life, or preparing for the loss of a loved one who is dying. Accept and support this behavior. Attempts to cheer up the person ignore the real concerns and issues that the depressed person is trying to deal with.

Acceptance

Acceptance or resolution of the fact that the loss will occur or has occurred is necessary for the grieving person to move on with life. Acceptance helps the dying person peacefully move on to death. For the family of a child with an unexpected illness, acceptance helps them incorporate the diagnosis and all associated healthcare needs into their lifestyle and routine.

ANSWER: Tung appears to be in denial, as evidenced by his statement regarding George getting well. We do not have much information to base the assessment of Loan, but her experience with her brother and the day-to-day care she provides George lead us to believe she is in the accepting stage of grief. Ashley is still wishing that she could take her brother's place. She is in the bargaining stage of grief. George has stated that he is dying and he is making plans for his own death. He also appears to be in the accepting stage.

Bereavement Tasks

The grief process is rarely orderly and predictable; it typically includes a series of tasks that the survivor engages, often referred to as *grief work* (Lindemann, 1994). Rando (2000) suggests that a person must complete six bereavement tasks and that the process of working through these tasks facilitates adjustment to the loss. These tasks are

1. Recognizing the loss
2. Reacting to the separation
3. Recollecting and reexperiencing the deceased and the relationship
4. Relinquishing old attachments to the deceased and to the shared world
5. Readjusting to allow movement into a new world without the loved one, but without forgetting the old world
6. Reinvesting in the new world

Anyone who experiences a loss or the death of a loved one is at risk for dysfunctional or complicated bereavement. Complicated bereavement is present if, based on the time since the loss or death, there is some compromise, distortion, or failure of one or more of the six tasks of bereavement. Such individuals are unable to accept the loss, experience the pain, or move on to a life that is different. Such mourners often try to deny, repress, or avoid aspects of the loss, including the step of relinquishing the relationship with the deceased child or other loved ones (Rando, 2000).

Parents are at high risk for complicated bereavement. Individuals are also at risk if the loss was sudden or unexpected, or if the relationship with the child or other family members was characterized by anger, ambivalence, or dependency. Other risk factors for complicated bereavement occur when losses are perceived as preventable, there are unaddressed loss issues from the past, there are mental health problems, and the mourner perceives a lack of support. Although research verifies that support groups may be of assistance to such individuals (Heiney,

Ruffin, & Goon-Johnson, 1995), referral for mental health counseling might be needed for persons experiencing dysfunctional bereavement.

Recognizing the Loss

In recognizing the loss, a person accepts the reality of the loss. Parents of a child with a chronic illness, congenital defect, or disfigurement must accept the reality that their child will not be like other children. For the parents of a dying child, they must accept that their child will not recover or return and that the child will not be a part of their lives again (Rando, 2000).

During this task, ill, disabled, or disfigured children recognize that they are different from their peers. The child's level of cognitive understanding affects this perception of the loss. The dying child needs to understand what it means to be dead and what causes a person to die. Ask the child about his or her observations so that misconceptions can be corrected. Have these discussions occur as soon as possible after the diagnosis, death, or loss to avoid missed opportunities to talk and to avoid sending the message that the loss is not to be discussed. Often, the challenge is not to get the child to talk, but to be sure that, when the child wants to talk, someone is there to listen.

Reacting to the Separation

Reaction to the separation has been described as experiencing pain. The grieving person must feel, identify, accept, and express the psychological reactions to the loss (Rando, 2000). This can bring out intense and painful feelings.

There is also a need to identify and mourn secondary losses that occurred with the primary loss (Rando, 2000). For the parents whose child has died, this can mean loss of the socialization they enjoyed when they served as class parents in their child's school. For the boy whose father died, this might mean there is no one to take him on the father-son camping trip. An illness can separate a child from peers and family, with frequent exacerbations of the illness and hospitalizations curtailing previously enjoyed activities.

Often, a child displays aggression, sadness, anger, or other strong emotional reactions. Address these reactions when they occur, and discuss appropriate methods to express the emotions. Most important, determine the source of the emotional reaction. Strong emotional responses frequently result from unexpressed fears and concerns or from a misunderstanding of the relationship between events.

Recollecting and Reexperiencing the Deceased and the Relationship

The next task is to review and remember realistically the relationship with the person who died or to remember how relationships were before the onset of illness or other loss. This often involves reviving and reexperiencing the feelings that come with these memories. This process allows the grieving person to acknowledge both the good memories and the unpleasant ones, and prevents memorializing the person as a saint when it is not warranted (Rando, 2000). For the parents of a child who dies, this can mean realizing that the child made them

angry, too, and that the surviving sibling is not their only child who could be difficult. For the child, it might mean acknowledging that not everything an older sibling did was good and that not all of the older child's behaviors should be emulated.

In cases of loss in which severe dysfunction or death of a child occurs, the sibling survivor might take on roles and attributes of the affected child. These roles can be positive, such as taking on the love of a sport, or negative, such as taking on the physical symptoms of the child's illness or a love of the reckless driving that led to the accident or subsequent death. The sibling might want to keep possessions and pictures of the affected child (when healthy) and should be given the opportunity to choose these items. The sibling might also reenact rituals or events that were a part of the previous life with the loved one. Allow the child to do so, but also address the feelings behind these activities to help the child acknowledge and deal with them.

Relinquishing Old Attachments to the Child and the Shared World

To go on with life without the deceased child or with the child in an altered state and appearance, the grieving individuals must give up their ties to the world they shared. This does not mean that they must dramatically change their lives, but it does mean that they must acknowledge that the child is no longer a part of their life or that the future will be different from the one they *would* have shared (Rando, 2000). For the parents, it can mean recognizing that life no longer revolves around the activities shared with the child. For a child, it might mean accepting that the loved one will not be the person who will provide help and support as the child moves into adulthood and begins to raise a family.

Moving Into a New World Without the Loved One

Bereaved persons must begin to move into a new reality in which the deceased person does not have an active part (Rando, 2000). Parents of a child who died might plan a vacation in the middle of the school year. A child whose best friend died of complications of cystic fibrosis might join the soccer team, even though they made a pact not to do things that they could not both participate in. At the same time, treasured traditions shared with the now deceased child may be continued among other family members. Pictures of the child remain on the wall, with new photos added of current events and the family members who participated in those special moments.

Reinvesting in the New World

An active reinvestment in the new world without the loved one, or with the loved one's new limitations, is the final step. It is not enough to simply move on; the person must become involved in the world again (Rando, 2000). Parents might begin planning for other children who are wanted for themselves, not as replacements, for the child who has died or who is severely ill. Siblings must con-

tinue normal physical and emotional development. A toddler needs to develop autonomy and increased physical abilities, such as bladder and bowel control. The school-aged child needs to increase participation in activities in school and with peers. Continued achievement in school and other activities is also important. The adolescent needs to begin to differentiate from the family, even if the death of a family member has drawn the adolescent into new and closer attachments to family members.

The time for the completion of the bereavement process is much longer than was once thought. For most individuals, the time period is 18 months. When a child has died, the time can be even longer. It is not unusual for a parent to have a resurgence of the grief reaction at certain trigger points long after the date of a death, such as when the child would have been starting high school or a first job. Grieving persons must be prepared for the occurrence of these feelings and must be helped to understand that the feelings are normal. Healing takes time and cannot be rushed.

Bereavement Responses of the Dying Child

Children who are dying react to their impending death in a multitude of ways, usually based on their cognitive and developmental level. They will have a wide range of feelings, which might include regression, anger, sadness, loneliness, isolation, and fear. Frequently children will have wisdom beyond their years related to perceiving the seriousness of their illness and possibility of death, which might seem at times to be broader than their parents' understanding and acceptance (Davies & Jin, 2006). In 1978, Bluebond-Langner published results of a study, the results of which remain valid in today's society. The study demonstrated how dying children became aware of their own impending death. She defined five stages of awareness:

1. The child interprets the parents' behavior as being different from when they have a simple illness, leading the child to the understanding that there is something seriously wrong.
2. The child sees family members crying, becomes used to the hospital, perceives that they are receiving "special" treatment, and learns about his or her disease and its implications.
3. They have more knowledge about the waxing and waning of their illness as well as the purposes and implications of their treatment.
4. They are increasingly aware of their differences from healthy peers and start expecting that their disease is a permanent condition.
5. They know the limitations of medical care and they prepare for impending death (Bluebond-Langner, 1978).

Bereavement Responses When a Parent Loses a Child

QUESTION: You attend George's funeral. After the funeral, Tung asks you, "How long will it feel like this?" What is an appropriate response to say to Tung?

The death of a child is one of the most difficult experiences that a parent can face. The child whose parent has died loses a part of their past, but the parent whose child has died loses a part of their future. Successful bereavement is facilitated when family members are helped to recognize that they will each mourn differently. Individual parents might progress through grieving differently. They might vary in both degree and display of response and speed with which they achieve resolution. Individual reactions change over time. Each person comes to the end of the acute grief reaction at a different point during the ensuing 1 to 2 years.

For some parents, the death of a child is a time of great personal growth accompanied by immeasurable pain. For others, it is a time of overwhelming sadness that does not remit for years, if ever. The time and pattern of the bereavement process for the grieving parent is much longer than for bereavement from other losses, and often there is never full resolution of the grief. With skilled care by the entire healthcare team, however, the parent can be helped to successfully complete the bereavement process and move on to a life without the child (Armstrong-Dailey, 2001; Kachoyeanos & Selder, 1993).

Although each parent reacts to the death of the child in a unique way, several patterns are seen. Parents who had ambivalent relationships with their child or were unable to help their child in the time before death report more problems with bereavement than those who had a good relationship and were able to support the child at the time of death. Parents whose child died after a chronic illness have less acute responses than those whose child died after an accident or brief illness. The ability to clearly identify the cause of death also helps parents in their time of grief. Parents who are with their child at the time of death or who see their child soon after the death are better able to realize that the child is dead. Such visits also reduce concerns about the nature and extent of the damage to the child's body, and decreases fantasies about the child's death (e.g., the hope that the child is not in fact dead and will someday reappear) (Kachoyeanos & Selder, 1993).

If procedural items (e.g., gathering information for the death certificate or making funeral arrangements) must be processed, present these activities in such a way that recognition of the value and dignity of the child is demonstrated. Parents often find it difficult to make decisions at this time, and encouragement to see their child and to involve the siblings is appropriate (Kachoyeanos & Selder, 1993). The sense of uncertainty pervades the total experience. Parents report that they do not know how to act or communicate their needs, which includes the feeling that they have no language to express themselves. Because information helps decrease uncertainty, having questions answered is helpful to bereaved parents; however, the new information can also raise more questions (Kachoyeanos & Selder, 1993).

Parental responses to the death of their child continue long after the classic 1- or 2-year grieving period common with the death of friends, grandparents, or parents when the child is an adult. Parents must undergo a life transition as they move from the old reality to a new reality: from life with their child to life after their child's

death. This transition process is characterized by a sense of uncertainty and a variety of trigger events (Kachoyeanos & Selder, 1993).

Trigger events reinforce the fact that the parent's reality has changed. The first trigger event is the actual death of the child. At this time, the parents must accept the irrevocability of the death. Trigger events continue long after the child's death. Doing something that was previously done with the child, passing the site of the accident where the child died, or hearing music that the child liked are examples of events that can reactivate memories of the child and feelings about the child's death. The reality of the child's death is reinforced when special dates such as birthdays or family holidays occur. These dates can be used as special occasions to remember the child. The dates might also have been times when developmental achievements (e.g., beginning to walk, joining the Girl Scouts, graduation, marriage, or birth of a grandchild) would have taken place. Triggers are experienced by parents regardless of how old the child was at death or how much time has elapsed since the child's death (Kachoyeanos & Selder, 1993).

Parents need to structure a new reality after the child's death. This effort is apparent in many of their actions. Parents often compare themselves with others in judging how well they are doing. Talking with other parents who have lost a child and participating in support groups help the parents learn that their reactions are normal. These activities help parents learn strategies for coping with their pain and the challenges they face. They learn that they will emerge from the period of deep and painful grief (Kachoyeanos & Selder, 1993).

A frequent concern from parents is the need for reassurance that they were good parents. They may overtly ask whether they provided good care to the child or brought the child for treatment at the right time. Others seek affirmation of their parenting skills indirectly by listening to comments of those who cared for their child. Thus, a random remark while looking at pictures of the child such as "aren't those pajamas pretty" can provide positive feedback, whereas a simple statement such as "look at how messy that bib was" can be interpreted as a negative evaluation of the parents' ability to meet even the most basic hygienic need of their child.

Parents often have a strong desire to return to the "normal" world they knew before the child's death (Kachoyeanos & Selder, 1993). This desire might lead the parent to engage in an activity, such as suddenly taking a family vacation to a theme park with the other children, which appears inappropriate in light of the recent death. Often, such activities are undertaken with the hope that they will make the negative and painful emotions dissipate. This rarely happens.

There could be fears by the parents that they or other family members might forget the child or how the child looked when well. As a result, they engage in "presencing" by looking at pictures or videotapes in which the child appears and keeping the child's possessions for months, sometimes years. When the possessions are given away, they are given away to someone meaningful. Although keeping the possessions intact permanently

might be a sign of dysfunctional grief, it is generally better for the parents to delay dismantling the child's room and disposing of the child's possessions for several months (Kachoyanos & Selder, 1993). This allows them time to thoughtfully decide what they want to keep and what they want to give away.

ANSWER: There are many therapeutic answers. We cannot guess how long George's father will feel intense grief. Platitudes are not acceptable. One example is to acknowledge his grief and say, "I can only imagine how much it must hurt."

Bereavement Responses When a Child Loses a Loved One

Children do not need to have a loved one die or to experience a great loss themselves to learn to cope with grief. As children see grief and loss around them, discuss these issues with them. This prevents development of the belief that discussion of grief and death is taboo. The loss of a pet can be a powerful learning experience. If a pet runs away, the child can be encouraged to discuss feelings about the missing animal. If the pet dies, this is a chance for the child to talk about how the pet died, why it died, and how that death makes both the adult and child feel. The child can also be introduced to the rituals that the family's culture uses to say goodbye to a dead loved one and to express grief and sadness.

Discuss causes of loss honestly, with both internal and external causes acknowledged. When the cause of a death is unknown, this uncertainty can be stated. Flowery analogies or stories may only confuse the child.

In the case of suicide, saying that the person had an illness that affected their thinking, causing the person to take his or her life, is a better explanation than saying that the person was unhappy or disappointed with life. For the child who was a significant part of the suicide victim's life, this explanation helps alleviate misconceptions if the child thinks he or she was a cause of the person's unhappiness.

After a death, some changes in the child's life are inevitable. Behavior of adults around the child changes as they grieve. The child's daily routine may change during the acute phase surrounding the death and the funeral, and because of the absence of the loved one. Help parents understand how important it is to have as few additional changes around the time of the death as possible. A safe, familiar environment and routine are essential for the child during the bereavement period. Avoid unnecessary changes in the child's daily life (e.g., changing sleeping arrangements, place of residence, and degree of contact with remaining family members, school, or daycare center).

Even the most skillful and sensitive care does not guarantee that each child will have a smooth progression through the bereavement process. However, when the child's needs and reactions are recognized and addressed, the child has the opportunity to successfully navigate the painful time after the death.

To deal with the powerful reactions experienced after the death of a loved one or the grief associated with an unexpected personal loss, children must learn to deal with strong feelings such as longing, anger, sadness, and confusion. When children display behaviors that indicate they are having these feelings, regardless of the reason, address the feelings. Teach parents to not ignore strong or negative feelings or to do things to take the child's mind off the feelings. This approach does not make the feelings, or the events that caused them, go away. When well-meaning adults seek to protect the child in this way, they deny the child the opportunity to acknowledge and then learn to cope with feelings and fears. Acknowledging strong and unpleasant feelings and helping the child work through those feelings lets the child know, via both verbal and nonverbal messages, that the feelings are normal. The child will also develop the core skills needed to deal with such emotions throughout life.

Even very young children are aware when someone around them has died. The child senses and observes the changes, without being told. All children need an opportunity to discuss the emotions that accompany their grief and to learn about the ramifications of a particular death on themselves and their family.

KidKare ■ Focus discussions about death on the child's specific questions and what is behind those questions. Exhaustive explanations and teaching sessions are usually not appropriate.

Even young children benefit from discussions of what happens to the body after death. If the child asks or indicates a desire to go to the funeral, if at all possible, grant this request. Prepare the child for the funeral experience. Explanations can be given regarding the events that will occur during the funeral service, how people may respond during the service, and how witnessing these events may make the child feel. Throughout the service, ensure the child is accompanied by a trusted adult, who can control his or her own grief, to serve as a resource and support for the child.

KidKare ■ Explain to the child specifics about what will happen and what will be seen. Prepare the child for how the coffin looks and that the dead person will look asleep. Tell the child that people might cry and be upset because they are sad that the person has died. If the child goes to the cemetery, explain to the child that the coffin might be placed in the ground and dirt shoveled in to cover it. Assure the child that it is all right if he or she wants to leave at any time during the ceremony.

Death of a Parent

A child whose parent has died needs special attention. Because of the unique bond between the child and

parent, particularly the infant and mother, death of a parent results in both loss of self (the part that was bound to the parent) and loss of other (the parent who died). The remaining parent and other family members are also grieving, making it hard for them to meet the child's needs for consistent support and attachment. The child might worry that the surviving parent will die, too. The loss of a parent is difficult for the child. Adults often have several significant persons in their life with whom they form attachments; however, a child usually has only two significant attachments: those to each parent. The parent meets the child's physiologic and emotional needs and gradually helps the child meet those needs independently. When a parent dies, someone else must take over the missing parent's role, be it the other parent or someone else. Infants and young toddlers need immediate and consistent replacement of this primary caregiver role.

Activities shared with the dead parent might no longer be enjoyed. For the infant or toddler, this can be eating or the development of new abilities like smiling, rolling over, or toilet training. Young children who cannot express themselves verbally may display emotions through play or other behaviors. For the older child, this could be going to the movies or special school events. The child often regresses for a short time. In some cases, problems might not be evident initially; they may occur at the beginning of the next developmental phase, such as the progression from school age to adolescence.

Death of a Grandparent

Depending on their relationship, involvement, and frequency of contact with the child, death of a grandparent might elicit many of the same behaviors associated with the death of a parent. In some cases, the grandparent may have been the primary caregiver of the child. In other cases, grandparents may have a lesser role in the day-to-day family constellation. In all cases, it is important to acknowledge the grandparent's death with the child and determine the child's understanding of the causes of the death and the degree to which they are feeling the loss.

Death of a Sibling

QUESTION: Review Nursing Interventions 13–3. What interventions would you incorporate into a plan of care for Ashley following her brother's death?

Siblings of the deceased child need care based on their age, developmental stage, and relationship with their sibling. Do not protect siblings from all information about the child's illness or give them evasive answers to their questions about the death. During the past few years, there has been a dramatic improvement in the emotional health of siblings of children who have died. Studies of bereaved siblings indicate that they are often more mature than their peers. They have similar, or higher, scores on measures of adjustment and self-concept than their peers who did not lose a sibling. This is a very different finding from that of 10 to 15 years ago, when as

many as 50% of siblings of children who died had behavioral or emotional problems (Walker, 1993).

These positive changes have been attributed to alterations in how death is dealt with in American society. Death is spoken of more openly than it once was, and care for the siblings is integrated into plans of care.

Siblings of deceased children experience stress as the result of the death. If the child was ill before the death, this stress is compounded by the changes in family structure and environment as a result of the illness. This stress will pass if the siblings are given the help and support they need during and after the acute phase of grief. Siblings need to grieve, to say goodbye. Outdoor activities, yelling, singing, play therapy, support groups, and art therapy may help the grieving child. A multidimensional home care program that addresses physical, emotional, and other needs of the family during the terminal phase of an illness is also beneficial (Fig. 13–9). Teach parents about the needs of the siblings and ways to help them progress through the bereavement process (see Nursing Interventions 13–3).

Assure parents that the child who died was unique and their remaining children cannot, and should not, take over the life of that child. Neither current nor future children should be made into "replacement" children to compensate for the lost child. Replacement children are given the burden of assuming their own identity as well as that of the dead child.

Parents need help to understand how their actions and the home environment can positively or negatively affect the future self-concept and emotional health of surviving siblings. Children who demonstrate a positive self-concept have been made to feel special and are reported as being highly competent. Children who experience low self-concept report that they feel that they do not compare favorably with the deceased child or that another child has displaced them.

Physical and somatic complaints by siblings are not uncommon. Siblings might be frustrated at their inability to change what is happening or have feelings of guilt and anger. Often they are living in a household of sorrow and may feel responsible for the event or think that if they had died the parents would not be as sad. Many times, parents are so preoccupied with the care of the dying child or with their own grief that they overlook the healthy siblings. All siblings need to feel like an important member of the family and need a responsible and caring adult to help them cope with their grief and loss.

ANSWER: Although Ashley is cognitively an adult in her understanding of death, she will probably need continued support. Teaching her the normal emotions that accompany grief and bereavement is important. Ashley's family and culture are very stoic. She may wonder if she is the only one feeling this way or if something is wrong with her because of the intensity of her grief. It will be important for Ashley to develop new routines and a new focus. She will be graduating from high school soon; it is hoped that this can be a focus for her and her parents. Ashley, because of her experience with depression, has an established relationship with a counselor. She also has supportive relationships with the school nurse and some of her high school teachers.

NURSING INTERVENTIONS 13–3

Helping Siblings Grieve

- Teach the sibling about the normal emotions that accompany grief and bereavement:
 - Help the sibling identify and express feelings about the child who has died.
 - Let the sibling know that feeling sad, angry, or scared is okay for adults and for the children, and that crying is okay (even for boys).
 - Assess what the sibling knows and wants to know about the child's death and provide necessary teaching.
 - Involve siblings in family discussions about the dying child and after the child's death.
 - Encourage siblings to express their feelings and thoughts in their own way through discussion, writing letters, poetry, art.
 - Share your own memories and feelings with the sibling.
 - Allow laughter and fun times, which can occur even in the midst of great sadness.
 - Decrease the sense of abandonment by being with the sibling both physically and emotionally.
 - Consider whether the sibling relationship was positive or negative and how that has affected grieving.
 - Use physical touch as a way of reassuring and comforting the sibling.
- Reassure the sibling that it is not likely that anyone else (particularly the parents) will also die within the near future.
- Look for evidence that the sibling is protecting the parents (e.g., by not telling them his or her fears and concerns or trying to lessen the parents' grief).
- Promote normalcy in the sibling's life and routines:
 - Continue to expect the sibling to have responsibilities at home and at school.
 - Encourage the sibling's involvement with friends and peers.
 - Be aware that, if other children are added to the family at some point in time (e.g., by adoption or birth), the sibling of the child who died may feel displaced by the new addition.
- Educate parents not to
 - Give any indication that the surviving child is not "as good" as the deceased sibling
 - Indicate that the surviving child is in any way responsible for the sibling's death
 - Express a preference for or wish to have a child who in some way (e.g., gender, ability) is like the child who died
 - Display a preference for the deceased child by comments or comparisons

Death of a Friend

Children might face death in the ranks of their peers, school staff, family, or community. The cause is often acute or chronic illness, but increasing numbers of children are exposed to death as a result of violence. Schools need to include content about death and dying in the school curriculum and have a crisis plan that can be activated quickly after a death in the school community. The school nurse plays a significant role in the development and implementation of a death education curriculum and crisis plans.

Implement educational programs about the facts of death; recognizing depression; understanding grief; and fostering effective communication between child and teacher, child and child, and child and family. Include in the discussion how to interact with a bereaved student who is returning to school, how to accept and address their grief, and the importance of resuming a normal relationship. Teach staff and students how to recognize students who are grieving or who are at risk for suicide. Provide detailed information on ways to help those individuals obtain assistance.

Alert! Emphasize with students that when a friend talks about taking his or her own life, or the life of others, it is essential to share this information with a counselor, teacher, or some other trusted adult. In this case, getting the friend help is more important than keeping a secret.

The school crisis plan should detail all needed steps from the notification of student, faculty, and staff about the death to the implementation of long-term support services. The crisis plan should be flexible enough to be used if the person who died is a student, faculty, or staff member, or significant person in the community, and whether death is from illness, suicide, or violence.

Policies about holding memorial services on campus and student attendance at funeral services on school days should be developed. The plan would also include a detailed plan about how the students' and staff's emotional needs will be met on both an acute and long-term basis. A training program for staff and teachers for both the acute event and residual problems is needed. A plan

FIGURE 13–9. Dying at home allows siblings an opportunity to be together, sharing laughter and building memories.

to evaluate the outcome each time the plan is implemented is essential.

The suicide of a student, staff member, or community member requires special attention. Students might want to follow the example of the student who committed suicide because they desire the same attention or because it appears to be a particularly attractive way to deal with the concerns of adolescence. The death must be acknowledged and the usual grief activities completed.

A recurrence of grief reactions can occur on anniversary dates (e.g., 1 year after a bus crash that killed members of the junior class on the way to school). Remind faculty to look for signs of an increased grief response on significant occasions, such as the day the star football player would have received the district trophy if he had not died after a car accident.

Grief support groups have been found to be very helpful for school-aged and adolescent children. Sessions held at school have the advantages of being easy to attend and occurring in a setting familiar to the child. Support groups can also be based at sites where the loved one of a child was treated.

Bereavement Support for Pediatric Healthcare Providers

QUESTION: Imagine yourself caring for a dying child. When that child dies, what support would you need?

The death of a child can be a traumatic event for the care provider. This is true whether interactions with the child and family were brief or longstanding, or whether the child's death was unexpected or the anticipated outcome of an illness or injury. Even the most emotionally balanced nurse can experience an acute response to the death of a child. Caring for the dying child causes increased stress because nurses often feel helpless or limited in their ability to alleviate distress for the child (Docherty, Miles &

Brandon, 2007; Papadatou, Martinson, & Chung, 2001). This might not happen with each child's death, but it does happen and it is normal. Nurses must learn to care for and support themselves and their peers when faced with the strong emotions and responses that accompany death (Fig. 13–10).

Contrary to popular belief, one does not “get used to” working with dying children and their families. Professional caregivers can, however, develop coping skills through education and by their personal and professional experience in caring for the dying child. Those staff that have built up a repertoire of skills can recognize their own feelings, allow time and distance for their own grieving, develop personal support mechanisms, and gain personal satisfaction in assisting children and families through the illness and dying process. In addition, these staff can also serve as mentors to less experienced staff by modeling skill and compassion in dealing with death as an experience-based personal growth process.

Care providers have repeatedly documented that working with terminally ill children is intense and often overwhelming. Furthermore, it is recognized that a nurse's grief is different from that of a surviving family member's grief (Rashotte, Fothergill-Bourbonnais, & Chamberlain, 1997). Therefore, models of normal grief and bereavement processes used for adult family survivors are not sufficient as a framework to understand the grief responses and processes of healthcare providers who have cared for a child who has died.

The death of a favorite patient can be stressful and painful for nurses working with dying children. Yet, nurses often report personal renewal from the experience of helping the child and family. They simultaneously grieve for the loss of the child while renewing their personal and professional commitment to the larger mission of achieving a cure for most of the children in their care. Several studies have explored the responses of healthcare providers to the loss of pediatric patients. One researcher described a form of “emotional tension” present in the struggles verbalized by 15 American nurses who work with terminally ill children (Kaplan, 2000). In this qualitative study, nurses voiced their struggle to balance the

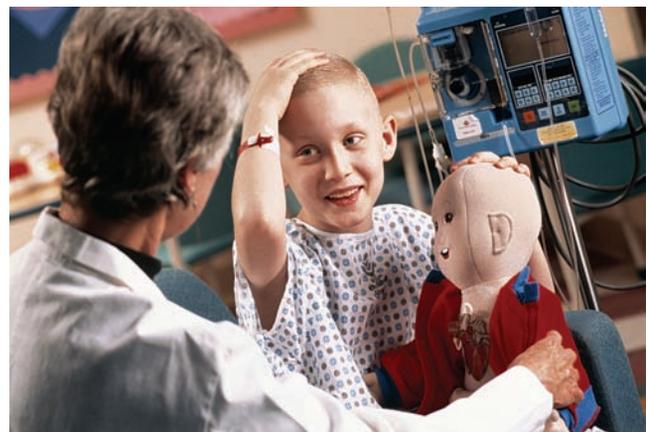

FIGURE 13–10. Caring for a dying child is stressful but can also be extremely rewarding.

intense emotional feelings that exist when treating dying children with their need to be competent care providers. The nurses' emotional experiences were influenced by the relationships they had established with the child and by the child's dying process. A number of the nurses acknowledged that they hid their emotional responses when the child was doing poorly or had died, and that they experienced personal suffering when their patients were dying. However, they also reported that they were unable to grieve properly. They described recognizing the need to grieve and express feelings, and acknowledged that doing so was an appropriate manner in which to respond to a child's death. Barriers to grieving included several work environment issues. The work environment did not integrate time or space for care providers to process emotional feelings and reactions to the dying process and death of their patients. Instead, nurses felt that they had to hide in the bathroom to express themselves fully. Often, the nurses were asked to care for a newly diagnosed child within minutes of another patient's death, without an opportunity to regroup or refocus. Kaplan (2000) believed that, in general, society does not consider the fact that these care providers have worked intensely with their patients, and within the confines of their work have developed a type of relationship that results in a grief reaction. In this regard, these care providers, as well as other medical providers, are disenfranchised grievers.

Unit-based interventions and activities give all hospital personnel involved with the care of the child a chance to remember the child and express their grief (Chart 13–3). They also reinforce the fact that not all children die and that some children treated for serious or terminal illness survive and flourish. Such programs are found to be helpful by staff members by legitimizing the staff's grief experience and providing an opportunity for grief to be openly shared with colleagues.

CHART 13–3 CARE FOR THE HEALTHCARE PROVIDERS WHO WORK WITH DYING CHILDREN

Plan unit-based memorial services to be held throughout the year.

Provide support sessions for staff members from all services (nursing, social work, medicine, housekeeping).

Keep a memorial book on the unit with pictures, letters, and poems about the children.

Provide critical stress debriefings after particularly difficult deaths.

Identify specific nurses who will care for the dying child and who can offer support to each other as well as to the family and the child.

Plan a yearly party with survivors.

Rotate staff members to settings where they see children who are doing well.

Often, an individual nurse wants to attend the funeral or reach out to the family. This might be an essential step to help the nurse resolve his or her own grief. Families can find such expressions of caring and grief both helpful and comforting. To be most therapeutic for the family, keep the focus on the family.

caREminder

When visiting the family, avoid platitudes. Call the child by name and use direct language. For example, say, "I'm so sorry that Mary died" rather than "your child has expired." This lets the parent know that you see the child as a unique, special person, and it helps the parents internalize the reality of the death.

When a nurse does attend the funeral or visit the family at home, the visit should not be so brief that the family feels further abandonment and isolation. However, be sensitive to whether the family welcomes the visit. If a personal telephone call is made, give the family the opportunity to decline to talk. You can simply tell the family member that you were thinking of them and then ask whether it is a good time to talk.

As nurses, we might not be able to prevent a child's death, but we can have an impact on the dying process by helping to alleviate pain and suffering; facilitate coping; and provide physical and emotional support to the patient, family, and colleagues. Developing the professional maturity to recognize and use strengths can enable a nurse to provide beneficial care to dying children and their families on an ongoing basis. Knowing when to step back, gather strength, and renew oneself is an important part of the process and will help us learn from every patient.

ANSWER: Nurses who care for dying children often care for each other and must develop the ability to understand their own needs. Nurses, too, need quiet time to say goodbye to a child. Nurses will often attend a funeral together, both to support each other and to acknowledge to the family this death is a loss for them as well. To work with children who die, nurses need to develop their own spiritual concepts of life and death. It is not easy, but there is reassurance and satisfaction in knowing that you can give something few others can. One activity that is important to many nurses who work with dying children is to also spend time with healthy children.

UNIT III

Managing Health Challenges

The Neonate With Altered Health Status

Case History

Ben and Abby Goldman are expecting their first child. Abby has been told that she has an incompetent cervix. She miscarried her first two pregnancies and has been on bed rest since the 20th week of her pregnancy. Her membranes ruptured while she was sleeping and, despite medical efforts to stop labor, Abby delivered Gabriella Ruth Goldman at 28 weeks' gestation.

Abby's membranes were ruptured for almost 48 hours before Gabriella was delivered, and Abby received two doses of betamethasone. Gabriella underwent a spontaneous vaginal delivery, and her Apgar scores on blow-by oxygen were a 5 at 1 minute and a 6 at 5 minutes. Her heart rate was consistently more than 100 beats per minute. Her respiratory effort remained irregular and her muscle tone improved from flaccid at 1 minute to some flexion at 5 minutes. She would grimace in response to gentle stimulation at both 1 and 5 minutes. On oxygen, her central color was pink, but her extremities were cyanotic. Although she initially demonstrated irregular respiratory effort, she quickly began having periods of apnea and was not able to maintain her respiratory effort. She was intubated and placed on a ventilator. She received surfactant therapy via endotracheal tube. A peripherally

inserted central catheter line was placed and she began a course of antibiotics.

At birth, Gabriella weighs 1,282 grams, is 37 cm long, and her head circumference is 27 cm. She has lots of dark brown hair and abundant fine lanugo over her body. Without careful positioning, her arms are flaccid at her side and the pinna of her ear folds flat to her head. Her skin is pink with visible veins; the plantar surfaces of her feet are smooth, with no creases and only a few red marks; the demarcation of her breast is barely visible; and her genital area has a prominent clitoris and noticeable labia minora.

During subsequent weeks, Gabriella faces many challenges: thermoregulation problems, sepsis, hypoglycemia, patent ductus arteriosus (PDA), difficulties weaning from the vent, hyperbilirubinemia, gastrointestinal reflux, and retinopathy of prematurity (ROP). Abby and Ben are in the neonatal intensive care unit (NICU) as much as possible and want to understand what Gabriella is going through. The nurse in the NICU has to possess many skills, and must be both an intensive care nurse with a nonverbal patient and a family-centered nurse who provides information and support to Gabriella's family.

CHAPTER OBJECTIVES

1. Explain the etiology, prognosis, and patient outcomes of common disorders affecting the preterm newborn.
2. Describe the pathophysiologic principles related to developmental alterations in the term newborn.
3. Describe the nursing assessment measures that help to identify developmental disorders and common problems associated with the high-risk newborn.
4. Identify appropriate uses of the Ballard scale, the neonatal behavioral assessment scale, and the assessment of the preterm newborn behavioral scale that assist the healthcare team in identifying developmental disorders and healthcare problems of high-risk newborns.
5. Discuss nursing care for a neonate with altered health status.
6. Identify interdisciplinary interventions commonly used for each health challenge in newborns.

See [thePoint](#) for a list of Key Terms.

The neonatal period is a vulnerable time in the human life cycle. Healthy term newborns often make the transition to extrauterine life without complications and continue to thrive through the newborn period. However, some term newborns experience complications during these periods.

The premature newborn faces the transition to extrauterine life with immature body systems, including the respiratory, cardiac, and central nervous systems. Preterm births comprise 12.8% of all live births in the United States (Hamilton, Martin, & Ventura, 2007). Neonatal mortality depends largely on birth weight and gestational age; those with greater weight and term gestational age have the lowest mortality rates.

Newborns demonstrate illness through insidious signs and symptoms. Therefore, astute assessment skills are needed to identify early signs of impending problems. For example, subtle changes in the newborn's breathing or feeding patterns and behavior may be the earliest signs of neonatal sepsis. Early recognition of these signs is vital to provide prompt interventions and prevent complications.

The focus of this chapter is to describe nursing assessments and outline interdisciplinary interventions used to assist and support the high-risk newborn's transition to extrauterine life and continued growth and development.

DEVELOPMENTAL AND BIOLOGIC VARIANCES

The term and preterm newborn are different in many ways. A term newborn is born after 37 weeks of gestation and, as a result of complete intrauterine development, possesses the necessary physical attributes to successfully

adapt to the extrauterine environment. A healthy term newborn at birth is pink (although hands and feet may remain blue for the first 24 hours) and exhibits strong muscle tone and reflexes, vigorous cry and respiratory effort, normal respiratory rate, and a normal cardiac rate and rhythm.

The preterm newborn is defined as one born before 37 weeks' gestation and is extremely vulnerable to developmental problems because the central nervous system (CNS) and other organ systems are immature. The uterus provides a warm, slightly oscillating, fluid-filled, quiet environment in which all physiologic and developmental needs are met. In stark contrast, the NICU subjects the newborn to loud and sudden noises, constant bright light, painful procedures, irregular patterns of handling, and rapid temperature changes, all of which may have detrimental effects on the developing immature systems of the premature newborn. The NICU environment may precipitate hypoxia as a result of needed medical and nursing procedures, leading to damage of the developing CNS and other body systems. Reducing light, noise, and temperature changes and providing periods of "hands-off" care improve weight gain and behavioral assessment scores (Als et al., 1994).

Late preterm newborns are infants born between 34 and 36 6/7 weeks' gestation (Hubbard, Stellwagen, and Wolf, 2007). These infants are a high-risk population because they experience more problems, such as respiratory distress, thermoregulation problems, hypoglycemia, and feeding problems than term infants (Hubbard et al., 2007), and have increased mortality (Tomashek et al., 2007). To identify those who may be at risk, carefully assess transitional events and the early course of late preterm infants.

The sick term newborn is less vulnerable than the premature newborn to developmental problems, because the term neonate's CNS and other biologic systems (pulmonary, gastrointestinal) are more mature and organized. However, certain conditions or disease processes, such as sepsis, meconium aspiration, congenital anomalies, and birth trauma can present challenges to the term newborn, leading to a stay in the NICU and potential long-term complications (Fig. 14-1).

ASSESSMENT OF THE NEONATE WITH ALTERED HEALTH STATUS

Infant mortality and morbidity has decreased even for the smallest of newborns, such as those born at 24 to 26 weeks' gestation. A goal is to improve not only survival of the premature newborn, but also neurodevelopmental outcome, and to reduce important morbidities such as cerebral palsy (CP), retinopathy of prematurity (ROP), and intraventricular hemorrhage (IVH). Researchers are investigating how the NICU environment, routine handling and nursing care, and family involvement contribute to the overall outcome of the preterm newborn.

Surgery, premature body systems, and withdrawal from intrauterine drug exposure are examples of factors

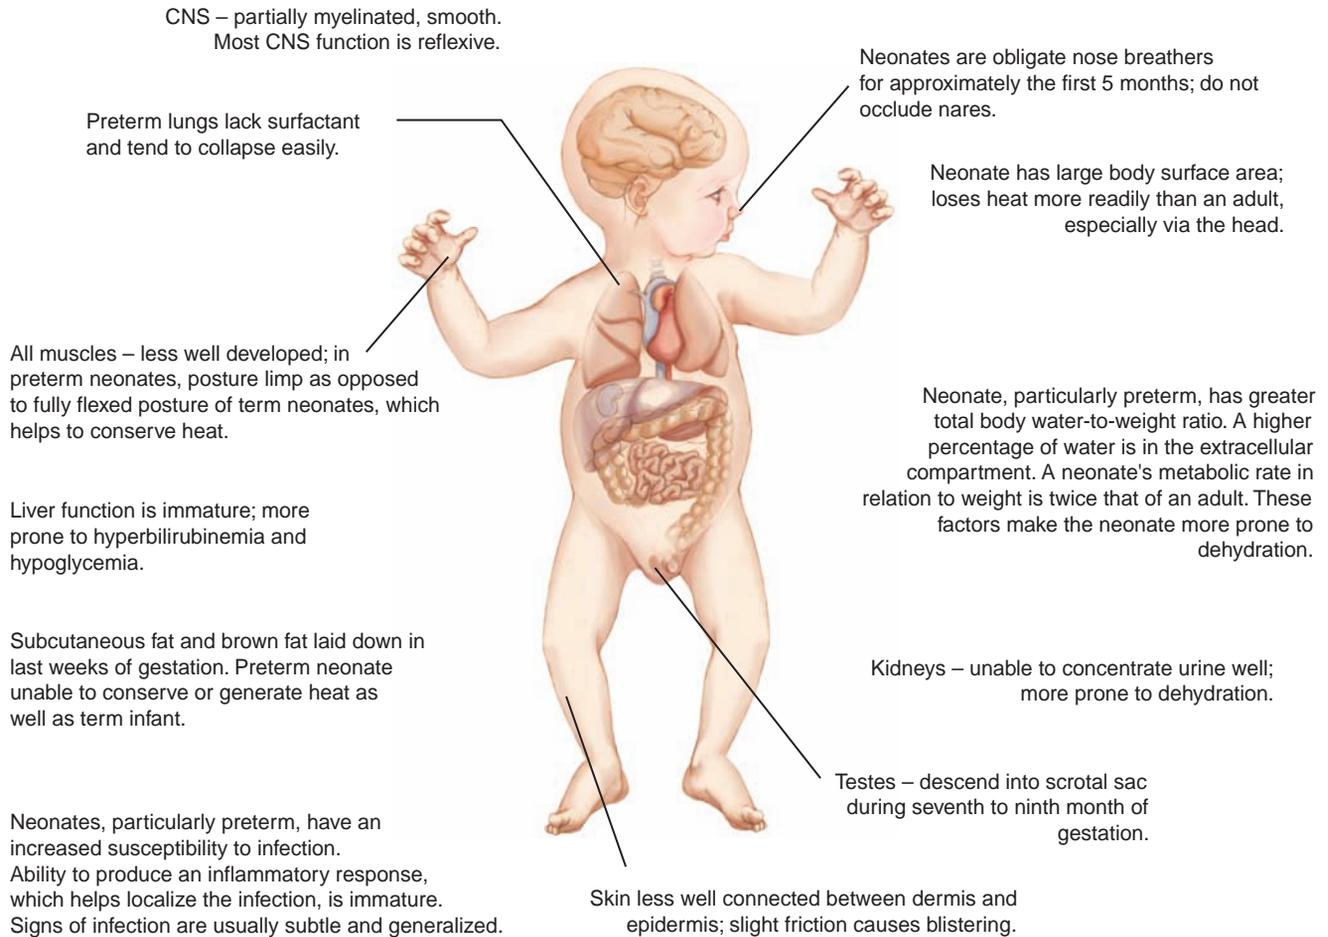

FIGURE 14–1. Developmental and biologic variances in the neonate.

that may inhibit the normal progression of neurobehavioral development. Additionally, studies of the NICU environment have shown that the bright lights, noise, and common procedures, such as suctioning the endotracheal tube, changing the infant’s position, or assessing vital signs, can cause deleterious changes in vital signs (Harrison, Roane, and Weaver, 2004; Yung-Weng & Ying-Ju, 2004). Although techniques to assess and manage pain in the hospitalized infant have progressed greatly, undertreated pain continues to affect the neurobehavioral development of the newborn.

Assessing for developmental problems in the newborn involves evaluating neurologic and behavioral functioning. The neurologic examination focuses on the presence, quality, and symmetry of reflexes (see Table 8–10), such as the grasp and Moro’s reflexes, and the quality of muscle tone. The behavioral examination complements the neurologic examination and helps to describe the quality of behavioral performance. The combination of these two assessments is the neurobehavioral assessment that determines the newborn’s behavioral capabilities, interactive qualities, and adaptations to the extrauterine environment. Use information obtained from this assessment to plan interventions that support and optimize the newborn’s development.

Focused Health History

QUESTION: What are some pertinent aspects of Gabriella’s history that place her at risk?

The purpose of the health history is to collect data regarding the quality of progression in the high-risk newborn’s development. Whether the nurse is caring for the newborn in the regular newborn nursery, the NICU, or the family’s home, specific health patterns are important to assess for all newborns. After delivery, a healthy term newborn is generally cared for in a nursery where the nurse focuses on establishing feedings and promoting normal function of body systems. Review the labor and delivery records to determine the presence or absence of prenatal care, general health of the mother, length of labor, and any difficulties encountered during labor, such as maternal fever or fetal distress. Note also delivery difficulties, such as the need to use forceps or vacuum extraction at the time of delivery. This information alerts to any potential problems in the newborn.

In the delivery room or within the NICU, review the labor and delivery records and begin neonatal records to help identify potential problems. Focus on the primary problem of the newborn that prompted NICU admission.

In the home or at a clinic visit, ask the primary caregiver for information related to the newborn's current health and developmental status. Assess the quality of the caregiver's attachment and responsiveness to the newborn's needs during the interview (Focused Health History 14–1). Obtain information related to the health of the mother during pregnancy, the quality of the labor and delivery, and the initial newborn course. This information assists the nurse to focus on specific health patterns and physical characteristics that may be altered if the pregnancy or neonatal course was difficult. Specific at-risk newborns include those who were admitted to the NICU, born prematurely, or experienced a difficult transition, as evidenced by a low Apgar score (less than 6) at 5 minutes. Responses to the nurse's health history questions can suggest developmental delays and guide the physical examination.

ANSWER: Gabriella's gestational age is her greatest risk because she is 12 weeks premature. Her Apgar scores are objective measurements that also reflect her status. Although her heart rate was more than 100 beats per minute at all times, she was unable to manifest a vigorous response because of her prematurity. The length of time the membranes were ruptured also is an identifiable risk factor. If amniotic fluid can come out, then organisms can enter; rupture of membranes more than 24 hours before birth places an infant at risk for a systemic infection.

Focused Physical Assessment

Physical assessment of the newborn involves inspection, observation, smell, palpation, percussion, and auscultation. Assess key parameters during the examination of all newborns (Focused Physical Assessment 14–1) (see [thePoint](#) for Supplemental Information: Growth Parameter Assessment). The purpose of the neonatal examination is to identify existing abnormalities (congenital anomalies) and provide baseline data for comparison as the newborn adapts to the extrauterine environment. Assess the newborn at delivery, immediately on admission to the nursery, and then frequently thereafter.

Apgar scoring (Fig. 14–2) was developed as a quick delivery suite evaluation of newborns' immediate adjustment to extrauterine life. Record the Apgar score at 1 and 5 minutes after birth and repeat every 5 minutes until the infant's condition stabilizes. A total score of 0 to 3 indicates severe distress, requiring immediate resuscitation. Scores of 4 to 6 signify moderate difficulty, whereas scores of 7 to 10 indicate the absence of difficulty. Many healthy newborns do not receive a score of 10 because their hands and feet remain blue (acrocyanosis) until they are 24 hours of age. The Apgar score is also affected by other factors, including the degree of prematurity,

maternal sedation or analgesia, and the presence of neuromuscular disorders in the infant.

Although the Apgar score is a useful tool to evaluate the progression of resuscitation, it is not prognostic (American Academy of Pediatrics, Committee on Fetus and Newborn and American College of Obstetricians and Gynecologists, Committee on Obstetric Practice, 2006). Apgar scores are normal in most children who subsequently develop CP, and the incidence of CP is very low among infants with scores of 0 to 3 at 5 minutes. Apgar scores do not determine the timing of resuscitative measures. The standard of care for neonatal resuscitation requires that assessment and intervention begin immediately at birth, not a full minute later (American Heart Association, 2005).

Diagnostic Criteria for Evaluating the Neonate With Altered Health Status

QUESTION: What information is missing from the case study to complete the neuromuscular maturity component of the Ballard? How many points did you assess Gabriella for the physical maturity of the Ballard?

The specific diagnostic tests and procedures used to assess a newborn depend on the suspected disorder (Diagnostic Tests and Procedures 14–1) (for more information see [thePoint](#) for Procedures: Blood Drawing from Peripheral Sites: Heel Stick and Finger Stick). Prenatal tests commonly performed to determine fetal well-being are amniocentesis, chorionic villus sampling, fetal ultrasonography, and specific blood tests (e.g., maternal serum alpha-fetoprotein, triple-marker screening). Routine newborn screening for metabolic diseases is discussed in Chapter 27.

Several assessment scales are available to assist in evaluating the progression of development in the newborn. The most common are the Ballard scale, the Neonatal Behavioral Assessment Scale (NBAS), and the Assessment of Preterm Newborn Behavior (APIB) scale.

Ballard Scale

The Ballard scale (Ballard et al., 1991) is a tool to assess specific neuromuscular and physical characteristics of the newborn to determine gestational age (Fig. 14–3). The Ballard scale may be used from birth to the extremely premature and term newborn through day 5 of life.

After the gestational age assessment is completed, plot the weight, length, and head circumference to identify newborns in whom these measurements are **appropriate for gestational age (AGA)**, **large for gestational age (LGA)**, or **small for gestational age (SGA)**, because each group has specific clinical and risk factors. Based on the intrauterine growth chart (Battaglia and Lubchenco, 1967), babies are classified as AGA if they weigh between the 10th and 90th percentiles, LGA if they weigh more than the 90th percentile, and SGA if they weigh less than

FOCUSED HEALTH HISTORY 14–1

The Neonate With Altered Health Status*

Current history	<p>Infant's age in weeks, corrected age (age adjusted for prematurity, calculated by subtracting the number of weeks born before 40 weeks of gestation from the chronologic age)</p> <p><i>Current medications/therapies:</i> Seizure medications, diuretics, sodium/potassium supplements, specialized formulas, supplements, need for apnea monitoring</p> <p>Symptoms of concern in the neonate:</p> <p><i>Poor feeding patterns:</i> Increased time to complete feedings, poor nipping, inability to coordinate suck and swallow, frequent regurgitation, cyanosis with feedings, poor intake</p> <p><i>Altered elimination patterns:</i> Fewer wet diapers, constipation, diarrhea, water-loss stools</p> <p><i>Central nervous symptom variations:</i> Altered sleep/wake cycles (sleeping less than 3 hours between feeds, abrupt changes between states), hypotonia, hyperextension of head, lethargy, unresponsiveness to stimuli, irritability, unable to console, asymmetric movements of extremities, bicycling motion of lower extremities</p> <p><i>Delayed acquisition of developmental milestones:</i> Not tracking, not reaching for objects, smiling late, turning over late</p> <p><i>Poor growth:</i> Poor weight gain along own growth curve, poor head growth</p> <p><i>Cardiorespiratory:</i> Respiratory distress (tachypnea, periodic breathing, apnea, retractions, nasal flaring, grunting, pallor, cyanosis), need for oxygen, tachycardia, bradycardia, poor peripheral pulses, capillary refill longer than 3 seconds</p> <p><i>Problems with thermoregulation:</i> Hypothermia (respiratory distress, peripheral vasoconstriction, hypoglycemia, acidosis), hyperthermia (tachycardia, warm extremities, sweating)</p> <p><i>Metabolic instability:</i> Symptoms of hypoglycemia (apnea, pallor, cyanosis, lethargy, hypotonia, poor suck, jitteriness, temperature instability, high-pitched cry, seizures)</p>
Past medical history	<p><i>Birth history:</i> Spontaneous breathing at birth, meconium staining, prematurity, NICU admission, need for assisted ventilation, Apgar scores (5-minute Apgar score < 7 may be associated with asphyxia, traumatic delivery, hemorrhage, nuchal cord), seizures, drug exposure (type/presence of withdrawal), hypoglycemic events, type of delivery, complications of delivery, maternal health, prenatal care</p> <p><i>Infant health:</i> History of other illnesses and hospitalizations, whether follow-up appointments have been maintained, current immunization status and any reaction to them, any identified allergies to medications, topical agents, foods</p>
Nutritional assessment	Adequate growth (head circumference, weight, length) plotted on growth chart, recent weight loss/gain, poor feeding, decreased activity
Family medical history	Family history of illness, genetic conditions, other premature or ill offspring
Social history	Adequate income and resources to provide food, safe home, transportation to clinic visits; adequate heat and running water in home, telephone; how family is adjusting to the birth of this infant
Growth and development	Achievement of developmental and physical milestones, response to environment, activity patterns, presence of sleep/wake periods

*This history focuses on the neonate; see Chapter 8 for a comprehensive health history.

FOCUSED PHYSICAL ASSESSMENT 14-1

The Neonate With Altered Health Status

Assessment Parameter	Alterations/Clinical Significance
General appearance	<p>Normal: Spontaneous movements, flexed position, palmar grasp, lusty cry, normal muscle tone</p> <p>Frog position of legs, decreased muscle tone, weak grasp associated with prematurity</p> <p>Decreased movement, weak palmar grasp: Birth asphyxia, neurologic damage</p> <p>High-pitched cry: Prematurity, neurologic abnormality, drug withdrawal</p> <p>Increased muscle tone: Drug exposure, birth asphyxia</p> <p>Hypotonia: Neurologic damage</p>
Integumentary system	<p>Color</p> <p>Normal: Pink; acrocyanosis during first 24 hours of life</p> <p>Central cyanosis: Congenital heart disease</p> <p>White/pale: Respiratory distress, hypothermia, hypovolemia, anemia, sepsis</p> <p>Mottled: Acidosis, hypotension, hypothermia, shock</p> <p>Jaundice in first 24 hours of life: Hemolysis, sepsis, biliary atresia</p> <p>Jaundice after first 24 hours of life: Immature liver</p> <p>Plethoric, ruddy: Polycythemia, hyperthermia</p> <p>Normal: Mature, intact, presence of subcutaneous fat, vernix, scant lanugo, milia, erythema toxicum; capillary refill < 3 seconds.</p> <p>Thin, translucent blood vessels; lack of vernix, abundant lanugo: Prematurity</p> <p>Lack of subcutaneous fat: Prematurity, IUGR</p> <p>Petechiae: Trauma, sepsis</p> <p>Edema: Trauma</p> <p>Peeling skin, long fingernails and toenails: Postterm</p> <p>Meconium staining: Meconium aspiration, fetal distress</p> <p>Forceps marks: Trauma, asphyxia</p> <p>Prolonged capillary refill: Hypovolemia, acidosis, hypothermia</p>
Head and neck	<p>Normal: Normocephalic, minimal head lag</p> <p>Microcephalic: TORCH syndrome/transplacental infections, congenital anomalies</p> <p>Hydrocephalic: Congenital anomalies, IVH, meningomyelocele</p> <p>Encephalocele: Herniated brain</p> <p>Anencephaly: Absent cerebral tissue/neural tube defect</p> <p>Molding: Difficult delivery, prolonged labor</p> <p>Cephalhematoma: Difficult delivery, use of vacuum extraction</p> <p>Caput succedaneum: Pressure on presenting part, prolonged labor</p> <p>Full anterior fontanel: Increased ICP, IVH</p> <p>Sunken anterior fontanel: Dehydration</p> <p>Increased head lag: Hypotonia, prematurity</p> <p>Asymmetric tonic neck reflex: Prematurity, neurologic dysfunction</p> <p>Decreased neck ROM: Fetal positioning</p> <p>Fractured clavicles: Birth trauma</p>
Eyes	<p>Normal: Clean, white sclera; blink reflexes present; presence of red reflexes; eyes on line with ears</p> <p>Sclera yellow or hemorrhage present: Jaundice, birth trauma</p> <p>Absent blink reflex: Neurologic damage, facial nerve paralysis</p> <p>Absent red reflex: Congenital cataracts, retinoblastoma</p> <p>Low-set ears: Trisomy 21</p>
Ears	<p>Normal: Adequate cartilage formation</p> <p>Cartilage flattened, folded: Prematurity</p>
Nose and oral cavity	<p>Normal: Well-formed structures, intact palate and mouth structures</p> <p>Nose off midline: Congenital malformation</p> <p>Nares not patent: Choanal atresia</p> <p>Hard/soft palate not intact: Cleft lip/palate</p> <p>Absent gag reflex: Neurologic abnormalities</p> <p>Absent or weak sucking or rooting reflex: Prematurity, neurologic difficulties</p>

Assessment Parameter	Alterations/Clinical Significance
Thorax and lungs	<p>Normal: Symmetric chest wall; easy breathing with clear breath sounds</p> <p>Asymmetric expansion: Pneumothorax, phrenic nerve damage</p> <p>Grunting, nasal flaring, retractions: Surfactant deficiency/pneumonic sepsis, retained lung fluid</p> <p>Respiratory rate: 40 to 60 breaths per minute normal; tachypneic: congenital heart disease, respiratory distress</p> <p>Rales/rhonchi/wheezing: Fluid in alveoli, decreased ventilation, PDA</p> <p>Decreased breath sounds: Pneumothorax, diaphragmatic hernia, surfactant deficiency, pneumonia</p>
Cardiovascular system	<p>Normal heart rate: 80 to 150 beats per minute (term), 120 to 160 beats per minute (preterm)</p> <p>Irregular rate: Supraventricular tachycardia, congenital heart block</p> <p>Bradycardia: Hypothermia, sepsis, apnea</p> <p>Tachycardia: Hypovolemia, hyperthermia, anemia, acidosis, congestive heart failure</p> <p>Murmur: First 24 hours of life may be normally heard, congenital heart disease, PDA, acidosis, anemia</p> <p>Active precordium: PDA of prematurity</p> <p>Decreased pulses: Congenital heart disease</p> <p>Increased pulses: PDA</p>
Abdomen	<p>Normal: Palpate sharp edge of liver 1 to 2 cm below costal margin; umbilical cord with three vessels; meconium passage within 24 hours after birth</p> <p>Distention: Obstruction, NEC, renal abnormality, fetal hydrops</p> <p>Scaphoid (sunken abdomen because of intestines in chest): Diaphragmatic hernia</p> <p>Decreased bowel sounds: Obstruction, NEC</p> <p>Hyperactive bowel sounds: Hypermotility, colitis</p> <p>Tense/tender: NEC, abdominal mass</p> <p>Enlarged liver: Hepatosplenomegaly, hemolysis, sepsis</p> <p>Two-vessel cord: Congenital anomalies, renal anomalies</p> <p>Bowel loops palpable: Obstruction, feeding intolerance</p> <p>No stool within first 24 hours: Obstruction, imperforate anus, Hirschsprung's disease</p> <p>Water-loss stools: Diarrhea, colitis, rotavirus, feeding intolerance</p> <p>OB+ stools: Anal fissure, NEC, colitis</p> <p>Reducing substance positive: Carbohydrate intolerance</p> <p>Bright red streaks: Anal fissure, colitis</p> <p>Meconium plugging: Hirschsprung's disease, cystic fibrosis</p>
External genitalia	<p>Normal: Well-formed, sexually differentiated structures</p> <p>Blood-tinged discharge: Maternal hormones</p> <p>Ambiguous genitalia: Congenital anomalies, adrenal hyperplasia</p> <p>Nonpatent anus: Congenitally imperforate anus</p> <p>Penis, meatus displaced to ventral surface: Hypospadias</p> <p>Penis, meatus displaced to dorsal surface: Epispadias</p> <p>Failure to void within first 24 hours: Renal obstruction, polycystic kidneys</p> <p>Undescended testes: Prematurity</p> <p>Fluid-filled scrotal sac: Hydrocele</p>
Musculoskeletal system	<p>Normal: Intact spine, normal muscle tone for gestational age</p> <p>Spine not intact: Meningomyelocele</p> <p>Muscle tone as noted under general appearance</p> <p>Limited ROM in all four extremities: Clavicle injury, brachial plexus injury</p> <p>More/less than 10 digits/webbing: Congenital syndromes</p> <p>Buttock creases asymmetric: Hip dysplasia</p>
Growth and gestational age	<p>Plot preterm infant growth parameters on growth charts specifically for preterm infants (accessible at http://members.shaw.ca/growthchart/). Once an infant surpasses 50 weeks, use the regular Centers for Disease Control and Prevention growth charts.</p> <p>SGA/IUGR: Smoking during pregnancy, poor maternal nutrition, transplacental infection, drug exposure</p> <p>LGA: Diabetic mothers/postterm</p> <p>Ballard Scale score estimates gestation age</p>

AGA, appropriate for gestational age; ICP, intracranial pressure; IUGR, intrauterine growth retardation; IVH, intraventricular hemorrhage; LGA, large for gestational age; NEC, necrotizing enterocolitis; OB+, occult blood-positive; PDA, patent ductus arteriosus; ROM, range of motion; SGA, small for gestational age.

Sign	0	1	2
Heart rate	Absent	Slow, < 100 beats per minute	> 100 beats per minute
Respiratory effort	Absent	Slow and irregular	Good, strong cry
Muscle tone	Flaccid	Some flexion of extremities	Active motion
Reflex irritability	None	Grimace	Cough or sneeze
Color	Pale, blue	Body pink, extremities blue	Completely pink

FIGURE 14–2. The Apgar scoring system evaluates the neonate’s adjustment to extrauterine life at 1 and 5 minutes.

the 10th percentile. Although easy to administer, the Ballard scale may give erroneous results in cases of prematurity, neurologic disorders, and asphyxiated newborns.

Neonatal Behavioral Assessment Scale

The NBAS is a comprehensive tool used to assess the healthy full-term newborn’s behavior (see Diagnostic Tests and Procedures 3–1). This tool combines evaluation of the reflexes, motor capacity, state regulation, and interactive abilities. To use the tool, the examiner observes the newborn through various states of sleep, arousal, and wakefulness, and evaluates the interactions between the newborn and the environment. The results obtained demonstrate the newborn’s ability to organize states, habituate to the external environment and stimuli, regulate motor activity, respond to reflex testing, orient to visual and auditory stimuli, interact with the caregiver, and self-console (Brazelton, 1984). The tool is also useful to demonstrate to parents how their newborn responds to caregiving.

The preterm newborn may be assessed with a modified NBAS that includes both the original full-term scale and additional subscales specifically focused on the preterm newborn’s behavior. The preterm newborn behaves differently from the full-term newborn. The preterm newborn may be better served if tested using the APiB, which is more discrete in its assessment of preterm neonatal functioning.

Assessment of Preterm Newborn Behavior Scale

The APiB is useful for preterm and high-risk full-term newborns from birth to 44 weeks’ gestation. Administering the APiB requires specialized training and an experienced clinician. The focus of this assessment is to determine how newborns cope (their competence) with the environment and the quality of their responses (Als et al., 2005). The information gained from this tool assists in assessing the infant’s degree of fragility and tolerance to interactions, and in determining what modifications can be made to the environment to enhance the newborn’s ability to interact.

ANSWER: Gabriella’s maturity as measured by the square window maneuver, the arm recoil, the popliteal angle, the scarf sign, and the heel-to-ear maneuver are missing. Based on the description of Gabriella in the case study, she has 1 point for skin, 1 point for lanugo, 1 for plantar surface, 0 for breast, 1 for eye/ear, and 1 for genitals. This is a total of 5 points.

TREATMENT MODALITIES

Care for the newborn focuses on assisting the infant in transitioning to extrauterine life and then maintaining physiologic stability, particularly thermoregulation and prevention of hypoglycemia and infection.

Newborns are more likely than any other age group to require resuscitation, and how the infant is cared for at birth may have lifelong effects. Fortunately, most newborns make the transition to extrauterine life smoothly. Very small percentages (approximately 10%) require some level of assistance. To best serve these newborns, the Neonatal Resuscitation Program trains healthcare professionals to skillfully perform neonatal resuscitation in an evidence-based, standardized, methodical manner (AHA, 2005). It teaches integrated steps including evaluating the infant, making decisions, and taking actions based on the overall evaluation. One goal of the program is to have at least one person at every delivery whose primary responsibility is the newborn and who is able to initiate resuscitation. Additionally, either that person or another healthcare professional immediately available has the skills to perform a complete resuscitation.

Most infants respond to warming, drying, positioning, suctioning, and stimulation. Some infants require more vigorous steps such as ventilation, chest compression, endotracheal intubation, and administration of medications. Decisions for care are based on the infant’s overall response to previous actions.

Monitor the infant after immediate stabilization at birth and implement interventions as indicated to ensure adequate cardiorespiratory adaptation, thermoregulation, normoglycemia, initiation of feedings, and bonding with parents. An overriding dictate of neonatal care, especially important for premature infants with a more immature CNS and other body systems, is that care is delivered in a developmentally appropriate manner. Two treatment modalities that meet this mandate are skin-to-skin holding (kangaroo care) and developmental care.

Skin-to-Skin Holding

Skin-to-skin holding, or kangaroo care (Fig. 14–4), is the practice of holding an infant, clothed only in a diaper, skin-to-skin against the bare chest of the father or between the breasts of the mother (NIC 14–1). Offer parents the opportunity to provide skin-to-skin holding (Tradition or Science 14–1).

Diagnostic Tests and Procedures For Evaluating the Neonate With Altered Health Status

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Responsibilities
Radiograph: Chest, abdominal	To examine soft tissue and bony structure; Abdominal: To diagnose free air in abdomen and evaluate bowel and other organs	Evaluate lung aeration, lung expansion, lung disease, heart size; bony structures density; intramural air = necrotizing enterocolitis	Shield newborn with gonad shield; protect self with lead apron; keep others 10 ft away from area. Hold newborn during procedure to ensure adequate positioning and avoid rotation.
Pulse oximetry	To measure oxygen saturation of blood, noninvasive, measures amount of light absorbed by hemoglobin in the blood	Saturations <80% may indicate poor blood oxygen content. Saturations >100% may indicate hyperoxia.	Protect probe from phototherapy light. Ensure correlation with heart rate. Change site every 12 hours to avoid skin breakdown resulting from pressure. Test may be inaccurate in anemic patients.
Ultrasound (head, abdominal, fetal)	Evaluation of internal anatomic structures through emission of sound waves to evaluate tissue density, movement of tissue, and flow of blood	Heart defects and pulmonary artery pressures; presence of blood in ventricles, brain masses, and in fetal structures	Assist to position newborn. Sedate as needed.
Pneumogram	Twelve- to 24-hour sleep study to measure the presence of apnea, bradycardia, and desaturations	Results read by physician; presence of apnea/bradycardia indicates need for apnea monitor at home.	Ensure monitor is on and apnea/bradycardia episodes are documented on test strip.
Transcutaneous monitoring	Measurement of CO ₂ and O ₂ transcutaneously that correlates with blood CO ₂ and O ₂ . Skin is heated to measure values.	Transcutaneous CO ₂ values more accurate than O ₂ values. High CO ₂ readings may indicate hypoventilation.	Change probe site every 2 to 4 hours. Monitor for skin burns. Obtain blood gas sample to correlate findings.
Arterial blood gas	Analysis of arterial oxygenation, CO ₂ retention, and loss or gain of buffer system acid versus base by the blood system	Normal findings: pH: 7.35 to 7.45 PaCO ₂ : 35 to 45 mmHg PaO ₂ : 50 to 80 mmHg HCO ₃ : 22 to 26 mEq/L Base Excess (BE): 5 to +5 Elevated PaCO ₂ indicates hypoventilation. Decreased PaO ₂ indicates hypoxemia.	Avoid allowing air into sample. If sample obtained from heel as capillary blood gas extremity, must have good perfusion to obtain accurate results. Capillary blood values for pH and CO ₂ usually correlate with arterial values; do not rely on O ₂ values, which do not correlate well.
Hemoglobin/hematocrit	To determine the amount of circulating red blood cells (hematocrit) and oxygen-carrying capacity of the blood (hemoglobin)	Range for hemoglobin values is 17 to 19 g/dL; for hematocrit, value is 50 to 63 mL/dL	Heel stick samples may have higher values as a result of sludging of red blood cells.
Serum glucose	To detect the presence of hyperglycemia or hypoglycemia	Normal values: Term newborn: 40 to 120 mg/dL Preterm newborn: 30 to 160 mg/dL	Do not draw sample from a central line with glucose infusing because erroneous values may result.

Developmental Care

QUESTION: Looking at Nursing Interventions 14–1, what is an aspect of care that, according to the assessment given in the case study, is appropriate for Gabriella from the delivery room through discharge?

Developmental care is a philosophical approach to caring for the newborn based on the specific behavioral responses of the infant to caregiving and other activities. Sick premature infants respond to their environments differently than healthy term infants do. The focus of developmental care is to provide an environment and interaction pattern that the sick infant's neurobehavioral and physiologic organization can tolerate. Healthcare providers learn to interpret the meaning of infant behaviors. The nurse watches each infant for behavioral and physiologic cues and varies care based on the infant's response.

caREminder

Behaviors that indicate stress in the premature infant include facial grimace, yawning, tongue protrusion, hiccoughing, finger splaying, gaze aversion, fussing, crying, and vomiting. Physiologic stress cues include changes in heart or respiratory rates (tachycardia, bradycardia, tachypnea, apnea), grunting, gasping, cyanosis, and decreased blood oxygen levels (reflected in decreased oxygen saturation or transcutaneous carbon dioxide [TcPco₂] levels). The infant exhibits these signs when the environment is stressful, such as in the presence of bright lights and loud noises or when handled excessively.

To effectively deliver developmentally appropriate care, specific elements both in the NICU environment and in the individual infant are considered (Nursing

Interventions 14–1). Care may be clustered (many caregiving activities provided at one time) if the infant demonstrates organized and stable behavior. Alternatively, perform only one caregiving activity (such as diapering) if the infant demonstrates decompensation (desaturation or bradycardia).

Providing developmental care is the standard of care in the NICU and permeates all interactions with the newborn (see [thePoint](#) for Procedures: Developmental Care of the Newborn). Implementing developmental care decreases the time the premature newborn is on the ventilator and on supplemental oxygen, improves short-term growth, and reduces length and cost of hospital stays (Symington & Pinelli, 2003). Individualizing care, such as offering nipple feedings when infants are in quiet awake states, results in more successful feeding—an important discharge criterion for the premature infant. Additionally, premature newborns provided with developmental care have improved neurodevelopmental outcomes to 24 months corrected age (Symington & Pinelli, 2003). Developmental care is a family-centered concept that improves both medical and developmental outcomes for premature newborns.

ANSWER: Gabriella's posture is identified as flaccid and it is noted that her arms are not flexed. She lacks the physical strength and neuromuscular maturity to assume and maintain a flexed position. The aspect of care that will be begun in the delivery room is developmentally appropriate positioning. Premature infants benefit in several ways from a flexed spine and flexed extremities as they adjust to an extrauterine environment. Developmentally appropriate positioning helps to maintain body temperature and prevents skin breakdown and cranial molding (flattening of the head). Nurses will position Gabriella to promote the development of strong flexor tone, just as she would have if she had remained in utero.

NURSING PLAN OF CARE FOR THE NEONATE WITH ALTERED HEALTH STATUS

Although health challenges in newborns can result from various causes, the presence of any one of these challenges can create common healthcare needs for the newborn and family. Challenges result from immature functioning of body systems in the newborn, particularly the premature infant. The stress on family functioning processes associated with the birth of a sick infant also must be addressed. These challenges are outlined in Nursing Plan of Care 14–1.

ALTERATION IN NEONATAL HEALTH STATUS

Several disorders place the newborn at risk for ongoing health problems. Congenital anomalies, prematurity, low

NIC 14–1 Nursing Interventions Classification: Kangaroo Care

Definition: Promoting closeness between parent and physiologically stable preterm infant by preparing the parent and providing the environment for skin-to-skin contact

Activities:

Discuss parent reaction to premature birth of infant
 Determine image parent has of premature infant
 Determine and monitor parent's level of confidence in caring for infant
 Encourage parent to initiate infant care
 Explain kangaroo care and its benefits to parent
 Determine whether infant's physiologic status meets guidelines for participation in kangaroo care
 Prepare a quiet, private, draft-free environment
 Provide parent with a reclining or rocking chair
 Have parent wear comfortable, open-front clothing
 Instruct parent how to transfer infant from incubator, warmer bed, or bassinet and how to manage equipment and tubing, as appropriate
 Position diaper-clad infant in prone upright position on parent's chest
 Wrap parent's clothing around or place blanket over infant to maintain infant's position and temperature
 Encourage parent to focus on infant, rather than high-technologic setting and equipment
 Encourage parent to gently stroke infant in prone upright position, as appropriate
 Encourage parent to gently rock infant in prone upright position, as appropriate

Encourage auditory stimulation of infant, as appropriate
 Reinforce eye contact with infant, as appropriate
 Support parent in nurturing and providing hands-on care for infant
 Encourage parent to hold infant with full, encompassing hands
 Encourage parent to identify infant's behavioral cues
 Point out infant state changes to parent
 Instruct parent to decrease activity when infant shows signs of overstimulation, distress, or avoidance
 Encourage parent to let the infant sleep during kangaroo care
 Encourage breast-feeding during kangaroo care, as appropriate
 Encourage parent to provide kangaroo care from 20 minutes to 3 hours at a time on a consistent basis, as appropriate
 Encourage postpartum mothers to change position and get up every 90 minutes to prevent thrombotic disease
 Monitor parents' emotional reaction to kangaroo care
 Monitor infant's physiologic status (e.g., color, temperature, heart rate, and apnea), and discontinue kangaroo care if infant becomes physiologically compromised or agitated

From Bulechek, G. M., Butcher, H. K., & Dochterman, J. M. (2008). *Nursing interventions classification (NIC)* (5th ed.). St. Louis, MO: Mosby. Reprinted with permission.

birth weight (LBW), perinatal asphyxia, and birth trauma are examples of conditions that require skilled nursing assessment and interventions to promote healing and optimal development. In addition, specific diseases of the newborn follow predictable trajectories. The most common disorders are discussed in this section.

Congenital Anomalies

Congenital anomalies are abnormalities or defects that are present at birth. Such defects are the leading cause of infant mortality in North America and Europe (Dastgiri et al., 2002; Heron, 2007; Kung et al., 2008). Approximately 3% to 4% of all births involve either a minor or major congenital anomaly; however, the specific incidence varies according to the defect, the geographic area (possibly because of environmental factors or a limited gene pool), or cultural practices such as **consanguinity** (sharing blood, having a common ancestor). Mating between people who are closely related can result in an

increased incidence of progeny who are homozygous for autosomal recessive traits possessed by both parents.

Anomalies are inherited through gene transmission (**genotype**: the specific genetic makeup of the individual), or are initiated by a stimulus during embryogenesis at the time when developing structures are vulnerable (**phenotype**: the specific manifestation of a trait, the observable characteristics of the person). Normal phenotypic variations occur, such as hair and eye color, height, or weight. Stimuli or **teratogens** (agents that can disrupt fetal growth and produce birth defects) that can produce phenotype anomalies include drugs, environmental toxins, radiation, infection, diet, and metabolic disorders (see Table 3–1). Defects may occur alone or in a typical pattern with other abnormalities (identified as a syndrome, association, or sequence).

Pathophysiology

The inheritance of genetic traits, abnormalities, or diseases is determined by both the type of chromosome where the

TRADITION OR SCIENCE 14–1

Is skin-to-skin holding detrimental or beneficial to preterm infants?

EVIDENCE-BASED PRACTICE

For more than a decade, multiple studies (Chwo et al., 2002; Ferber & Makhoul, 2008; Kledzik, 2005; Ludington-Hoe et al., 2004; McCall et al., 2005) have demonstrated the benefits of kangaroo care for infants, including

- Significantly increased sleep time
- Reduced activity
- Less agitation, apnea, and bradycardia
- Improved stability of oxygen saturation
- Decreased hypothermia
- Reduced pain behaviors with painful stimuli

Mothers report improved lactation with kangaroo care (Furman, Minich, & Hack, 2002). Parents who participate in kangaroo care increase their comfort level in providing care and report increased fulfillment and ability to know their infants, thus promoting parental attachment (Johnson, 2007; Roller, 2005).

Although meta-analysis is difficult to perform, and further research would be desirable to validate positive outcomes (Anderson, Moore, Hepworth, & Bergman, 2003; Conde-Agudelo, Diaz-Rossello, & Belizan, 2003), evidence demonstrates that kangaroo care has clinical benefit for both infants and parents, has no apparent negative effects, and therefore should be incorporated into nursing practice.

gene is located (autosome or sex chromosome) and by whether the gene itself is recessive or dominant. Autosomal diseases are inherited through the nonsex chromosomes (pairs 1–22); sex-linked diseases are inherited through the X chromosome. Diseases are not inherited through the Y chromosome (Table 14–1 and Fig. 3–3).

Chromosomal aberrations are disorders caused by changes in the number or structure of chromosomes. Chromosomal aberrations do not follow the straightforward patterns of single-gene inheritance. Sometimes an error occurs while chromosomes are being sorted during the production of the sperm or the egg; this is called *nondisjunction*. Nondisjunction can occur during meiosis I or meiosis II. During meiosis I, the error occurs when the homologous pairs both travel into the same daughter cell. The result is two daughter cells that have two copies of the chromosome and two cells that are missing that chromosome. In meiosis II, the error occurs when the sister chromatids do not separate and thus go into the same daughter cell. At fertilization, the egg (23 chromosomes) and the sperm (23 chromosomes) fuse to create a zygote, which has 46 chromosomes. If a sperm or egg, because of nondisjunction, carries an extra copy of one of the chromosomes, the reproductive cell will contain a total of 24 chromosomes, instead of 23. If this sperm or egg is

fertilized by a normal sperm or egg, the result will be a total of 47 chromosomes instead of 46, resulting in **trisomy**. *Monosomy* occurs when there is only one copy of a chromosome that is normally present in two copies. These eggs and sperm have 22 chromosomes, not the normal 23. When fertilized, the outcome is 45 chromosomes in total. A fetus with monosomy of the autosomes is generally less likely to survive than one with trisomy. Changes in the number of sex chromosomes (e.g., Turner's syndrome, Klinefelter syndrome) cause milder effects than trisomy or monosomy.

Many other disorders are caused by the effects of multiple genes or by interactions between genes and the environment. Such inheritance is classified as multifactorial. Multifactorial disorders are difficult to analyze, because they do not follow the single-gene patterns of inheritance, and their genetic causes are often unclear. Examples of conditions caused by multiple genes or gene–environment interactions include neural tube defects, cleft lip and palate, pyloric stenosis, congenital heart disease, diabetes, obesity, schizophrenia, and certain types of cancer.

Not all congenital anomalies result from genetic aberrations. Prenatal exposure to teratogens may also cause congenital anomalies (see Chapter 3).

Assessment

Prenatal diagnosis of some congenital anomalies may be possible with ultrasonography, amniocentesis, or chorionic villus sampling. Obstetric factors may suggest anomalies such as polyhydramnios, which may result from a problem with swallowing (e.g., a CNS disorder such as anencephaly) or from a blockage of the gastrointestinal tract (e.g., intestinal atresia); oligohydramnios, which may result from low urine output because of genitourinary anomalies; or intrauterine growth retardation (e.g., fetal alcohol syndrome, trisomy 18, maternal opioid use, maternal phenylketonuria).

Some congenital anomalies are physically obvious at birth and apparent on physical examination (e.g., cleft lip and palate). Other anomalies are more subtle, and the history, although always essential, provides important data (e.g., Fragile X, in which affected boys often have delayed acquisition of developmental milestones; as they grow older, physical signs of the condition become more pronounced). See Table 14–2 for clinical features of selected congenital aberrations.

Diagnostic testing depends on the suspected aberration or anomaly. Chromosomal analysis, DNA analysis, and fluorescent in situ hybridization may be useful in confirming a chromosomal or genetic aberration. Biochemical genetic studies (metabolic screening) involve the study of enzymes in the body to detect abnormalities, such as inborn errors of metabolism or amino acid and organic acid disorders (see Chapter 27). Testing may be done from a sample of blood, urine, spinal fluid, or other tissue.

Interdisciplinary Interventions

Treatment of congenital anomalies is based on the defects. Pathology and treatment of many defects are

NURSING INTERVENTIONS 14–1

Providing Developmentally Appropriate Care

Element	Intervention
Environment	<p>Provide calm and soothing ambiance.</p> <p>Avoid loud, sudden noises; pad trash can lids; close isolette portholes gently; carefully place items on top of isolettes; decrease decibel level of telephones, intercoms, and overhead music.</p> <p>Lighting should be modifiable to provide adequate lighting for examinations and procedures, but be able to dim for rest and to facilitate eye opening in the infant to interact with parents or the environment.</p>
Positioning	<p>Support the infant in a flexed, tucked position either with a positioning aid (bumper, nest, blankets) for rest or with the caregiver's hands during procedures.</p> <p>Side-lying or prone positioning is best.</p> <p>Change position gently while supporting the infant in a tucked position; avoid extreme limb extension.</p>
Handling	<p>Avoid giving too much stimulation at one time.</p> <p>Approach the infant slowly (e.g., place your hands on the infant gently for a few seconds then gently turn infant over instead of abruptly opening isolette and flipping infant on his or her back).</p> <p>Observe the infant's cues for tolerance of handling and indications to reduce or stop stimulation.</p> <p>Procedures may need to be implemented in stages, allowing the infant to recover before proceeding (e.g., pause and provide containment or a pacifier to suck on).</p>
Self-regulation	<p>Observe the infant for behaviors used to self-soothe (e.g., hand-to-mouth movements).</p> <p>Support self-soothing behaviors or positions of the infant.</p> <p>Post a list of the infant's stress cues, cues that indicate relaxation, and self-soothing methods of the infant.</p>
State regulation (the newborn's ability to regulate his/her behavioral state)	<p>Observe infant for differentiated sleep/wake cycles.</p> <p>Provide a calm, stable environment.</p> <p>Time activities to coincide with the infant's patterns (e.g., offer feedings when the infant is in a quiet awake state).</p> <p>Swaddle to promote state regulation during stressful procedures (e.g., endotracheal tube suctioning, heel stick)</p>
Caregiving event	<p>Incorporate all the previous interventions into care delivery.</p> <p>Provide care when the infant is in a quiet, awake state, if medically feasible.</p> <p>Observe the infant's cues and modify care based on them.</p> <p>Talk softly to the infant (as tolerated).</p> <p>Have two caregivers perform noxious procedures: one to perform the procedure and one to support the infant with containment and promotion of self-soothing behaviors.</p> <p>Plan procedures prior to implementation; consider necessity of procedure versus physiologic cost to the infant; have all equipment readily available.</p>

discussed in the chapter specific to the primary system that is affected. Many congenital anomalies result in long-term or permanent alterations in health and development (see Chapter 12) or limited life span. If genetic

factors are suspected, the parents should receive genetic counseling (see Chapter 3).

Genetic counseling and prenatal diagnosis provide parents with knowledge to make informed decisions

NURSING PLAN OF CARE 14–1: FOR THE NEONATE WITH ALTERED HEALTH STATUS

Nursing Diagnosis: Ineffective thermoregulation related to immature skin structure, decreased amount of subcutaneous tissue, or physiologic stress

Interventions/Rationale

- Maintain external heat source whenever the isolette door must be opened for procedures.
When the isolette door is open, heat is lost to the environment and the infant may experience cold stress. External heat source is required to prevent cold stress (see thePoint for Procedures: Warming Devices, Use of).
- During bathing, provide an external heat source.
Bathing can induce cold stress in the preterm and term neonate. Provide an external heat source (such as a heat lamp) to minimize cold stress.
- Use radiant warmers for larger neonates who require close observation.
Radiant heat warmers provide radiant heat with the benefit of open access to the neonate for close visual observation and nursing care. Although used also for the preterm infant, radiant heat warmers do not provide humidity and may increase insensible water losses in the preterm neonate with immature skin.

Expected Outcomes

- Neonate will be maintained within a neutral thermal environment.
- Neonate will have a stable temperature between 36.4 and 37.0°C (97.5 and 98.6°F).

Nursing Diagnosis: Risk for infection related to effects of immature immune system

Interventions/Rationale

- Strict hand hygiene is required immediately prior to touching neonate.
Hand hygiene is the single most important intervention to prevent nosocomial infections in the NICU.
- Ensure clean preparation of expressed breast milk and/or formula for feeding.
Bacteria can be introduced into feedings during preparation. Bacteria in feedings can cause bloodstream infection in the at-risk neonate. Nurses preparing feedings at the bedside must ensure clean technique.
- Ensure sterile technique for all invasive procedures (endotracheal tube suctioning, central line insertion, and care).
Sterile technique helps to prevent the introduction of bacteria during invasive procedures.

Expected Outcomes

- Neonate will remain infection free.

Nursing Diagnosis: Risk for impaired skin integrity related to thin skin from immaturity

Interventions/Rationale

- Use emollients to maintain skin integrity and prevent dry, cracked skin.
Emollients help to keep the skin intact by preventing cracking and bleeding.
- Use humidity to avoid dry, cracked skin.
Humidity helps to reduce dry skin and keep the skin intact.
- Use tape and adhesives minimally, to prevent epidermal stripping; use barrier to tape (such as pectin-based products) whenever possible.
Tape and adhesives make a strong bond to the epidermis of the low-birth weight neonate. Because the skin of the premature neonate is immature, when tape is removed, the epidermis remains bonded to the tape or adhesive, causing epidermal stripping. This wound provides a portal of entry for bacteria and may lead to infection.
- Remove antiseptics (povidone iodine, alcohol) as soon as possible, using normal saline wipes.
The immature skin of the preterm neonate is thin and a poor barrier to anything put on the skin. Topical antiseptics may be easily and quickly absorbed into the bloodstream. Removal with normal saline wipes is the safest way to limit absorption by the skin.

Expected Outcomes

- Neonate will have intact skin.

Nursing Diagnosis: Delayed growth and development related to poor feeding and weight gain

Interventions/Rationale

- Minimize caloric loss by maintaining infant in neutral thermal environment; if in open crib, move away from window and avoid drafts. May need to limit time outside isolette to avoid cold stress and loss of calories.
Maintaining a neutral thermal environment will limit the loss of calories for thermoregulation and will maximize growth.
- Limit nipple (bottle or breast) attempts to 30 minutes to decrease calories used for feeding intake.
Calories are needed to nipple or breast-feed. Limiting the attempts to 30 minutes will help maximize the calories available for growth.

Expected Outcomes

- Neonate will demonstrate adequate growth and feeding patterns.

NURSING PLAN OF CARE 14–1: FOR THE NEONATE WITH ALTERED HEALTH STATUS (CONTINUED)

Nursing Diagnosis: Risk for impaired parent–infant attachment related to effects of hospitalization, sick infant’s ability to interact with parents

Interventions/Rationale

- Explore parent’s understanding of child’s condition and causative factors.
Parents may blame themselves for causing the child’s condition. Accurate understanding may facilitate a more realistic perspective and enable the parents to interact more positively with the infant.
- Encourage skin-to-skin care by parents.
Providing skin-to-skin care may help the parents to recognize the unique role they play in their child’s life and how they can contribute to the infant’s care and physiologic well-being. Parents demonstrate more positive affect, touch, and adaptation to infant cues when participating in skin-to-skin care.
- Support parent’s competence in assessing their infant’s behavioral cues and responses.
Reinforces parental role and the parent’s ability to meet their child’s needs.
- Involve parents in providing care for their infant.
Reinforces parental role and the parent’s ability to meet their child’s needs.

Expected Outcomes

- Parents will participate in the newborn’s care, as appropriate, and will begin to verbalize positive statements regarding the newborn.
- Parent–infant attachment will occur.

Nursing Diagnosis: Interrupted family processes related to reaction to an acutely ill newborn

Interventions/Rationale

- Assess the family’s stress levels, coping mechanisms, and support systems.
Knowledge of stressors and support can be used to assist family members and build on their strengths.
- Encourage family discussion of feelings and acknowledge their normalcy.
Venting of feelings may help decrease anxiety and validate that what they are experiencing is normal.
- Involve family in caring for their infant.
Helps maintain normalcy and reinforces the parent’s ability to provide adequate care.

Expected Outcomes

- Family will visit the newborn frequently, maintain mutual support, and seek external resources as needed.

Nursing Diagnosis: Risk for disorganized infant behavior

Interventions/Rationale

- Assess for the infant’s behavioral cues that indicate stress, avoidance, approach, and regulation, and deliver care accordingly.
Each infant differs in the ability to regulate the environment and communicate needs. Reading and responding appropriately to the infant’s cues demonstrates to the infant that he or she can influence the environment, and contributes to the infant’s physiologic stability.
- Teach parents to recognize the infant’s cues and how to respond.
Facilitates parental role attainment.
- Support parent’s competence in assessing their infant’s behavioral cues and responses.
Reinforces parental role and the parent’s ability to meet their child’s needs.
- Structure the environment to minimize stimuli. Cluster caregiving activities when possible. Monitor the infant for stress cues when interacting and providing care.
Minimizing stimuli may facilitate behavioral organization. Clustering care provides longer periods of uninterrupted sleep.

Expected Outcomes

- Infant will maintain physiologic and behavioral stability.
- Infant’s behavioral cues will be recognized, and interventions will be implemented to assist infant in maintaining physiologic and behavioral stability.

Nursing Diagnosis: Deficient knowledge: Well-child care or complicated home care

Interventions/Rationale

- Provide multiple sources of parent education including videos, reading material, and hands-on demonstration.
Providing multiple methods of teaching is the best way to present new material to adult learners.
- Provide opportunities to room-in whenever possible.
Rooming-in (staying with the infant and all required equipment in a homelike environment within the hospital; parent provides all care to the infant) gives the parents a chance to be the primary care providers for their infant, to work with the actual equipment they will have in the home, and to give the medications. This care is provided with support as needed from the NICU staff.

Expected Outcomes

- Parents will be able to provide competent care of the newborn after discharge.

TABLE 14-1

Patterns of Single-Gene Inheritance

Pattern	Description	Examples of Conditions
Autosomal dominant	One copy of the mutated gene is capable of passing on the trait (causing disease), even though the matching gene from the other parent is normal. The mutated gene dominates the outcome of the gene pair. Typically occurs in every generation of an affected family; a vertical transmission pattern.	Familial hypercholesterolemia, achondroplasia, Marfan syndrome, retinoblastoma, neurofibromatosis 1, Treacher Collins syndrome, Huntington's disease
Autosomal recessive	Two copies of the mutated gene are necessary to have the trait, one inherited from the mother and one from the father. An affected child usually has unaffected parents who each carry a single copy of the mutated gene (they are <i>carriers</i> of the affected gene). Typically, disorders are not seen in every generation of an affected family; a horizontal transmission pattern. Often, the disease results in a defective enzyme in a biochemical pathway.	Cystic fibrosis, sickle cell disease, Tay-Sachs disease, congenital hypothyroidism, galactosemia, phenylketonuria, albinism
X-linked dominant	Caused by a mutated gene on the X chromosome. Very rare. Females are more frequently affected than males, because daughters have 100% inheritance from fathers combined with 50% from mothers, whereas sons only have 50% from mothers. All daughters of an affected male and a normal female are affected; all sons are normal. Affected females and normal males have a risk that half the sons will be affected and half the daughters will be affected. Fathers cannot pass X-linked traits to their sons. Families with an X-linked dominant disorder often have both affected males and affected females in each generation.	Vitamin D-resistant rickets (hypophosphatemic rickets), Rett syndrome
X-linked recessive	Caused by a mutated gene on the X chromosome. Males are more frequently affected than females, because females with a mutation in a gene on the X chromosome usually have a nonmutated gene on their other X chromosome that can compensate for the mutation. An affected man has two unaffected daughters who each carry one copy of the abnormal gene, and two unaffected sons; an unaffected woman who carries one copy of an abnormal gene for an X-linked recessive disorder has the risk for an affected son, an unaffected daughter who carries one copy of the abnormal gene, and two unaffected children who do not have the abnormal gene. Fathers cannot pass X-linked traits to their sons. Families with an X-linked recessive disorder often have affected males, but rarely affected females, in each generation.	Color-blindness, glucose-6-phosphate dehydrogenase (or G6PD) deficiency, hemophilia, Duchenne muscular dystrophy, Becker muscular dystrophy, Lesch-Nyhan syndrome

TABLE 14-2

Selected Genetic Aberrations

Condition/Incidence	Clinical Features*	Outcome/Prognosis	Interventions
<i>Single-Gene Inheritance</i>			
Treacher Collins syndrome (mandibulofacial dysostosis) 1/50,000 births	Downward sloping palpebral fissures Coloboma (notch in the lower eyelids) Underdeveloped facial bones Small jaw and chin (micrognathia) Small, abnormally shaped, or absent external ears Large mouth Conductive hearing loss and cleft palate often present Normal development and intelligence	Normal life span	Supportive care as needed Maintain airway, intake Hearing aids Anticipatory support for psychological issues Speech–language therapy Reconstructive surgery
Achondroplasia (dwarfism) 1/20,000 to 1/40,000 births 80% are new mutations	Short stature (approximately 4 ft) Trunk is normal, limbs short, upper arms and thighs are more shortened than the forearms and lower legs Short fingers, space between middle and ring fingers (trident hand) Large head with prominent forehead Joint laxity Midface hypoplasia (nose flat at the bridge) Delayed motor milestones; normal intelligence	Infants who are homozygous for achondroplasia seldom live beyond a few months Unexpected infant death in 2% to 5% likely from central apnea secondary to compression of arteries at the level of the foramen magnum Mortality increases in third to fourth decade of life	Track growth and head circumference using growth curves standardized for achondroplasia (Horton et al., 1978) For infants, provide firm neck and back support (no umbrella strollers) and limit uncontrolled head movement (no swings or carrying slings) Symptomatic management of frequent middle ear infections and dental crowding Anticipatory support for psychological issues Teach measures to control obesity, starting in early childhood Modify the environment to accommodate the child's short stature Dress as appropriate to age, not size Growth hormone therapy, lengthening of the limb bones, and surgery to correct bowing of the legs may be done (refer to Trotter et al. [2005] for more information)
Marfan syndrome 1/5,000 births	Connective tissue disorder, very tall, slender, long, extremities Joint laxity Long, narrow face; arched palate; crowded teeth Pectus excavatum or carinatum Scoliosis Flat feet Myopia, glaucoma Femoral, inguinal hernias Aortic root dilatation, aortic regurgitation, mitral valve prolapse	Slightly shortened life span because of cardiovascular complications Survival into the 60s	Advise against contact sports or weightlifting (may contribute to development of aortic aneurysm) Symptomatic management of complications associated with aortic dilatation

TABLE 14 – 2

Selected Genetic Aberrations (Continued)

Condition/Incidence	Clinical Features*	Outcome/Prognosis	Interventions
Fragile X syndrome 1/4,000 to 6,000 males, 1/8,000 females	Delayed developmental milestones, learning disabilities, and cognitive defects, typically combined with behavioral problems (e.g., inattention, hyperactivity, autism) With age, physical features become more apparent—characteristic long, narrow face with jutting jaw; large ears and high forehead; enlarged testicles (macroorchidism); flat feet; unusually flexible finger joints; high-pitched, jocular speech	Usually males are more severely affected than females Typically normal life span	Special education program with modifications in classroom environment and curriculum Speech–language and occupational therapy (OT) Medication to manage hyperactivity, attention difficulties, or other behavioral problems For adolescents with mental impairment, vocational training
Lesch-Nyhan syndrome 1/380,000 births	Deficiency of the enzyme hypoxanthine–guanine phosphoribosyltransferase Self-mutilation (lip and finger biting, head banging) Hypotonia Spastic muscle movements Severe gout Cognitive challenge	Death often in the second to third decade of life	Prevent self-injury: behavioral extinction techniques, reduce stress (which increases self-mutilation); restraint may be necessary Symptomatic treatment: allopurinol for gout, lithotripsy for kidney stones; baclofen or benzodiazepines may be used for spasticity
<i>Chromosomal Aberrations</i>			
Trisomy 21 (Down syndrome) 1/600 to 800 births; risk increases with increasing maternal age	Protruding tongue Transverse palmar crease Oblique palpebral fissure Hypotonia Hyperflexibility Variable cognitive challenge Higher incidence of congenital heart defects, digestive problems (e.g., gastroesophageal reflux disease, celiac disease), leukemia, hearing loss, hypothyroidism	Life span may be limited by associated conditions Often live beyond fifth decade; premature aging occurs	Monitor growth Chart using growth charts for typical children and for children with Down syndrome (specific growth charts available [see www.growthcharts.com]) (Cronk et al., 1988, Styles et al., 2002) Refer to lactation consultant (hypotonia and protruding tongue may interfere with feeding) Refer to early intervention program, full-inclusion in school based on abilities Speech–language and OT therapy Teach measures to control obesity Symptomatic care for associated defects (see Van Cleve and Cohen [2006] for more information)
Trisomy 18 (Edwards syndrome) 1/6,000 births	Weak cry Classic clenched fist with the index finger overlapping the third and fourth fingers Hypoplastic nails Wide-spaced eyes Micrognathia	Most die within the first year of life	Supportive care

(Continued)

TABLE 14-2

Selected Genetic Aberrations (Continued)

Condition/Incidence	Clinical Features*	Outcome/Prognosis	Interventions
	Deformed and low-set ears Prominent occiput Clubfeet and rocker-bottom feet Cognitive challenge		
Trisomy 13 (Patau syndrome) 1/10,000 births	Midline anomalies are characteristic, such as holoprosencephaly (failure of the forebrain to divide properly), cleft lip and palate Microphthalmia Ear malformations Polydactyly Apnea Cognitive challenge	Most do not survive beyond early infancy	Symptomatic care
Turner syndrome (45XO) 1/2,500 female births	Short stature Webbing of the neck Low hairline on the back of the neck Ptosis Broad chest with widely spaced nipples Lymphedema (puffiness or swelling) of the hands and feet Infertile, with failure to go through puberty Skeletal abnormalities Heart defects (coarctation of the aorta) Kidney problems Normal intelligence, mild learning problems (math; visual-spatial coordination tasks, such as mentally rotating objects in space)	Normal life span	Monitor cardiac status and blood pressure (hypertension common, resulting from coarctation or kidney problems) Teach healthy diet and physical activity to reduce obesity Anticipatory support for psychosocial issues Modify the environment to accommodate the child's short stature; dress as appropriate to age, not size Medications: growth hormone (for stature) or estrogen replacement therapy (to stimulate acquisition of secondary sexual characteristics) (refer to Friás et al. [2003] for more information)
XXY males (Klinefelter syndrome) (47XXY) 1/800 male births	Tall stature Before puberty, small penile length, small testes May have low levels of the hormone testosterone beginning during puberty, which may cause gynecomastia, reduced facial and body hair, and infertility Normal intelligence; mild learning and speech and language difficulties	Normal life span	Cognitive and psychosocial testing, speech and language therapy, and remedial education as indicated Testosterone therapy at onset of puberty (to promote acquisition of secondary sexual characteristics, muscle mass)
<i>Other Genetic Causes</i>			
CHARGE syndrome 1/8,500 to 10,000 births	Coloboma Heart defect Atresia, choanal Retarded growth and development Genital hypoplasia Ear anomalies/deafness Major criteria: Coloboma, choanal atresia Visual impairment, blindness	High infant mortality If child survives 1 year, will likely survive childhood	Symptomatic care Early referral for appropriate developmental and educational services Physical therapy to facilitate mobility Provide a structured environment that allows the child to antici-

Selected Genetic Aberrations (Continued)

Condition/Incidence	Clinical Features*	Outcome/Prognosis	Interventions
	Ear anomalies of external ears (absent or hypoplastic lobes, asymmetry, decreased cartilaginous folds, triangular concha) and of inner ear (ossicular malformations, chronic serious otitis), hearing loss Cranial nerve dysfunction causing asymmetric facial palsy and/or swallowing/feeding difficulties Balance, speech problems Cleft palate Tracheoesophageal fistula, esophageal atresia, omphalocele Heart defects Genital hypoplasia, typically recognized only in males (micropenis/cryptorchidism) Autism or autisticlike behaviors (possibly resulting from combined vision and hearing deficits) Developmental delay		pate events and gain a sense of control Educational support to address multisensory impairment

*Presentations of many conditions vary widely; all features may not be present. See Chapter 30 for more interventions specific to cognitive challenge. Many condition-specific organizations exist; information and support from these organizations are often helpful.

regarding the current pregnancy and its outcome, or future pregnancies. If a defect is identified prenatally, parents can learn about the condition and prepare themselves to care for their affected child; if the defect is serious, parents can decide whether to terminate the pregnancy. Arrangements can also be made to deliver the infant at a facility that is prepared to care for the infant. Prenatal therapy is possible for some conditions (diaphragmatic hernia, uropathy, spina bifida, hydrocephalus), but is experimental.

When an anomaly is identified at or after birth, inform parents promptly. More extensive discussions can occur after definitive diagnosis, when more information is available and the family has had some time to process the information, although shock and grief over the loss of their “perfect” child may interfere with their ability to assimilate information. Give the family a realistic appraisal of the condition, its prognosis, and the interventions available. Encourage them to participate actively in decisions regarding their child’s care. Frequent, open communication is the key in providing care that lessens the parents’ feelings of helplessness and facilitates their identification with their role as parents.

Care needs, teaching, and anticipatory guidance vary based on the prognosis and associated defects. Initially, the

parents are often in shock and are going through the grief process. Provide a calm, nurturing environment; clear, concise information; and opportunities to hold the baby and create memories (e.g., pictures, hand or footprints). If the infant survives, routine infant care and teaching is important, in addition to any special care needs.

Disorders of Prematurity and Low Birth Weight

Low birth weight (LBW) is defined as a birth weight less than 2,500 g (5.5 lb), and **very low birth weight (VLBW)** is a birth weight less than 1,500 g (3.5 lb). **Extremely low birth weight (ELBW)** is a birth weight less than 1,000 g (2.2 lb). The preterm birth rate in the United States is 12.7%; LBW infants account for 8.2% of all births and VLBW infants account for 1.49% (Martin et al., 2007). The increase in premature births is largely attributable to an increase in multiple births.

The causes of premature delivery remain unknown. Maternal or fetal sepsis and high-risk pregnancies, such as those with multiple gestation, abruptio placentae, and pregnancy-induced hypertension, all contribute to premature delivery. In many cases, no specific causal factor can be identified, and in some cases there are multiple causal factors.

Prematurity and LBW are the major contributors to the newborn mortality rate; these newborns account for almost 25% of neonatal deaths (Heron, 2007). Racial differences exist as well, with African American infant mortality rates approximately 2.5 times the rates for white or Hispanic infants (Heron, 2007).

LBW without prematurity (i.e., a birth weight that is low despite a pregnancy carried to term) is considered **intrauterine growth retardation (IUGR)** and is associated with causes of poor placental circulation such as maternal hypertension, smoking during pregnancy, substance abuse, and cardiac or pulmonary problems. Often, no cause can be identified in the newborn with IUGR. Such newborns may be symmetrically growth retarded, meaning that all growth parameters are compromised, or asymmetrically growth retarded, meaning that head circumference is AGA but birth weight and other growth parameters are compromised.

When women present to the hospital in preterm labor, methods to stop labor are administered, including tocolytics. When these measures fail and preterm delivery is likely, administration of antenatal steroids decreases the incidence of IVH and respiratory distress, and serves an overall protective function to the preterm newborn.

Pathophysiology

Premature newborns have a higher incidence of morbidity and mortality than term newborns. This higher incidence is likely related to LBW. Premature birth before 23 weeks' gestation is generally not compatible with life. At 24 weeks, survival to discharge is 54%, increasing to 82% at 26 weeks and 95% at 30 weeks (Jones et al., 2005). Based on birth weight, 62% survive at 600 to 699 g, 79% at 700 to 799 g, and 96% at 1,000 to 1,099 g (Jones et al., 2005).

Although premature infants have the necessary anatomic structures, many problems occur because all body systems are extremely immature. This immaturity leads to problems with thermoregulation, surfactant deficiency, chronic lung disease (CLD), PDA, sepsis, IVH, apnea of prematurity, feeding and nutrition problems, necrotizing enterocolitis (NEC), and ROP. Each of these disorders requires different specific care in addition to the general assessment and care required for premature and LBW newborns.

Assessment

The premature newborn has physical characteristics different from those of term newborns (see Focused Physical Assessment 14–1). Premature newborns' posture lacks flexion and their muscle tone is decreased. This flaccidity is obvious when the very premature newborn is supine, because the arms and legs remain extended. Also, the arm recoil is slow and reduced. As the newborn grows and matures, so does the strength and ability for flexion.

The skin is thin and may be transparent. Blood vessels are easily discernible. The skin can be very moist and

even gelatinous. The more premature the newborn is, the thinner and more gelatinous the skin. This thin skin is a poor barrier to the elements (Developmental Considerations 14–1), and exposure to caustic agents may not only impede skin integrity but also may lead to systemic effects.

Lanugo is very fine, downy body hair that develops in utero (after about 22 weeks' gestation) and is shed during the seventh to eighth month of gestation (Fig. 14–5). As the fetus grows, lanugo is abundant and then decreases again near term.

Color is an important indicator of well-being in any newborn. Inspect the mucous membranes, including the lips and tongue, for central cyanosis. Monitor for other color abnormalities, including jaundice and ruddiness, which may indicate pathology, especially if they occur within the first 24 hours.

Assess the quality and quantity of respirations; note signs of respiratory distress. Auscultate lung sounds in the axillae of the premature infant. **Periodic breathing** (clusters of breaths separated by intervals of apnea) is common in the premature newborn, and apnea may indicate sepsis, especially during the first 12 hours of life.

Observe the chest to assess movement and symmetry, as well as the presence or absence of an active precordium. An active precordium is easily seen on the thin chest of a premature newborn and may indicate a PDA. Auscultate all heart borders. Note the quality and location of murmurs, which are common to the premature newborn.

The head of the premature newborn is large in proportion to the rest of the body. This disproportion reflects the cephalocaudal progression of growth.

DEVELOPMENTAL CONSIDERATIONS 14–1

Factors Modifying Cutaneous Water Losses in Preterm Infants

- Young gestational age TEWL increases proportionally with degree of prematurity
- Increasing postnatal age TEWL decreases as child matures
- Increased ambient temperature TEWL increases as temperature increases
- Increased ambient humidity TEWL decreases proportionally as humidity increases
- Use of radiant warmer TEWL increases 40% to 100%
- Radiant warmer with heat shield TEWL increases 20% to 40%
- Phototherapy TEWL increases by up to 50%

FIGURE 14–5. Lanugo on a premature neonate.

Gently palpate the anterior fontanel to assess for fullness or depression. Normally, the anterior fontanel is soft and flat. Often, the sutures of the premature head are overriding, causing a palpable ridge, especially after the first 4 to 5 days of life.

The abdomen of a premature newborn is soft and slightly rounded, but not generally distended unless resuscitation at birth included bag-and-mask ventilation, which may have forced air into the stomach. Auscultate the abdomen for bowel sounds in all four quadrants. Abnormal abdominal examination findings are distention, discoloration, observable bowel loops, and absence of bowel sounds. If the premature newborn is receiving enteral nutrition, perform an abdominal examination before every feeding and measure the abdominal girth at regular intervals. Also note feeding residuals (food that is present in the stomach 3 hours after feeding), including amount and color. Stools may be tested for the presence of occult blood and reducing substance. Stools containing microscopic amounts of blood will test positive for occult blood, which may be an early sign of NEC or another feeding disorder. Stools that contain more than 0.5% sugar will test positive for reducing substance; this finding is abnormal and may indicate feeding malabsorption.

Interdisciplinary Interventions

The birth of a sick or premature infant is a stressful event for the family. Sources of parental stress include illness of the infant, separation of parents and other family members from their infant and each other, and a need for increased emotional and financial support (Griffin, 2006). Use a family-centered approach to provide effective support to these families in crisis by

- Establishing caring relationships with parents
- Treating parents as partners in the care of their infant
- Providing technically competent care to the infant
- Providing clear explanations to the parents
- Giving parents an opportunity to see and touch their infant in the delivery room or prior to transport

Conversely, specific behaviors by nursing staff may increase the stress experienced by the mother and family (Fenwick et al., 2001). These behaviors include

- Restricting the mother's access to the infant
- Using negative language and demeanor (such as lecturing, ordering, short conversations, unfriendly attitude)
- Directing the mother in infant care (as opposed to teaching infant care)
- Ignoring or minimizing the mother's concern for her infant

Nurses in the NICU have a vital role in supporting families during the prolonged hospitalization of their sick newborn. Using a family-centered approach, with an empathetic and active listening demeanor, will greatly improve the mother's experience and support the family as a whole.

Community Care

In general, as immaturity increases and birth weight decreases, the likelihood of intellectual and neurologic deficits (e.g., CP, hearing and vision defects, learning difficulties) increases. Surveillance for neurodevelopmental delays or problems, provision of early intervention and special education resources, and long-term follow-up must be provided for all newborns experiencing a major illness.

Thermoregulatory Problems

QUESTION: Gabriella is at risk for hypothermia for many reasons: her weight-to-surface area ratio, her lack of fat stores, and her inability to maintain a flexed position. Look carefully at Nursing Interventions 14–2. What nursing interventions would prevent or ameliorate heat loss specifically for Gabriella?

Maintaining a normal temperature is vital to the premature newborn, because hypothermia leads to deleterious consequences (Chart 14–1). Term newborns respond more efficiently to hypothermia than preterm newborns. Limited ability to produce heat, coupled with many mechanisms of heat loss, make the premature newborn very susceptible to hypothermia. The term newborn is able to increase muscle activity, initiate nonshivering or chemical thermogenesis, and utilize brown fat stores to generate heat. The preterm newborn is unable to increase muscle activity or to assume a flexed position because of poor motor tone and limited brown fat stores. Additionally, premature newborns may be unable to initiate thermogenesis, because of limited stores of fat and insufficient amounts of other chemicals such as glucose, liver enzymes, and hormones.

Nonshivering thermogenesis involves the release of norepinephrine to mobilize brown fat to increase metabolic rate and generate heat. The quantity of brown fat increases with increasing gestational age. In the term newborn, brown fat is located in the axillae, between the scapulae, in the mediastinum, around the liver, and down the

NURSING INTERVENTIONS 14–2

Mechanisms of Heat Loss and Prevention Techniques

Heat Loss Mechanism	Example	Prevention Techniques
<i>Convection:</i> Heat loss occurring when heat is exchanged between two objects within the same environment	Loss of heat from the neonate's skin to the cooler, surrounding air. For example, cold drafts in the delivery room or nursery will lead to heat loss through convection. The premature neonate is especially vulnerable to this type of heat loss, because the amount of body surface exposed is increased as a result of the lack of a flexed posture from poor muscle tone.	Warm the delivery room or nursery. Avoid drafts. Prewarm the isolette. Transport the neonate in an isolette. Use plastic sleeves on the isolette portals. Swaddle the neonate with warmed blankets.
<i>Conduction:</i> Loss of heat through direct contact with an object that is cooler	Placing a neonate on a cold scale or next to cool blankets	Pad the scale with a warm blanket before weighing. Use warm blankets to dry the neonate.
<i>Evaporation:</i> Loss of heat through conversion of water to its gaseous state	A newly delivered neonate who is wet with amniotic fluid and a neonate receiving a bath Extremely premature neonates are very vulnerable to evaporative heat loss as a result of thin and extremely permeable skin.	Dry the neonate quickly after delivery or bathing. Warm all solutions before applying to the neonate. Administer warmed oxygen.
<i>Radiation:</i> Loss of heat between two objects in the environment across a gradient that are not in direct contact with each other	Loss of neonate's body heat to the surrounding, cooler incubator walls	Avoid placing the bassinet/isolette near cold walls or windows. Use a double-walled isolette. Prewarm the isolette.

spine (Fig. 14–6). Use of brown fat increases the metabolic rate considerably and is initiated when the newborn is in an environment colder than the neutral thermal range. A neutral thermal environment is one in which the newborn

maintains a normal core temperature with minimal oxygen consumption and calorie expenditure. Heat loss is generated through convection, conduction, evaporation, and radiation (see Nursing Interventions 14–2).

CHART 14–1 THERMOREGULATION IN PRETERM INFANTS

Predisposing factors for thermoregulatory problems:

- Lack of subcutaneous and brown fat stores
- Thin skin
- Immature CNS
- Limited ability to assume a flexed posture
- Increased surface area-to-body mass ratio

Consequences of hypothermia:

- Increased metabolic rate and oxygen demand
- Apnea
- Respiratory distress
- Cyanosis

ANSWER: After delivery, drying Gabriella quickly is a measure to prevent evaporation; however, one of the most effective interventions is to transfer the infant to a double-walled isolette at a neutral thermal temperature setting to minimize heat loss from convection, conduction, and radiation. Nurses have struggled with the feelings that neonates in isolettes are not as accessible, but this treatment provides much better protection from heat loss and fluid and electrolyte disturbances.

Assessment

Carefully monitor the temperature of the newborn to detect hypo- or hyperthermia early. Although controversy exists regarding the exact optimal body temperature for preterm infants, term infants do best with an axillary

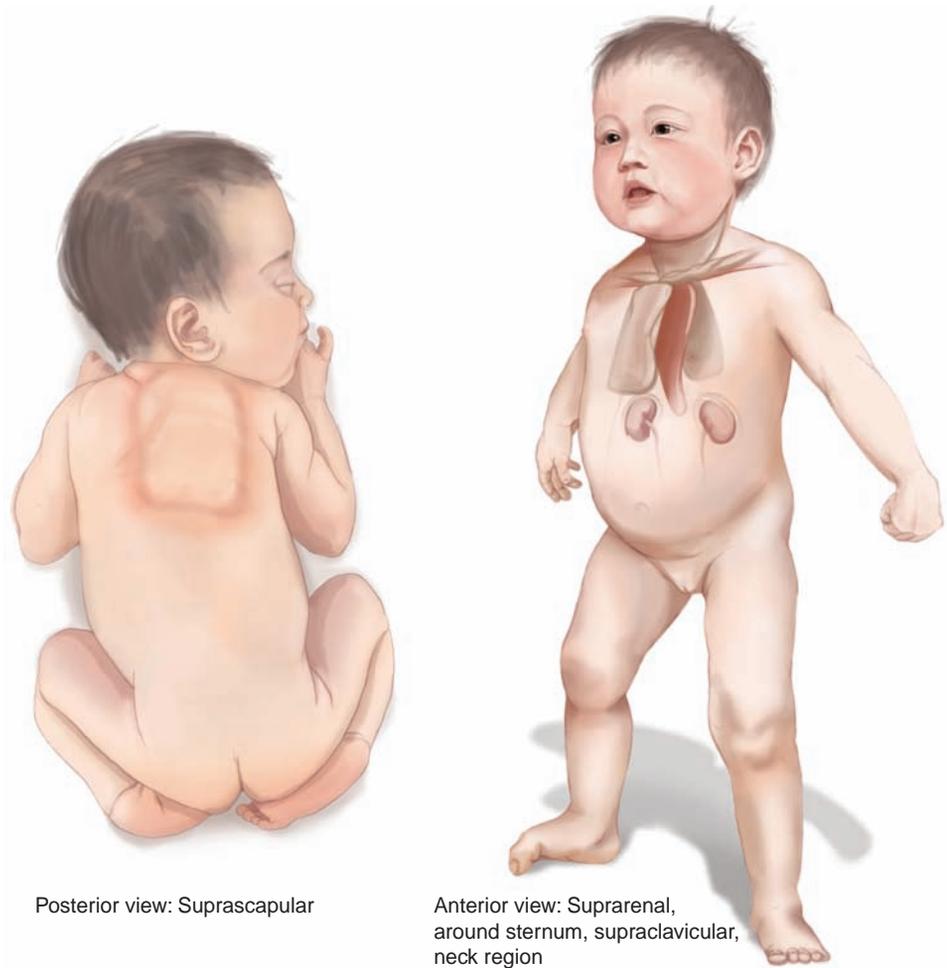

FIGURE 14-6. Location of brown fat in term neonates.

temperature between 97.2 °F and 99.9 °F (36.2 °C and 37.7 °C). Hypothermic newborns may appear pale, with acrocyanosis or central cyanosis, mottling, and signs of respiratory distress. Chronic hypothermia in newborns may present as poor weight gain, metabolic acidosis, apnea, and bradycardia. Hyperthermia presents with an elevated temperature, heart rate, and respiratory rate, and the skin may appear ruddy.

Interdisciplinary Interventions

Preventing cold stress, promoting a neutral thermal environment, and monitoring for hypothermia are cornerstones to caring for all newborns, especially premature infants (Clinical Judgment 14-1). Nursing interventions to decrease heat loss begin at delivery: Warm the delivery room and quickly dry the newborn to prevent evaporative heat loss. Remove the wet linen to prevent conductive heat loss. Also warm the scales, stethoscopes, and blankets, and place a cap on the premature newborn's head to prevent heat loss. Other devices that may be used in the NICU to promote a neutral thermal environment include radiant warmers, isolettes, heat shields, plastic wraps, and warming pads (Fig. 14-7).

Extremely preterm infants present special thermoregulation concerns in the delivery room, because their very

thin skin leads to increased evaporative heat loss (Fig. 14-8; Tradition or Science 14-2).

Closely monitor the newborn's skin and core temperatures, and the isolette or ambient temperature. Apply a skin probe to continuously monitor skin temperature in all premature newborns under a radiant warmer or in an isolette. The skin temperature is the first to decrease in cold stress. The lower left abdomen is the ideal place for a skin probe; avoid areas over brown fat and bone, such as over the liver and the spine. Secure the skin probe in place; if it is accidentally dislodged, the device may sense cooler room air, generate heat in response, and overheat the infant. Monitor the location of the probe to prevent thermoregulatory problems. Do not allow the newborn to lie on it, which may increase the temperature readings artificially. Monitor the newborn's core temperature by the axillary route, every hour until it is stable, and then every 2 to 3 hours.

KidKare ■ Avoid routine rectal temperatures, because they may cause tissue damage and are stressful to the newborn.

Compare the isolette ambient temperature with previous measurements of ambient temperature to detect

CLINICAL JUDGMENT 14-1

Preterm Infant With Hypothermia

Yolanda is an infant, 32 weeks' gestation, just admitted to the NICU after a precipitous delivery in the emergency department. She was placed under the radiant warmer on admission. Vital signs are heart rate, 160 beats per minute; respiratory rate, 80 breaths per minute; temperature, 96.4 °F (35.8°C) axillary; and weight, 2,330 g. Yolanda has nasal flaring with grunting; pulse oximeter readings are dropping into the 80s. She is pale with acrocyanosis, has a weak cry, is floppy, and shows minimal response to stimulation. Laboratory values are as follow: pH, 7.31; blood bicarbonate, 18 mEq/dL; serum glucose, 25 mg/dL.

Questions

1. What data from the assessment are indicative of a clinical problem?
2. What are pertinent nursing diagnoses that must be considered at this time?
3. Considering Yolanda's history, which nursing diagnosis must be addressed immediately and why?
4. What nursing actions must be implemented to prevent further deterioration in Yolanda's status?
5. What parameters must be monitored carefully until Yolanda is normothermic, and routinely after that?

Answers

1. Low temperature, symptoms of respiratory distress (grunting, nasal flaring, tachypnea), oxygen saturation in the 80s, pale, floppiness with minimal response to the environment. Acrocyanosis would be normal during the first hours after birth; central cyanosis would indicate a problem. An infant of 32 weeks' gestation would be hypotonic but should demonstrate limb recoil with stimulation and would respond to the environment. Abnormal laboratory values include pH and bicarbonate levels that reflect acidosis, and a serum glucose value of 25 mg/dL, which indicates hypoglycemia.
2. Hypothermia
Impaired tissue perfusion: cardiopulmonary, cerebral, gastrointestinal, peripheral, renal
Impaired gas exchange
Risk for infection
Risk for disorganized infant behavior
Risk for impaired parent/child attachment
3. Hypothermia must be addressed immediately because it will create or exacerbate other clinical problems such as respiratory distress, acidosis, and hypoglycemia. Tachypnea is caused by the increased oxygen demand from the increased metabolic rate to keep warm. Hypothermia leads to peripheral vasoconstriction, resulting in decreased tissue perfusion and subsequent hypoxia and metabolic acidosis. These lead to pulmonary vasoconstriction, which results in increased pulmonary artery pressure and right-to-left shunting of blood, worsening the hypoxia. Hypoxia may impair surfactant release, further worsening the respiratory distress and acidosis. Increased metabolism also consumes glucose, leading to hypoglycemia. Breakdown of glycogen to glucose while hypoxic generates extra lactic acid, worsening the acidosis.
4. Ensure that the temperature probe for the radiant warmer is positioned on a solid mass surface or the trunk or lower extremities, not on air-filled cavities such as the stomach or lungs. Position the probe on the surface of the infant that faces the heat source; the infant must not lie on the probe. Ensure that the warmer is on servocontrol (controlled by the infant's temperature, not manually). Position the warmer away from drafts and opening doors. Make sure that Yolanda is dry and on dry linen. If these are in place, Yolanda may require an additional heat source such as a heat lamp, warmed blankets, or artificial heat blankets. Prewarm equipment such as stethoscopes and scales.
5. Temperature 97.2 to 99.1 °F axillary (36.2–37.3 °C), cardiorespiratory status, arterial blood gases (pH, bicarbonate, oxygen), blood glucose

temperature instability, which is an early sign of sepsis. As the newborn's skin temperature decreases, the ambient temperature will increase accordingly. Investigate further if any changes in ambient temperature occur.

Clustering care, if the newborn tolerates this approach, is one method to reduce heat loss and limit fluctuations in temperature. Collaborate with other members of the healthcare team to time procedures and examinations to

limit heat losses and to provide extended sleep periods. However, remain alert to signs of stress in the newborn (as previously discussed), because some newborns are unable to handle many procedures or care activities performed at one time. Individualized care is the goal; assess the ability of the newborn to tolerate interactions and handling. If the newborn exhibits signs of stress, the nurse may need to stop and give the newborn time to recover.

FIGURE 14-7. Various methods help neonates maintain thermoregulation. (A) Isolette. (B) Radiant warmer. (C) Plastic wrap. (D) Combination unit: radiant warmer and isolette.

Radiant Warmers

Radiant warmers provide heat quickly and efficiently and allow access to the newborn for stabilization and resuscitation measures. However, they allow for convective heat loss and an increased insensible water loss from the skin,

FIGURE 14-8. At birth, the body of an extremely preterm infant may be placed in a plastic bag to conserve heat.

especially in the ELBW newborn. Therefore, use radiant warmers for initial stabilization only and move the newborn to an isolette as soon as possible.

Isolettes

An isolette provides minimal radiant and convective heat losses and allows for constant visual observation of the newborn. Use the portholes, which allow for minimal heat loss during nursing care, at all times. Avoid opening the isolette unnecessarily. Most isolettes have double walls, which serve as a buffer to radiant heat loss because the inside wall is warmed by the ambient air temperature of the isolette.

Heat Shields

Heat shields are effective in decreasing convection and radiant heat loss and assist in providing a microenvironment around the newborn. Made of Plexiglas or plastic, heat shields are an additional tool to assist with temperature instability. However, because these devices may also block the warming equipment from providing heat to the newborn, they may be inappropriate for use in the cold-stressed newborn.

TRADITION OR SCIENCE 14–2

What is the best method to maintain body temperature in the delivery room of the ELBW infant?

EVIDENCE-BASED PRACTICE

Studies demonstrated an improvement in delivery room and NICU admission temperatures in ELBW infants placed in a thermoregulation wrap (polyethylene or vinyl bag) at delivery compared with those preterm newborns cared for using standard Neonatal Resuscitation Program thermoregulation techniques (drying and removing wet linen) (Cramer et al., 2005; Knobel, Wimmer, & Holbert, 2005; Mathew et al., 2007; Vohra et al., 2004; Wimmer et al., 2002). Polyethylene wrap should be used for infants weighing less than 1,500 g (American Academy of Pediatrics and American Heart Association, 2005; Knobel & Holditch-Davis, 2007).

Plastic Wraps

Plastic wraps have been used to reduce evaporative heat losses when premature newborns are cared for in radiant warmers. Plastic wraps are often reserved for the ELBW newborn who may have excessive heat and insensible water losses from thin, gelatinous skin. Most premature newborns are cared for within isolettes and combination units, which make the plastic wrap unnecessary.

Combination Units

Combination units, such as the Giraffe Omnibed, serve as both a radiant warmer (in the open position) and an isolette (in the closed position). Often used for the very preterm newborn, these combination units provide the benefits of an isolette (with built-in humidification system) in addition to the benefits of quick and easy access to the newborn (for surgeries and other procedures).

Surfactant Deficiency

QUESTION: Gabriella is responding well to the surfactant therapy she received. What is the role of the nurse assessing and responding to Gabriella's changing lung compliance?

Respiratory distress, common in premature newborns, is often the presenting symptom of many diseases and problems. Respiratory distress may be caused by sepsis, hypoglycemia, hypothermia, or lung immaturity. In utero, the placenta performs respiratory functions, because the fetus' lungs are filled with fluid and do not participate in air exchange. At delivery, the lungs normally become air filled, are perfused by blood, and participate in oxygen and carbon dioxide exchange. To perform this function, the lungs must inflate properly, a process that requires the presence of surfactant.

Pathophysiology

The lungs of a premature newborn lack a phospholipid called **surfactant**, which is necessary for effective respiratory function. Surfactant acts like a detergent to reduce the surface tension of the lungs, promoting their expansion. Without surfactant, the lung collapses after every expiration and reinflates with great difficulty, requiring the newborn to generate intense pressures with every breath. Surfactant is generally produced in the lung at approximately 35 weeks' gestation, but production may be delayed by maternal complications such as diabetes.

Assessment

The diagnosis of surfactant deficiency is based on maternal history, neonatal physical examination, and laboratory and radiographic findings (Table 14–3). The newborn with surfactant deficiency displays signs of moderate to severe respiratory distress, including sternal, substernal, and intercostal retractions; grunting; and nasal flaring. Central cyanosis is common, and hypotension may be present if the newborn is severely distressed and acidotic.

Surfactant deficiency is diagnosed by chest radiograph and clinical presentation (presence of respiratory distress, carbon dioxide retention, and oxygen requirements). Although not routinely used for diagnosis, laboratory studies include a lung profile that may reveal an immature lecithin-to-sphingomyelin ratio. The lung profile may be done on the amniotic fluid at the time of rupture of the membranes, or a tracheal aspirate may be obtained from the newborn. Analysis of arterial or capillary blood gases may reveal respiratory acidosis from carbon dioxide retention and hypoxemia. Electrolyte levels may show

TABLE 14–3

Indicators of Surfactant Deficiency

Maternal History/Factors	Physical Examination of Newborn	Lab/Radiographic Findings
Premature labor	Cyanosis	Lecithin-to-sphingomyelin ratio <2:1 on tracheal aspirate
Fetal gestational age <35 weeks	Labored breathing	Respiratory/metabolic acidosis
Lack of treatment with corticosteroids	Retractions	Reticulogranular pattern on chest radiograph
Lecithin-to-sphingomyelin ratio <2:1 on amniotic fluid	Tachypnea	Massive atelectasis on air bronchogram
Absent phosphatidylglycerol	Grunting	
	Nasal flaring	
	Poor tissue perfusion	
	Skin mottling	
	Hypotension	

dehydration, especially in the extremely premature newborn, from the increased insensible water loss that occurs through thin skin. Finally, the chest radiograph may reveal a reticulogranular or “ground-glass” pattern evenly throughout the lungs, caused by massive atelectasis.

Nursing Diagnoses and Outcomes

Nursing diagnoses and outcomes generally applicable for newborns with a health challenge are presented in Nursing Plan of Care 14-1. In addition, the following nursing diagnoses and outcomes may apply for a newborn with surfactant deficiency:

Impaired gas exchange related to effects of poor lung compliance and atelectasis

Outcomes: Infant will display blood gas levels within normal limits.

Infant will show no signs of adverse effects from assisted ventilation or oxygen administration.

Interdisciplinary Interventions

Care of the newborn in respiratory distress caused by surfactant deficiency involves monitoring all body functions and supporting the newborn with supplemental oxygen and assisted ventilation if needed. The mainstay of treatment for surfactant deficiency is administration of exogenous surfactant. Many types of exogenous surfactant are available; all require intratracheal administration. Exogenous surfactant coats the lungs to improve ventilation and oxygenation, and to reduce protein leakage that commonly accompanies surfactant deficiency. Protein leakage occurs in damaged lungs, causing pulmonary edema. Overall, the most commonly reported response after administration of surfactant is rapidly improved oxygenation and a decreased need for respiratory support.

The use of exogenous surfactant has improved initial outcomes for newborns with surfactant deficiency. However, the incidence of CLD, a morbidity associated with surfactant deficiency, has not changed over many years (Stevens et al., 2007).

Surfactant administration may have adverse effects on the newborn. Instilling surfactant into the trachea may cause acute reduction in oxygenation by blocking large and small airways. Careful ventilation is needed to minimize this effect. When surfactant is administered, lung compliance may suddenly increase. Because of this rapid change in lung compliance, pneumothorax can occur. Monitor ventilation requirements carefully and decrease pressures, according to the newborn’s response, to avoid overdistending the lungs.

The nurse, in collaboration with respiratory therapists and the medical team, must be vigilant in monitoring chest wall expansion, improved breath sounds, and a decreased need for oxygen. Decrease the amount of supplemental oxygen according to the newborn’s overall skin color and the pulse oximeter readings. The nurse has an important role in monitoring the newborn before, during, and after administration of surfactant (Nursing Interventions 14-3).

NURSING INTERVENTIONS 14-3

A Neonate Receiving Surfactant Administration

Before Surfactant Administration

- Obtain and record baseline vital signs.
- Note ventilator settings, oxygen settings, pulse oximeter readings, and transcutaneous monitor readings.

During Surfactant Administration

- Note amount instilled and neonate’s response.
- Monitor vital signs continuously.
- Watch for cyanosis and improved chest wall movement.
- Increase oxygen and ventilation as needed.

After Surfactant Administration

- Avoid suctioning for at least 4 hours if possible.
- Monitor vital signs frequently.
- Carefully observe for signs of improvement, including increased oxygenation, decreased need for respiratory support, and improved chest movement.
- Wean ventilator settings as needed.

ANSWER: An infant’s response to surfactant therapy can be very dramatic. The nurse must be very attentive. The change in lung compliance may mean that the inspiratory pressure previously required just to open Gabriella’s “stiff lungs” is now enough to almost bounce her off the bed. Just as dramatic may be the change in oxygenation. Gabriella became noticeably pinker even as the nurse decreased the oxygen percentage delivered by the ventilator. The nurse focuses on the infant’s response to the mechanical ventilation and communicates the changes or adjusts the ventilator settings, within ordered parameters, to maintain optimal ventilatory support. For example, the nurse may decrease the amount of supplemental oxygen to maintain her oxygen saturation within normal limits (85%–95%) and wean the ventilator settings to the lowest amount of pressure to minimize lung trauma. The nurse also relays and explains the changes to concerned family members (the mother is often still receiving care).

Chronic Lung Disease

Despite surfactant replacement, newer ventilators, and improved ventilation strategies, CLD occurs. Lung disease is the result of positive-pressure ventilation (PPV)

and exposure to supplemental oxygen. PPV is not physiologic (negative pressure is how air enters the lung in normal breathing), and alternating lung over- and underinflation leads to ventilator-induced injury. Lung tissue that is overinflated sustains cellular disruption, which initiates the inflammatory process within the lung. Excess fluid in the lung (from the inflammatory process) leads to the need for ongoing assisted ventilation, supplemental oxygen, and diuretics (to control the fluid in the lungs).

The most commonly accepted definition of CLD is oxygen dependency at 28 days of life, regardless of gestational age. The estimated incidence among premature infants is 20% (Baraldi and Filippone, 2007). However, no standard, evidenced-based definition of CLD exists, making research results involving CLD patients difficult to interpret and compare. The incidence of CLD clearly increases with decreasing gestational age. The cause of CLD is multifactorial (Chart 14–2).

Infants with CLD may continue to have respiratory problems throughout childhood. Those infants who require supplemental oxygen at discharge from the NICU are at an increased risk for rehospitalization for respiratory problems throughout the first 2 years of life. To prevent complications after discharge, work collaboratively with the medical team to determine the discharge plan for infants with supplemental oxygen. Teach parents methods to reduce harmful exposures in the home (pets, environmental tobacco smoke) that may exacerbate respiratory symptoms, use of home apnea monitoring, and administration of medications.

Patent Ductus Arteriosus

QUESTION: Gabriella does have difficulties with her ductus arteriosus relaxing, which allows additional blood flow to be diverted back to the lungs. Of the symptoms mentioned, which do you think are the early warning signs that a PDA exists?

The ductus arteriosus is a fetal shunt located between the pulmonary artery and the aorta. In fetal circulation, the ductus arteriosus allows the majority of oxygenated

blood from the placenta to flow directly to the systemic circulation, bypassing the lungs. After birth, the oxygen content of the blood increases, and the ductus arteriosus functionally closes in response. In PDA, the fetal shunt persists after delivery—that is, the ductus arteriosus stays open. This condition is common among preterm newborns. Because vascular resistance in the pulmonary artery is less than the systemic pressure in the aorta, persistence of a PDA leads to excessive blood volume in the pulmonary circulation, causing pulmonary edema. Diagnostic signs include the presence of congestive heart failure (a late sign), unstable blood pressures and widened pulse pressures, bounding peripheral pulses, metabolic acidosis, pulmonary edema, and an increasing need for oxygen support. A PDA is diagnosed from a bedside echocardiogram, a chest radiograph, and the presence of clinical symptoms (see Chapter 15).

Initially, treatment of PDA during the neonatal period includes fluid restriction, diuretics, and ventilator support. If the newborn remains symptomatic of PDA, medication therapy is initiated to close a PDA. Indomethacin or ibuprofen, prostaglandin inhibitors that promote ductal closure, are both equally effective in closing the PDA; ibuprofen is better tolerated by the neonatal kidney but may still cause adverse effects (Giniger et al., 2007). These drugs are most effective when given during the first week of life. Side effects include elevated blood urea nitrogen and creatinine, decreased urine output, and decreased platelet function. Evaluate these values at regular intervals during treatment.

If administering indomethacin or ibuprofen is ineffective, the premature newborn may need surgical closure of the PDA. Potential complications include phrenic nerve paralysis, lung contusions, sepsis, and ligation of the pulmonary artery. Mortality and morbidity is highest in the very sick, unstable newborn. Details of surgery and complications are discussed in Chapter 15.

ANSWER: Often, the first sign the nurse sees is an unexplained drop in oxygen saturation on the pulse oximeter. The appropriate action is to initiate problem solving starting with Gabriella and the airway, breathing, and circulation (ABC). Is her airway open? Place a stethoscope on her chest and assess breath sounds and heart sounds. The PDA usually creates an easily identifiable “washing machine” murmur. Thus, the change in oxygenation and the presence of a murmur are two early warning signs that blood is shunting through the ductus arteriosus into the pulmonary circulation.

CHART 14–2 RISK FACTORS FOR CHRONIC LUNG DISEASE

- Birth weight less than 1,500 g
- Premature birth
- Surfactant deficiency
- Treatment with positive-pressure mechanical ventilation and high concentrations of inspired oxygen
- Evidence of baro/volutrauma
- History of infection

Neonatal Sepsis

QUESTION: Why is Gabriella treated as if she is septic?

Sepsis is a common complication in premature newborns because of their inability to adequately respond to infection, their exposure to bacteria from invasive devices,

their thin skin, and their poor nutritional state. Additionally, sepsis may result transplacentally before birth, from prolonged rupture of membranes, or from direct contact with the vaginal canal during birth. Maternal or fetal sepsis may be a cause of premature delivery, which often complicates the newborn's hospital course and results in increased mortality. The premature newborn's immature immune system responds poorly to infection, because limited neutrophil storage and altered neutrophil function weaken the inflammatory response.

Sepsis can kill a newborn within hours because of the infant's inability to localize infections. The nurse must be vigilant for the subtle signs of sepsis and articulate them to the other members of the healthcare team. Early identification and treatment of infection can prevent serious complications.

Assessment

Signs of sepsis in premature newborns are often vague, subtle, and nonspecific, making diagnosis difficult. Apnea, lethargy, temperature instability, poor feeding, respiratory distress, increasing oxygen requirements, and hyperbilirubinemia are all signs of sepsis in the newborn. Cardinal signs of sepsis include poor feeding, increased apneic spells, jaundice, temperature instability, increased oxygen requirement, and lethargy (see Chapter 24 for further discussion of sepsis). When infection is a potential problem, the physician or advanced practice nurse will initiate a specific (septic) workup that commonly includes the following:

- Complete blood count (CBC)
- Blood cultures
- Tracheal aspirate for culture
- Urine culture
- Chest radiograph
- Lumbar puncture, to determine if meningitis is present

Positive cultures, plus a CBC showing an elevated or decreased white blood cell count, an increased number of immature white cells, and decreased platelets may indicate the presence of sepsis. Additional tests that may be performed on the cerebrospinal fluid to determine the presence of infection include glucose level, white blood cell count, and protein level.

Interdisciplinary Interventions

Preventing infections in the ELBW infant population is paramount, because neonatal infections among this high-risk group are associated with poor neurodevelopmental and growth outcomes in early childhood (Stoll et al., 2004). Preventing nosocomial infection is particularly challenging in the NICU, where the cause of almost half the infections cannot be identified (Gastmeier et al., 2007). More research is needed to determine the best, most effective methods of prevention. Meticulous hand hygiene is a mainstay in preventing nosocomial infections and must be followed by all healthcare professionals. Patient screening, isolation or cohorting infants, and use of protective clothing are also used (Gastmeier et al., 2007).

Because of the newborn's decreased ability to respond to infection, broad-spectrum antibiotics are initiated immediately; waiting for laboratory test results would delay treatment. The nurse's role is to assist with the diagnostic workup, including obtaining many of the blood samples. Additionally, maintain an ongoing assessment of the newborn, and document and communicate findings with the rest of the team. Sepsis in the newborn can escalate quickly, necessitating vigorous interventions such as intubation, volume resuscitation, initiation of dopamine and dobutamine drips to support cardiovascular function, and other resuscitative efforts. Each of these interventions has specific indications. For example, intubation is required when the newborn is apneic or in respiratory failure. Volume resuscitation in the form of normal saline restores intravascular volume that may be depleted as a result of capillary leak of fluid into the subcutaneous tissue. Dopamine and dobutamine are medications that are used to maintain blood pressure and to improve cardiac contractility.

caREminder

Every member of the family and healthcare team has a role in preventing infection. Handwashing is the number one way to prevent the transmission of nosocomial infections. All individuals must perform hand hygiene before and after handling any newborn.

Use sterile technique for all invasive procedures, such as suctioning the endotracheal tube and initiating intravenous (IV) lines. Also handle central lines using sterile technique, because these lines are an easy portal of entry for microorganisms.

ANSWER: Gabriella will be treated from birth as if she is septic because her mother's membranes ruptured prematurely (which may be because of an infection) and the membranes were ruptured for 48 hours before her delivery (which allows plenty of time for an organism to enter the uterus). Many of the symptoms of sepsis are also symptoms of prematurity. It is impossible to know whether Gabriella is floppy because of an infection, because she will be floppy at only 28 weeks' gestation. A CBC and blood culture are drawn prior to the administration of antibiotics, but as a result of their immature and inadequate response to infection, preterm infants are treated with broad-spectrum antibiotics quickly, without waiting for cultures to confirm the diagnosis.

Intraventricular Hemorrhage (IVH)

IVH (bleeding within the ventricles in the brain) is almost exclusively a problem related to prematurity, specifically in infants of less than 28 weeks' gestation. IVH is the most common brain injury in premature infants, and its incidence is directly related to the degree of prematurity. Although the incidence of IVH has declined over the years because of advances in perinatal medicine (specifically the

prenatal administration of corticosteroids), it remains at 25% to 30% for infants who weigh less than 1,500 g (Patra et al., 2006), with higher rates in the presence of decreasing gestational age, PDA, and respiratory distress syndrome.

The causes of IVH are not completely understood, but may involve the dynamic interaction between the hemodynamic status of the newborn and the fragility of the capillary bed. Clearly, preterm newborns with respiratory distress are at an increased risk for IVH. In addition to preterm birth, other risk factors include

- Chorioamnionitis
- Preeclampsia
- Hypotension
- Hypothermia
- Umbilical lines

Pathophysiology

Normally, the blood vessels of the brain are protected from fluctuations in blood flow through autoregulation. Autoregulation allows the arterioles to constrict and dilate despite fluctuations in systemic pressure to ensure constant blood flow to the brain. The premature newborn is unable to autoregulate because the CNS is immature and, as a result, blood flow to the brain varies. This fluctuation directly affects the flow to the germinal matrix: a temporary, highly vascularized structure located in the subependyma of the ventricular walls in the brain of premature newborns that produces precursor cells that will later develop into neurons and glial cells for eventual migration into the cerebral cortex. The thin-walled blood vessels of this structure are easily ruptured.

PPV, hypoxia, hypotension, and rapid volume expansion can contribute to IVH. A very sick premature newborn may have hypotension from a persistent PDA and may require assisted ventilation, which increases the risk for the development of an IVH. In IVH, the blood vessels in the germinal matrix, located in the subependymal area of the ventricles, rupture and bleed into the lateral ventricle. If the hemorrhage is large, a blood clot may form within the ventricle, or blood may spread throughout the ventricular system and into brain tissue. IVH is categorized as grades I through IV (Chart 14–3), based on results of cranial ultrasonography.

CHART 14–3 CLASSIFICATION OF INTRAVENTRICULAR HEMORRHAGE

- Grade I: Germinal matrix hemorrhage only
- Grade II: Germinal matrix hemorrhage with extension into the ventricles
- Grade III: Germinal matrix hemorrhage with dilated ventricles
- Grade IV: Intraventricular hemorrhage with extension into brain tissue

Prognosis

Prognosis for a newborn with IVH depends on the severity of the hemorrhage and the presence of associated problems, such as asphyxia and sepsis. Overall mortality for newborns with severe IVH (grades III and IV) is about 75% (Linder et al., 2003), but this rate increases if ventricular dilation and posthemorrhagic hydrocephalus develops. Newborns with grade I or II hemorrhages generally have a low incidence of long-term neurologic sequelae. ELBW infants who require long-term ventilation have high rates of neurodevelopmental impairment. A large study found that 24% of infants who were ventilated for 60 days or longer survived without impairment; however, of those ventilated for 120 days or longer, all survivors were impaired (Walsh et al., 2005).

Common complications of IVH are ventricular dilation, posthemorrhagic hydrocephalus, and periventricular leukomalacia. Ventricular dilation occurs in approximately 50% of newborns with IVH; it is caused by a clot that blocks the flow of cerebrospinal fluid. Posthemorrhagic hydrocephalus results from progressive ventricular dilation and occurs in 31% of all grades III and IV IVH (Linder et al., 2003). Moderate to severe IVH has the highest incidence of developing hydrocephalus. Signs and symptoms of hydrocephalus include increasing head circumference, change in level of consciousness, apnea and bradycardia spells, and increasing need for respiratory support.

Periventricular leukomalacia is an ischemic injury to the white matter in the brain. This injury is commonly noted in newborns who die of IVH. The true incidence of periventricular leukomalacia is unknown, because this complication cannot be accurately detected with bedside cranial ultrasound testing.

Assessment

Common symptoms of IVH include a sudden decrease in hematocrit, severe and sudden unexplained deterioration of vital signs, bulging fontanel, changes in activity level, and sudden lethargy. The diagnosis is confirmed by cranial ultrasonography. More than 90% of newborns with IVH bleed within the first 4 days of life, and 50% bleed within 24 hours of birth.

Nursing Diagnoses and Outcomes

Nursing diagnoses and outcomes generally applicable for newborns with a health challenge are presented in Nursing Plan of Care 14–1. In addition, the following may be applicable for a newborn with IVH:

Ineffective cerebral tissue perfusion related to effects of blood within the ventricle

Outcome: Newborn will maintain cerebral perfusion pressure adequate to provide oxygen and nutrients to the brain.

Interdisciplinary Interventions

Preventing IVH is the most important goal, because once IVH has occurred, the damage to the CNS is irreversible. Nursing procedures such as endotracheal tube suctioning

and rapid infusions of fluid can cause IVH (McLendon et al., 2003). Nurses are crucial in implementing IVH prevention techniques, because many of these techniques involve the way that care is delivered to this fragile population (see Nursing Interventions 14–4).

Acute management of IVH includes support of all vital functions, including increasing ventilation pressures and supplemental oxygen to maintain normal ventilation and oxygenation, providing packed red blood cells to correct anemia caused by bleeding, and infusing volume replacement to maintain tissue perfusion. During the acute event of an IVH, monitor all vital signs carefully and frequently, because the newborn's condition may be extremely unstable.

Apnea of Prematurity

Apnea is defined as a cessation of respiratory air flow for 20 seconds or longer in the preterm newborn and 15 seconds or longer in the term newborn (see Chapter 16). Pathologic apnea is a pause in respiration associated with cyanosis, marked pallor, hypotonia, or bradycardia. *Apnea of prematurity* (AOP) refers to apnea in newborns of less than 37 weeks' gestation; it usually presents between days 2 and 7 of life. As the premature newborn develops and matures, the incidence of apnea decreases. All newborns are periodic (irregular) breathers. However, the cessation of breathing for longer than 20 seconds is abnormal and requires intervention, regardless of gestational age. The incidence of AOP decreases as gestational age at birth increases. It is estimated that more than 50% of preterm infants experience AOP, with nearly all experiencing AOP when they weigh less than 1,000 g at birth (Finer et al., 2006).

Apnea in the newborn may be the first presenting sign of many problems. Specifically, apnea can result from sepsis, seizures, metabolic disturbances, and intrauterine drug exposure.

Pathophysiology

AOP is a result of the immaturity of the CNS, which fails to initiate breathing. The medulla oblongata, the most inferior part of the brain stem, controls respiratory drive. As a result of prematurity, the patterned firing of the neurons in this section of the brain is altered. Additionally, premature newborns' response to hypoxemia and hypercarbia is diminished, leading to apnea. Bradycardia may follow apnea, leading to the often-used term in the NICU of *apnea-bradycardia spells* or *A/B spells*.

Assessment

Apnea that occurs in premature newborns with no underlying disease is generally categorized as AOP. The physical examination reveals a vigorous premature newborn with no signs of sepsis or metabolic disturbances. If you observe cessation of breathing, intervene as needed; report all incidences to the medical team. To initiate the appropriate treatment, it is important to investigate all potential causes of apnea. AOP is a diagnosis of exclusion, in that no specific diagnostic tests exist.

If AOP continues, and the infant is approaching discharge, a pneumocardiogram may be performed. This study continuously measures heart rate, respiratory rate, and pulse oximetry values during a specified period. This information is plotted on a graph and can clearly demonstrate the occurrence of apneic spells and any associated bradycardia and desaturation. Results from this study are used to determine the type of apnea, rule out any possible treatable cause, and determine discharge needs such as home cardiac monitoring.

Nursing Diagnoses and Outcomes

Nursing diagnoses and outcomes generally applicable for newborns with a health challenge are presented in

NURSING INTERVENTIONS 14–4

Reducing the Risk of Intraventricular Hemorrhage

- Optimize the peripartum management of the ELBW newborn in the delivery room (standard resuscitation team, standardized resuscitation techniques).
- Implement methods to improve temperature upon admission to the NICU, such as using the polyethylene wrap in the delivery room, preheating the isolette or combination unit, putting a hat on the neonate's head.
- Minimize stressors using developmental care techniques: reduce environmental noise, light, and noxious stimuli; support infant in a flexed, tucked position; avoid unnecessary procedures and routine suctioning.
- Monitor infant for stress cues and alter interventions based on these observations.
- Promote self-comforting behaviors in infant.
- Manage pain.
- Avoid tight bili masks (eye shields).
- Maintain the infant's head in a neutral, midline position as often as possible for the first 3 days of life.
- Perform vigilant monitoring of hemodynamic and respiratory status and intervene immediately to avoid rapid changes in these vital functions that may lead to IVH.
- Avoid overhydration.

Nursing Plan of Care 14–1. In addition, the following may be applicable for a newborn with AOP:

Ineffective breathing pattern related to effects of an immature CNS

Outcomes: Infant's apnea and bradycardia spells will be recognized immediately and stimulation initiated.

Infant will experience no adverse sequelae resulting from ineffective breathing pattern.

Interdisciplinary Interventions

Nursing interventions include close monitoring for apnea and subsequent bradycardia, and appropriate documentation. During an apnea–bradycardia spell, gently stimulate the newborn by rubbing his or her back or foot to initiate breathing. If this measure is not effective, provide more vigorous stimulation, progressing to bag-and-mask ventilation as necessary (Fig. 14–9).

Documentation is extremely important and should include the following:

- Duration of apneic episode
- Lowest heart rate during the episode
- Lowest oxygen saturation
- Interventions performed

Position the newborn in the prone position to minimize the number of apneic episodes. The prone position improves oxygenation and decreases the work of breathing.

The medical team initiates pharmacotherapy if the spells are severe or frequent. Severe or frequent spells cause the body to shunt blood from nonvital organs, such as the bowel, to vital organs such as the heart and brain. Treatment is initiated to control the spells, avoid ischemic damage to the bowel, and prevent the development of NEC.

Treatment includes respiratory stimulants such as the methylxanthines (aminophylline, theophylline, and caffeine) and, when needed, doxapram to decrease the occurrence of apnea. These drugs act by stimulating the CNS and increasing alveolar ventilation. Common side effects of caffeine and theophylline are tachycardia and irritability. Additionally, oral formulations may be irritating to the gut and lead to feeding intolerance. These medications should not be given if the heart rate is more than 180 beats per minute. If medications are not successful, continuous positive airway pressure (CPAP) may be initiated through a nasal device to help decrease the work of breathing and improve lung compliance.

Most newborns outgrow AOP and can be successfully weaned from medications and CPAP. However, some symptomatic newborns, those with cyanotic color changes and bradycardia, require medications at discharge and home apnea monitoring. Teach parents how to correctly administer medications and monitor for side effects. Also provide teaching related to the apnea monitor and newborn cardiopulmonary resuscitation (see TIP 16–4).

Community Care

Newborns discharged with home apnea monitors and medications to treat apnea need close follow-up (see

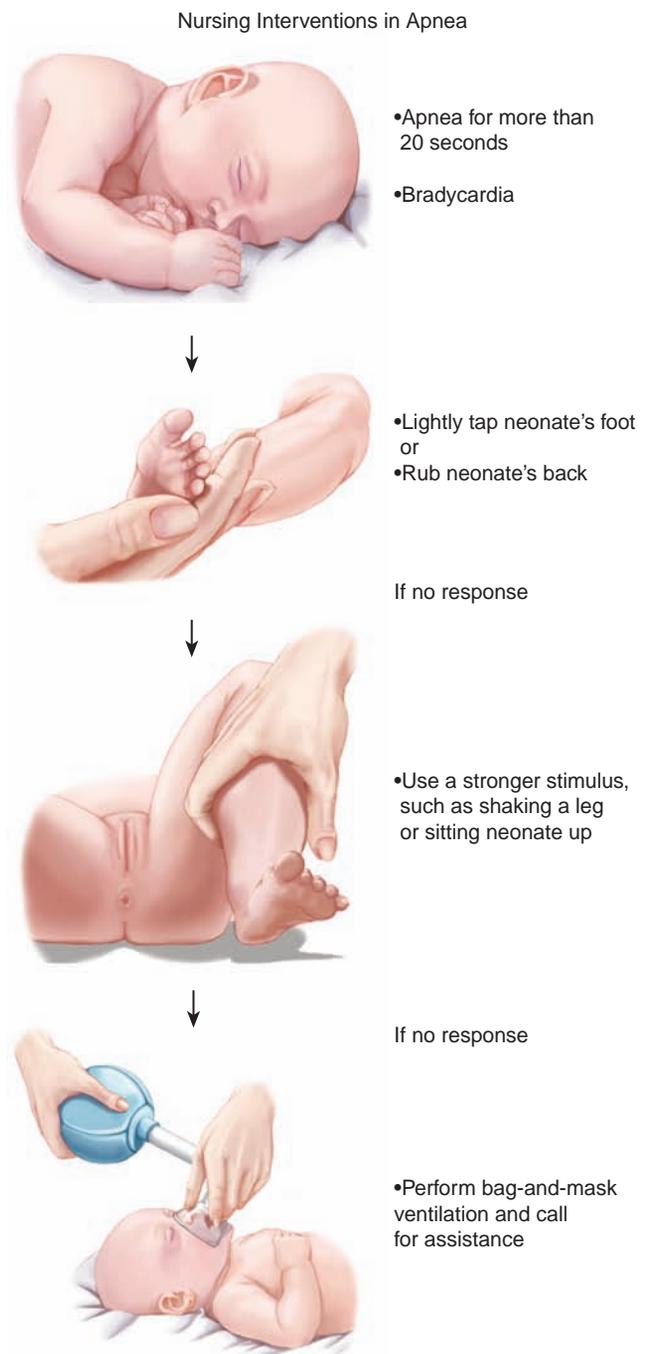

FIGURE 14–9. Nursing interventions progressively increase in invasiveness for apnea of prematurity.

thePoint for Procedures: Apnea Monitors). Nurses and respiratory therapists provide follow-up visits in the home to ensure that the family is comfortable with the home apnea monitor and with techniques for handling emergencies. Provide ongoing reinforcement of teaching at this time.

Typically, the newborn is seen in the clinic 1 to 2 weeks after discharge, depending on his or her stability. At this first clinic visit, the physician or advanced practice

nurse reviews with the primary caregiver the number and severity of apneic spells and interventions required, if any. Adjustments are made to the home apnea monitor alarms as needed, and the medications are reviewed for appropriate dosing. Weaning from medications proceeds according to the newborn's progress and number of apneic spells.

Feeding and Nutrition Problems

QUESTION: Abby has been reading about the benefits of breast milk for premature infants. She asks you the day after Gabriella's birth, "When will I be able to breast-feed Gabriella?" What will be your response to Abby's question?

Premature newborns require a high caloric intake for growth, tissue repair, and development of subcutaneous fat. Premature newborns have immature gastrointestinal systems, however, and require additional specialized support to obtain nutrition and maintain growth. Although sucking reflexes are present early in development, effective and coordinated suck-swallow reflexes do not develop until 32 to 34 weeks' gestation. Therefore, providing enteral nutrition to the premature newborn is challenging.

Assessment

The premature newborn should grow along the natural progression of intrauterine growth, had the pregnancy carried to term. To determine if adequate growth is occurring, plot the weight, length, and head circumference of the newborn on the appropriate intrauterine growth curve weekly. Newborns who fall below the curve are not growing appropriately, and treatment is initiated.

Nursing Diagnoses and Outcomes

Nursing diagnoses and outcomes generally applicable for newborns with a health challenge are presented in Nursing Plan of Care 14-1. In addition, the following may apply for a newborn with feeding and nutrition problems:

Imbalanced nutrition: Less than body requirements related to inability to take enteral feedings and acute illness

Outcome: Newborn's caloric and nutritional needs will be met via enteral or parenteral routes.

Interrupted breast-feeding related to inability or decreased ability to breast-feed and acute illness

Outcomes: Newborn will demonstrate normal growth as measured on the intrauterine growth curve.

Newborn will gain weight at a rate of 15 to 30 g/day.

Interdisciplinary Interventions

Feeding and nutritional assessment are the most important interventions for nurses caring for premature newborns. Parenteral nutrition is used initially until the newborn has become stable and ready to handle enteral

feeding. Parenteral nutrition includes administering solutions containing amino acids, dextrose, vitamins and minerals, and lipids through a peripheral or central venous catheter (e.g., peripherally inserted central catheter [PICC] or tunneled catheter [e.g., Broviac]; see Chapter 17). Weaning from parenteral nutrition is begun slowly as enteral feedings are introduced.

caREminder

Often, the quality of feeding tolerance and behavior are the first clues to other problems. For example, one of the first signs of an infection in a premature newborn may be feeding intolerance.

Signs and symptoms of feeding intolerance may include emesis, gastric residuals that are greater than 30% of the previous feeding, or bilious emesis or aspirates. Assess for these subtle changes and collaborate with other healthcare team members to intervene early and avoid complications.

Perform an abdominal examination before any feeding. If bowel loops, abdominal distention, or decreased bowel sounds are present, notify the medical team to determine a course of action. If the abdominal examination is normal, initiate feeding. Nursing Interventions 14-5 provides instruction for administering gavage feedings (see [thePoint](#) for Procedures: Enteral Tube Placement and Management: Naso/Orogastric Tubes and Weighted Tubes; Feeding, Infant).

NURSING INTERVENTIONS 14-5

Administering Gavage Feedings

- Introduce a feeding tube through the mouth into the stomach.
- Aspirate slightly to measure the residual (the amount of formula left in the stomach since the previous feeding).
- If the residual is not abnormal (green, bilious, or greater than 30% of the previous feeding), administer the feeding.
- Monitor the newborn's color and ability to tolerate the process during tube insertion and feeding administration. Provide a pacifier to encourage nonnutritive sucking during feeding.
- Apnea and bradycardia are potential side effects during tube insertion, and cyanosis may occur during the feeding. If these complications occur, immediately discontinue the feeding, clear the airway if needed, and administer supplemental oxygen.

Initially, enteral feedings are offered slowly and are termed *trophic, minimal enteral feeds (MEFs)*, also called *stimulation* or *stim* feeds because they are used to prime the gut for absorption. Premature newborns are fed slowly and gradually, taking up to 3 weeks to achieve complete enteral feeds. This gradual approach is needed, because premature newborns commonly experience initial problems, and the instability of other body systems can make enteral feeding undesirable.

Breast milk is the enteral feeding of choice, because it contains easily digested proteins, antibodies, and immunoglobulins, and has a high protein content. Expressed breast milk (EBM) from the premature newborn's mother has both a higher protein and fat content than breast milk from a term infant's mother. If breast milk is unavailable, the infant may be fed human breast milk donated to an established human milk bank. The human milk bank screens all donors and pasteurizes the EBM. If EBM is unavailable either from the mother or the human breast milk bank, formulas specially designed for premature infants are used because they contain additional minerals, different types of fat, and extra protein to support the growth of premature newborns. Initially, formulas are introduced cautiously and are slowly increased in volume as the newborn demonstrates tolerance.

Because of their inability to suck and swallow efficiently, premature newborns are fed through intermittent or continuous gavage feedings. Intermittent bolus gavage feedings are more physiologically appropriate and may improve production of the enteric hormones required for successful feeding. Continuous gavage feedings are often better tolerated by the extremely premature newborns because of their small gastric volumes. During gavage feedings, offer the infant a pacifier to promote the association of sucking with feeding. Another route of feeding is through a nasojugal tube, with the tip placed in the jejunum, bypassing the stomach. This approach is generally reserved for newborns who do not tolerate gastric feedings and is used only for continuous drip feedings.

As infants mature and achieve the ability to coordinate breathing, sucking, and swallowing, which typically occurs at about 32 to 34 weeks' gestation, oral feedings are introduced (see [thePoint](#) for Procedures: Feeding, Infant). Infants should be medically stable, able to maintain physiologic stability (maintain color and cardiorespiratory parameters and tolerate caregiving activities and environmental stimuli), and able to sustain regular breathing patterns and oxygen saturation during nonnutritive sucking. Other feeding readiness cues are fussiness without crying, hand-to-mouth behaviors, rooting, and hiccups. See Nursing Interventions 14–6 for information on oral feeding of the infant.

NURSING INTERVENTIONS 14–6

Feeding the Premature Infant

- Provide a quiet environment and remove distractions.
- Remain focused on the infant throughout the feeding, avoiding ongoing conversations with others.
- The infant should be in the awake, alert state for successful feeding; attempt to awake the infant with a soft voice, change the diaper, and ready the infant for the feeding experience.
- Elicit the rooting reflex by stroking the infant's lips with the nipple.
- Place the nipple in the mouth when a positive rooting response has been initiated.
- Allow infants to set the pace for feeding; if they pause, wait for them to resume sucking.
- Be alert to signs of stress (bradycardia, desaturations, behavioral stress cues) and stop the feeding if they occur, to allow a rest period.
- After feeding, hold the infant in an upright position for at least 5 minutes and note behavior.

Breast-feeding the Premature Infant

- Offer skin-to-skin holding frequently (as infant tolerates) to promote suckling at the empty breast. As feeding progresses, the infant may suckle at the full

breast. This practice encourages the infant to become familiar with the natural nipple and also enhances mother's own milk supply.

- Obtain assistance from a certified lactation consultant to assist with placing preterm infants to breast. Breast shields and different breast-feeding positions may be used to enhance the infant's efforts at the breast.
- Milk transfer (how much the infant takes from the breast) can be a concern because preterm infants have low sucking pressure. Careful monitoring of weight gain or loss, along with urine and stool output, is helpful in determining whether the infant's intake is adequate.

Bottle-feeding the Premature Infant

- Swaddle the infant and hold in a neutral head–neck flexion (avoiding extension and excessive flexion) and in midline.
- Avoid twisting, turning the bottle in the infant's mouth, or moving the infant's jaw passively, because these actions inhibit coordination of suck–swallow–breathe and only increase milk flow.

ANSWER: One response to Abby's question about breast-feeding Gabriella is: "You are absolutely right that your breast milk is the best source of nutrition for Gabriella. In fact, you should begin pumping your breasts to stimulate milk production. You need to let your body know that Gabriella needs milk even though she is not strong enough to nurse yet. Save all the milk you express and label it with the date and time, even if it is only a little bit. We will give her the first milk you express first, because it has the highest amounts of immune properties. The combination of coordinating breathing around sucking and swallowing is not easy to do; feeding is physically challenging. Somewhere between 32 and 34 weeks' gestation, premature babies are able to start nursing a little. First Gabriella will get her fluids and calories through the IV in her arm (her PICC line). Then we will begin to give her your breast milk through a tube to her stomach, and when she gives us cues that she is ready, we will start putting her to your breast to nurse. So to answer your question, maybe in 6 weeks, maybe a little bit sooner than that. But we will start giving Gabriella your breast milk as soon as it is safe for her."

Necrotizing Enterocolitis (NEC)

NEC is an acquired disease characterized by necrosis of the mucosal and submucosal layers of the gastrointestinal tract. It most commonly occurs in infants less than 33 weeks' gestation and in those weighing less than 1,500 g (Barclay et al., 2007), although there are reports of it developing in term newborns. Overall mortality is 10% to 30%, depending on the severity of the disease and associated problems; surgery is required in 20% to 40% of cases (Barclay et al., 2007).

Pathophysiology

The causes of NEC are not completely understood. It appears to be initiated when the body shunts blood away from vital organs (such as the bowel) during hypoxemia. This shift leads to decreased blood flow to the bowel, causing bowel wall ischemia. Then bacteria colonize the bowel and form a substrate (foundation) that allows bacterial invasion of the bowel wall.

Timing, method, and type of feeding for premature newborns and its association with NEC continue to be controversial. Clearly, infants who develop NEC have been exposed to some type of enteral substrate for bacterial growth, either EBM or formula. EBM use is associated with a lower incidence of NEC than formula use.

Assessment

NEC produces gastrointestinal and systemic signs and symptoms that must be immediately reported to the medical team, including abdominal distention, visible bowel loops, and a shiny, possibly discolored abdomen. Additionally, bilious or large feeding residuals, grossly bloody or occult-positive stools, lethargy, decreased bowel sounds, and sepsislike symptoms occur with NEC. Sepsislike symptoms are further described as temperature instability, poor perfusion, metabolic acidosis, and hypotension.

Radiograph of the abdomen reveals dilated bowel loops, ileus, or the classic sign of NEC: **pneumatosis intestinalis** (air in the bowel wall). Perforation of the bowel wall may ensue with late NEC, requiring immediate surgery.

Nursing Diagnoses and Outcomes

Nursing diagnoses and outcomes generally applicable for newborns with a health challenge are presented in Nursing Plan of Care 14–1. In addition, the following may be applicable for a newborn with NEC:

Ineffective gastrointestinal tissue perfusion related to effects of hypoxic insult

Outcome: Newborn will demonstrate adequate intestinal circulation, as evidenced by tolerance to feedings or no signs of NEC.

Interdisciplinary Interventions

Nursing interventions revolve around immediate recognition of early signs of NEC, including increasing gastric residuals and abdominal distention. Perform an abdominal examination: Inspect the abdomen for the presence of loops or distention, auscultate for bowel sounds, palpate for distention, and examine the stools for presence or absence of blood. Additionally, evaluate gastric residuals for amount and color. If the residuals are bilious or greater than 30% of the previous feeding, hold the feeding and notify the medical team.

When NEC is diagnosed, assess the condition of the newborn and be alert to signs of a worsening condition, including unstable vital signs, increasing blueness of the abdomen, increasing abdominal girth, hypotension, and metabolic acidosis. A decompression gastric tube is inserted to empty the stomach and reduce the air in the intestine. Enteral feeds may not be restarted until 7 to 10 days after the initial event and then are done with great caution.

Surgical intervention is initiated if bowel perforation occurs. NEC is a dynamic disease, in which segments of bowel wall worsen while others recover. The timing of surgery will dictate what is seen when the abdomen is entered. The goal is to remove the necrotic areas of the bowel and preserve as much healthy bowel as possible. One complication of surgery for NEC is short-bowel syndrome, in which a large portion of the gut is removed, as a result of necrosis, and the newborn is left with minimal amounts of intestine for absorption. These newborns have long-term feeding and nutrition difficulties and may be frequently hospitalized throughout infancy and childhood. They are often dependent on parenteral nutrition, with associated risks of central venous line complications, sepsis, cholestasis, and liver failure. The goal of establishing enteral nutrition, facilitating intestinal adaptation through which the remaining small bowel gradually increases its absorptive capacity, is never achieved in some children.

Retinopathy of Prematurity (ROP)

ROP is a disorder affecting the retinas of extremely premature newborns. It is a pathologic fibrous process that

results from injury to the developing premature retinal vasculature. ROP occurs in very premature newborns; newborns born at 34 weeks' gestation or later are unlikely to develop ROP. ROP is covered in detail in Chapter 28.

Birth Injuries

Birth injuries include trauma that occurs surrounding the birth (Chart 14–4). Birth injuries such as lacerations and bruising may also occur during cesarean sections or during resuscitation. Birth trauma is estimated to occur in 2% to 7% of all deliveries (Parker, 2005).

Injuries that occur intrapartum are often related to an abnormal fetal presentation, such as breech or abnormal fetal position leading to compression fractures. Additionally, oligohydramnios (decreased amniotic fluid) may be associated with epidermal shearing of the skin caused by excessive rubbing against the uterine wall without the amniotic fluid as a cushion. The risk of nerve injury is increased with breech positions, prolonged or precipitate labor, prematurity, multiple gestation, and shoulder dystocia.

Common birth injuries are soft tissue injury, extracranial hemorrhage, fracture, and peripheral nerve injury. Soft tissue injuries include bruising, abrasions, and petechiae over the presenting part. Edema may also be present. Because each of these injuries requires different care, they are covered in detail after a general discussion of assessment and care of newborns with birth injuries.

Assessment

A complete and thorough physical examination is imperative to quickly identify birth traumas. Note any history of a difficult or prolonged labor, LGA status, or birth to a diabetic mother. Birth injury may cause reduced range of motion in the extremities or asymmetric movements. The skull may have edema, petechiae, or soft tissue swelling. Skin tears and bruising suggest soft tissue injuries. Radiographs reveal any bone fractures.

Nursing Diagnoses and Outcomes

In addition to the nursing diagnoses listed in Nursing Plan of Care 14–1, the following may be applicable to the newborn with a birth injury:

CHART 14–4 PERINATAL EVENTS/CONDITIONS ASSOCIATED WITH BIRTH INJURIES

- Macrosomia
- Vacuum extraction
- Abnormal fetal presentation
- Oligohydramnios
- Use of forceps
- Shoulder dystocia
- LGA infant
- Precipitate labor
- Second stage of labor exceeding 60 minutes

Acute pain related to fracture, skin breakdown, or edema
Outcome: Newborn's pain will be managed appropriately.

The infant will show no signs of pain, such as increased crying or poor feeding.

Risk for injury related to improper positioning of paralyzed extremity

Outcome: Newborn's affected extremity will be positioned properly. The infant will display normal joint range of motion.

Impaired skin integrity related to disruption of skin surface from trauma

Outcome: Newborn will show adequate wound healing.

Interdisciplinary Interventions

Most injuries, such as a fractured clavicle or caput succedaneum, need supportive care only. Other injuries need splinting and immobilization. The nurse collaborates with other healthcare team members, including the physician and occupational therapist, to provide needed interventions.

Soft Tissue Injuries

Soft tissue injuries are generally self-limiting and require only supportive care and reassurance to parents. Scleral hemorrhages may be noted soon after birth and are a result of increased pressure on the fetal head during delivery. Edema, petechiae, and bruising also result from increased pressure on the presenting part of the fetus. Closely monitor petechiae, because they also may be a symptom of a bleeding disorder or sepsis.

Extracranial Hemorrhage

The descent through the birth canal can be stressful to the fetus. For successful vaginal delivery to occur, the fetal skull bones override one another to accommodate the small space of the pelvic inlet and vaginal tract. As a result, the head may undergo molding. Additionally, the obstetrician may facilitate delivery of the fetal head by applying forceps (metal tongs that are applied to the sides of the fetal head) or vacuum extraction (application of a suction device to the fetal presenting part) to assist delivery. Both forceps and vacuum extraction devices may potentially cause trauma to the fetal head, leading to edema and bleeding.

Caput succedaneum and *cephalhematoma* are the most common birth injuries; subgaleal hemorrhage (SGH) is relatively rare (Fig. 14–10). *Caput succedaneum* is localized scalp edema that occurs over the presenting part in a vertex delivery. The edema is often marked with bruising, petechiae, and broken skin. The edema is above the periosteum and crosses the suture lines of the skull. This benign injury resolves within 2 to 3 days after birth.

Cephalhematoma is subperiosteal bleeding over the cranial bone. This type of hemorrhage commonly occurs after traumatic deliveries during which forceps were used, vacuum-assisted deliveries, prolonged and difficult labors, and primiparous births.

An SGH occurs when shearing forces rupture blood vessels that bridge the subgaleal space. The subgaleal space is

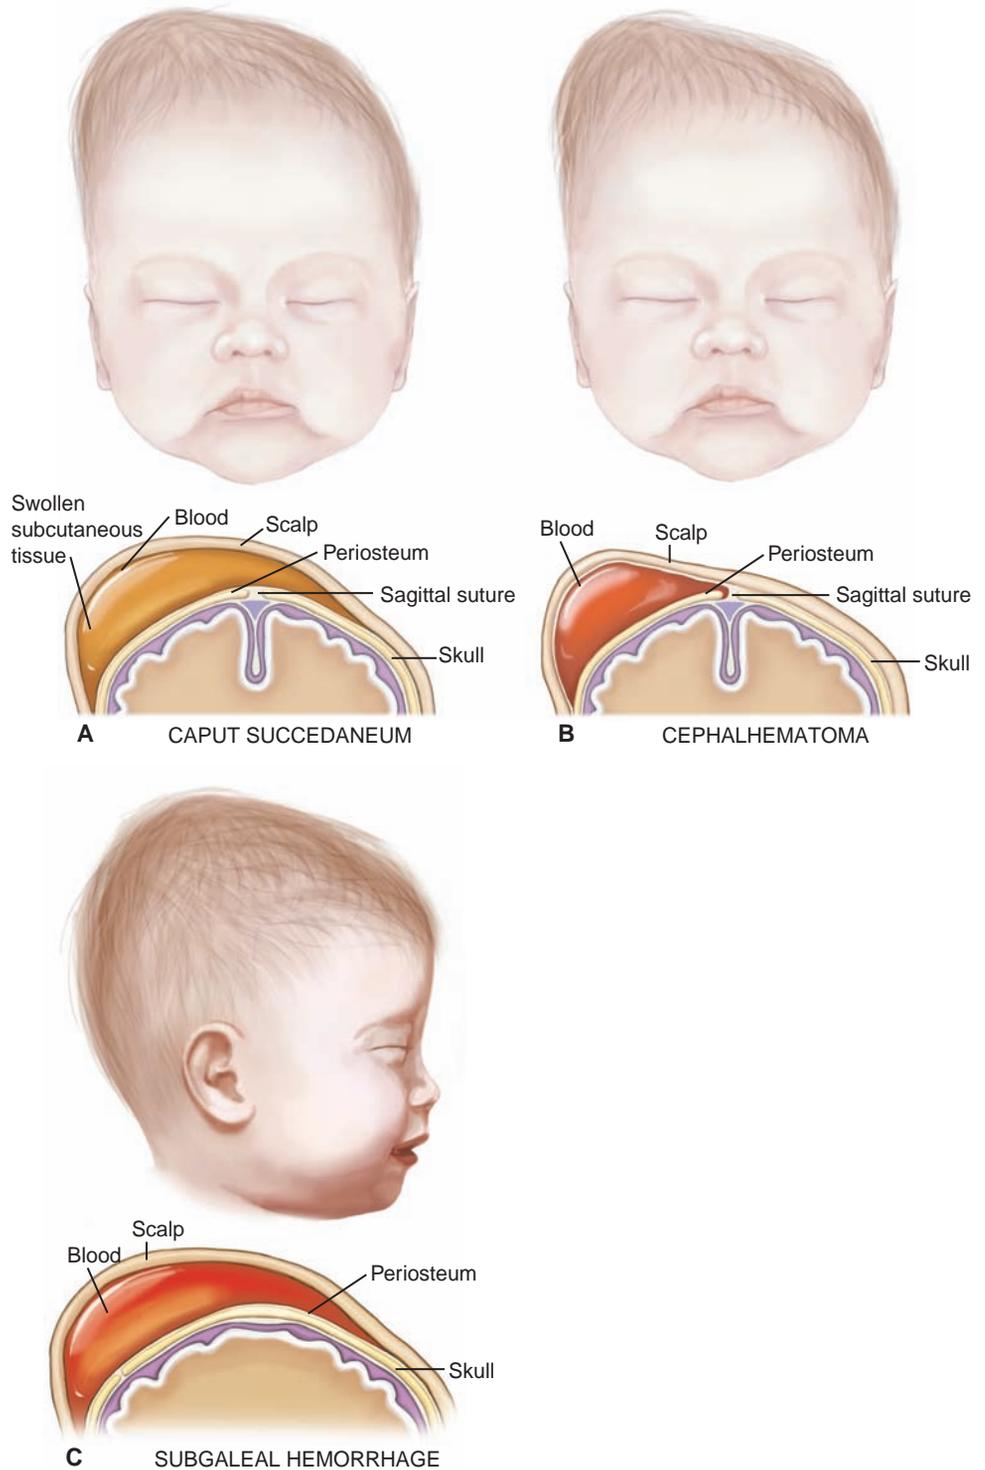

FIGURE 14-10. Caput succedaneum (A) and cephalhematoma (B) are common birth injuries. (C) Subgaleal hemorrhage may also occur.

a potential space (a space that is normally empty, but has the capacity to hold several hundred milliliters of blood) located between the scalp and the skull. The incidence of SGH is approximately 1 in 2,000 live births (Modanlou, 2005). Vacuum-assisted deliveries substantially increase the risk for SGH. SGH is associated with considerable morbidity and mortality during the immediate postdelivery period, but the long-term outcome for survivors is good (Kilani & Wetmore, 2006). SGH presents with subtle

edema that extends to the neck and behind the ear. The edema may not be present at delivery but will evolve during the next several hours. The affected area of the scalp will be boggy and fluctuating, with dependent edema. In large, very severe SGH, the ear will become edematous and pushed forward, and the eyes will become puffy. Hypovolemic shock may ensue if SGH diagnosis is delayed.

Assess for skull and scalp abnormalities and note the location of any edema, petechiae, or bruising. Edema that

crosses the suture line suggests caput succedaneum. Skull indentation is an important finding that possibly indicates an underlying fracture, and it requires further investigation, such as a radiograph. Assess for signs of increased intracranial pressure such as a full or tense anterior fontanel, irritability, poor feeding, and apnea.

A cephalhematoma differs from a caput succedaneum in that it does not cross suture lines, has little or no ecchymosis, and takes longer to resolve—as long as to 2 months. Also, a cephalhematoma can continue to bleed, leading to anemia. Hyperbilirubinemia may also be a prolonged problem resulting from lysis of the blood underneath the periosteum. If this complication develops, closely monitor the serum bilirubin level to provide prompt interventions for hyperbilirubinemia, including phototherapy. On occasion, a cephalhematoma may overlie a skull fracture.

Skull Fracture

Skull fractures may result from fetal skull passage through the maternal ischial spines, sacral promontory, or symphysis pubis, or from the use of forceps. Normally, the fetal skull tolerates the pressure generated by birth, because its incompletely ossified bone is flexible. However, application of forceps or a traumatic delivery may result in a skull fracture.

Skull fractures related to birth trauma can be linear or depressed. Linear skull fractures are most often present over the frontal or parietal bones and rarely occur over the occipital bone. The newborn is often asymptomatic, with only a cephalhematoma noted on physical examination. Diagnosis is made by skull radiograph. Healing takes place without intervention, and the only monitoring needed is for increased intracranial pressure, including measuring the head circumference, monitoring for a bulging or tense anterior fontanel, and noting irritable or lethargic behavior.

A depressed skull fracture is associated with forceps delivery and appears over the parietal bone. It is evident on physical examination as a visible skull indentation. The newborn is often asymptomatic and will rarely require intervention. In rare cases, depressed skull fractures may be associated with intracranial bleeding. In these cases, the newborn may exhibit signs of increasing intracranial pressure and will require ongoing evaluation.

Clavicular Fracture

Clavicular fractures are the most common fractures diagnosed as birth trauma. Clavicles are at risk for fracture during shoulder dystocia or in a breech delivery with arms extended. Assess carefully because the newborn is often asymptomatic or merely exhibits limited movement in the affected arm, local swelling or tenderness at the site of the fracture, and an abnormal Moro's reflex. Crepitus may be noted at the fracture site as well. Crepitus is the sound made by fractured bone fragments rubbing together.

A fractured clavicle is diagnosed by physical findings and radiograph. Treatment is determined by the severity of the fracture. Generally, arm immobilization using a soft splint in a flexed position against the chest is all that is needed.

Callus formation, as detected by radiograph at the fracture site, is often noted by 10 days of age and indicates healing.

Nursing interventions include periodically checking for skin breakdown, removing the splint for bathing, and teaching the parent. Parent education includes the correct application of the splint, frequency of skin checks, and follow-up appointments.

Peripheral Nerve Injuries

Peripheral nerve injuries result from stretching or hyperextension of nerve tissue. They generally occur during birth or traumatic or difficult delivery. Nerve damage ranges from very limited edema that resolves quickly to complete paralysis. The most common peripheral nerve injuries are facial nerve palsy and brachial plexus palsy (Fig. 14–11).

Facial nerve palsy results from prolonged pressure on the facial nerve from the maternal pelvis or forceps that causes nerve damage. Presentation of facial nerve palsy varies and ranges from inability to close the eye or open the mouth to paralysis of the lower portion of the face. The injury is apparent at birth or within a few days after birth. Most newborns recover spontaneously, with slow improvement of movement within 3 weeks.

Brachial plexus palsy results when the cervical and thoracic nerve roots are damaged as a result of excessive lateral flexion and traction on the neck. The injury is usually unilateral and occurs most frequently on the left side. Clinical presentation varies with the location and extent of damage. At birth, the newborn has decreased movement from the shoulder to the hand. *Erb–Duchenne* paralysis, the most common type, is caused by damage to the C5 and C6 nerve roots, and presents as shoulder and upper arm paralysis. The arm is adducted and internally rotated, and kept in the “waiter’s tip” position; Moro’s reflex and biceps and radial reflexes are decreased or absent. *Klumpke’s* paralysis involves damage to the C8 to T1 nerve roots that affects the lower arm and hand. The affected arm remains flaccid, with the hand in a clawlike position. The Moro’s and grasp reflexes are absent. *Erb–Duchenne–Klumpke* paralysis involves damage to the entire brachial plexus that affects the hand and arm. The upper and lower arm and hand are completely paralyzed. Brachial plexus injuries have a good prognosis. With supportive care, most newborns recover.

Peripheral nerve palsies are supportively managed. Management includes immobilization with a soft splint or brace and institution of passive range-of-motion exercises at day 10. The nurse, in collaboration with the physical therapist, provides parent education to reinforce ongoing therapy. Surgical intervention, if needed, is considered at 3 to 6 months of age (Brauer & Waters, 2007).

Perinatal Asphyxia

Because the fetus depends on a steady supply of maternal blood to deliver oxygen until the lungs take over, any interruption in that flow during birth can result in perinatal asphyxia. The incidence of perinatal asphyxia is rare, less than 1 case per 1,000 live births (Becher,

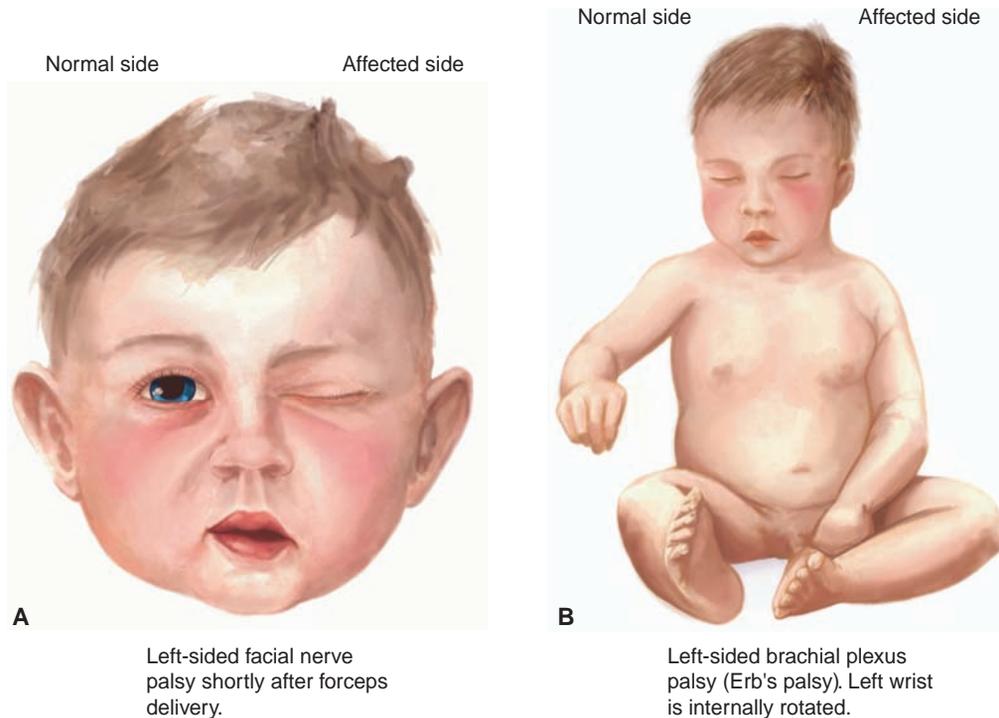

FIGURE 14-11. Facial nerve palsy (A) and brachial plexus palsy (B) are common peripheral nerve injuries in neonates.

Stenson, & Lyon, 2007). Causes of perinatal asphyxia include interrupted umbilical blood flow, abruptio placentae (separation of the placenta from the uterus prior to delivery), placental insufficiency (inadequate placental perfusion), and trauma during delivery. A common cause of fetal hypoxia is umbilical cord compression during birth. The easily compressed vein in the umbilical cord interrupts blood flow to the fetus, while the less distensible arteries continue to pump blood into the placenta, causing fetal hypotension.

Common causes of placental insufficiency are maternal anesthesia, pregnancy-induced hypertension, and oxytocin (Pitocin) hyperstimulation that does not allow for adequate placental perfusion. The fetus responds to placental insufficiency with bradycardia and decreased variability as noted on the fetal monitor.

Trauma during delivery is another potential cause of fetal asphyxia. Cephalopelvic disproportion may lead to the fetus becoming “stuck” in the birth canal or compressing the cord while moving through the canal. In severe cases, the clavicle is purposefully fractured to deliver the newborn quickly. The use of high forceps also denotes a difficult delivery in which the fetus does not easily fit through the birth canal. These situations may lead to fetal asphyxia. Carefully evaluate newborns with these risk factors and history.

Pathophysiology

The fetus initially responds to hypoxia with tachycardia. Tachycardia increases cardiac output. Simultaneously, blood is shunted away from the kidneys and gut to the heart and brain. With worsening fetal hypoxia and acidosis, hypotension results from cardiac and respiratory

failure. The heart rate may increase slightly, but eventually decreases, and bradycardia ensues. These events are often recorded on the fetal monitor during labor. The fetal monitor reveals a loss of beat-to-beat variability, fetal tachycardia, then bradycardia, and poor short-term variability and late decelerations.

Prognosis

The prognosis for perinatal asphyxia and resultant hypoxic ischemic encephalopathy varies, ranging from death immediately after birth, to severe neurologic deficits, to no sequelae. Perinatal asphyxia accounts for about 6% to 8% of cases of CP (Reddihough & Collins, 2003). The prevalence of CP is approximately 2.3 per 1,000 live born infants (Meberg & Broch, 2004). Hypoxic ischemic encephalopathy (HIE) is a clinical syndrome present in newborns with brain injury caused by perinatal asphyxia. In 39% of infants of normal birth weight, a perinatal or neonatal cause of CP was identified, with 79% of these cases attributable to HIE (Meberg & Broch, 2004).

Apgar scores alone are poor predictors of the adverse neurologic sequelae of perinatal asphyxia. Therefore, combining the Apgar score with the entire clinical picture, including timing of onset and severity of seizures and neurologic examination findings, gives a better estimation of outcome.

Assessment

The initial signs of perinatal asphyxia appear immediately after birth. The newborn is limp, cyanotic, bradycardic, and apneic. Muscle tone, reflexes, and spontaneous

movement are extremely depressed in the asphyxiated newborn and are often the last parameters to return during recovery. The intrapartum history may reveal substantial fetal distress, including prolonged bradycardia, late decelerations, and poor fetal heart rate variability.

All body systems may be affected, including the heart, kidneys, lungs, metabolic system, and the brain. The heart may show signs of damage, including poor contractility, within the first 24 hours after birth. Other clinical findings include central cyanosis, tachypnea, rales in the lower lung fields, hepatomegaly, and a systolic murmur.

Clinically important perinatal asphyxia almost always affects the kidneys. The effects on glomerular filtration and tubular function depend on the degree, severity, and duration of the decreased blood flow to the kidneys.

Respiratory distress, including sternal, substernal, and intercostal retractions, grunting, and nasal flaring, is common. Acute hypoglycemia and hypocalcemia are metabolic complications.

Brain damage from asphyxia is manifested by HIE that appears soon after birth and continues for 7 to 10 days. HIE may produce cerebral edema for up to 72 hours after birth and seizures for 24 to 48 hours after birth. Seizures that occur within the first 24 hours are a grave sign, often indicating poor neurologic outcome. HIE produces subtle and generalized tonic seizures as a result of CNS insult and developing cerebral edema.

caREminder

To determine whether the newborn's movements are tremors or seizure activity, check for subtle signs of seizures, such as lip smacking, rapid eye movements, and tongue thrusting (Table 14–4).

Blood tests are used to determine the presence of asphyxia. Cord blood gases are obtained from the umbilical cord immediately on delivery and demonstrate severe acidosis and hypoxemia. Neonatal blood gas samples demonstrate metabolic and respiratory acidosis. Electrolyte levels indicate hypoglycemia and hypocalcemia.

A bedside echocardiogram demonstrates poor heart function and decreased contraction of the ventricles. Oliguria (urine output <1 mL/kg/hour) and hematuria are

common, and the blood urea nitrogen and creatinine levels are elevated.

Nursing Diagnoses and Outcomes

Nursing diagnoses and outcomes generally applicable for newborns with a health challenge are listed in Nursing Plan of Care 14–1. In addition, the following may be applicable to a newborn with perinatal asphyxia:

Disturbed sensory perception (visual, auditory, kinesthetic, gustatory, tactile, olfactory) related to effects of anoxia

Outcome: Newborn will show no signs of neurologic deterioration and will respond appropriately to the environment.

Interdisciplinary Interventions

Care of the asphyxiated newborn is complex. It begins at delivery and continues in the NICU. Depending on the extent of asphyxiation and sequelae, community care may be ongoing.

Delivery Team Management

The initial stabilization process is labile and often unpredictable. The neonatal team usually consists of a nurse, respiratory therapist, and physician. They must act quickly at delivery to establish an airway and begin ventilation. Other resuscitative measures include cardiac compressions, if the heart rate is very low, and emergency medications such as epinephrine administered through the endotracheal tube or through an umbilical venous catheter inserted by the resuscitation team. The nurse's role in resuscitating an asphyxiated newborn involves assessing heart rate and initiating compressions. Also, the nurse may assist the respiratory therapist in establishing and maintaining an adequate airway by stabilizing the endotracheal tube, applying PPV, and assessing for breath sounds. Quick and efficient stabilization is imperative to the newborn's survival.

Neonatal Intensive Care Unit Team Management

On the newborn's arrival to the NICU, quickly ensure the presence of a patent airway, establish baseline vital signs, and promote thermoregulation. Perform a complete physical examination to detect any congenital anomalies or other complications. Evaluate the newborn's muscle tone, response to care, and reflexes to establish a baseline neurologic assessment that will be helpful for later comparison.

The nurse assists with placement of invasive lines to better monitor blood pressure and obtains specimens for laboratory tests. Closely monitor for aberrations in all laboratory values, and perform bedside glucose, hemoglobin, and hematocrit testing as ordered. Also monitor the newborn's response to treatments and assist in determining the extent of organ involvement. For example, meticulous monitoring of urine output aids in

TABLE 14–4

Differentiating Seizures From Jitteriness

Assessment Findings	Seizures	Jitteriness
Ceases with passive flexion	No	Yes
Activity induced	No	Yes
Associated with cyanosis or bradycardia	Yes	No
Eye deviations	Yes	No

assessing renal damage. Documenting neurologic symptoms helps to determine CNS damage.

The medical team aggressively treats the newborn by promoting oxygenation, providing ventilation, and administering medications. The physician evaluates chest radiographs, serial blood gas levels, and other laboratory studies to guide treatments. The goals of treatment are to avoid hypercapnia, control seizures, and restrict IV fluids to prevent cerebral edema. Closely monitor for signs of cerebral edema and increasing intracranial pressure (Chart 14–5).

Phenobarbital is the medication of choice to control seizures. If seizures continue after IV administration of phenobarbital, phenytoin (Dilantin) may be initiated. Other supportive therapies with seizures include correcting any metabolic abnormalities, ensuring an adequate airway, and promoting oxygenation and ventilation. Monitor the newborn's response to the seizure medications by noting the time that the seizures stopped and observe for side effects. The most common side effect of phenobarbital is respiratory depression.

The family is often distressed by the unexpected events of the birth and will need reassurance and frequent updates about the newborn's condition. Explain the current treatments and, if indicated, the newborn's responses to the family. Facilitate communication with the physician. If sequelae are severe, involve the social worker as soon as possible to provide additional support to the family.

Therapeutic hypothermia is a new therapy recently reported to reduce the number of deaths and improve neurodevelopmental outcome in infants with moderate to severe perinatal HIE (Jacobs, Hunt & Tarnow-Mordi, 2007). Therapeutic hypothermia involves either a cooling cap placed on the newborn's head or total body cooling using a cooling mattress bed to induce hypothermia (33–34 °C, 91.4–93.2 °F) with the purpose of reducing the body's core temperature and, subsequently, the temperature within the brain. The goal is to begin therapeutic hypothermia within 6 hours after birth (the earlier it is initiated, the more favorable the outcome), if the newborn meets specific clinical criteria, and to continue cooling for 72 hours after birth. Although not completely understood, brain cooling provides protection to the brain through multiple pathways, including reducing cellular metabolism and energy depletion, and reducing edema and excitatory transmitters.

CHART 14–5 SIGNS OF INCREASING INTRACRANIAL PRESSURE IN THE NEWBORN

- Increasing lethargy
- Increasing head circumference
- Tense anterior fontanel
- Widening sutures
- Apnea
- Deteriorating vital signs
- Seizures

Infants of Diabetic Mothers

Infants of diabetic mothers include all infants affected by abnormal maternal glucose levels, whether those levels result from gestational diabetes (abnormal glucose levels induced by pregnancy) or from preexisting maternal diabetes. Approximately 3% to 10% of all pregnancies are complicated by glucose control problems, most of which are caused by gestational diabetes (Nild & Georgieff, 2004). The infant of a diabetic mother is at risk for many problems. To decrease the risk to the newborn, the mother's blood glucose level must be assessed and properly controlled before and during pregnancy to minimize hypoglycemia and hyperglycemia. Diabetes screening should begin at week 26 to 28 of gestation. Common problems in infants of diabetic mothers include macrosomia (increased adipose tissue) and subsequent traumatic delivery, hypoglycemia within a short time after delivery, respiratory distress from surfactant deficiency, electrolyte disturbances, polycythemia, and congenital anomalies.

Pathophysiology

Insulin does not cross the placenta, but glucose does. The fetus increases its own production of insulin in response to the high glucose levels from the mother. This state of hyperinsulinism leads to macrosomia, increased fat accumulation, and LGA status. Because of the hyperinsulinemia, hypoglycemia occurs rapidly after delivery when the maternal supply of glucose abruptly ceases. The hyperinsulinemia can last for several days, and the infant may require IV therapy to maintain normal glucose values.

Infants of diabetic mothers have a higher incidence of respiratory distress and surfactant deficiency than other newborns. Poorly controlled maternal diabetes appears to impair fetal pulmonary maturation (Moore, 2002). This association has led many obstetricians to delay delivering these infants until 37 to 38 weeks, to ensure adequate lung maturity.

Hypocalcemia and hypomagnesemia are also common problems of infants of diabetic mothers resulting from the newborn's decreased hypoparathyroid functioning. The frequency and severity of abnormal maternal blood glucose levels can contribute substantially to the likelihood of congenital abnormalities (Wender-Ozegowshka et al., 2005), such as congenital heart disease, and CNS defects, such as lumbosacral agenesis.

Assessment

A maternal history of diabetes mellitus or gestational diabetes is usually present, but many mothers exhibit no history or have not obtained appropriate prenatal care. Infants of diabetic mothers have a characteristic appearance as a result of the increased subcutaneous fat: full face, smaller head circumference-to-weight ratio, and a larger weight-to-length ratio. The placenta and umbilical cord are often very large.

A complete assessment is vital to detect congenital anomalies, specifically congenital heart defects. Close observation is necessary to detect hypoglycemia, which may

be asymptomatic or may be marked by lethargy, a high-pitched cry, jitteriness, and seizures. Monitor for respiratory distress and auscultate for cardiac murmurs. Evaluate hemoglobin and hematocrit results to monitor for polycythemia. A polycythemic newborn appears ruddy in color. Also monitor electrolytes for the presence of hypocalcemia; supplemental calcium may be necessary.

Because of the infant's large size, traumatic deliveries and subsequent birth traumas are common. If the infant exhibits decreased movement or cries when an extremity is moved, investigate further for injury. Not all diabetic mothers are identified before delivery. Therefore, most LGA newborns are at risk for blood glucose problems; perform serial blood glucose determinations after birth.

Interdisciplinary Interventions

Monitor closely for the signs and symptoms of hypoglycemia; obtain blood glucose values every 30 to 60 minutes after birth until values stabilize, then every 2 to 4 hours for 24 hours until stability is confirmed, and initiate early feedings, as appropriate (see [thePoint](#) for Supplemental Information: Care Path: An Interdisciplinary Plan of Care for the Infant of a Diabetic Mother). Feedings are contraindicated if respiratory distress is present, because of the risk of aspiration. IV fluids are initiated if feedings are withheld.

Intrauterine Exposures

Teratogens such as infectious agents, radiation, high temperatures, and chemicals have deleterious effects on the developing fetus. The effects often depend on dose, timing, and genetic resilience or susceptibility. Infants exposed to drugs or alcohol may suffer short-term withdrawal and long-term effects on growth and neurodevelopment. They may also be exposed to social and environmental risk factors associated with parental substance abuse.

Fetal Alcohol Spectrum Disorders

Ethyl alcohol ingestion by pregnant women is the most common identified cause of teratogenesis (chemically induced physical or mental anomalies) in a fetus. These anomalies fall into the category of fetal alcohol spectrum disorders (FASD), a group of disorders that includes fetal alcohol syndrome (FAS).

About 10% of pregnant women report consuming alcohol, with 2% binge drinking (Tsai et al., 2007). Although the incidence of FAS is estimated at 0.33 to 2.2 cases per 1,000 live births in the United States and at 0.97 per 1,000 live births in the developed world (May et al., 2007), this is likely an underestimate, because many newborns with FAS are not diagnosed properly.

FASD represents a continuum of structural anomalies, and behavioral and neurocognitive disabilities associated with maternal prenatal chronic, heavy, or binge alcohol ingestion. The child may not have the characteristic facial features, so FASD may not be recognized until school

age, when intellectual, cognitive, social, and behavioral difficulties are apparent.

Newborns most severely affected by alcohol ingestion present with FAS, a syndrome of growth deficiency and characteristic facial features associated with a strong history of prenatal maternal alcohol ingestion. Additionally, mild to moderate cognitive deficiency and delayed motor and language development are recognized early during infancy. Newborns with FAS have lower thresholds for arousal than healthy newborns, and are more restless and irritable.

Pathophysiology

The active ingredient of alcohol is ethanol. Ethanol's metabolites are readily transferred across the placenta and to the fetus. Ethanol is a CNS depressant and it migrates into the fetal brain, liver, kidneys, and pancreas. The rate of fetal ethanol metabolism is half that of the adult, and the fetus relies on the placenta for ethanol clearance. This combination of circumstances produces amniotic fluid with high ethanol levels and a newborn who may appear intoxicated at birth.

Ethanol and its metabolites are teratogens, depending on the time of exposure. Weeks 3 through 8 of gestation are the most vulnerable times for toxicity, because cells are dividing and organs are developing. The exact amount of maternal alcohol ingestion that causes FAS is not clear, but a "threshold level" appears to exist at which organogenesis is disrupted. This threshold is unknown, however, so the Surgeon General's Advisory on Alcohol Use in Pregnancy urges any pregnant women or women who are considering becoming pregnant to abstain from alcohol use completely (Carmona, 2005).

Prognosis

FAS is the leading known preventable cause of cognitive challenge in developed countries. The prognosis for these newborns may be poor, because the damage done to the CNS is irreversible and results in lifelong learning problems and disabilities. Fewer than 10% of individuals with FAS or alcohol-related neurodevelopmental disorders are able to achieve success in living and working independently (Weber et al., 2002). As these children grow and develop, educational programs can help these individuals realize their potential, but cannot offer a cure. Early diagnosis and interventions are important to help newborns with FAS develop into self-sufficient adults. Some will require constant supervision, whereas others may live independent lives. Academic struggles are common, because adolescents with FAS have significantly lower intelligence scores and specifically struggle in mathematical subtests (Howell et al., 2005).

Assessment

Diagnosis can be challenging, because the physical characteristics common to newborns with FAS are general and broad, and not all newborns with FAS look or act the same. Physical manifestations of FAS range from mild to severe. Common signs of FAS include SGA status (in length, weight, or both), microcephaly, poor growth,

smooth, wide philtrum, thin vermilion border (upper lip), short palpebral fissures, low-set ears, and micrognathia (small chin) (Fig. 14–12). Additionally, congenital heart disease such as ventricular septal defect, atrial septal defect, and tetralogy of Fallot are associated with prenatal alcohol exposure. Renal anomalies may also occur. The diagnosis is made by reported maternal alcohol consumption during pregnancy and the presence of a cluster of anomalies.

FAS newborns are small at birth and fail to grow normally or demonstrate appropriate catch-up growth. Head growth is often less than the 10th percentile. Facial anomalies are common and affect the midface. Other complications of FAS include irritability, poor feeding stemming from ineffective coordination of suck and swallow, and hypersensitivity to external stimuli. Newborns with FAS are less able to habituate to aversive stimuli as measured by the NBAS. Alcohol withdrawal often presents within 24 hours after birth, with tremors, irritability, and abdominal distention.

CNS effects in most children with FAS take the form of microcephaly and other brain abnormalities (Sowell et al., 2008). The most profound effect of FAS is cognitive challenges resulting in poor academic performance. Most children with FAS do not have below average intelligence and may not qualify for special education services based on basic psychological testing; specialized testing is required to document deficits in executive functioning such as planning, organization, and attention (Green, 2007).

Nursing Diagnoses and Outcomes

Nursing diagnoses and outcomes generally applicable for newborns with a health challenge are presented in Nursing Plan of Care 14–1. In addition, the following may be applicable for a newborn with FAS:

Imbalanced nutrition: Less than body requirements, related to poor nipping

Outcomes: Newborn will ingest adequate calories and nutrients.

Newborn will display adequate growth.

Interdisciplinary Interventions

Nursing interventions are mainly supportive during the neonatal period. To minimize CNS irritability and hypersensitivity to the environment, gear nursing interventions to maintaining a quiet environment that promotes normal wake and sleep patterns. Additionally, cluster care if the infant tolerates it, and minimize unnecessary handling.

Nutritional management is critically important for the newborn with FAS because poor feeding is common. Optimize calorie intake and promote normal suck–swallow patterns.

Disorders Related to Exposure to Stimulants, Opioids, or Other Substances

The incidence of substance abuse among pregnant women, including use of opiates, marijuana, cocaine, hallucinogens, inhalants, tranquilizers, stimulants, and sedatives, has been reported to be 4% (Substance Abuse and Mental Health Services Administration, 2007). Prenatal drug exposure has far-reaching implications for the newborn, the family, the healthcare professional caring for these mothers and newborns, and society at large.

Stimulants such as methamphetamine and cocaine, and opioids such as heroin, are common drugs abused prenatally. Polydrug use (use of more than one drug) is common and most users deny it when asked (Kuczkowski, 2007). Polydrug use during pregnancy results in newborns with lower birth weight, shorter length, and smaller head circumference than infants whose mothers did not use these substances during pregnancy. The fetus exposed to intrauterine drugs may exhibit **neonatal abstinence syndrome (NAS)** (withdrawal symptoms after birth). These classifications of drugs are considered together in this section despite their major pharmacologic differences, because many substance-using mothers are polydrug users. In addition, withdrawal symptoms may be similar.

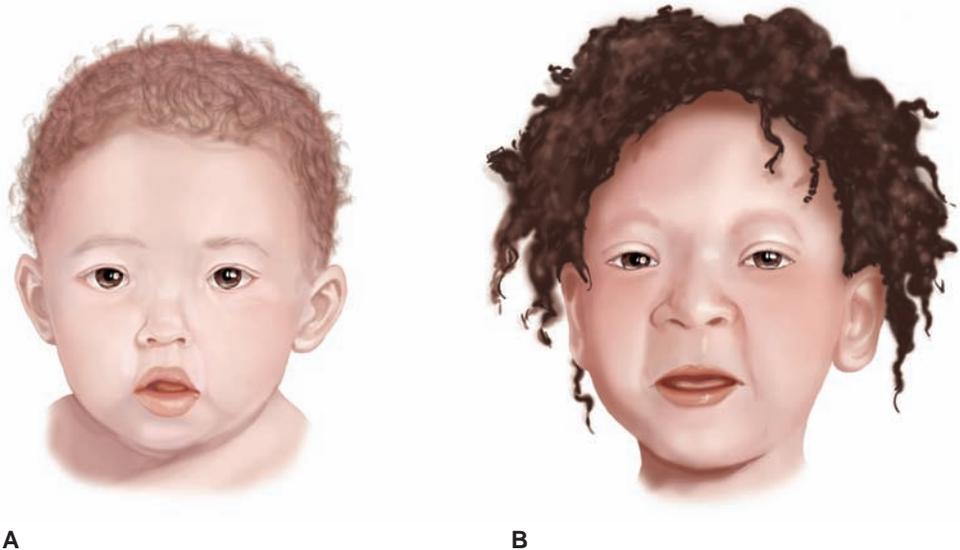

FIGURE 14–12. Typical facial characteristics of fetal alcohol syndrome include short palpebral fissures, a smooth, wide philtrum, a thin vermilion border, and micrognathia. Child at age 1 month (A) and 3 years (B).

Stimulants

Cocaine is a stimulant that increases dopamine release and decreases uptake of norepinephrine. When used during pregnancy, cocaine and other stimulants cause massive vasoconstriction throughout the body, including the vessels in the uterus and placenta. As a result of the increase in blood volume that occurs with pregnancy, the vasoactive effects of cocaine are enhanced. The vasoconstrictive properties of cocaine lead to preterm labor, placental insufficiency, or abruptio placentae. Additionally, cocaine's vasoconstrictive properties may decrease blood flow to the placenta and fetus, causing substantial vasoconstriction, subsequently leading to short-term hypoxic episodes in the fetus.

Cocaine has potentially teratogenic effects, and its use during pregnancy increases the risk of birth anomalies, especially during the first 3 months of gestation. Cocaine crosses the placenta quickly, and metabolites can be detected in the fetus for up to 4 days after exposure. Common birth defects associated with cocaine use include genitourinary malformations, prune-belly syndrome, limb defects, cardiovascular defects, brain lesions, and cerebral infarcts. Maternal cocaine use is associated with IUGR, including reduced head circumference. Other malformations associated with cocaine use include congenital heart disease, encephalocele, and microcephaly. Withdrawal symptoms are uncommon and are usually mild when present. Perhaps the most serious complications of cocaine use during pregnancy are the increased risks of preterm delivery and abruptio placentae. Cocaine appears to have a specific effect on birth weight, even more potent than that of tobacco use. When these substances are used during pregnancy, LBW is common.

Methamphetamine has effects similar to those of cocaine, including vasoconstrictive properties that may alter blood flow and oxygen supply to the fetus. Currently, long-term effects on the fetus from methamphetamine exposure are unknown.

Opioids

Opioids are CNS depressants that produce feelings of relaxation. Codeine, heroin, methadone, and morphine are the most commonly abused opioids. Heroin is six times as potent as morphine and highly addictive. These drugs readily cross the placenta; at birth, when the maternal supply ceases, the newborn may show signs of withdrawal at 24 to 72 hours.

Heroin reduces uteroplacental blood flow and inhibits fetal growth. Combined with inadequate maternal calorie and protein intake, it produces IUGR, including poor brain growth. During pregnancy, maternal heroin use creates fetal addiction. Abrupt withdrawal from heroin during pregnancy is not recommended, however, because maternal withdrawal symptoms are detrimental to the fetus. If the mother attempts to stop using heroin or if her intake is erratic, fetal withdrawal and possibly death may occur. Often, the mother is placed on methadone maintenance during her pregnancy to avoid fetal death. Metha-

done is a synthetic opioid drug that works as a substitute for heroin. The benefits of methadone maintenance are that the level of drug can be maintained as a constant at an exact dose, and that the drug does not exert the mood-altering effects of heroin. Methadone withdrawal can also harm the fetus.

Newborns exposed to intrauterine opioids are at high risk for child abuse as a result of their withdrawal behaviors, such as irritability and decreased sleep. These behaviors are difficult to manage, especially for a drug-abusing mother who has limited coping skills or resources. Withdrawal behaviors may last for up to 6 months. These infants are also at increased risk of neurodevelopmental problems (Hunt et al., 2008).

A majority of pregnant women treated with methadone also smoke cigarettes (Burns et al., 2007). Intrauterine exposure to opioids and nicotine increases the risk of LBW and preterm birth. Tobacco use in conjunction with methadone use during pregnancy increases the severity and length of withdrawal in the newborn (Choo et al., 2004). The neonatal team caring for newborns prenatally exposed to tobacco and methadone can expect a slower taper of medications and prolonged, difficult withdrawal behaviors. These infants may require prolonged hospitalization because of the severity of withdrawal symptoms, although this possibility has not been demonstrated in research studies.

Assessment

Obtain a complete maternal history regarding all legal, illegal, over-the-counter, and prescription drug use to identify newborns at risk. The neonatal abstinence scoring system (Finnegan, 1985) is a tool used to assess the severity of drug withdrawal behaviors in term infants. This scoring system attempts to rate withdrawal behaviors on an objective scale. It lists 21 symptoms commonly seen in newborns during withdrawal. Score the newborn 2 hours after birth and then every 4 hours for the first 5 days of life. If the symptoms are increasing in severity, then score the newborn every 2 hours. This tool was tested on term newborns, not preterm newborns.

Score newborns whose mothers are suspected drug users every 2 to 3 hours for the first 48 hours of life, regardless of the initial score. Thereafter, if the newborn scores 7 or less, complete scoring every 4 hours for 48 hours. A score of 7 or less is categorized as mild withdrawal. Use nursing judgment to avoid waking the newborn unnecessarily.

If the score is 8 or more, medication is initiated, and scoring continues for 5 days. Each scoring interval rates the newborn's behavior during the entire 2- or 4-hour interval, not just the behavior present at the time of scoring. Awaken the newborn to elicit reflexes and specified behavior.

Cocaine-exposed newborns demonstrate increased muscle tone, tremors, and prolonged retention of primitive reflexes. The cocaine-exposed newborn does not present with specific withdrawal behaviors and may only demonstrate irritability several weeks after birth. Premature delivery and associated problems are the primary

challenges for the cocaine-exposed newborn (see earlier discussion of prematurity and LBW).

For opioid-exposed newborns, the prenatal and labor and delivery history may show high-risk maternal factors such as a lack of prenatal care or an admitted history of drug use. Drug-addicted pregnant mothers commonly do not obtain prenatal care or obtain it only sporadically. Labor and delivery events are also important, including the presence of meconium or fetal distress. Heroin-addicted newborns have a greater than normal incidence of meconium aspiration.

The physical examination findings and mental state of the mother are also helpful. Often, the mother admits to heroin use or to having taken illicit drugs in the past. Needle tracks from illicit drug injections are also high-risk findings. The mental status examination findings may be helpful if the mother is able to answer questions coherently.

At birth, assess gestational age to determine whether the newborn has grown appropriately in utero. Many drug-exposed newborns are SGA but have a head circumference that is proportionally large. This type of SGA is described as “head-sparing SGA.”

On admission to the nursery, assess the newborn further. Newborns exposed to opioids display withdrawal symptoms within 2 to 6 days after delivery, when the drug blood level becomes critically low (Chart 14–6). CNS symptoms appear first, followed by gastrointestinal disturbances. The most common symptom of NAS is tremors.

The increased activity, poor feeding, irritability, increased metabolic rate, and decreased sleep typical of NAS lead to inadequate weight gain and growth. Investigate each withdrawal symptom as it appears, to help rule out other causes, such as hypoglycemia or hypocalcemia.

CHART 14–6 SYMPTOMS OF OPIOID WITHDRAWAL IN THE NEONATE*

Tremors
 High-pitched cry
 Sneezing
 Irritability
 Increased muscle tone
 Poor feeding
 Diarrhea
 Weight loss and inadequate weight gain
 Decreased sleep
 Poor state control
 Increased sensitivity to environmental stimuli
 Increased activity

*Symptoms appear gradually and progress in severity and frequency. Most symptoms appear by 3 days and can last 4 to 6 weeks or longer, depending on the drug.

Tremors are not uncommon with other abnormalities, such as hypoglycemia, hypocalcemia, or hypomagnesemia; these conditions must be ruled out before treating for drug exposure.

At the time of admission, maternal blood work and urine samples may be sent, depending on the mother's history and presentation. Legal issues regarding such testing are determined on a state-by-state basis. Generally, if the maternal history poses a risk, the newborn's urine sample is sent to the laboratory for qualitative toxicologic assessment immediately after birth. Urine collected more than 36 hours after birth is likely to test negative for drugs. Meconium or hair samples, if available, are superior samples for toxicology screening, because these samples show long-term drug exposure.

Nursing Diagnoses and Outcomes

Nursing diagnoses and outcomes generally applicable for newborns with a health challenge are presented in Nursing Plan of Care 14–1. In addition, those identified in TIP 14–1 are also applicable for a newborn with intrauterine drug exposure.

Interdisciplinary Interventions

For mild withdrawal symptoms, reduce noise levels and darken the environment to assist the newborn to be calm and to sleep. Advise other healthcare workers not to disturb the newborn and to talk quietly while near the bedside. Provide periods of undisturbed sleep, limiting examinations and procedures.

KidKare ■ To help calm the irritable newborn, provide boundaries in the crib with blankets, offer a pacifier, and swaddle the infant. Cluster care activities to promote longer periods of sleep and to avoid unnecessary handling.

Skin care can be a challenge in these newborns as a result of frequent, watery stools. Also, skin breakdown at the knees and nose is common from rubbing against the blankets during irritable spells. Apply barrier creams to the diaper area to prevent skin breakdown. Protect knees by using sheepskin or occlusive dressings.

Teach the parents about withdrawal symptoms and treatment (see TIP 14–1). Provide this teaching objectively and clearly, avoiding causal and accusatory statements. It is vital that the family understand the withdrawal course, treatment (including medication administration), and expected behaviors. Model appropriate interactions and infant care to assist the parents to learn coping and calming skills for their newborn.

Based on the neonatal abstinence score, the prescriber may start medications such as phenobarbital, morphine, diluted tincture of opium (DTO), or paregoric to control the withdrawal symptoms. Finnegan (1985) recommends initiating pharmacotherapy only after other common metabolic conditions have been ruled out. Pharmacologic

TIP 14-1 A Teaching Intervention Plan for the Child With Neonatal Abstinence Syndrome

Nursing diagnoses and family outcomes

- Impaired skin integrity related to frequent, loose stools
Outcomes: Family will state reason for skin breakdown. Family will demonstrate appropriate cleansing and application of diaper cream.
- Sleep deprivation related to irritability
Outcomes: Family will state importance of sleep to overall health. Family will demonstrate swaddling and calming techniques, darkening environment. Family will safely and accurately administer medications.
- Imbalanced nutrition: Less than body requirements related to increased activity and poor sleep cycles
Outcomes: Family will feed newborn safely and efficiently. Family will state need for increased calories. Family will prepare specialized formula accurately and store it safely.
- Impaired parenting related to drug abuse and decreased resources/support
Outcome: Family will complete needed referrals and seek and utilize resources.

Interventions

- Teach parent/caregivers about
- **Medications**
Measure medication carefully and give at designated times. Administer medications as prescribed, and give phenobarbital in small amount of formula. Monitor for lethargy or increased irritability; give only what is prescribed to avoid overdose. Keep medications out of reach of children.
 - **Nutrition**
Promote small, frequent feedings; use high-calorie (24 cal/oz) formula.
 - **Special Considerations**
Promote adequate sleep by providing quiet environment, swaddling, offering pacifier; allow prolonged periods of sleep.
 - **Skin**
Protect diaper area with barrier creams.
 - **Psychosocial**
Provide referrals to community resources (public health department, mental health services, addiction treatment center, food subsidy programs).
If caregiver feels “out of control” and unable to cope, call a friend to watch infant, call healthcare provider, close door and allow infant to cry.
 - **Contact Healthcare Provider if:**
The infant develops water-loss stools, increase in irritability, vomiting, fever more than 100.4 °F (38 °C), lethargy, poor feeding, or accidental overdose.

intervention is indicated if the score is more than 8 for three consecutive scores or if the average of three consecutive scores is 8 or more. Additionally, if the total score is 12 or more for two consecutive intervals, therapy should be initiated before the 4-hour interval has elapsed (Finnegan, 1985).

Phenobarbital is used to suppress the major CNS aberrations. Because of its effectiveness in controlling irritability and improving sleep patterns, phenobarbital is often used to treat infants with symptoms from poly-drug exposure. In contrast, morphine, DTO, and paregoric are most effective in pure opioid withdrawal,

because these drugs actually replace what is missing in the body. Paregoric contains opium alkaloids that are antispasmodics and phenanthrene derivatives that are analgesics and opioids. Therefore, this drug decreases diarrhea. However, paregoric contains alcohol (44% to 46%), is difficult to titrate, and may require a longer course of therapy than other drugs (Finnegan, 1985).

Dual therapy (using more than one drug to treat symptoms) may be more effective than monotherapy. Infants treated with DTO and phenobarbital had improved neuro-behavioral organization during the first few weeks of life (Coyle et al., 2005).

A nutritional consultation may be helpful to optimize caloric intake. A formula with 24 cal/oz may be needed to meet the metabolic needs of these newborns. Bottle-feeding may be ineffective, and an experienced occupational therapist may assist with nipple evaluation and interventions. Breast-feeding is not recommended for newborns of mothers with a drug history. Some drugs, especially cocaine, are passed to the infant through breast milk. Often the newborn will need IV fluid and nutrition

to maintain proper growth. Such treatment requires a longer hospitalization.

Community Care

A clinical social worker assists with the placement of the newborn if the mother is unable or unwilling to care for her newborn. Working closely with the clinical social worker is vital to provide the best home care situation for the mother and newborn. Additionally, the clinical social worker assists the mother to obtain necessary social services, parenting classes, and referrals (Clinical Judgment 14–2).

Disorders Related to Tobacco Smoke

Environmental tobacco smoke poses another risk to the fetus. Tobacco smoke reduces maternal blood oxygen levels, and nicotine readily crosses the placenta, appearing in fetal blood at levels higher than those seen in maternal serum.

Although difficult to quantify, environmental tobacco smoke exposure and maternal smoking in pregnant women

CLINICAL JUDGMENT 14–2

Infant of a Substance-Abusing Mother

Hannah is a 3-day-old term newborn who is SGA, delivered to a mother who is taking methadone and abusing heroin. Hannah is irritable and has increased muscle tone, diarrhea, frantic sucking, and vomiting. Her vital signs are as follows: heart rate, 180 beats per minute; respiratory rate, 70 breaths per minute; no other signs of respiratory distress; temperature, 100.6 °F (38.1 °C) axillary; weight, 1,800 g.

Questions

1. What other assessment data should the nurse collect?
2. Which assessment findings are abnormal?
3. What is the cause for Hannah's symptoms?
4. What nursing interventions should initially be implemented?
5. How will the nurse know that Hannah is improving?

Answers

1. Quality of Moro's reflex, presence of skin breakdown (knees, chin), number of hours spent sleeping between feedings, comparison of birth weight to current weight to determine presence of significant weight loss (>10% of birth weight), presence of tremors (while disturbed or undisturbed), nasal congestion or rhinorrhea, sweating, and mottled skin
2. Irritability, increased muscle tone, diarrhea, frantic sucking, vomiting, rapid respiratory rate, elevated temperature; weight indicates SGA

3. Hannah is experiencing neonatal abstinence syndrome (or NAS). After delivery, when the supply of heroin and methadone is gone, the infant responds with active withdrawal symptoms. These may occur any time after delivery, but are most common within 48 to 72 hours. The most common symptoms include CNS irritability and gastrointestinal hypermotility. Weight loss is a result of the hypermetabolic state in which there is increased oxygen consumption at the cellular level.
4. Initiate the Neonatal Abstinence Score Sheet to provide ongoing documentation of behaviors in an objective format. Provide a quiet and darkened environment. Swaddle with blankets and provide rhythmic rocking. Provide small, frequent, and calorie-dense feedings. Offer a pacifier. Collaborate with the medical team to initiate medications to alleviate the withdrawal symptoms. Include the parents by demonstrating appropriate interventions that assist in calming the infant.
5. Neonatal Abstinence Score Sheet scores of 8 or less, daily weight gain, sleeping at least 3 hours between feedings, coordinated suck–swallow patterns with minimal spillage of formula, no vomiting or regurgitation, presence of awake/alert states, appropriate response to caregiver interactions

leads to preterm delivery (Fantuzzi et al., 2007) and lower birth weight (Ward, Lewis, & Coleman, 2007). Smoking is associated with an increased rate of term SGA delivery (Aagaard-Tillery et al., 2008). Environmental tobacco smoke continues to pose a risk to newborns after delivery. Children exposed pre- and postnatally have more wheezing, rhinitis, crying, and irritability than children with nonsmoking parents (Johansson, Ludvigsson, & Hermansson, 2008)

Pathophysiology

The components of cigarette smoke, including nicotine and carbon monoxide, inhibit cell uptake of amino acids in the placenta. These amino acids are the building blocks of proteins that are essential for adequate fetal growth. Without these proteins, LBW may occur. Additionally, nicotine produces vasoconstriction and may lead to reduced placental blood flow, reducing blood flow to the fetus and limiting the availability of nutrition and oxygen.

In response to this vasoconstriction and limited blood flow, the fetus increases its production of fetal red blood cells, inducing polycythemia. Although compensatory, polycythemia has inherent problems because the blood is more viscous than normal and can begin to sludge, leading to further hypoxia from blocked blood vessels.

Interdisciplinary Interventions

Nursing interventions are geared to prevent smoking and support smoking cessation programs and techniques. Recognizing smoking as an addiction is an important conceptual step in truly assisting the individual with cessation. Encourage smoking cessation during pregnancy or at least reducing the number of cigarettes smoked. After birth, if parents are unwilling to stop smoking, encourage them to refrain from smoking inside the home.

Neonatal Hyperbilirubinemia

QUESTION: On the seventh day after birth, Gabriella's unconjugated bilirubin level rises enough to require phototherapy. You discover Abby crying by Gabriella's isolate. She says to you, "I don't understand why this has happened." The cascade of hemoglobin breakdown is not easy for healthcare professionals to understand; it is predictably

baffling to parents. How will you explain this development to Abby? Why would you indicate that for hyperbilirubinemia in the premature infant, phototherapy is the therapy of choice?

In utero, the placenta serves as the primary organ to clear bilirubin from the fetus' system. After birth, the newborn liver must take over the task of excreting bilirubin, while production of bilirubin increases from excessive breakdown of red blood cells. **Hyperbilirubinemia** is defined as excessive levels of bilirubin in the blood, often caused by a pathologic process.

Jaundice is a yellowing of the skin that is one of the most common physical findings during the initial newborn period. Jaundice occurs when bilirubin is deposited into the subcutaneous tissue, and it becomes visible when the serum bilirubin levels exceed 7.0 mg/dL. Jaundice caused by normal physiologic processes occurs in 45% to 65% of all healthy term newborns (Goulet et al., 2007), generally peaking at 3 to 5 days of life (Keren et al., 2008), and is even more frequent in infants less than 38 weeks' gestation (American Academy of Pediatrics, 2004).

Alert! Jaundice that occurs within the first 24 hours of life or after 2 weeks of life signifies an abnormal physiologic process and should be followed up immediately.

Breast-fed infants have a higher incidence of jaundice than those who are not breast-fed. This higher incidence may be related to the quality of suckling at the breast. Newborns who have difficulty breast-feeding may develop jaundice from dehydration and caloric deprivation. If the newborn is healthy, with no signs of other causes of jaundice, then continued, frequent breast-feeding is recommended.

Premature newborns are at risk for hyperbilirubinemia resulting from immaturity of the liver, relatively limited albumin binding sites, and, often, severe illness that requires prolonged parenteral nutrition. Premature newborns often present with elevated bilirubin levels that peak at about 1 week of life, in contrast to the term newborn, in whom levels peak at around day 4 of life. Common causes of hyperbilirubinemia in the newborn are increased bilirubin production (from increased breakdown of red blood cells), decreased excretion of bilirubin, or both (Table 14-5).

TABLE 14-5

Common Causes of Hyperbilirubinemia

Increased Bilirubin Production	Decreased Bilirubin Excretion	Increased Production and Decreased Excretion
Hemolytic disease	Prematurity	Prematurity
Bacteremia	Bowel obstruction	Bacterial infections
Cephalhematoma	Hypothyroidism	Congenital infections
Excessive bruising	Hypoxia	
Polycythemia	Breast milk jaundice	

Pathophysiology

Bilirubin is the end product of the breakdown of heme, a substrate of hemoglobin. It is released into the bloodstream as red blood cells are broken down. Newborns produce bilirubin at more than twice the rate of the adult (about 6–8 mg/kg/day). This large bilirubin production is necessary, because newborns' red blood cells have a short life span. Newborns also have a greater number of circulating red blood cells than adults, resulting in part from the naturally occurring hypoxic intrauterine environment.

In utero, bilirubin produced by the fetus crosses the placenta to maternal circulation and is excreted by the maternal liver. After delivery, the newborn begins to build up bilirubin levels that exceed the capacity of the neonatal liver (which can excrete only approximately two thirds of the circulating bilirubin). After the red blood cell has been broken down and the bilirubin is released into the bloodstream, it binds to albumin in the plasma. After all the albumin-binding sites are saturated, bilirubin circulates freely in the plasma. This freely circulating bilirubin has a high affinity for fatty tissue, such as brain tissue, and can therefore cause serious neurologic sequelae if allowed to remain at high levels. Hypoxia and subsequent asphyxia decreases the pH of the blood, impairing albumin's ability to bind bilirubin. Asphyxia also causes damage to other organs, such as the liver, which may impair its ability to metabolize and excrete bilirubin.

After the bilirubin reaches the liver, it is transferred from the albumin to the liver cell. In the liver, the bilirubin is transformed in the presence of the hepatocyte microsomal enzyme glucuronyl transferase and is conjugated for excretion into bile. Most of the bilirubin, approximately 95%, is excreted into bile. The bile is secreted into the intestine, and the bilirubin is expelled through the stool. Newborns may have delayed intestinal motility coupled with poor fluid intake, which leads to decreased urine and stool output, thus delaying bilirubin excretion. In this situation, the bilirubin in the stool is reabsorbed through the intestine, causing higher levels of circulating bilirubin.

There are two types of bilirubin: conjugated and unconjugated. Conjugated bilirubin has been converted in the liver to a water-soluble form that is easily excreted in the biliary tree. Unconjugated bilirubin has not been converted in the liver and is fat soluble. Fat-soluble bilirubin has a high affinity for extravascular tissue, including fatty and brain tissue.

The newborn's liver is immature, and the large amount of bilirubin that is produced and cannot be excreted is deposited in the skin, producing jaundice. This process accounts for the jaundice occurring in healthy term newborns after 24 hours of life.

Prognosis

If the hyperbilirubinemia has been controlled, and the level of unconjugated bilirubin has been kept to a minimum, the prognosis for a full recovery with no sequelae

is good for the term newborn (Ip et al., 2004). Conversely, if the unconjugated bilirubin level is high, bilirubin may accumulate in nervous tissue, and bilirubin encephalopathy may occur. Bilirubin encephalopathy presents with jaundice, lethargy, poor feeding, arching of the back, and a high-pitched cry. Bilirubin encephalopathy occurs when bilirubin crosses the blood–brain barrier and damages the CNS. **Kernicterus**, a term often used to describe bilirubin encephalopathy, is a postmortem diagnosis involving yellow staining of brain tissue. Infants with bilirubin encephalopathy have long-term neurologic disabilities such as motor deficits (they are often unable to walk), hearing loss, and difficulty speaking; it can even lead to death.

Any newborn with a bilirubin level that meets the requirements for an exchange transfusion (in which the entire blood volume in the body is exchanged with new blood to immediately lower the bilirubin level) is at risk for hearing deficits.

Assessment

Jaundice is the first clinical manifestation seen in newborns with elevated bilirubin levels. Noting the onset of clinical jaundice is important, because the appearance of jaundice before the first 24 hours of life or after the third day is abnormal and may indicate a hemolytic process, sepsis, or other abnormal condition requiring prompt intervention. Assess for jaundice in the newborn a minimum of every 8 to 12 hours.

Assess the blood types of the mother and newborn to determine whether risk factors for jaundice, such as ABO or Rh incompatibility, are present. Additionally, evaluate the obstetric history to determine whether the delivery was complicated or traumatic enough to have caused extensive bruising.

Visible jaundice tends to progress from the face downward. Guidelines to use when estimating the extent of involvement of jaundice are as follows:

- Light jaundice: Appears on the face
- Slightly higher jaundice: Appears on face, trunk, abdomen
- Hyperbilirubinemia: Visible orange color extending to the thighs or the entire abdomen

Once visible jaundice appears, send a blood sample to the laboratory for serum bilirubin determination or perform a transcutaneous bilirubinometry (or TcB) test; further follow-up is indicated. An infant's risk of developing significant hyperbilirubinemia may be assessed by using the infant's predischarge bilirubin level and gestational age (Keren et al., 2008).

caREminder

Assess total serum bilirubin according to the newborn's hours of age and taking into account any risk factors. Plot the total serum bilirubin and notify the physician or nurse practitioner of the results.

The term newborn's serum bilirubin levels peak at the fifth postnatal day. Newborns with elevated levels that increase more than 5 mg/dL/day are at high risk for sequelae and require treatment for hyperbilirubinemia.

Assess the newborn's liver size, presence of bruises or petechiae, and level of activity. Newborns with a hemolytic process often have hepatosplenomegaly. Newborns with hyperbilirubinemia may have excessive extravascular blood or bruising. High levels of bilirubin may lead to lethargy and decreased tone.

Monitor the newborn's intake and amount of weight loss. A newborn who feeds poorly at the breast or is disinterested in feeding after 24 hours is at risk for developing hyperbilirubinemia. Newborns often lose weight during the first week of life, but excessive weight loss (more than 10%) may indicate dehydration, which concentrates the blood, leading to an elevated serum bilirubin level.

Anemia is rare in newborns with physiologic jaundice, but it may occur in hemolytic jaundice because of the excessive breakdown of the red blood cells. Hemolytic jaundice is an abnormal process and requires frequent assessments of severity and progression. Additionally, specific laboratory tests are ordered to determine the extent of the hemolytic process. Newborns who appear pale should have screening hemoglobin assessment. Other clinical signs of anemia include tachycardia and hypotension.

Bilirubin encephalopathy is a particular risk for newborns with serum bilirubin levels more than 20 mg/dL. This condition may manifest in poor feeding, hypotonia, and lethargy. More severe brain damage may reveal itself in high-pitched crying, spasticity, opisthotonos, and seizures. Neurologic deficits such as deafness, altered gait, and decreased mental ability may persist.

Simply inspecting the newborn is not an effective method to determine whether jaundice is present. Blood studies including total and direct bilirubin, Coombs' tests, and blood grouping are performed at the first sign of visible jaundice. Additionally, TcB is now available as a noninvasive method to assess jaundice. TcB uses a special device by which the jaundice levels are assessed through the skin. TcB correlates well with total serum bilirubin and can be used as an alternative to total serum bilirubin determination in the term infant with physiologic jaundice (Ip et al., 2004).

Interdisciplinary Interventions

All newborns discharged from the newborn nursery should have bilirubin levels assessed (American Academy of Pediatrics, 2004). Additionally, all newborns should be seen by a healthcare provider 48 to 72 hours after discharge from the nursery to reassess the progression of jaundice, the establishment of healthy feeding routines, and weight gain or loss. Newborns with high risk factors, including poor establishment of breast-feeding, must be seen within 24 hours of discharge.

Acute assessment skills are vital to initiate early treatment for jaundice. As discussed earlier, jaundice appearing after the first 24 hours of life in a healthy term newborn is physiologic jaundice and often requires no treatment. Monitor feeding behavior (infants should

nurse 8–12 times per day) and the number of wet diapers to ensure adequate intake and output. Daily total and direct bilirubin levels may be ordered by the physician if jaundice continues to increase. Increasing lethargy, poor feeding, and decreasing output are all signs of worsening jaundice and require evaluation by a physician or nurse practitioner (see [thePoint](#) for Care Path: An Interdisciplinary Plan of Care for the Infant With Hyperbilirubinemia). Hyperbilirubinemia is treated with phototherapy, exchange transfusions, or medications.

Phototherapy

Interpret bilirubin levels according to the infant's age in hours (American Academy of Pediatrics, 2004). Initiation of phototherapy is determined by the prescriber. Treatment with phototherapy involves the use of a range of bilirubin levels, rather than an absolute number, and allows the clinician to assess many clinical variables of each newborn. For example, a newborn with severe bruising from a traumatic delivery who is not breast-feeding well may need phototherapy, initiated at the lower end of the range. In contrast, a healthy, vigorous breast-feeding newborn may not need phototherapy for hyperbilirubinemia until a higher level is reached. The exact level of bilirubin at which phototherapy is needed has not been determined. A combination of factors is considered when initiating treatment, including high-risk factors (excessive bruising, poor feeding), gestational age (infants at 37 weeks' gestational age or less are at increased risk), and bilirubin levels. Phototherapy works by converting bilirubin in the skin to a water-soluble form that can be excreted by the liver without conjugation. It is initiated for any form of unconjugated hyperbilirubinemia and can be used in conjunction with other treatments such as exchange transfusion. Phototherapy is most effective in treating slowly developing hyperbilirubinemia and is an adjunct treatment for the more rapidly increasing forms of hyperbilirubinemia, such as those caused by hemolytic processes. Phototherapy can be delivered by placing the newborn under fluorescent phototherapy lights (Fig. 14-13), or by wrapping the neonate in a fiberoptic blanket (see [thePoint](#) for Procedures: Phototherapy). Natural sunlight also aids in altering the structure of bilirubin so that it can be excreted from the body.

Phototherapy Lights

Bilirubin can absorb only light of certain wavelengths. White, blue, and green lights can be used to deliver phototherapy. The differences between the colored lights are the spectral band each one emits. The blue lights have been shown to be more effective for photodegradation, because of the narrow spectral band they emit. Although blue lights are more effective, they may cause headaches in healthcare workers and may also obscure the newborn's color because the blue hue they emit is deceiving. Green light penetrates the skin better; however, clinical application can be difficult, because the green hue can make the newborn appear sick. These lights, like the blue ones, can be unpleasant for healthcare providers to work with.

Phototherapy is delivered by placing the newborn unclothed underneath the phototherapy lights to expose

FIGURE 14–13. Protect the eyes and maintain a normal temperature in an infant undergoing phototherapy.

the skin to the light. It is the nurse's responsibility to ensure that the phototherapy light is positioned appropriately and the light intensity is evaluated. Follow the manufacturer's directions for using the lights and positioning them relative to the infant. If the light is too far away, insufficient energy is delivered to the skin, thereby reducing the efficacy of phototherapy. If the light is too close to the infant, too much energy is directed to the skin, potentially leading to hyperthermia; if halogen lights are used, the heat they generate increases the risk of burning the infant. If infants can maintain their temperature, place them in a bassinet with the lights as close as possible, within about 10 cm of the infant (except in the case of halogen lights) (American Academy of Pediatrics, 2004). Assess the infant's temperature in an open crib frequently (e.g., every 30 minutes for the first hour, then every 2 hours and as needed). If the infant requires an isolette to maintain temperature, position the lights as close as possible. Measure the luminosity (intensity) of the light at least once per shift by using a phototherapy meter placed at the level of the newborn while he or she is undergoing phototherapy. The purpose of measuring the intensity is to ensure a minimum level of microwatts emitted from the lights. If the level is too low, ensure that the lights are directly over the infant. If the level is still too low, obtain a new phototherapy unit to ensure maximum therapy. Usually, a measurement of 10 to 12 $\mu\text{W}/\text{cm}^2$ exposed to the skin surface is effective.

During phototherapy, cover the newborn's eyes to prevent microscopic injury to retinal cells. Apply and secure eye patches or phototherapy masks when phototherapy is initiated; keep them in place at all times while the newborn is under the phototherapy lights to protect the eyes from damage. When properly applied, the mask covers the eyes but does not occlude the nares.

Alert! Check the position of the phototherapy mask frequently to ensure it has not shifted to obstruct the nares. Also ensure that excess pressure is not applied across the nose when positioning the mask.

The infant must remain in a crib or isolette while under the phototherapy light. Usually this requirement limits opportunities for parent–infant bonding to times when the baby is removed from the phototherapy light for feeding. During feedings, turn off the lights and remove the eye patches to provide stimulation and to inspect the eyes for drainage or edema.

Fiberoptic Blanket

The fiberoptic blanket (e.g., BiliBlanket) is also available to treat hyperbilirubinemia. This device is a bank of phototherapy lights that is flexible and is wrapped around the newborn, much like a blanket. Although not as effective as special blue lights, fiberoptic lights in the form of a blanket, in addition to bank lights (double phototherapy), is a useful adjunct therapy when bilirubin levels are dangerously high.

When a fiberoptic blanket is used, place it below the armpits, wrapped around the torso, and secured in place so that the light cannot reach the infant's eyes. A major advantage of the fiberoptic blanket is that it permits greater opportunity for parent–infant bonding. Parents can pick up, hold, and feed their infant while phototherapy is in progress (Fig. 14–14). Also, the fiberoptic blanket allows greater environmental stimulation, because the infant is not restricted to a specific phototherapy light location and does not need to wear eye shields.

Nursing Management

To improve efficiency of the treatment, expose as much of the skin as possible to the light and expose the newborn to the light as much as possible. The newborn is usually diapered to contain urine and stool. This diapering also serves to protect the reproductive organs, because the side effects of phototherapy on these organs are unknown.

Monitor the newborn's temperature closely by obtaining axillary temperature measurements; hyperthermia is not uncommon. Hypothermia may also be a problem if the room has drafts, which can lead to convective heat loss.

Metabolic rate and insensible water loss may increase during phototherapy. Metabolic rate changes may be caused by hyperthermia, which is a common problem for newborns, because phototherapy lights (except for the fiberoptic lights) emit heat. Newborns require increased calories to balance this metabolic rate and to assist with eliminating bilirubin through the intestinal tract. Reduce insensible water loss by keeping the skin temperature constant and avoiding heat. Monitor for dehydration.

Frequent feedings are also essential to prevent dehydration. Dehydration is common in newborns who have poorly established feeding patterns and lethargy. High bilirubin levels tend to make the newborn listless and lethargic, leading to poor feeding. Also, water-loss stools, commonly referred to as *bili stools*, may occur as a result of photodegradation of bilirubin. Increase breast-feeding

FIGURE 14–14. (A) Fiberoptic blanket equipment. (B) The fiberoptic blanket is wrapped around the infant to direct radiating light to the skin.

or bottle-feeding during treatment to offset both calorie loss and dehydration.

Skin care is essential for the newborn undergoing phototherapy, because the frequent water-loss stools in combination with dry skin can lead to skin breakdown. Frequent diaper changes and position changes may prevent breakdown of the skin. Lotions are generally not applied to the skin of newborns who are receiving phototherapy because of the risk of skin burns. However, avoiding lotions has not been extensively researched, and this practice may vary at institutions. It is also common for the newborn receiving phototherapy to develop a rash similar to a heat rash. This rash requires no treatment and often resolves when phototherapy treatment is discontinued.

Newborns with a high direct bilirubin level (>2.0 mg/dL) should not receive phototherapy. A high direct hyperbilirubinemia level is associated with liver disease, such as neonatal hepatitis or congenital obstructive jaundice. Although conjugated bilirubin is generally not toxic to the newborn's CNS, it must be evaluated carefully. When used in these cases, phototherapy causes "bronze baby" syndrome, producing a gray-brown discoloration of the skin and darkening of both serum and urine. These effects are benign and lessen after the phototherapy lights are removed, but they may take months to fully resolve.

Exchange Transfusion

If phototherapy is ineffective in resolving the hyperbilirubinemia, and the bilirubin level continues to increase—approaching levels at which kernicterus may occur—more drastic interventions may be required. Exchange transfusion, which involves removing the newborn's blood and replacing it with new blood, is described in more detail later in the section on hemolytic disease of the newborn (HDN). This procedure is rarely done for newborns with physiologic jaundice and is most commonly used for severe hemolytic processes involving intractable anemia, as occurs in HDN.

Community Care

It is imperative that parents know how to assess jaundice. Nurses are the primary educators of parents with newborns and are in a pivotal role to provide vital information related to general neonatal care. Discharge teaching related to jaundice includes explaining

- What causes jaundice and its common signs and symptoms
- How to evaluate feeding and output quantities
- How to monitor for changes in activity level and skin color
- When to call the physician

Teach parents how to assess the jaundice in their newborn's skin by focusing on the progression of jaundice, which begins in the face and moves to the abdomen and lower extremities. Teach them to monitor the number of wet diapers per day to help evaluate adequate intake. Also, stress the importance of noting the newborn's activity, because increasing jaundice leads to lethargy and poor feeding. Finally, encourage them to use indirect sunlight through a window to help decrease jaundice, because sunlight photodegrades bilirubin from the skin, much as phototherapy does.

Phototherapy can be used in the home setting with select newborns and their parents. Before initiating home phototherapy, whether with the fiberoptic blanket or the traditional bank of lights, assess the newborn and the parents to determine the appropriateness of home treatment. The ideal candidate is a healthy, full-term newborn with no other underlying disease or problems who has a well-established feeding pattern. The parents must be willing and able to provide the phototherapy treatment and to carefully monitor the newborn's skin color, feeding vigor, and activity. Detailed parent training and education is a must for home phototherapy to be successful (Community Care 14–1).

COMMUNITY CARE 14–1

The Newborn Receiving Fiberoptic Phototherapy at Home

Home phototherapy for neonatal jaundice is a safe, cost-effective alternative to extended hospitalization when the newborn meets certain criteria. These criteria include

- No health problems other than neonatal hyperbilirubinemia
- Gestational age of more than 37 weeks
- Birth weight greater than 2,500 g
- Apgar score at 5 minutes of 7 or higher
- Age between 2 and 7 days at start of home phototherapy
- Safe home environment with grounded electric outlet
- Infant's caregiver willing and able to follow through on instructions for using the home phototherapy system
- Infant's caregiver willing and able to monitor key indicators of the newborn's physical state
- Infant's caregiver agreeable to allowing daily nursing assessment and drawing of necessary blood specimens

The fiberoptic system is a common means of home phototherapy and, generally, the nurse is responsible for teaching the infant's caregivers about its use. In addition, the nurse provides instruction on care of the newborn who is receiving phototherapy at home. Outcome objectives for the infant's caregivers include the following:

- Identify components of the fiberoptic system.
 - For blanket: Illuminator box, cable connector, and fiberoptic blanket with disposable cover
 - For lights: Light bank
- Set up fiberoptic system and be sure it is working.
- For blanket: Wrap the newborn in the fiberoptic blanket, placing it below the armpits and securing it around

the torso, so that light cannot reach the neonate's eyes and to reduce exposure of reproductive organs.

- For lights: Apply eye shield correctly. Identify complications of eye shield applied too tightly or loosely.
- Diaper newborn to reduce exposure of reproductive organs to light.
- Monitor the newborn's body temperature.
- Monitor the newborn's output.
 - Frequency and description of voidings
 - Frequency and description of bowel movements
- Monitor newborn for signs of dehydration.
 - Decreased urine output
 - Decreased body weight
 - Decreased skin turgor
 - Dry mucous membranes
 - Sunken eyeballs
 - Sunken fontanels
 - Irritability
 - Lethargy
- Provide newborn with frequent feedings to help prevent dehydration and enhance the effectiveness of phototherapy.
- Interact with infant while phototherapy is in progress. When using the blanket, the caregiver can hold the infant. When using the light bank, turn off the lights during feedings, remove the eye shield, and hold the infant. Replace the shields and reposition the infant before reinitiating phototherapy.
- Discuss the importance of ongoing blood tests and nursing assessments for the newborn receiving phototherapy at home.
- Provide the caregiver with a telephone number to call for concerns about the newborn or the fiberoptic system during home phototherapy.

ANSWER: Here is an example of an explanation you could give to Abby, a parent of a premature infant with hyperbilirubinemia: "All babies, when they are inside their mothers, have a lot of red blood cells. Because their lungs are not working, they are getting all of their oxygen from their mother, and they need more red blood cells to have enough oxygen. When they are born and the lungs begin to function, they do not need so many red blood cells, so the red blood cells start breaking down. The liver is in charge of breaking down the red blood cells, but premature babies have very immature livers. Gabriella's liver is having a hard time keeping up with the amount of red blood cells that need to be processed. When a red blood cell breaks down, bilirubin is released. The liver breaks down the bilirubin and it is excreted

in stool. When the liver can't keep up, like Gabriella's right now, there is extra bilirubin circulating around that gets deposited in the skin. A little bilirubin in the skin is not harmful, but if we let the amount of circulating bilirubin get really high, it can deposit in the brain and that is harmful. Fortunately, certain wavelengths of light can help break down the bilirubin and make it water soluble and easier to excrete. So Gabriella is under these phototherapy lights to help her break down bilirubin. We make sure her eyes are protected from the lights, she has enough fluids—first, to make sure she does not get dehydrated and, second, to help her excrete the extra bilirubin. We make sure she is comfortable and we turn her regularly, so that all of her skin is exposed to the light—just like getting an even tan."

Hemolytic Disease of the Newborn (HDN)

HDN causes destruction of erythrocytes (red blood cells) in the neonate whose blood is not compatible with the mother's blood. Because erythroblasts (immature circulating erythrocytes) appear in great numbers in the fetal blood as the body attempts to increase production of red blood cells in response to the anemia that occurs when erythrocytes are destroyed, HDN is also known as *erythroblastosis fetalis*.

The incidence of HDN has decreased remarkably since the 1960s, when Rh immunoprophylaxis (RhoGAM) became available. Rh immunoprophylaxis provides a means of preventing the generation of Rh isoantibodies in the mother who is Rh negative and whose baby is Rh positive.

In HDN, maternal antibodies destroy fetal erythrocytes. HDN can result from any one of a number of incompatibilities among erythrocyte antigens, the most common of which are related to the Rh factor and to the ABO blood groups. Erythrocyte antigen incompatibilities may cause the generation of maternal isoantibodies that can subsequently enter the fetal circulation and destroy fetal erythrocytes. However, even when the blood of the newborn and that of the mother are incompatible, HDN does not necessarily occur, because some mothers at risk do not actually develop and transfer isoantibodies to the neonate.

When the Rh factor is involved, the neonate's erythrocytes are Rh positive and the mother's erythrocytes are Rh negative. When the ABO blood groups are involved, the neonate's erythrocytes are positive for the A or B antigens (or both) and the mother's erythrocytes are usually negative for both of these antigens. HDN is rare when the mother possesses the A antigen and the newborn possesses the B antigen or vice versa. Blood group incompatibility is more common than Rh factor incompatibility, but Rh factor incompatibility is more likely to result in major physical alterations for the neonate.

WORLDVIEW: The potential for HDN varies among racial and ethnic populations according to the extent to which the different red blood cell antigens are present or absent. For example, the possibility of HDN secondary to Rh factor incompatibility is greater among whites than among other groups, because approximately 15% of the white population is Rh negative. About 5% of the black population is Rh negative; thus, this group has less potential for Rh factor incompatibility. Among Chinese, Japanese, and Native Americans, Rh factor incompatibility is unusual, because Rh-negative individuals are rare in these populations.

Pathophysiology

Because HDN stemming from Rh factor incompatibility generally is more serious than that resulting from ABO incompatibility, Rh factor incompatibility is the primary focus in this discussion. Although a number of antigens are present in the Rh system, the common terms *Rh positive* and *Rh negative* refer to the D antigen. Rh-positive erythrocytes have the D antigen, whereas Rh-negative erythrocytes do not have the D antigen.

HDN develops during pregnancy when maternal anti-D antibodies cross the placenta into the fetal circulation and coat Rh-positive fetal erythrocytes. This event targets fetal erythrocytes for destruction, primarily by the reticuloendothelial cells of the spleen.

Maternal anti-D antibodies are produced after the mother is exposed to fetal Rh-positive blood. Most often, such exposure occurs through transplacental hemorrhage during pregnancy or through bleeding at the time of childbirth. Maternal anti-D antibodies remain with the mother and tend to have a greater effect on subsequent pregnancies in which the fetus is Rh positive.

In ABO incompatibility, anti-A and anti-B antibodies occur naturally in people who lack the A or B antigens. These antibodies are formed when the immune system is stimulated by the A and B matter found in food and bacteria.

The primary pathophysiologic alterations associated with HDN are anemia and hyperbilirubinemia. Anemia is a concern both before and after the birth of the affected child. It occurs when red blood cell production cannot keep pace with red blood cell destruction. Initially, the body responds by increasing red blood cell production in the bone marrow, as demonstrated by an increased reticulocyte count. Also, extramedullary sites of erythropoiesis develop in the liver and spleen. As anemia progresses, the fetus will become tachycardic as a compensatory mechanism to improve oxygen delivery to body tissues. When prolonged, this tachycardia leads to congestive heart failure and *hydrops fetalis*, a condition characterized by massive edema. Ultimately, death may occur.

Before birth, hyperbilirubinemia usually does not occur, because bilirubin is removed from the fetus by the placenta. After birth, however, hyperbilirubinemia secondary to hemolysis presents as a major concern.

Prognosis

The prognosis for HDN has improved with the use of advanced diagnostic and therapeutic measures. In particular, intrauterine diagnosis and treatment have contributed substantially to decreasing the morbidity and mortality associated with severe HDN. The most noteworthy advance with regard to HDN has been the development of Rh immunoprophylaxis to prevent the formation of maternal anti-D antibodies, thereby preventing HDN.

Assessment

The hallmark of HDN is jaundice secondary to hyperbilirubinemia. Unlike physiologic jaundice of the neonate, jaundice associated with HDN usually appears within 24 hours of birth.

Manifestations of anemia may be present, depending on the neonate's ability to produce the number of red blood cells needed to compensate for the increased rate of erythrocyte destruction. Efforts to maintain a balance between production and destruction of red blood cells usually lead to some degree of hepatosplenomegaly. When balance is not achieved, the neonate becomes anemic, pale, and lethargic. These newborns are often

severely ill, with congestive heart failure, and severe generalized edema (hydrops fetalis), including pleural effusions and ascites.

Alert! Severe anemia in HDN may have a delayed onset. Continue to be alert for signs of anemia in the neonate with HDN, even when such signs are not initially present.

Laboratory manifestations of HDN during the prenatal period generally show an increasing concentration of bilirubin in the amniotic fluid and decreasing numbers of erythrocytes in the fetal blood. When the maternal pregnancy history and the maternal anti-D titer indicate that the fetus is at risk for HDN, amniocentesis and fetal blood sampling procedures may be used as early as the 18th week of gestation to identify the presence and severity of HDN.

Amniocentesis is performed to obtain a sample of amniotic fluid. The concentration of bilirubin in the fluid is measured with a spectrophotometer. The amniotic fluid's optical density at a wavelength of 450 nm is determined, and the fluid may then be classified by Liley zone (Chart 14-7). Depending on the initial optical density, amniocentesis is repeated every 1 to 4 weeks to determine whether the optical density is increasing. Severe HDN is associated with increasing optical density.

Fetal blood sampling by percutaneous umbilical sampling under ultrasound guidance provides a more accurate means of assessing HDN during the prenatal period. However, it involves considerable risk for fetal-maternal hemorrhage. Thus, it is usually reserved for the fetus whose amniotic fluid bilirubin concentration indicates severe HDN. Also, it is used when amniocentesis is contraindicated.

After birth, the primary laboratory manifestation of HDN is an elevated level of indirect (unconjugated) bilirubin. This laboratory value may be somewhat elevated during the first week of life as a result of physiologic jaundice. However, in HDN, the bilirubin level is pathologic and may increase quickly. Also, HDN is associated with a positive direct antiglobulin (direct Coombs') test, which indicates attachment of the maternal anti-D antibody to the neonate's red blood cells.

Perinatal and postnatal blood counts with HDN usually show an increase in reticulocytes and nucleated red blood cells, which are signs of increased erythrocyte production. Hemoglobin levels are decreased when anemia is present.

CHART 14-7 LILEY ZONE CLASSIFICATION OF AMNIOTIC FLUID BILIRUBIN LEVELS

Zone I: Absent or mild HDN

Zone II: Mild to moderate HDN

Zone III: Severe HDN

Nursing Diagnoses and Outcomes

Nursing diagnoses and outcomes generally applicable for newborns with a health challenge are listed in Nursing Plan of Care 14-1. Those applicable to a newborn with jaundice or hyperbilirubinemia were presented earlier. Refer to Nursing Plan of Care 23-1 for those for a child with anemia. The following nursing diagnoses and outcomes also apply to a newborn with HDN:

Fear that neonate will incur chronic impairment or die as a result of HDN

Outcomes: Family verbalizes fears concerning potential for chronic impairment, stillbirth, or death of neonate with severe HDN.

Family receives informational and emotional support.

Interdisciplinary Interventions

Management of the neonate with HDN requires close monitoring of the red blood cell profile and bilirubin levels. These laboratory values provide evidence of worsening anemia and hyperbilirubinemia or of improvement in response to therapeutic interventions.

Two primary interventions are associated with the management of HDN: phototherapy and exchange transfusion. Phototherapy is discussed in detail earlier in the section on hyperbilirubinemia.

Exchange Transfusion

Exchange transfusion (removal of blood and replacement with new blood) is indicated for neonates with moderate to severe HDN and for those with rapidly increasing bilirubin levels. LBW and high-risk infants receive their first exchange transfusion sooner than other neonates with HDN. Exchange transfusion helps to correct both anemia and hyperbilirubinemia.

Exchange transfusion for Rh incompatibility uses donor blood that is Rh negative. With ABO incompatibility, the donor blood is group O. Using this blood type prevents infusion of red blood cells with the antigen that would attract the respective maternal antibody and be prematurely destroyed.

During exchange transfusion for HDN, 5 to 20 mL of the neonate's blood is alternately removed and replaced with donor blood. The total volume of exchange is usually twice the neonate's blood volume (about 170 mL/kg body weight). Caution is exercised to avoid fluid overload, and aseptic technique is maintained throughout exchange transfusions. Generally, exchange transfusion is done through arterial and venous umbilical catheters. Neonates at risk for HDN have moist dressings applied to the umbilical cord shortly after birth to prevent it from drying and to keep the umbilical vessels suitable for access, should an exchange transfusion become necessary.

During and after an exchange transfusion, observe the neonate closely to identify and respond quickly to complications that may occur.

- Note vital signs frequently, monitoring for arrhythmic, hypotensive, respiratory, and body temperature alterations.
- Obtain blood samples, particularly checking for hypoglycemia, electrolyte alterations, and acid–base imbalance.
- Note seizure activity that may occur secondary to hypocalcemia.
- Measure intake and output accurately, noting imbalance between these measurements.
- Note adverse reactions to blood transfused to the neonate.
- Inspect umbilical cord site, monitoring for hemorrhage.

Despite an effective exchange transfusion, “rebound” hyperbilirubinemia may occur as the concentration of tissue bilirubin equilibrates with that of serum bilirubin. Additional exchange transfusions may be required if hyperbilirubinemia continues or increases.

Recombinant erythropoietin (or rEPO) has been helpful in treating infants with severe HDN-associated anemia (Manoura et al., 2007).

Treating HDN in the Unborn Child

When amniocentesis or fetal blood sampling results indicate severe HDN in the unborn child, intervention is necessary to prevent stillbirth. Induction of premature birth is likely when fetal development reaches the point at which survival outside the uterine environment can be expected, usually at a gestational age of 32 weeks or more.

When it is too early to induce premature birth, severe HDN is managed by intrauterine blood transfusion under the guidance of ultrasonography. The preferred method is by intravascular transfusion through the umbilical vein.

Despite the increased ability to diagnose, monitor, and treat HDN, substantial interdisciplinary interventions are directed toward preventing this disorder. Prevention by immunoprophylaxis is possible in cases of Rh factor incompatibility. Generally, Rh immunoprophylaxis is provided by giving anti-D gamma globulin, within 72 hours of childbirth, to mothers who are Rh negative and whose babies are Rh positive. Rh immunoprophylaxis is recommended after spontaneous and induced abortions, and may be given to women who experience vaginal bleeding during the first trimester of pregnancy. Rh immunoprophylaxis may also be administered to women during pregnancy, usually during the 28th week of gestation.

Rh immunoprophylaxis is effective in most women who receive it and, as a result, the incidence of HDN has decreased remarkably. It is important that women at risk for anti-D antibody formation be identified so that Rh immunoprophylaxis can be given in a timely manner.

Community Care

HDN is likely to provoke stress for parents and other family members. Particularly with severe HDN, there may be fear that the baby will die or live with chronic impairment. Be sensitive to the family’s stress. Educate them about HDN, relay ongoing information about the baby’s physical state, and provide emotional support.

The nurse and other members of the interdisciplinary healthcare team have a major role in the prevention and early treatment of HDN. In addition to patient care and family education, provide community education that underscores the importance of early prenatal care. Prenatal care identifies women at risk for giving birth to children with HDN, and their unborn children are monitored for evidence of HDN.

Discharge planning may include instruction in and provision of care for hyperbilirubinemia and plans to monitor hemoglobin levels for anemia for 8 to 12 weeks. Folic acid and, in some cases, B₁₂ supplementation may be given. Home phototherapy using the phototherapy light or, more commonly, the fiberoptic blanket, is an option for children with HDN. Generally, this therapy continues until the serum bilirubin level decreases to less than 10 mg/dL.

Neonatal Hypoglycemia

QUESTION: Why is Gabriella at risk for hypoglycemia?

The brain is glucose dependent; it must have a continual supply of glucose to function properly. The fetus receives a continuous supply of glucose from the placenta. During the third trimester, the fetus begins to store energy in preparation for delivery and the first few hours after birth. At delivery, the maternal supply of glucose ceases and the newborn initiates glycolysis, glycogenolysis, and gluconeogenesis. These processes mobilize liver glycogen to maintain normal serum glucose levels. Glucose values decrease rapidly after birth and stabilize by 3 to 4 hours of life. At this time, enteral feedings (breast-feeding or formula) are initiated to maintain normal glucose values.

The definition of hypoglycemia is controversial, and opinions vary regarding an exact safe level of glucose. A pragmatic approach has defined hypoglycemia as blood glucose values less than 40 mg/dL in the term infant (Jain et al., 2008). Severe and sustained hypoglycemia in the healthy term newborn is unusual. Most healthy term newborns have the ability to withstand the stress of labor, the subsequent loss of a glucose source (with the cutting of the umbilical cord), and the brief period in which glucose supplies are limited (because of limited breast milk supply from the mother). Healthy term newborns are well equipped with alternative fuel sources, such as fatty acids, that assist to protect the brain.

Certain newborns are at risk for hypoglycemia, however, and nurses must be vigilant in identifying these newborns and providing prompt treatment. These newborns include preterm and late preterm infants, who may be cared for in the newborn nursery; infants of diabetic mothers; infants who are LGA, SGA, or have experienced IUGR; and any newborn presenting with clinical illness (hypothermia, respiratory distress, jaundice during the first 24 hours of life, abnormal body movements).

Alert! Serious consequences of hypoglycemia include brain damage resulting in developmental delay and learning disabilities. Prompt assessment of newborns with risk factors can prevent such complications.

Prognosis

The prognosis is related to the duration and severity of the hypoglycemia as well as to the underlying cause. Newborns with symptomatic and recurrent hypoglycemia are more likely to have long-term sequelae than those newborns who are asymptomatic. However, transient hypoglycemia is the most common type during the neonatal period. This type is of short duration and rarely recurs. Major long-term sequelae of severe, prolonged hypoglycemia are neurologic, including cognitive challenge and cerebral atrophy.

Assessment

Most normal nurseries and NICUs have specific protocols for screening high-risk newborns for hypoglycemia. SGA and LGA newborns and those of diabetic mothers should all receive a screening glucose evaluation by capillary blood glucose methods at the bedside shortly after birth and then at regular intervals. Signs and symptoms of hypoglycemia are nonspecific and variable (Chart 14–8), and mimic many other diseases, such as sepsis. Because of the lack of obvious symptoms in some infants, maintain a high index of suspicion of hypoglycemia based on history or presence of subtle signs.

Interdisciplinary Interventions

Nursing interventions include preventing hypoglycemia and promptly identifying newborns at risk. Newborns at risk may be fed early, either at the breast or with formula. If the newborn is unable to feed well or is in respiratory distress, IV therapy to administer glucose is initiated to maintain normal glucose levels. In severe cases of

CHART 14–8 SYMPTOMS OF HYPOGLYCEMIA IN THE NEWBORN

- High-pitched cry
- Apnea
- Cyanosis
- Irritability
- Lethargy
- Respiratory distress
- Hypotonia
- Pallor
- Seizures
- Tremulousness

refractory hypoglycemia, corticosteroids may be administered either intravenously or intramuscularly. Corticosteroids such as hydrocortisone are used to decrease peripheral glucose utilization and increase gluconeogenesis.

Obtain bedside glucose measurements every 30 minutes in newborns treated for hypoglycemia until stable values are achieved, and then every hour for 3 hours to ensure stability. Assess for the presence of symptoms of hypoglycemia, as mentioned earlier.

ANSWER: Gabriella is at risk for hypoglycemia because of her immaturity and her lack of fat stores.

Because of her prematurity, she will not immediately establish a feeding schedule as a full-term infant would. Therefore, initially her glucose level will be tied to her IV fluids and the patency of that line.

Meconium Aspiration

Meconium aspiration is a condition in which the infant, either before or during the birth process, passes its first meconium stool and breathes the material into the respiratory tract with some of its first breaths. Meconium is a very viscous, sticky, forest-green liquid that consists of gastrointestinal secretions, bile acids, salts, mucus, pancreatic juice, cellular debris, amniotic fluid, swallowed vernix caseosa, lanugo, and blood. The substance can be found in the fetal gastrointestinal tract as early as the 16th week of gestation.

Meconium staining of the amniotic fluid (indicating that the substance was passed before birth) is seen in 7% to 22% of term deliveries (Xu et al., 2007). Meconium aspiration syndrome (MAS) will develop in 6.6% to 30% of these infants; about 1% to 3% of live births (Xu et al., 2007). The clinical picture includes respiratory distress and radiographic findings of aspiration (“fluffy” appearance on radiograph) in an infant whose symptoms cannot otherwise be explained. The most widely accepted theory regarding the reason for the passage of meconium into the amniotic fluid suggests that it occurs with relaxation of the anal sphincter during an episode of fetal hypoxia. During intrauterine asphyxia, insufficient oxygen is transported to the fetal intestine, which relaxes anal sphincter tone and evacuates the meconium. Passage of meconium may, however, also represent a maturational event: It is rare before 37 weeks’ gestation, but is increasingly common in pregnancies lasting longer than 40 weeks.

Pathophysiology

Regardless of the cause, when meconium is passed into the amniotic fluid, it can be aspirated into the lungs, creating many mechanical and physiologic changes. The degree of severity of the condition is related to the viscosity of the meconium, which is usually described as thick, moderate, or thin. A large amount of thick meconium could rapidly cause complete obstruction of the upper airways, with associated hypoxia, hypercapnia, and acidosis. More commonly, diffuse particles of meconium

migrate to smaller peripheral airways, causing obstruction, air trapping, and surfactant inactivation. Partial or complete mechanical obstruction results in air trapping, atelectasis, overdistended or hyperexpanded regions, and possible pneumothoraces. Obstruction is caused by a ball-and-valve effect in which air is allowed into the lung but is obstructed from exiting.

Chemical inflammation, infection, or both in the lower airways is also seen in this syndrome. Ventilation-perfusion mismatches ensue, creating hypoxia and acidosis. These factors produce pulmonary vasoconstriction and may result in persistent pulmonary hypertension of the newborn.

Prognosis

Historically, the diagnosis of meconium aspiration held connotations of high morbidity and mortality, especially related to poor neurologic outcomes. Today, most infants with meconium-stained amniotic fluid suffer little or no pulmonary sequelae. Of the infants who develop MAS, approximately one third require mechanical ventilation (Dargaville et al., 2007) with about 5.5% mortality (El Shahed et al., 2007). CP has been identified in some cases as a possible sequela of meconium staining and aspiration, but insufficient data exist to prove or refute this contention. Anoxic encephalopathy is an uncommon but tragic outcome in some instances of meconium aspiration. Several reports have documented abnormal long-term pulmonary function among children who had MAS as newborns. The most common abnormalities noted were spontaneous wheezing and exercise-induced bronchospasm, suggesting small airway injury and disease. CLD may occur when a prolonged period of mechanical ventilation is required. When severe MAS is accompanied by persistent pulmonary hypertension of the newborn, it is often fatal.

Assessment

Newborns with MAS are often term, postterm, or SGA. Symptoms range from mild respiratory distress to severe hypoxemia and respiratory failure. Infants with minimal meconium aspiration characteristically present with tachypnea and mild cyanosis. Those with more severe MAS have marked respiratory distress with cyanosis, irregular or gasping respirations, grunting, and intercostal and substernal retractions. The chest is typically hyperinflated, and the anteroposterior diameter of the thoracic cage is increased. Arterial blood gas values show evidence of severe hypoxemia, hypercapnia, and combined respiratory and metabolic acidosis. Lung sounds may be diminished.

Nursing Diagnoses and Outcomes

In addition to those discussed in Nursing Plan of Care 14-1, the following nursing diagnoses and outcomes apply to the newborn with MAS:

Ineffective airway clearance related to effects of meconium in lungs

Outcome: Newborn will maintain patent airway.

Impaired gas exchange related to effects of altered ventilation and perfusion of lungs

Outcome: Newborn will maintain oxygen saturation of at least 92%.

Interdisciplinary Interventions

Infants delivered through meconium-stained amniotic fluid require expert care at delivery. To prevent MAS, newborns delivered through meconium-stained amniotic fluid may receive intrapartum and nasopharyngeal suctioning to clear the airway of meconium prior to delivery of the shoulders. Routine intrapartum suctioning is no longer recommended, based on current research (American Heart Association, 2005).

Newborns who are delivered through thick, particulate meconium and are not vigorous at birth are intubated, suctioned, ventilated with a resuscitation bag and 100% oxygen, and admitted immediately to the NICU, where they are placed on mechanically assisted ventilation. Additional measures may include surfactant therapy and use of a high-frequency oscillatory ventilator. Surfactant therapy may be effective in MAS patients, because the presence of meconium in the lungs produces inflammation and may deactivate the surfactant that the newborn is producing. The high-frequency oscillatory ventilator is useful in treating severe MAS. (A full discussion regarding mechanical ventilation support for MAS is beyond the scope of this chapter.)

Monitor for development of pneumothorax. Signs and symptoms of pneumothorax include bradycardia, hypotension, carbon dioxide retention, and hypoxemia. The treatment for pneumothorax includes a thoracentesis to immediately remove the air source.

If there is no or poor medical response to the high-frequency oscillatory ventilator, surfactant therapy, or other treatments, and the newborn has signs of persistent pulmonary hypertension, inhaled nitric oxide (iNO) may be used. iNO selectively dilates the pulmonary bed, thereby increasing pulmonary blood flow. Use of iNO has substantially reduced the need for extracorporeal membrane oxygenation (ECMO) therapy. However, some infants do not respond to iNO, and ECMO support is considered. ECMO is a highly invasive therapy involving temporary cardiopulmonary bypass (Fig. 14-15). Because of this procedure's invasiveness, ECMO candidates must meet

FIGURE 14-15. Extracorporeal membrane oxygenation (or ECMO) is a highly invasive therapy involving temporary cardiopulmonary bypass.

specific criteria for treatment, including reversible disease, severe hypoxemia, persistent air leak (pneumothorax), and mortality rates greater than 80% with current therapies. The goal of ECMO therapy is to allow the lung disease to improve over a period of days by giving the lungs a “rest.” ECMO therapy carries many potential complications, such as alterations in cerebral blood flow. The survival rate of newborns receiving ECMO therapy is variable and dependent on the facility at which it is performed. In general, infants requiring ECMO for MAS have a 94% survival rate (Frenckner and Radell, 2008).

ECMO therapy for MAS is very expensive, both financially and emotionally. Intensive nursing care (sometimes with a 2:1 or greater ratio of specialized pump technicians and nursing staff to one infant) is needed, as well as specific technologic requirements. Care of the infant on ECMO therapy is similar to care of the infant undergoing cardiopulmonary bypass surgery for congenital heart defects. It is beyond the scope of this chapter to discuss such care in depth. We refer you to texts concerning pediatric critical care for further information.

As in other diagnoses involving illness in the newborn, the psychosocial and emotional manifestations in parents and family members include shock, fear, anxiety, and grief over the loss of the expected “perfect” or “normal” infant. Mothers especially require sensitivity and honest, supportive communication regarding the infant’s prognosis, because they are undergoing fatigue, pain, and hormonal fluctuations immediately after childbirth.

Social service and other counseling interventions are imperative for family support. Because tertiary centers are often located many miles away from home and the usual support systems, assistance with securing food, transportation, lodging, and resources for sibling care is required.

See [thePoint](#) for a summary of Key Concepts.

The Child With Altered Cardiovascular Status

Case History

Recall Gabriella Goldman from the previous chapter? Born prematurely, she is now 6 days or 29 weeks' gestational age. The staff has attempted to wean Gabriella from the ventilator and supplemental oxygen with little success. She has just started receiving gavage feedings of her mother's breast milk. So far, she is tolerating her feedings. She continues to have a peripheral intravenous (IV) access for fluids and medication administration.

Late on the night shift, Gabriella's respiratory rate increases and her oxygen saturation decreases. The nurse caring for Gabriella follows the ordered parameters and increases her inspired oxygen percentage. Gabriella vomits during two of her gavage feedings; her oxygen saturation and her heart rate decrease during the most recent feeding. The morning

nurse begins a thorough assessment and notes Gabriella's breathing is moderately labored at a respiratory rate of 56 breaths per minute. Her breath sounds are coarse, but she is moving air well. The nurse notices a continuous heart murmur that definitely was not there the day before. Gabriella is also receiving 5% more oxygen than she was the day before.

Gabriella's nurse notifies the nurse practitioner and anticipates a chest radiograph and echocardiogram to confirm the clinical suspicion of a patent ductus arteriosus (PDA). Gabriella's healthcare team discusses the merits of different treatments, fluid restriction alone, indomethacin or ibuprofen and fluid restriction, or surgery. You may wish to read ahead to Defects with Increased Pulmonary Blood Flow for a discussion of a PDA.

CHAPTER OBJECTIVES

1. Identify genetic, environmental, maternal, and multifactorial influences on congenital heart disease.
2. Describe specific assessment skills that assist in the identification and care of the child with altered cardiovascular status.
3. Identify invasive and noninvasive diagnostic tools that help in evaluating children with suspected heart disease.
4. Describe information to include in the teaching plan when preparing a pediatric cardiac patient for a procedure.
5. List nursing interventions and potential complications during the acute and convalescent phases of postoperative care for the cardiac patient.
6. Explain the pathophysiology associated with, presentation of, and interdisciplinary interventions for the child with heart failure, cyanosis, and acquired heart disease.
7. Describe the anatomic variations associated with the more common congenital defects, and explain the hemodynamic consequences of these defects.
8. Discuss the various medical and surgical treatments of congenital heart defects, and differentiate between curative and palliative procedures.

See [thePoint](#) for a list of Key Terms.

Altered cardiovascular status in children typically occurs as one of two primary types of heart disease: congenital and acquired. Congenital heart disease (CHD) is a functional or structural disease of the heart that is present at birth, even though the illness may not manifest itself clinically until later in life. Mortality from CHD is declining in the United States, although CHD remains a major cause of death in infancy and childhood. The incidence of CHD is 6 per 1,000 live births; if diagnoses of potentially serious bicuspid aortic valve are included, the incidence is 19 per 1,000 live births (Hoffman & Kaplan, 2002). Several factors cause the occurrence of CHD to be underestimated. Efforts to record all true cases of CHD are limited. Researchers may have difficulty ascertaining statistics on children with CHD in rural areas, in areas with a high population of indigent families, and in underdeveloped nations. Another reason for faulty statistics may be the failure to record children with mild versions of a defect, such as mild pulmonary stenosis or mild coarctation of the aorta.

Historically, many children with congenital heart defects did not survive to adulthood. Many now survive, and the number of adults with severe CHD nearly equals the number of children (Marelli et al., 2007).

caREminder

The presence of CHD is diagnosed by 4 to 6 weeks of age in only 52% to 65% of all cases (Martinez, Romero, & de

Aguilar, 2005; Stephensen et al., 2004). Do not assume that the presence of a cardiac condition would already have been ruled out in the older child who presents with questionable symptoms.

The incidence of CHD is more than twice as high in preterm infants than in term infants (Tanner, Sabrine, & Wren, 2005). The incidence of CHD in stillborn fetuses is up to 10 times higher than that among live-born infants, and miscarried fetuses are also thought to have a much greater incidence of CHD (Hoffman, 1995).

Various factors related to the incidence of CHD include genetic, environmental, maternal, and multifactorial influences. Parents of a child with CHD may express concerns that the condition will recur if they have a family history of CHD or if one of their children is affected with a congenital heart defect. Either case suggests a *genetic* influence. The likelihood that CHD will recur in a family depends on specific lesions, chromosomal issues, gender, race, and environmental factors. CHD risk to subsequent siblings of a child with CHD is approximately 2% to 6%. The risk that parents with CHD will pass on heart abnormalities to their own children is also 2% to 6%. The risk increases by three to four times if more than one child in a family has a heart defect (Hoffman, 1990).

Environmental or teratogenic insults, such as the ingestion of drugs (recreational or prescribed) or alcohol during pregnancy, can increase the risk of heart defects in the fetus. Toxic exposure of the mother to some drugs such as lithium carbonate, especially early during the pregnancy, is known to be associated with heart disease in the child. Aspirin products have long been implicated as teratogens in CHD, but evidence in the scientific knowledge base does not support this conclusion (Cleves et al., 2004). *Maternal* conditions such as diabetes or lupus have caused cardiac problems in offspring. CHD is also thought to correlate with in vitro fertilization (IVF) procedures. Most cases of CHD fall into the category of *multifactorial* (or, caused by many factors). In these cases, the mother has no known environmental exposures or illnesses known to lead to CHD, and the family has no known history of CHD. When discussing the reasons for heart disease with family members, explain that any deaths of elderly family members from atherosclerotic heart disease are different from childhood heart disease.

Syndromes that affect other body systems can be associated with congenital heart defects. For example, Down syndrome, trisomies 13 and 18, heterotaxy syndrome (malposition of internal organs in conjunction with asplenia or polysplenia and complex CHD), and 22q11 deletion syndromes all are associated with congenital heart defects. Approximately 5% to 8% of children with CHD have a chromosomal defect (Arabi et al., 2007).

Cardiac conditions that develop after birth are known as *acquired heart disease*. Heart disease in children occurs in all cultures and in all ethnic populations.

DEVELOPMENTAL AND BIOLOGIC VARIANCES

QUESTION: What is the direction of blood flow through the ductus arteriosus in fetal circulation?

Developmental and biologic variances occur throughout development and can be divided into those that occur during embryologic development, those that manifest as a result of cardiovascular changes at birth, and those that occur during childhood development.

Fetal Structures and Circulation

The heart starts to form early during the first 3 weeks of embryologic development, with fetal cardiac circulation

essentially developed before the eighth week. During this vulnerable stage of fetal development, congenital heart lesions can occur. The heart in the fetus begins as a simple tube that, over a short time, is transformed into a functional, complex organ. One end of the primitive linear tube eventually gives rise to the arterial system, and the opposite end becomes the venous system. As the tube widens, it folds and bulges, evolving into four separate chambers. By the end of the third week of gestation, the heart is beating; by the fourth week, the atrium and the ventricles are visible heart structures (see Chapter 3).

In fetal circulation, blood flows from the placenta through the umbilical vein, through the liver and the ductus venosus, and then into the inferior vena cava (Fig. 15–1). At the vena cava, fetal blood from the liver mixes with blood from the lower portion of the body and then drains into the right atrium. Blood from the upper portion of the body, the head, the arms, and the brain returns to the right atrium through the superior vena

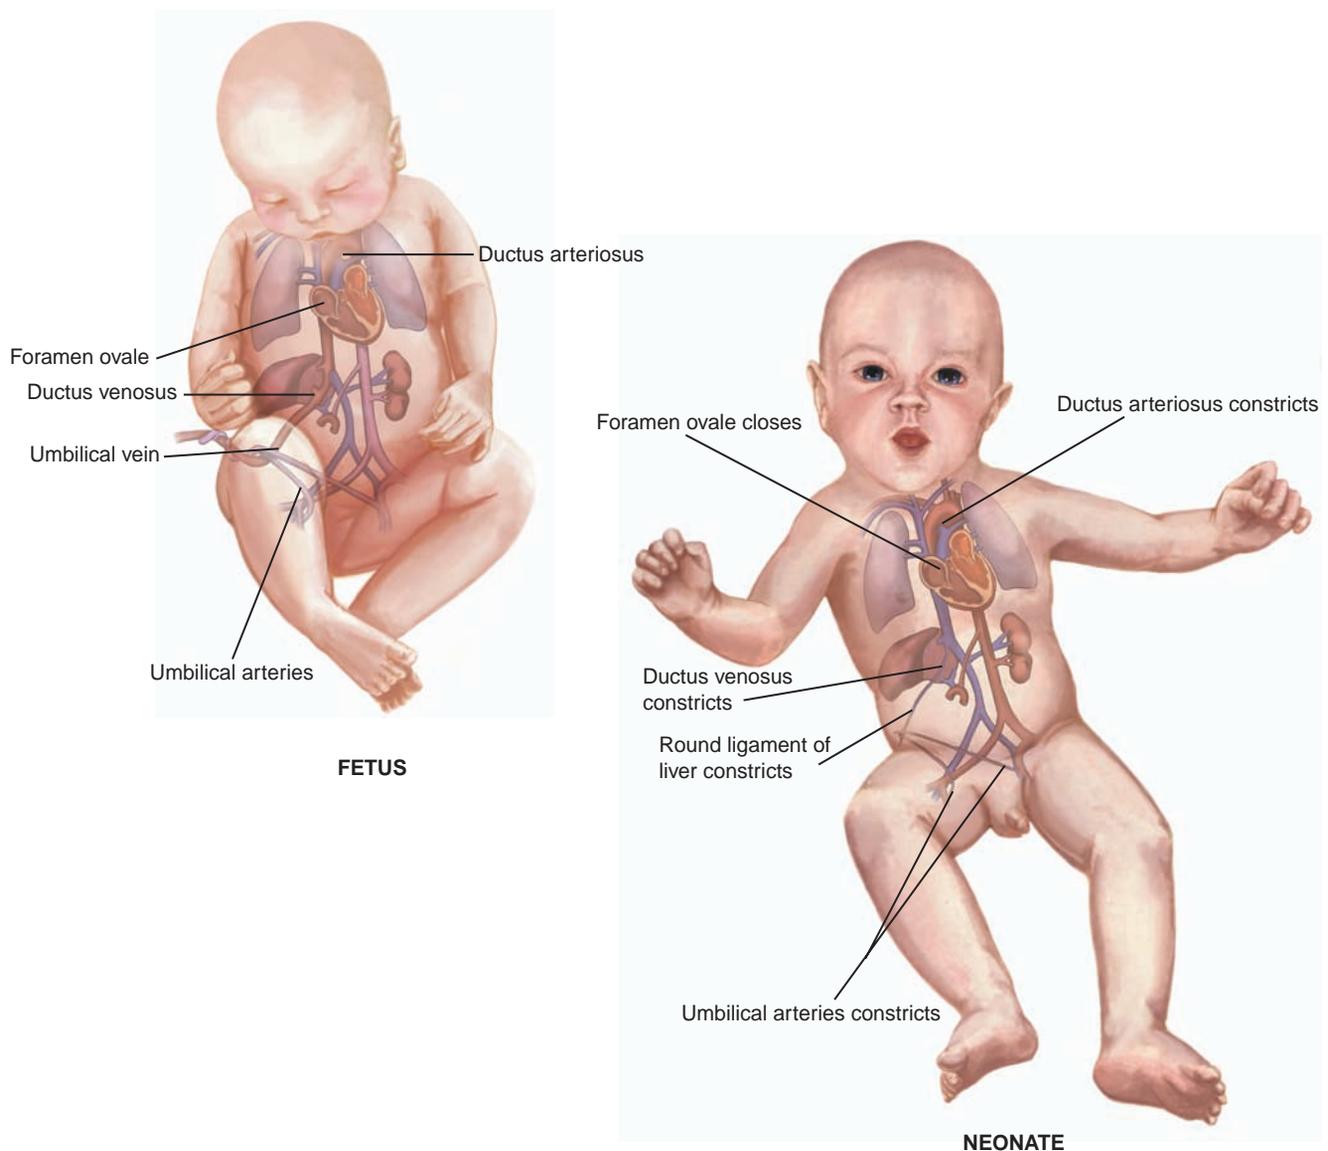

FIGURE 15–1. Fetal circulation and changes at birth.

cava. After blood enters the right atrium, a division occurs wherein some blood bypasses the lungs through the foramen ovale into the left side of the heart, passing through to the left atrium, the left ventricle, and then out the aorta. The rest of the blood travels through the right atrium into the right ventricle and out the pulmonary artery. A portion of this blood travels through the lungs; the rest crosses the ductus arteriosus and flows into the descending aorta.

Fetal blood flow through the heart has more than one potential pathway. The vascular resistance in the placental, pulmonary, and systemic circulation is a major factor influencing distribution. The lowest vascular resistance is found in the placenta. In the fetus, pulmonary vascular resistance (PVR) is very high, whereas systemic vascular resistance (SVR) is lower. The fetus has a naturally hypoxic environment that acts as a vasoconstrictor on the pulmonary vascular bed, keeping resistance high. SVR is low because of the relatively large volume of flow through the placenta. These factors, combined with the areas of shunting, lead to a small volume of fetal blood circulating through the lungs.

The right ventricle in the fetus is the dominant ventricle, pumping slightly more than half the combined ventricular output. Pressures in both ventricles are equal, unlike in the adult, where normal right ventricular pressure is much lower. In the adult, cardiac output is influenced by stroke volume and heart rate. In the fetus, cardiac output is largely dependent on heart rate, because the fetus is unable to substantially increase stroke volume. A decrease in heart rate can cause a precipitous and life-threatening decrease in fetal cardiac output.

Birth-Related Changes

At birth, the organ responsible for oxygenation changes from the placenta to the lungs. The unique fetal circulatory structures—the placenta, the foramen ovale, and the ductus arteriosus—undergo abrupt changes at birth. In the fetus, the fluid-filled, not fully expanded lungs have a high PVR, making the pressure on the right side of the heart high and limiting blood flow to the lungs. At birth, alveolar oxygen tension increases, and a large volume of circulating blood shifts from placental flow to the pulmonary arteries. Together, these conditions cause vasodilation in the pulmonary vascular bed, thereby creating a lower PVR and lower right-sided heart pressure. This change in blood flow causes left atrial pressure to increase, forcing the flaplike foramen ovale to close, thereby creating higher pressures on the left side of the heart. Elevated arterial oxygenation and other factors cause shunting across the ductus arteriosus to cease. Constriction of the ductus arteriosus is generally achieved within the first few days of life. With closure of the ductus arteriosus and the foramen ovale, the two levels of circulatory shunting in the heart cease. When these anatomic shunts are no longer present, the transition to extrauterine circulation is complete.

At birth, the ventricular walls are of equal thickness. Eventually, the muscle of the left ventricle wall becomes

thicker from the work of pumping blood to the systemic circulation. This developmental process explains why neonatal systemic blood pressure is low during the early days after birth—the ventricular strengthening and pressure changes are still occurring.

Pediatric Variations

The structures and functioning of the cardiac system in infants and children differ from those in adults (Fig. 15–2). These normal biologic and developmental variations require a modified approach to cardiac assessment. Cardiac assessment variations are related to the natural progression of growth and development in children.

ANSWER: In fetal circulation, blood flows from the right to the left through the ductus arteriosus as one of two shunts that facilitates the circulatory detour of the pulmonary vasculature.

ASSESSMENT

Assessment for alterations in cardiovascular status includes a focused health history and focused physical assessment. The findings obtained are then supplemented with various diagnostic criteria for evaluating cardiovascular disorders.

Focused Health History

QUESTION: Which of the items identified in Focused Health History 15–1 apply to Gabriella?

A comprehensive pediatric evaluation must include a recording of the child's current history or chief complaint, the maternal and fetal history, the postnatal history, and the family history (Focused Health History 15–1).

For the current history, obtain information about the reason that the child and family are seeking an evaluation. For example, for a history of chest pain, note whether the pain is related to activity, the duration of the chest pain, whether the pain occurs while taking a breath, and whether the child has episodes of syncope or palpitation. For complaints of tachycardia or palpitations, note whether these episodes coincide with the ingestion of cold medications or antiasthmatic drugs. For infants, ask about feeding, because some patterns of feeding behavior may indicate cardiovascular problems. Determine whether the child has attained age-appropriate developmental milestones.

Ask about the pregnancy history, including any potential maternal/fetal teratogenic event that may have influenced cardiac development. A severe infection such as measles or influenza, especially when accompanied by high temperatures during the first trimester, has the

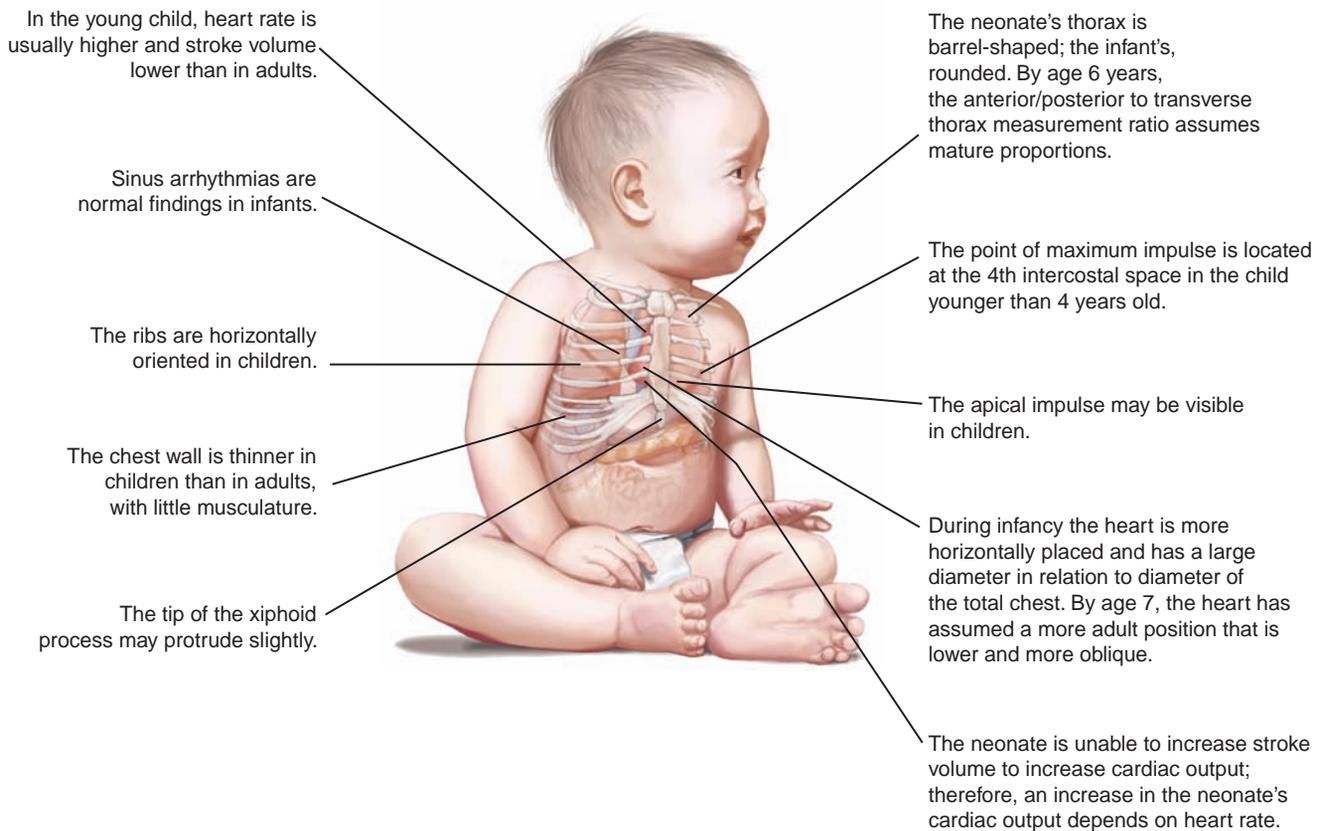

FIGURE 15–2. Developmental and biologic variances in the cardiovascular system.

potential to alter fetal cardiac development. Note whether the mother used medications before realizing that she was pregnant. For example, teratogens associated with CHD include dilantin, valproic acid, lithium, retinoic acid, and thalidomide.

caREminder

Phrase questions carefully during the interview to avoid inflicting feelings of guilt on the mother for actions or behaviors during her pregnancy that may have affected the child.

The fetal environment of a mother with a chronic illness such as diabetes or lupus can also cause negative outcomes on fetal development. Document any history of drug or alcohol use and the severity of abuse, if any (see Chapter 3). Evaluate the mother's nutritional status as well. This information is limited by what the mother can, or is willing to, reveal.

A family history relevant to cardiac problems and to other medical events also needs to be completed. Family histories are sometimes obtuse or vague. A typical vague historical account from a worried parent might be, "My mother said she had a baby that died and it was blue," or "My husband says his mother lost a child as an infant but she won't talk about it." When parents start exploring their past and talking to relatives, a more complete family history may evolve. In some cases, genetic counseling

may be warranted. Current family lifestyle (diet, exercise, tobacco use) should also be explored.

ANSWER: Under *past medical history*, Gabriella has a history of premature birth and in *current history*, Gabriella is recently experiencing vomiting.

Focused Physical Assessment

QUESTION: You are the nurse on the morning shift assessing Gabriella. Organize the information gathered from your review of the case study as it relates to inspection, palpation, and auscultation. Identify what additional areas you wish to assess. What information helps to differentiate if her problems are cardiovascular, respiratory, or gastrointestinal?

Physical assessment of the cardiovascular system uses the techniques of inspection, palpation, and auscultation (Focused Physical Assessment 15–1). Assess for **cyanosis** (bluish or purplish discoloration of the skin, mucous membranes, or both). The ability to visibly assess for cyanosis depends on the degree of desaturation and the natural skin hue of the individual. The more oxygen unbound to hemoglobin that is circulating in the body, the more

FOCUSED HEALTH HISTORY 15–1

The Child With Altered Cardiovascular Status*

Current history	<p>Chest pain: Frequency, duration, relation to activity, sporadic, short lasting or persistent, with or without exertion, with or without dizziness, syncope, or palpitation</p> <p>Heart palpitations, tachycardia, tachypnea, dyspnea, syncope, or parents' feeling baby's heart races</p> <p>Frequent vomiting</p> <p>Cyanosis, worse with feeding, defecation, or activity</p> <p>Puffy eyelids, scrotal or lower extremity edema</p> <p>Irritability, weak cry, difficulty in consoling</p> <p>Limited activity level, trouble keeping up with siblings</p> <p>Use of certain positions to ease breathing (e.g., calmer with head of bed elevated, squatting during play)</p> <p>Recent febrile illness, especially pharyngitis</p> <p>Arthralgia</p>
Past medical history	<p>Use of any medications (cold medication, antiasthmatic drugs)</p> <p>Prenatal/Neonatal History</p> <p>Maternal exposure to infections, prescription and over-the-counter medications; illicit drug or alcohol use during pregnancy; mother's history of chronic illness; history of premature birth</p> <p>Previous Health Challenges</p> <p>Syndrome or genetic disease that is associated with heart disease (e.g., trisomies 21, 13, 18; Turner syndrome; Marfan syndrome; fetal alcohol syndrome)</p> <p>Other condition that increases risk of acquired heart disease (e.g., diabetes); previous illness; history of heart palpitations, tachycardia, or syncope, or baby's heart races</p> <p>History of common communicable infections, particularly frequent respiratory illnesses, and ability to recover</p>
Nutritional assessment	<p>Intake, type, amount, and time it takes to feed</p> <p>Difficulty breast-feeding; if bottle-fed infants, duration longer than 20 to 30 minutes for a feeding or consuming less than 3 oz per feeding; tiring while feeding; vigorous sucking, then fatigue; need for frequent rest periods; tachypnea or diaphoresis during feedings</p> <p>Inadequate weight gain but normal height for age; inadequate gains in weight and linear growth</p> <p>Risk factors associated with acquired heart disease (e.g., high intake of saturated fats)</p>
Family medical history	<p>Any family history of childhood cardiac diagnosis, miscarriages, stillbirths for mother or on either grandparent's side</p> <p>Family history of cardiac disease occurring before age 55, any early (<40 years) deaths related to cardiac disease, familial hypercholesterolemia; other siblings with similar cardiac diagnosis</p>
Social and environmental history	<p>Activities and amount of physical activity, sedentary lifestyle</p> <p>Personal use of or presence of tobacco smoke in the child's environment</p>
Growth and development	<p>Drug or alcohol use</p> <p>Delayed acquisition of developmental milestones</p>

*This history is focused on the cardiovascular system. See Chapter 8 for a comprehensive health history.

FOCUSED PHYSICAL ASSESSMENT 15–1

Cardiovascular System

Assessment Parameter	Alterations/Clinical Significance
General appearance	<p>Fretfulness, lethargy, agitation, distress, weakness are common with hypoxia, heart disease, heart failure</p> <p>Underweight, linear growth below average are common with growth retardation caused by cardiac conditions</p> <p>Dysmorphic features associated with chromosomal aberrations are associated with heart disease (e.g., trisomies 13, 18, 21; Turner syndrome)</p> <p>Unusual positioning: Position of comfort with head elevated may indicate heart failure</p> <p>Squatting may be a sign of hypoxia; squatting reverses a right-to-left shunt, thus getting more blood to the lungs; children with tetralogy of Fallot may squat instinctively to improve oxygenation</p> <p>Fever may indicate bacterial illness</p>
Integumentary system	<p>Observe color at rest</p> <ul style="list-style-type: none"> • Pallor or mottling of skin is seen in severe anemia, heart failure, cardiogenic shock • Cyanosis in mucous membranes indicates central cyanosis, seen with hypoxia, CHD • Cyanosis or mottling of nail beds, palms, and soles of feet may be the result of cold or inadequate perfusion • Jaundice in infants is seen with severe heart failure <p>Diaphoresis, especially with activity or feeding, may occur in children with left-to-right shunts</p> <p>Clubbed digits (widened terminal phalanges) are a sign of chronic hypoxia</p> <p>Dependent edema may indicate heart failure</p> <p>Capillary refill longer than 3 seconds may indicate cardiovascular compromise or, in a cold child, vasoconstriction</p> <p>Rash may be seen with streptococcal and Kawasaki disease</p> <p>Scars from previous heart surgeries</p>
Face, nose, and oral cavity	<p>Periorbital edema is seen in heart failure</p> <p>Unusual facial characteristics (coarse features, widely spaced eyes, oblique palpebral fissure, low-set or malformed ears) or congenital anomalies (microcephaly, cleft lip or palate) may indicate syndromes or genetic conditions associated with heart disease</p> <p>Nasal flaring is a sign of respiratory distress; can be secondary to heart disease</p>
Thorax and lungs	<p>Observe for pulsation in chest, hyperactive precordium (apparent in normal children with thin chest walls and those with severe cardiac pathology)</p> <p>Bulging or prominence on the chest wall, especially on the left side where the apex of the heart is most commonly situated, may indicate cardiomegaly</p> <p>Asymmetric movement of chest suggests possible paralysis of the diaphragm (can result from injury to the phrenic nerve during cardiac surgery)</p> <p>Tachypnea, even with rest, chest retractions indicate respiratory distress, possibly resulting from heart failure</p> <p>Apical impulse palpation, downward or lateral displacement occurs with cardiomegaly; abnormal placement also occurs in dextrocardia, pneumothorax, diaphragmatic hernia, and pectus excavatum</p> <p>Presence of heaves or lifts indicates sustained forceful thrusting of the ventricles during systole; seen with aortic stenosis, left ventricular overload, and hypertension</p> <p>Thrills are the result of turbulent blood flow and indicate pathology</p> <p>Rales, rhonchi, wheezing are seen in heart failure</p>
Cardiovascular system	<p>Tachycardia in the absence of fever, crying, or stress may indicate cardiac pathology</p> <p>Normally no difference between femoral and brachial pulses or, in infants, between blood pressure in arms and legs; differentiation in blood pressure and pulses can be an indicator of coarctation of the aorta</p> <p>Weak pulses in left heart suggests obstructive lesions or heart failure</p> <p>Bounding pulses may indicate volume overload, aortic runoff lesion, aortic insufficiency</p> <p>Changes in rhythm associated with respirations is a normal variant in children (sinus arrhythmia); rhythm change not associated with respirations, or irregular rhythm, may indicate pathology</p> <p>Heart sounds are louder than in adults because chest wall is thinner</p> <p>Fixed splitting of S₂ is seen with atrial septal defect</p>

Assessment Parameter	Alterations/Clinical Significance
	Murmur (turbulence of blood flow): may or may not be present with a heart lesion, and murmurs vary with lesion; may be present with anemia; innocent murmurs common in school-aged children and not associated with pathology Gallop or rubs are associated with pathology If murmur present, note intensity, location, quality, and timing, and whether systolic or diastolic
Abdomen	Hepatomegaly is seen in heart failure (normally, in infants, the liver should not be palpable more than 3 cm below the right costal margin; in older children, the liver should not be palpable below the costal margin)
Neurologic system	Neurodevelopmental delays more common in children with CHD, possibly resulting from genetic syndromes, microcephaly, decreased cerebral perfusion, use of cardiopulmonary bypass, intraoperative hypothermic circulatory arrest

likely the child will appear cyanotic. Cyanosis is more easily seen in lighter skinned individuals and in natural light. In children with darker skin, cyanosis appears dark purplish black, an aubergine or eggplant color. Thus, when assessing a child with dark skin, inspect the nail beds, mucous membranes, palms of the hands, and soles of the feet. In newborns, who normally have acrocyanosis (peripheral cyanosis), determining whether a child actually has clinically significant cyanosis is more difficult. Collect other data, such as whether poor feeding and tachypnea are present, to gain a more complete clinical picture of the child. Perform cardiac inspection, which can reveal information about the child's cardiac status, without waking a sleeping child or disturbing an awake child. For example, observe movement of the shirt or child's clothing to evaluate respirations and chest movement. Look for any evidence of accessory muscle use. If possible, observe the infant during feeding, noting any tiring such as with sweating or skin color changes.

Palpate the chest for the apical impulse (AI), heaves, and thrills. The AI normally is noted as a gentle, nonsustained tap. In children younger than 4 years, the AI is normally at the fourth intercostal space (ICS), just left of the midclavicular line (MCL). In children between the ages of 4 to 7 years, the AI is at the MCL. For children older than 7 years of age, the AI is at the fifth ICS to the right of the MCL. Note any displacement of the impulse.

Also palpate the peripheral pulses for quality and equality, noting any irregularities in rate and volume between the right and left arms and legs. Assess the child's blood pressure. When taking blood pressure, the child must be in a relaxed state. If the child is stressed or fidgety, the risk of artificially high or low pressure is increased.

Alert! Indication of coarctation of the aorta (COA) is weaker pulses or lower blood pressure in the lower extremities than in the upper extremities. Bounding pulses can indicate a PDA or aortic insufficiency.

Palpate the liver borders to document evidence of hepatomegaly (enlarged liver) from right-sided heart failure. In smaller, thinner children, the liver is more easily palpable. When assessing a child, palpate the borders of the

liver. If the liver is distended, chart how many centimeters below the rib cage its borders are palpable.

Cardiac auscultation is another aspect of the physical examination. Auscultation of heart sounds requires more skill than other portions of the child's physical assessment. Do not expect to hear a murmur from all children with known cardiac lesions, because some malformations seldom produce abnormal heart sounds. Listen carefully and describe exactly what you hear (see Chapter 8 for more information regarding physical assessment of the cardiovascular system).

Auscultate the anterior chest, as well as the lateral and posterior chest area. Note the rate and regularity of the heartbeat, and the intensity and quality of the heart sound. Document any abnormality of the first and second heart sounds, such as a split heart sound or any extra heart sounds such as murmurs, gallops, or rubs. Identify the location on the thorax where the extra heart sound is heard most distinctly. This information aids in identifying the anatomic origin of a murmur. A murmur is also graded according to its intensity (loudness), which can help identify the severity of the murmur (see Table 8–8). Further evaluation may be required to distinguish an innocent or asymptomatic murmur from one that indicates the presence of a pathologic condition. The term *innocent* indicates that the murmur represents a normal finding, with no implication that a pathologic condition or process is present. Innocent murmurs can be exacerbated by factors such as fever, anemia, anxiety, and exercise, which can accentuate an innocent murmur that normally would not be audible.

ANSWER: So far, inspection reveals moderately labored breathing with a respiratory rate of 56 breaths per minute. Auscultation identifies coarse breath sounds and a continuous murmur. Palpation, which has yet to be completed, would include palpation of peripheral pulses, comparing the right and left sides. Because Gabriella has vomited twice during the past 12 hours, gently palpate her abdomen before her next scheduled feeding to determine whether it is soft (as opposed to distended and rigid). Also palpate for the degree of hepatomegaly. Use the stethoscope to assess Gabriella's bowel sounds. Check her recent stool pattern.

Revisit the assessment of heart sounds and determine where on her chest the murmur is loudest.

It is difficult with premature infants to single out the system experiencing difficulty. The nurse must perform a thorough and systematic assessment to accurately relay the complete picture. Gabriella's immediate change is respiratory (increased heart rate and increased oxygen requirement) and gastrointestinal (vomiting), but the presence of the murmur and the discovery of bounding pulses indicate cardiovascular involvement.

Diagnostic Criteria

QUESTION: The nurse anticipates a portable trans-thoracic echocardiogram (ultrasound).

Review Diagnostic Tests and Procedures 15–1, Evaluating Cardiovascular Status. Why is an echocardiogram the diagnostic test of choice?

Several diagnostic procedures augment information obtained from the history and physical examination of the cardiovascular system, and give direction to diagnosis and management of these children. **Cardiomegaly** (enlarged heart) visualized on a chest radiograph is commonly the first piece of evidence that causes healthcare personnel to consider the presence of a heart defect. Commonly used tests are described in Diagnostic Tests and Procedures 15–1.

ANSWER: In Gabriella's situation, blood flow through the ductus arteriosus is not a longstanding situation that would cause changes that could be seen by an x-ray (enlarged heart), although increased pulmonary vascular markings would likely be seen, nor is it an electrical conduction problem visible on an electrocardiogram (ECG). The echocardiogram is noninvasive, "images" the blood flow, and is ideal for diagnosing a recently symptomatic PDA in a premature infant.

TREATMENT MODALITIES

The cardiac team is composed of an interdisciplinary group of healthcare professionals who collaborate with the child and the family to create goals and a treatment plan. The cardiac team includes nurses, physicians, respiratory therapists, dietitians, social workers, and other ancillary personnel. In pediatric cardiac programs, healthcare team members meet regularly to discuss children with cardiovascular diagnoses and determine appropriate plans of care. The treatment options available for children with cardiac disease include interventional catheterization; cardiac surgery; pacemakers; cardiac transplantation; medical management using pharmaceutical, dietary, and activity interventions; supportive care; and community care.

Cardiac Catheterization

A cardiac catheterization suite is a specially equipped area in the hospital with an operating table, fluoroscopy cameras, hemodynamic monitoring equipment, and specialized personnel. Cardiac catheterization involves the use of catheters threaded into the heart to visualize the anatomy of the heart chambers or blood vessels and assist in treatment of the child's condition. Catheterization of the right side of the heart is completed by passing the catheter into the femoral vein and advancing it through the inferior vena cava to the right atrium, right ventricle, and pulmonary artery. If the foramen ovale is patent or if an atrial septal defect (ASD) is present, the catheter may be advanced from the right atrium into the left atrium through these openings to evaluate the left side of the heart. If there is no atrial or ventricular communication, evaluation of the left side of the heart is completed by passing a new catheter into the femoral artery and advancing it into the descending aorta, left atrium, and left ventricle.

If further anatomic clarification is needed after noninvasive imaging, if the child's history and assessment are not consistent with noninvasive imaging findings, or if the child has a very complex lesion, *angiography* is performed by rapidly injecting a radiopaque dye through the catheter at a predetermined location and recording the dye's movement, visualized by radiograph or fluoroscope, on videotape or film. This recording enables the healthcare team to replay the tape later to further visualize and analyze the structure of the heart.

Many, if not most, pediatric cardiac catheterizations are interventional, performed as outpatient procedures. The use of echocardiography has reduced the need for diagnostic cardiac catheterization in all but the most complex patients.

Interventional Catheterization

Some interventional procedures are performed urgently to save a life, whereas others may eliminate or delay surgery. Interventional catheterization can provide the child with a procedure that is associated with less physical and emotional trauma; a shorter, less expensive hospital stay than that required after surgery; and a faster recovery.

Standard interventional procedures include electrophysiologic studies with ablation, percutaneous balloon angioplasty, myocardial biopsy, atrial septostomy, placement of vascular occlusion devices, and stents and occlusion device closures.

Electrophysiology Studies

Electrophysiology study procedures are used for arrhythmias that do not respond to pharmaceutical management or when it is believed that the technique will eliminate the need for pharmaceutical management. Closed-chest catheter ablation techniques have been successful in diagnosing and then treating ventricular and supraventricular tachycardias. The preparation and procedures are much like those for diagnostic cardiac catheterization, but

Diagnostic Tests and Procedures 15– 1 Evaluating Cardiovascular Status

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
Chest radiograph	<p>Defines silhouette of heart, shows pulmonary markings (use posterior and lateral views).</p> <p>Provides a baseline prior to cardiac surgery and for comparison with cardiac changes postoperatively.</p> <p>Assesses status of noncardiac tissues (e.g., lungs, size of thymus, rib notching) that may be affected by compromised cardiac function.</p>	<p>Heart size and shape, may detect abnormal placement, enlargement of the chambers, and cardiomegaly.</p> <p>Pulmonary vascular markings, increased in some CHD, decreased in right-to-left shunting.</p> <p>A cardiothoracic ratio of <50% is normal; >50% indicates cardiomegaly.</p>	<p>Advise parents that variations from normal can help in the differential diagnosis of heart disease and can enable documentation of trends, such as increasing heart size.</p>
Pulse oximetry, transcutaneous	<p>Identifies and monitors child's oxygen saturation level.</p> <p>Helps the practitioner know when to wean a child off oxygen.</p> <p>Can reduce the need for arterial blood gas testing and can assist in titrating oxygen administration.</p>	<p>Normal values range from 94% to 100%. Values less than this range can be acceptable and expected in a cyanotic child. Typical values with CHD vary based on the lesion.</p>	<p>Position probe on finger, toe, earlobe, wrist, foot, or the spongy tissue between the thumb and the index finger.</p> <p>Observe data shown on the monitor readout, which generally include heart rate and oxygen saturation.</p> <p>Verify that a good arterial waveform is present and correlates with the heart rate indicated and with the child's auscultated heart rate to ensure a more accurate reading.</p> <p>Be aware that an inaccurate reading is more likely if the child is moving, experiencing peripheral vasoconstriction, is cold or in shock, or if the child has low cardiac output.</p> <p>Set and verify alarm parameters at the beginning of each shift. If readings fall below parameters, assess the child immediately for respiratory distress.</p>
Electrocardiogram (ECG or EKG)	<p>Provides a graphic display of the electrical activity of the heart.</p> <p>Produces data about the size and workload on the heart, assists in determining the anatomy of a defect and disturbances in conduction.</p> <p>Can be conducted continuously at the bedside (usually involves a three-lead system used to constantly monitor the child's heart rhythm), with multiple leads (typically a 12-lead), or via Holter</p>	<p>Interpretation is age dependent. ECG of a normal newborn is characterized by right ventricular dominance; normal QRS deflection is negative in lead I and positive in lead aVF. After infancy, the normal QRS is positive in leads I and aVF.</p>	<p>For a 12-lead ECG, assist the child in laying very still for approximately 1 minute.</p> <p>Use distraction for children who are unwilling to cooperate.</p> <p>Inform the child that no electricity is involved.</p> <p>Although most modern multilead ECG machines print out a diagnosis at the top of the ECG strip, the information given must be verified by a cardiac specialist, because this information may be inaccurate for the pediatric patient.</p>

(Continued)

Diagnostic Tests and Procedures 15–1 Evaluating Cardiovascular Status (Continued)

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
	monitoring (continuous ECG monitoring for 8 to 24 hours via electrodes attached to a small recorder carried by the ambulatory child with time, activities, and any symptoms in a diary recorded).		<p>Explain the use of leads and the need for them to adhere to the skin.</p> <p>During continuous bedside ECG monitoring, inspect the lead site daily and change the leads frequently.</p> <p>Ensure that the minimum and maximum heart rate alarm limits are set and that the alarms are functioning and activated.</p> <p>Teach the child and family how to keep a diary if Holter monitoring used.</p>
Cardiac enzymes (serum creatine kinase [CK] and lactate dehydrogenase isoenzyme [LDH])	Assess myocardial compromise via blood specimen.	<p>Normal total CK, 70 to 380 IU/L</p> <p>Normal total LDH, 327 to 874 IU/L</p> <p>Levels are elevated with myocardial damage, cardiovascular injury; central nervous system damage such as cerebral infarct and periventricular hemorrhage, pulmonary infarct, necrosis of the kidney, liver damage, and ischemic rhabdomyolysis.</p>	<p>Keep in mind that myocardial insult can occur in infants as a result of asphyxia, tricuspid insufficiency, and papillary muscle infarcts.</p> <p>In children, myocardial damage causes elevations for about 7 to 10 days after the insult.</p> <p>Analyses for cardiac enzymes in infarcts need not occur immediately.</p>
Brain natriuretic peptide	Measures an endogenous peptide hormone secreted by the cardiac ventricles in response to increased wall stress and related ventricular filling pressures via blood specimen. Differentiates between acute heart failure and lung disease. Monitors the effects of treatment for heart failure, cardiomyopathy.	Normal, <100 pg/mL. More than 100 pg/mL is an indicator for heart failure, ventricular dysfunction, rejection in pediatric heart transplant recipients, and persistent pulmonary hypertension.	Prepare child as age appropriate for blood specimen collection.
ECG (transthoracic)	Uses ultrasound to show anatomic visualization of heart structure (valves, ventricles, septa, atria, vessels). Measures chamber enlargement, wall thickening, stroke volume, and blood shunting. Assesses pericardial effusion. Indicates function of cardiac muscle and pumping ability.	Image of heart in motion can provide specific diagnosis of heart abnormalities, trends, and function such as PDA and ventricular septal defect.	<p>Tell the child and parents that the procedure is painless, but that it requires child to be still for approximately 20 to 45 minutes.</p> <p>Use play therapy, books, videos, and other distraction to help minimize activity.</p> <p>Anticipate the need for sedation in young children.</p> <p>Be aware that obesity, a thick chest, or motion by the child can obstruct visualization of structures.</p>

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
ECG (fetal)	Diagnoses CHD prenatally, as early as 18 to 22 weeks.	Four chambers in the heart and two great vessels If screening identifies that the four chambers are not equal in size, or the great vessels are unable to be visualized, or they did not arise in the correct location, refer the mother to a pediatric cardiologist.	Assess pregnant women for risk factors associated with CHD such as mothers with a family history of CHD, previous children with CHD, suspected chromosomal abnormalities (i.e., after amniocentesis), irregularities of fetal heart rates, or maternal diabetes. Anticipate change in plan for a routine delivery, such as delivering the infant in a high-risk unit and providing life-sustaining measures if required.
Transesophageal echocardiography/pacing	Uses an esophageal probe placed to provide ultrasonic pictures of cardiovascular structures and function, especially left atrium, pulmonary valve, mitral valve, and atrial septum. Supplemental information gathered from a standard transthoracic ECG. Can be done pre- and postoperatively to evaluate lesion and repair, and intraoperatively to assess the status of the surgical repairs after the child is disconnected from cardiopulmonary bypass and before the child's chest is sutured closed. Aids in developing differential diagnosis of complex arrhythmias. Allows stress testing of children who are unable to exercise.	Can pace and capture the rhythm of the heart to treat tachyarrhythmias.	Inform child and parents about the need for heavy sedation or general anesthesia for testing. Ensure the test is performed in a monitored situation. Assist with coordinating procedures, assessing and monitoring the child, administering the medications, and providing teaching.
Magnetic resonance imaging	Uses a magnetic field to clarify structures of the heart, especially aortic arch and branch pulmonary arteries. Allows measurement of ejection fraction, especially of right ventricle, and regurgitant function. Builds a three-dimensional model of the heart to visualize the anatomy.	Indicated when it is difficult to obtain desired image using ECG. Can sometimes obtain enough information to avoid cardiac catheterization. Displays abnormalities in cardiac chamber contraction and abnormal patterns of blood flow in the heart and great vessels.	Explain to child and parents that the test is noninvasive and there is no exposure to ionizing radiation (x-rays). Anticipate the need for sedation in young children; older children who can cooperate and hold their breath do not require sedation. Teach child that the machine makes loud humming and intermittent thumping noises; use music as a distraction. Remove all metal/magnetic items such as pins, hairpins, and metal zippers. Surgical implants such as pacemakers are a contraindication.

electrophysiology studies use catheters with multipolar electrodes that map the path of the heart's electrical impulses. After the arrhythmogenic tissue is located, accessory pathways can be destroyed through thermal energy delivered via the intracardiac catheter.

Percutaneous Balloon Angioplasty and Balloon Valvuloplasty

Percutaneous balloon angioplasty and balloon valvuloplasty techniques permit a balloon-tipped catheter to be floated into a vascular area or valve that is stenotic. Pulmonary stenosis, pulmonary valve stenosis, aortic valve stenosis, and COA are common indications for percutaneous balloon dilatation. The balloon that is inflated over the stenotic area deforms or ruptures the site to increase the luminal diameter by expanding the intimal lining of a vessel at the restricted area. By enlarging the vessel, these procedures decrease the pressure gradient and improve blood flow through the stenotic area.

Myocardial Biopsy

Myocardial biopsy is performed to collect a small piece of cardiac tissue for analysis. It is used to identify myocardial disease such as cardiomyopathy, and to detect the presence and degree of rejection in cardiac transplantation.

Atrial Septostomy

Atrial septostomy is performed using either balloon (Rashkind's procedure) or blade techniques. Atrial septostomy remains the standard initial palliation for infants with transposition of the great arteries. It may also be used for any lesion in which a large atrial communication is required to increase intracardiac shunting. This procedure is done in the catheterization laboratory or at the bedside. The catheter is introduced into the left atrium from the right atrium through a patent foramen ovale. Either the balloon is inflated and pulled back quickly to create a larger opening, or the blade on the tip of a catheter is crossed through the opening, where it incises the atrium as it crosses, thereby creating a larger opening. These techniques may sound harsh, but they can provide an effective tool in saving and improving the lives of infants.

Vascular Occlusion Devices

Various techniques have been developed to perform transcatheter vascular occlusion. A device can be implanted to embolize vessels such as the PDA. *Coil embolization* is one device used to occlude a vessel. A coiled wire is delivered through an end-hole catheter that is extruded out the end of the catheter at a predetermined location. On extrusion, the piece of steel coils back on itself, promotes clot formation, and acts to embolize the vessel. Soon after coil placement, fibrous tissue grows around the device, ensuring its immobility. Successful vessel closure using such devices may enable selected children to avoid surgical intervention. Coil embolization in the PDA or collateral vessel to occlude systemic flow to **pulmonary collaterals** (additional abnormally devel-

oping pulmonary vessels) may also enable some children to avoid surgery, resulting in fewer risks and less trauma.

Stainless steel *stents* may be inserted in areas of the pulmonary artery system that are stenotic. These stents are made of a stainless steel mesh, compressed into a small-diameter tube that expands when extruded into place, resembling a very small version of "chicken wire." Through expansion, the stent effectively increases the diameter of the vessel and endothelializes into the vessel wall over time.

Occlusion Device Closures

ASDs can be closed in the catheterization laboratory with an Amplatzer septal occluder—a self-expandable, double-disk device made from wire mesh. The device is placed through the atrial septum, is opened in the left atrium, and is pulled against the opening to occlude the ASD. Transcatheter closure of secundum ASD using the Amplatzer setal occluder has been found to be a safe and effective alternative to surgical repair (Wilson et al., 2008). Currently multiple other devices are under clinical investigation for the use in closing ventricular septal defects (VSDs) and replacing pulmonary valves.

Precatheterization Care

Initially, ascertain whether the child has undergone catheterization before and what the child remembers about the other experience. It is not unusual for a child with complex CHD to have had multiple catheterizations. Prepare parents and the patient for cardiac catheterization before the day of the procedure, in a relaxed setting and in an honest, open manner. Orient discussions toward deescalating anxiety in the child. Consider the age and maturity of the child when explaining the environment and the catheterization routine, and use a chronologic description of what will happen from admission to discharge (Fig. 15-3). Preparing the child and the family helps decrease anxiety and enables them to be better informed.

KidKare ■ ■ ■ During precatheterization teaching, assure the older child that the procedure will be done in the fold of the leg and that his or her genitalia will be covered. The child will probably not know where the "groin" is located, or what it is. Using the word fold or bend of the leg is much clearer to the child.

Teaching can include a tour of the catheterization laboratory, recovery area, and the areas where families and friends will be waiting. This helps to alleviate anxiety about the laboratory with all its technical equipment and strange personnel. During this tour, if possible, have the child meet a staff member dressed in catheterization lab attire who will be present on the day of the study. Explain the rationale for restraints, and the importance of staying in bed and keeping the affected leg immobilized after the procedure. If the child has a clear concept of time, include an explanation of how long the

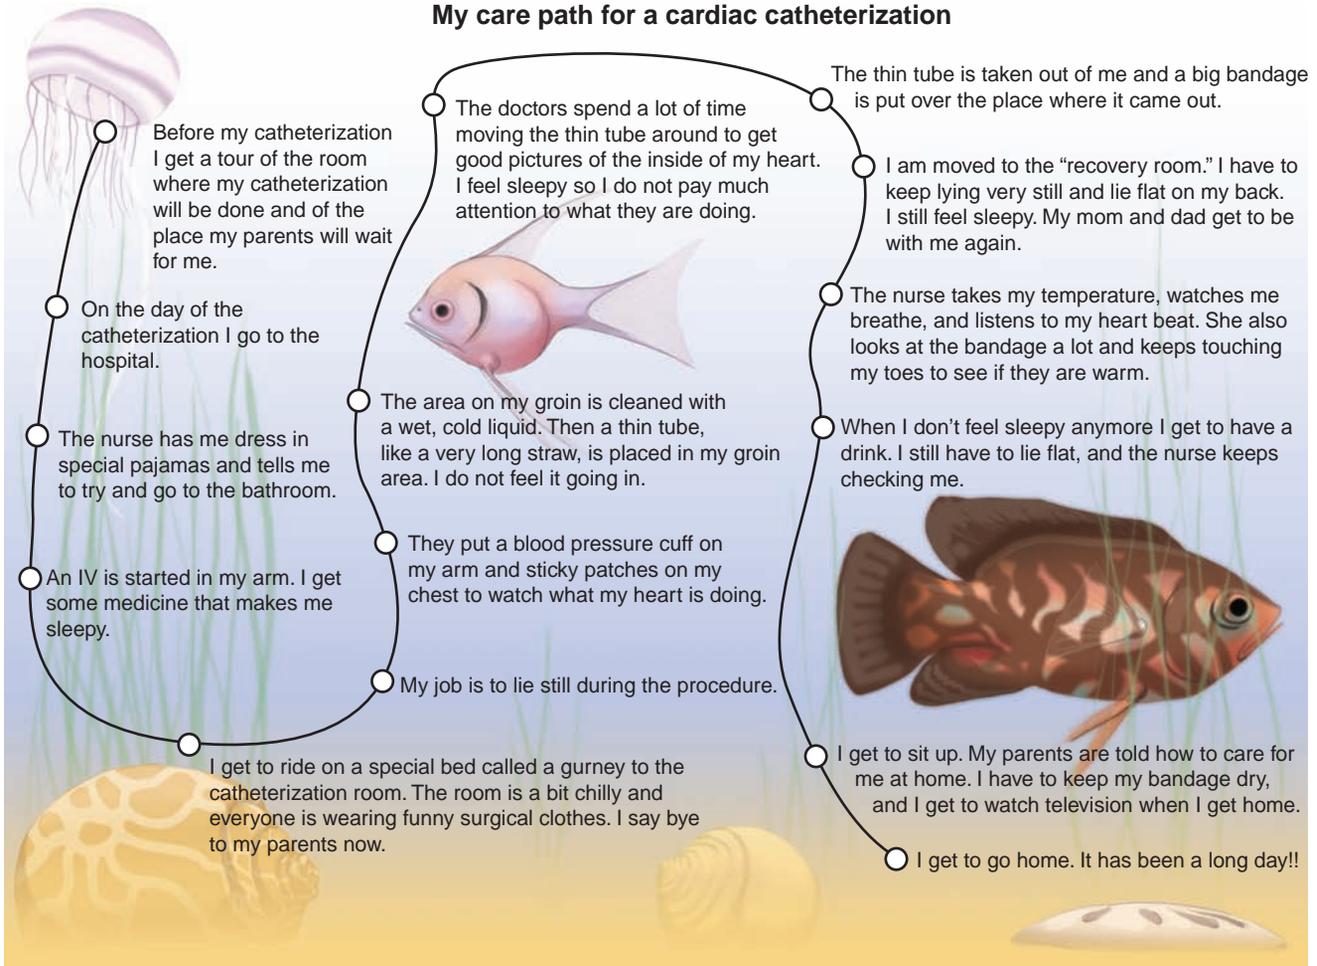

FIGURE 15-3. A care path for a child undergoing cardiac catheterization.

procedure will last. Assure the child that there is little pain or discomfort. A relaxed, informed child can develop a sense of personal control, anticipate events, and overcome misconceptions.

KidKare ■ Encourage the child to pick out a favorite toy, doll, or blanket to keep throughout the procedure and in the recovery area.

On the day of cardiac catheterization, perform a baseline assessment, which includes an evaluation of the child's physiologic status with an emphasis on the cardiac state and peripheral extremities. Palpate lower extremity pulses and mark them with a pen for easy location. Document height and weight accurately to ensure accurate calculations of drug doses and other parameters. If a child has signs of systemic infection, such as a runny nose, fever, or skin rash, the catheterization may be delayed. Verify that the child has had nothing to eat or to drink prior to the procedure, noting when the last fluids or food was ingested. Ascertain carefully whether the child has any history of allergies, because the contrast dyes used during angiography can trigger allergic reactions.

Elicit information about any adverse reactions from previous catheterizations.

If venous access has not been established, a peripheral intravenous line is started before catheterization to provide medication access and to prevent dehydration. During the catheterization, the child's feet are not easily accessible for inspection or to assess for infiltrations; therefore, avoid placing intravenous lines in the feet whenever possible.

Before the catheterization, administer the prescribed sedation. The choice of medication varies depending on the institution, age of the child, and type of catheterization planned. Procedural sedation is provided for routine catheterizations. General anesthesia may be used for procedures that place the child at greater risk or for more complex interventional catheterization. Before sedation, have the toilet-trained child void, preferably before transportation to the catheterization laboratory. After the child has been sedated, keep the child flat in bed to avoid the risk of injury resulting from altered mental status and potential complications from the catheterization process.

Care During Catheterization

During the procedure, the child receives continuous monitoring of vital functions, including blood pressure,

pulse oximetry, and cardiac rhythm. Emergency drug doses that are calculated before the procedure must be readily available.

The catheterization laboratory can be quite cool. Wrap the head and extremities of small children and infants in blankets or use a mechanical warming blanket to maintain adequate body temperature. An infant's temperature must be monitored continuously by a rectal probe. After the child is positioned securely, the site for catheter insertion is prepared. Preparation usually involves cleansing the side with chlorhexidine or other antiseptic and injecting topical lidocaine over the intended puncture site.

Catheters are introduced into the cardiovascular system through the venous system to the right atrium or through the arterial system to the left side of the heart. A percutaneous sheath is placed, usually using the groin's femoral artery, vein, or both. The sheath minimizes vessel trauma and allows various catheters to be inserted and withdrawn without creating any new insertion sites. Using fluoroscopy, the catheters are visualized as they are manipulated into different chambers and vessels (Fig. 15-4).

Accessing different areas of the heart and blood vessels enables pressure measurements and blood gas sampling in each area. The severity of an obstruction can be better

described by measuring the pressure **gradient** (the amount of pressure difference when passing from one area to another) in different areas. Blood samples obtained to determine oxygen saturation, drawn from various chambers, help to locate shunts and quantify the degree of shunting. During the procedure, angiography may be performed; the fluoroscopic cameras are moved to obtain all angles that will clearly delineate a child's cardiac defects on film.

Postcatheterization Care

Continuously assess the child's cardiovascular status after cardiac catheterization. Direct nursing measures toward preventing and monitoring potential complications (Chart 15-1; see [thePoint](#) for Care Path: An Interdisciplinary Plan of Care for the Child Undergoing Diagnostic Cardiac Catheterization).

Postcatheterization assessment includes recording vital signs, checking the insertion site, monitoring and comparing catheterized extremities, and assessing the child's level of consciousness. After the procedure, assess vital signs in a similar manner as for the postoperative patient (generally, every 15 minutes until the child is awake and stable, then every half hour for 3 hours, then hourly up

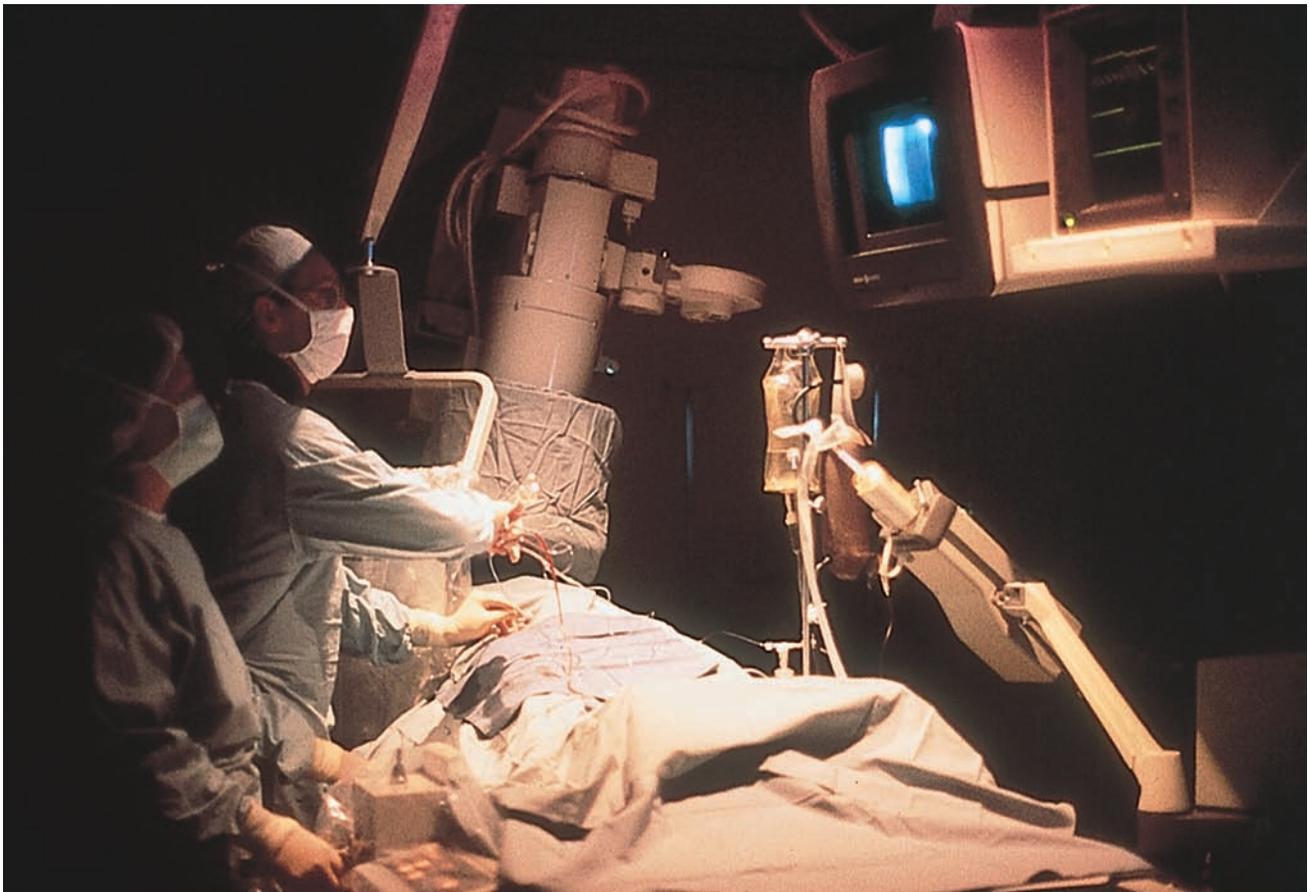

FIGURE 15-4. During cardiac catheterization, the child is under conscious sedation to prevent movement during the procedure. The physician introduces a catheter into the right or left femoral vessel, and observes the movement and manipulation of the catheter on a monitor.

CHART 15-1 POTENTIAL COMPLICATIONS AFTER CARDIAC CATHETERIZATION

Complication	Description
Hemorrhage	Vessel bleeding at insertion site, decreased hematocrit
Hematoma	False aneurysm, subacute hematoma
Vomiting	Caused by anxiety, NPO (nothing by mouth) status, sedative drugs
Hypovolemia	Status, blood loss, diuretic action of dyes
Hypotension	Caused by medications, bleeding, contrast media
Arrhythmia	Transient bradycardia, premature ventricular contractions
Venous occlusion	Usually transient, from a clot, intimal tear, or herniation
Loss of pulses	Loss of pulse in catheterized extremity, usually transient, caused by vessel vasospasm, usage of larger catheters; smaller child at greater risk
Arterial thrombus	Aggregation of blood factors causing arterial occlusion
Renal damage	Clearance of contrast media, hematuria, oliguria, anuria
Pulmonary embolus	Risks greater in patient with intracardiac mixing and polycythemia from venous stasis pressure at puncture site
Fever/infection	Low grade, 4 to 8 hours, catheter induced (rare)
Allergic reaction	From sedatives, contrast media (rare)
Perforation	Tamponade, cardiac perforation by angiographic catheter (rare)
Arteriovenous fistula	When both the artery and vein are punctured, a communication between them shunting blood from the distal extremity
Central nervous system insult	Strokes, seizures from air embolus (rare)
Death	Highest occurrence in infants (rare)

to 6 hours or more, as needed). When checking the child, assess for signs of hypotension such as cold clammy skin, increased heart rate, or dizziness. Cardiac monitoring and pulse oximetry are used to help assess the child's status until the child's condition stabilizes. During the recovery period, the child remains on bed rest with the head of the bed flat or elevated only slightly.

Encourage the child to remain flat in bed and keep the affected leg straight for the prescribed time. Toddlers may be more cooperative if placed in the prone position in a parent's lap. Explain the need for immobilization and frequent monitoring to family members. Caution the child to avoid sitting, raising the head, straining the abdomen, or coughing during the postcatheterization recovery period to reduce risk of bleeding.

When taking vital signs, inspect the dressing on the groin for evidence of bleeding or hematoma. If a hematoma is observed, mark the margins with a permanent marker and monitor for changes.

Alert! Even though clot formation has occurred at the catheter insertion site, hemorrhaging could occur during the recovery period. The groin dressing must remain intact and the site must remain uncovered to enable the nurse to note any blood drainage immediately.

With each set of vital signs, assess both lower extremities, including palpation of dorsalis pedis and posterior tibial pulses, and inspection for color, temperature, and capillary refill. Also ensure that the affected leg remains immobilized. The affected foot may be cyanotic or cooler temporarily, especially if vasospasm of the vessel occurs or if the child's core temperature is also low; notify the physician if this persists longer than 2 hours.

Assess level of consciousness and initiate clear liquids after the child is fully awake and the gag reflex is intact. Encourage fluids to help the kidneys filter out the contrast dyes. Give written and verbal discharge instructions, including signs and symptoms to watch for, to children and their parents before they return home (TIP 15-1).

Cardiac Surgery

QUESTION: Surgery is an alternative treatment for a PDA if the medical approach is unsuccessful. Cardiac surgery often elicits a strong emotional response from parents even though the surgical risks of PDA ligation are small. What critical information can be taught to Gabriella's parents that may help decrease their anxiety?

TIP 15–1 A Teaching Intervention Plan for the Child Going Home After Cardiac Catheterization

Nursing diagnosis and family outcomes

- Deficient knowledge: Lack of information regarding management of the child at home after a cardiac catheterization

Outcomes:

- Child will have complications related to cardiac catheterization recognized early and interventions implemented.
- Child and family will express concerns and will remain calm and supportive of the child.
- Child and family will follow written discharge instructions for care of the child and the puncture site.
- Family will contact physician to make follow-up appointments and if any complications occur.

Treatment of the child

Activity

- A child may resume normal activities, but no running, bike riding, skating, jumping, swimming, or other vigorous “roughhousing” or sports for the next 3 days.
- Children may return to school 2 days after discharge.

Catheterization Site

- Inspect the catheterization site daily for a week. Some bruising at the catheterization site is common. If there is drainage from the catheterization site, call your doctor.
- A small amount of blood on the bandage is normal. If bleeding that soaks through the bandage has occurred, hold pressure on the catheterization site until the bleeding stops and call the doctor.

Bathing

- After a catheterization, a child should avoid prolonged bathing for 2 days. A sponge bath or brief shower is permitted.

Diet

- Resume previous diet at home.

Pain

- Most children do not need any medicine for pain when at home, although a child may have some slight groin discomfort.

Behavior

- Even after a short stay in the hospital, it is possible to see temporary changes in the child’s behavior (e.g., irritability, irregular sleep pattern, bad dreams, an increase in “childish ways”). It is important to be understanding but at the same time keep basic discipline rules.
- Because illness and hospitalization affect the whole family, parents may see changes in the child’s behavior at home or in school *and* in the behavior of siblings.

Follow-up

- You should schedule a follow-up appointment within a week. After reviewing the catheterization procedure, the doctor will discuss the results and the plan of care with you.

Contact Healthcare Provider if:

- Your child has a fever higher than 101 °F during the week after the heart catheterization.
- The leg in which the catheterization was done becomes cooler, paler, or more numb than the other leg.

Advances in pediatric cardiovascular surgery during recent decades have helped to reduce mortality and have enabled definitive repairs at an earlier age than was formerly possible. The focus of care has moved beyond merely increasing survival by a few years to enabling a greater number of children with complex CHD to live to adulthood. Cardiac surgery may be palliative or corrective.

Palliative Surgeries

Surgeries that are not curative, but rather are performed for heart defects as a surgical bridge, are called **palliative**

procedures. These surgical interventions may allow the child’s condition to become more stable and provide time for the child to grow until a more definitive surgical procedure is possible. Sometimes palliative procedures are performed in stages to improve the long-term outcome for a particular heart defect.

Pulmonary Artery Banding

Pulmonary artery banding is provided to children who have conditions in which pulmonary blood flow to the lungs is excessive. These children cannot tolerate or are

not ready for total surgical repair, yet medical interventions have failed to manage heart failure, necessitating this procedure. Banding narrows the pulmonary artery, thereby minimizing pulmonary blood flow. Banding is performed via a lateral thoracotomy incision and placement of a Teflon tape band around the main pulmonary artery. If the band is too tight, reversal of the shunt and cyanosis may result. If the band is too loose, excess blood flow to the lungs will continue.

Shunts

For cyanotic infants, a **shunt** (an abnormal formation or artificially placed pathway through which blood flows from one area to another) is placed to increase pulmonary blood flow by creating an additional pathway for blood to reach the lungs. Some common lesions for which a shunt may be created in the neonate include pulmonary atresia, tricuspid atresia, tetralogy of Fallot, or severe pulmonary stenosis. Furthermore, a neonate or premature infant with medically unmanageable hypoxic spells or cyanosis may require shunt placement.

Infants with severe cyanosis from restricted blood flow to the lungs may benefit from a systemic to pulmonary artery shunt. A *Blalock-Taussig* shunt is a procedure in which the subclavian artery is anastomosed to the pulmonary artery. Access to the vessels is through a lateral thoracotomy incision. Because it is not an open-heart surgery, the shunt procedure is completed without putting the child on cardiopulmonary bypass. A modification of this procedure, known as the *modified Blalock-Taussig shunt*, is more frequently used; in this approach, a Gore-Tex tube graft is placed from the subclavian artery to the pulmonary artery. The shunt's size is selected to be large enough to maximize pulmonary flow while avoiding excessive flow and heart failure. Even children who are very small or quite ill can usually tolerate this procedure without major complications. Common problems of a Blalock-Taussig shunt procedure include thrombus or closure of the shunt, heart failure from excessive pulmonary blood flow if the shunt is too large, and hypoperfusion of the affected arm.

Slightly older children who have obstructive flow to the lungs may require a *Glenn's procedure*, also called a *bidirectional Glenn shunt*. The bidirectional Glenn shunt is a palliative surgery that optimizes the child's cardiovascular status and is frequently used as a staging procedure as part of the Fontan surgery (described later in this chapter). The bidirectional Glenn is an anastomosis of the superior vena cava to the pulmonary artery, which allows some blood to flow to the pulmonary system by bypassing the right side of the heart. This surgery is most commonly done through a midsternal incision.

Corrective Surgeries

The surgical trend in recent years has been toward surgical intervention early in life, often during infancy. The timing of surgeries depends on the anatomy of the lesion, the child's growth and development, any concurrent illnesses, and family needs. Parents are encouraged to schedule the surgery when other family events and sour-

ces of stress are minimal. Reasons to hasten surgery include preventing development of aorta pulmonary collateral vessels, avoiding deterioration of ventricular function, and minimizing risks of **pulmonary hypertension** (abnormally elevated blood pressures in the pulmonary artery). For children who develop irreversible pulmonary hypertension, surgery may no longer be an option. Surgery may have to be delayed because other medical conditions make the child a poor surgical candidate. Surgery may also be delayed to enable the child to grow. For example, if the child needs a valve replacement, it is to the child's advantage that surgery be delayed to allow the heart to grow larger. This delay enables placement of a larger valve, one that the child will not quickly outgrow.

Preoperative Teaching

As with any patient scheduled for surgery, the information given by the healthcare provider to the child and family must include an explanation of the intended surgery, complications that may occur, and a description of the medical equipment that will be used to support the child during the recovery period. Answer all questions honestly and in simple age-appropriate terms so the child and family can comprehend them (see Chapter 11 for preparing a child for surgery; Community Care 15–1). Giving the child and family a chronologic explanation of the events that will occur from admission to discharge is helpful (Nursing Interventions 15–1). Allow the child and parents to absorb information and to ask questions at their own pace. The preoperative teaching period is a good time to assess family needs, interactions, and patterns of coping. Incorporate this information into the

COMMUNITY CARE 15–1

Activity Recommendations for the Child With Cardiac Disease

Postcardiac Catheterization Routine

Keep the child out of school for 2 or 3 days or over a weekend.

No gym class or playground activities for 1 week.

After 1 week, the child can return to normal activities.

Postcardiac Surgical Care

Encourage fellow students to send cards and drawings to post on the wall in the ICU.

Avoid situations that could induce a blunt chest trauma.

Involve the school nurse in administering midday dosages of required medications as indicated.

Keep the child out of gym classes or playground activities for 6 weeks to allow time for the sternum to heal.

Keep the child out of school 1 week after discharge from hospital.

child's plan of care to ensure that the unique needs of the family are being met.

A preoperative tour of the intensive care unit (ICU) helps alleviate stress for the older child and for parents and family members who have had no prior experience with an ICU. It can be overwhelming for parents to see ventilators, monitors, and a large variety of tubes and lines entering and exiting any small child, much less their own (Fig. 15–5). During preoperative teaching, a visit with another child and parents in the ICU may alleviate some of their fears.

Explain to the parents the type of chest incision that the child will have. The surgeon makes this decision based on the type of surgery that is scheduled. (All cases of *cardiopulmonary bypass* [pump] require separation of the sternum.) Either a midsternal or a lateral thoracotomy incision is used for cardiac surgical procedures. Some surgeons use a mammary incision for female patients. This incision enables the patient to wear a V-neck shirt or swimsuit without showing a scar.

Tell parents that predicting exactly how long tubes and lines will be required, or how long their child will be in hospital after surgery is not possible. Provide general guidelines and explain that they will be given daily updates on their child's progress. For many routine surgeries, a child spends most of the hospital stay in the

ICU. Typically, a child who was once quite ill achieves a particular level of stability and may progress so quickly toward being able to return home that the parents are surprised.

Many hospitals have designated blood donor systems to encourage the family to have members donate blood for the child's surgery. After the blood has been drawn, it is screened for suitability and then is designated for use during the child's surgery. Teach parents that the designated blood donation procedure usually takes at least 3 days to have the blood available for transfusion.

caREminder

Any signs of a concurrent illness, such as an ear infection, cough, runny nose, or fever, may delay surgery. Advise parents to call the physician if any signs of infection occur during the immediate preoperative period.

Intraoperative Care

In the surgical suite, the child is intubated, and most of the monitoring and IV lines are placed before the chest incisions are made. Monitoring and invasive lines include ECG leads, nasogastric tube, pulse oximetry, indwelling

NURSING INTERVENTIONS 15–1

Cardiac Preoperative Teaching Topics

Chronologic Course of Events

Family blood donation
Preoperative day: ICU tour

FIGURE 15–5. The child returning from cardiac surgery often has many wires and tubes attached to monitors, pumps, and equipment. Parents should be prepared for how the child will look after surgery. As the child's condition improves, use of the equipment is discontinued. This infant is 2 days postcardiac surgery. He is alert and attached to only a few monitoring devices and equipment.

urinary catheter, peripheral IV lines, arterial line, and a minimum of one central line with *central venous pressure* monitoring. In cardiac patients with complex conditions, the surgical team may place direct intracardiac lines, such as left atrial and pulmonary artery lines, to monitor pressures.

Cardiopulmonary Bypass

If the heart and lungs will be connected to a cardiopulmonary bypass pump to oxygenate and perfuse the body while the heart is stopped, incisions are placed midsternally by separating the skin and then splitting the sternum. The right side of the heart is cannulated, capturing venous blood before it returns to the heart. Venous blood is shunted to the pump, where it is oxygenated and circulated, and its temperature is regulated. The oxygenated blood is returned to the body through the cannula in the ascending aorta. During the time on pump, the heart is stabilized with an electrolyte solution called *cardioplegia* that helps immobilize and protect the heart during surgery. The cardiopulmonary bypass pump also reduces

the body's metabolic rate and decreases oxygen demand during surgery by creating a hypothermic state.

After the cardiac surgical repairs are done, the child is rewarmed gradually until normothermia is achieved; as the child warms, the heartbeat will return. Occasionally, the surgeon may need to regulate the heart's rate and rhythm with a temporary pacemaker and wires. Before closing the chest, temporary pacing wires may be placed on the outside of the heart and passed through the chest wall. Mediastinal chest tubes are placed to evacuate any bleeding from around the heart; pleural chest tubes will reinflate the lung and drain fluid. Depending on the nature of the surgery and the monitoring needs, transthoracic central lines may be placed in the right or left atrium, the pulmonary artery, or both. These lines enable more detailed hemodynamic monitoring than that provided by a central venous pressure line alone. The sternum is closed and secured with wire. Finally, the skin is sutured shut. The chest may be left open with a Gore-Tex patch covering the area, to allow for swelling of the heart. In such cases, the chest is typically closed within 24 to 48 hours after surgery.

Nonpump Cases

Surgeries that do not require entering the heart and thus can be done without cardiopulmonary bypass are termed *nonpump cases*. Examples are repairs of coarctation of the aorta or PDA. These surgeries are usually completed using a lateral thoracotomy approach. With this approach, the pleural space is entered; therefore, chest tube placement is required before the chest is closed. Children will likely have a central line and an arterial line. Generally, nonpump cases will not have pacing wires or transthoracic lines placed.

ANSWER: If Gabriella did have surgery—in addition to an explanation of the intended surgery, possible complications, and devices or tubes that will be in place during recovery—also identify when the parents can be reunited with Gabriella and how her pain will be managed.

Postoperative Care

During the acute care phase, interventions focus on stabilizing the child, minimizing complications, and facilitating recovery. Small or abrupt changes in the status of a child must be efficiently noted and acted on during the critical postoperative period.

Vital sign parameters are defined by the surgical team and may vary from those typically associated with a normally functioning heart, depending on the specific needs of an individual child. For example, if the child still has intracardiac mixing after surgery, a liberalized range of oxygen saturation is considered acceptable. Continuous blood pressure monitoring is provided in the critical care unit through arterial catheters connected to a transducer and monitor. These catheters are placed in the femoral artery or the radial artery, or the umbilical artery in neonates. Perform and record a head-to-toe assessment, concentrating on the child's cardiopulmonary status, every shift and as needed for changes in status. Cardiac assessment is performed more frequently, dependent on the child's condition.

Managing Changes in Body Temperature

Hypothermia occurs during the immediate postoperative period because of core temperature cooling associated with cardiopulmonary bypass. Initiate warming measures on arrival to the ICU. Monitor the child's temperature continuously, using bladder or nasopharyngeal probes, which more closely approximate core temperature (measured from the pulmonary artery) than a rectal probe (Maxton, Justin, & Gillies, 2004) (Nursing Plan of Care 15–1).

As the child recovers, an elevated temperature can be associated with the need for pulmonary toilet (evacuation of accumulated mucus from the lungs). Initiate cooling measures, including a cooling blanket and administration of antipyretics. After the first postoperative day, spikes in temperature are indications that blood, sputum, and urine cultures must be drawn.

Maintaining Cardiac Output

Evaluate information from hemodynamic lines, vital signs, and peripheral pulses to obtain information about the child's volume or preload status. Problems with preload can be related to excessive chest tube drainage that is causing hypovolemia, or to fluid leaking into the interstitial spaces from the vascular bed. Administer volume replacement as required. A 5% albumin solution is a commonly used intravascular volume expander, unless the child is bleeding, in which case blood and other fluids are used.

Continuously evaluate the child's *afterload* (systemic vascular resistance) by assessing blood pressure, capillary perfusion, toe temperature, and urine output. Afterload may be increased in the vasoconstricted patient as a result of hypothermia or poor cardiac output. Vasodilators such as milrinone, nitroprusside, or nitroglycerin, infused intravenously, may reduce afterload. In the presence of poor cardiac function, vasoactive and **inotropic** (influences the contractility of a muscle) agents are administered intravenously and titrated to maintain adequate cardiac output. Commonly infused inotropic medications include dopamine, dobutamine, milrinone, and epinephrine.

caREminder

Peripheral vasoconstriction, assessed as cold feet and poor capillary refilling time, can be an early sign of diminished cardiac output. A thermometer probe placed on the toes can be used to monitor subtle changes in peripheral temperatures.

If diminished cardiac output is refractory to large dosages of multiple inotropic infusions, cardiac assist devices may be used. *Ventricular assist devices* are pumps used to provide critical support to a patient in severe refractory heart failure or as a bridge to transplantation. *Left ventricular assist devices* support heart function. Blood is diverted from the left heart and returned back to the aorta via a pump. *Extracorporeal membrane oxygenation* is prolonged external cardiopulmonary bypass that allows the cardiopulmonary system to rest so that reversible pathology can resolve. All support devices are invasive and are associated with a variety of complications. When the patient's cardiac function stabilizes, the child is weaned from support devices.

Minimizing Risk for Cardiac Tamponade

Cardiac tamponade occurs when a volume of fluid large enough to interfere with ventricular filling and pumping collects in the pericardial sac and critically suppresses cardiac output. It is most likely to occur during the immediate postoperative period, but may also occur during later stages of recovery. Signs and symptoms of cardiac tamponade include hypotension, muffled heart sounds, decreased systemic perfusion, sudden cessation of chest drainage, narrowing pulse pressures, widening mediastinum on chest radiograph, and increased right and left atrial pressures. Cardiac tamponade can lead to cardiac

NURSING PLAN OF CARE 15–1: THE CHILD WITH ALTERED CARDIOVASCULAR STATUS

Nursing Diagnosis: Decreased cardiac output related to effects of decreased preload/hypovolemia, postoperative bleeding, increased afterload, altered myocardial contractility, arrhythmias, or cardiac defects

Interventions/Rationale

- Obtain baseline and frequent assessments of vital signs (blood pressure, heart rate, respiratory rate), cardiac rhythm (ECG monitoring), quality and strength of apical and peripheral pulses, color and warmth of the skin, level of cyanosis (e.g., circumoral, digital, mucous membranes, clubbing). Assess for signs and symptoms of decreased cardiac output such as hypotension, edema, cool extremities, delayed capillary refill, weak peripheral pulses, mottled extremities, abnormal filling pressures, low urine output, and mental status changes. Notify healthcare prescriber immediately of major changes in child's status.

Baseline assessments provide an index upon which to compare changes. Rhythm disturbances may cause decreased cardiac output. Frequent assessment enables prompt detection of changes and interventions to address the alteration.

- Monitor intake and output, hemodynamic parameters, and laboratory values.

Low urine output may indicate decreased kidney perfusion from decreased cardiac output. Electrolyte imbalances may contribute to decreased cardiac output.
- Administer oxygen, as ordered. Monitor oxygen saturation and arterial blood gases as obtained.

Supplemental oxygen can help increase oxygen available to the myocardium. The need for oxygen is based on the defect and may be contraindicated in a child with low pulmonary pressures who is shunting blood to the lungs at the expense of the systemic circulation.
- Administer medications, such as vasodilators, vasoconstrictors, inotropes, as ordered, to facilitate euvolemia; monitor for desired effect and side effects. Titrate medications, as ordered.

Volume replacement can improve problems caused by decreased preload. Vasodilators may reduce afterload, and inotropes may improve heart contractility, both improving cardiac output. Titrating medications helps maintain a balance between contractility, preload, and afterload.
- Implement measures to conserve child's energy expenditure: limit child's activity; provide comfort measures to reduce fretting (provide pacifier, rock, play soft music); provide small, frequent feedings; encourage quiet activities (read stories, watch TV); encourage frequent rest periods; and schedule activities to provide periods of uninterrupted sleep.

Activity restriction may reduce workload on the heart. Extended feeding events can cause unnecessary energy expenditure.

Expected Outcomes

- Child will demonstrate a cardiac output adequate to maintain perfusion of body, as evidenced by stable vital signs, level of consciousness within normal limits, hemodynamic stability, adequate tissue perfusion and end organ perfusion (e.g., evidenced by urine output of 1–2 mL/kg/hour), and no signs of venous congestion.

Nursing Diagnosis: Impaired gas exchange related to effects of cardiac surgery and anesthesia, fluid shifts, hypoventilation, atelectasis, effusions, pulmonary congestion, pain, immobility, underlying congenital disease

Interventions/Rationale

- Assess quality and rate of respirations; auscultate chest for breath sounds and rubs; monitor oxygen saturation levels; draw arterial blood gases as ordered; and report diminished breath sounds, rales, rhonchi, rubs, cough, or decreased oxygen saturation retractions.

Frequent assessment enables prompt detection of changes and interventions to address the alteration. The presence of pericardial and pleural rubs can indicate effusion.
- Monitor temperature.

Fever can be an early indicator of atelectasis.
- Encourage coughing and deep breathing.

Coughing and deep breathing help to expand lungs and eliminate secretions.
- Position the child upright, if possible. Assist the child to ambulate after he or she is extubated and hemodynamically stable.

Upright positioning assists in allowing maximal diaphragmatic excursion. Early ambulation helps avoid hazards of immobility such as atelectasis and pneumonia.

Expected Outcomes

- Child will demonstrate adequate ventilation and gas exchange evidenced by adequate arterial blood gas results, minimal pulmonary secretions, and normal breath sounds.

Nursing Diagnosis: Risk for imbalanced fluid volume related to effects of volume overloading from myocardial dysfunction, use of diuretics, altered ratio of electrolytes from diuretic therapy, fluid administration, poor nutritional status, cardiopulmonary bypass, prolonged operative time, anesthesia, bleeding

NURSING PLAN OF CARE 15–1: THE CHILD WITH ALTERED CARDIOVASCULAR STATUS (CONTINUED)

Interventions/Rationale

- Assess vital signs and weight, and check for symptoms of fluid volume deficit (e.g., weight loss, poor turgor, tachycardia) or excess (periorbital or dependent edema, bulging fontanel in infants) and heart failure (e.g., irritability, tachycardia, tachypnea, dyspnea, rales, fatigue when feeding, anorexia, periorbital or dependent edema, oliguria, hepatomegaly). Notify healthcare prescriber of major changes.

Changes in these parameters may reflect alteration in fluid balance. Increased fluid volume can lead to heart failure.

- Calculate fluid requirements for the child. Evaluate whether they coincide with the order for fluid infusion and with the child's condition.

Fluid needs are calculated based on the child's weight and condition. Children with cardiac problems often require fluid restriction.

- Monitor intake and output; frequency is dependent on child's status.

Measuring intake and output provides information from which to calculate fluid balance.

- Administer fluids and medications, such as diuretics and fluids as ordered. Monitor for desired effect and side effects.

Fluids and medications are often necessary as mechanisms to treat symptoms and pathology, such as potassium and calcium imbalance, which are critical during the postoperative period.

- Use an infusion device (pump) to administer IV fluids.

Infusion devices provide more accurate fluid delivery than gravity alone and may prevent inaccurate fluid volume administration.

Expected Outcomes

- Child will exhibit clear breath sounds without signs of heart failure or edema; weight will approximate the dry weight (child's weight without excess fluid).
- Child will demonstrate electrolyte laboratory values within acceptable parameters.

Nursing Diagnosis: Hypothermia (postsurgical) related to effects of cardiopulmonary bypass, immaturity of the thermoregulation centers, low cardiac output state, cool surgical suite

Interventions/Rationale

- Assess the child for any signs of cold stress such as low core or skin temperature, cold or cyanotic extremities, pallor, and metabolic acidosis. Monitor the child's temperature.

Frequent assessment enables early detection of cold stress and interventions to reduce it.

- Maintain a neutral thermal environment. Use techniques for warming such as warming lights and warm blankets, changing the temperature setting on the ventilator, and increasing the room temperature. Cover the child's head. Keep neonates in a temperature-regulated warmer isolette or a radiant warmer bed. Warm equipment before putting it in contact with the child (e.g., stethoscopes). Warm fluids and blood products using a specially designed fluid warmer, especially if large amount of volume replacement is necessary.

An external heat source helps warm the child and may minimize cold stress, energy expenditure, and oxygen consumption. Most body heat is lost through the head. Cold stress will cause vasoconstriction and dramatically increase SVR, stress myocardial function, and reduce cardiac output.

Expected Outcomes

- Child will remain normothermic and free from complications of thermal imbalance.

Nursing Diagnosis: Risk for injury (neurologic) related to cardiopulmonary bypass, intracardiac mixing (emboli), low cardiac output, hypotension, hypoxia, electrolyte imbalances and fluid shifts, narcotics, anesthesia

Interventions/Rationale

- Assess neurologic status frequently. Check pupils; monitor for changes such as subtle alterations in behavior, in strength and equality of movement of extremities, or in vigor and coordination of suck.

Frequent assessment enables prompt detection of changes and interventions to address the alteration.

- Monitor for seizure activity, which in an infant can manifest as staring, tremors, or sucking.

Early detection of seizure activity enables prompt implementation of interventions.

- Administer anticonvulsant therapy as indicated and as ordered.

Medications may be required to control seizure activity.

- Be prepared to intervene for status epilepticus (e.g., with airway protection, medications).

Preparation enables prompt intervention.

Expected Outcomes

- Child will remain free of neurologic deficits. Seizures will be controlled with appropriate anticonvulsant therapy.

Nursing Diagnosis: Risk for infection related to pulmonary status, congenital defect, prolonged operative time, excessive postoperative bleeding, prosthetic devices, compromised nutritional status, surgical wound, use of indwelling catheters

Interventions/Rationale

- Adhere to strict hand hygiene (handwashing at sink or use of alcohol sanitizers) immediately prior to coming in contact with the child.

Hand hygiene is the single most important intervention to prevent nosocomial infections.

- Use sterile technique for all invasive procedures (e.g., endotracheal tube suctioning, central line care, wound care).

Sterile technique helps to prevent the introduction of bacteria during invasive procedures.

- Implement interventions to facilitate gas exchange (e.g., respiratory treatments, chest physiotherapy, suctioning).

Pooling of secretions and blood (as may occur with many congenital heart defects) in the lungs may result in pulmonary vascular congestion and may compromise pulmonary compliance, making the child more susceptible to respiratory infection.

- Teach child and parents to avoid contact with persons who are ill.

Avoiding contact with ill people reduces the child's risk of exposure to communicable diseases.

- Assess for signs of infection such as fever, abnormal lab values (e.g., white blood cell count), increased respiratory secretions, crackles, and rales, and intervene as indicated if present.

Early detection and intervention may reduce progression of infection.

Expected Outcomes

- Child will be afebrile, with a white blood cell count within normal limits.
- Child will be free of any signs and symptoms of infection.

Nursing Diagnosis: Imbalanced nutrition: Less than body requirements related to effects of increased caloric need, necessity for fluid limitations, child's inability to take in adequate calories without fatigue

Interventions/Rationale

- Calculate calorie and fluid requirements for the child. Evaluate whether the calories required can be delivered within the child's fluid restrictions. Consult with a dietitian.

Calorie and fluid needs are calculated based on the child's weight and condition. Children with cardiac problems often require fluid restriction but have increased caloric needs as a result of higher metabolic rates and body requirements for postoperative healing.

- Provide small, frequent feedings. Administer nasogastric feedings, as ordered.

Small, frequent feedings help meet the child's caloric requirements without fatiguing the child and reduces the risk of gastric distention, which compresses the diaphragm thereby limiting lung excursion and exacerbating respiratory distress. Nasogastric feedings may conserve energy, because the child does not need to suck.

- Weigh a hospitalized child daily. Assess length and head circumference (in children younger than 3 years of age) upon admission. Track trends in growth.

Daily weight monitoring and tracking trends provide feedback on adequacy of caloric intake, enable prompt detection of negative trends, and allow implementation of interventions to improve intake.

Expected Outcomes

Nursing Diagnosis: Anxiety related to unfamiliar environment, equipment, people, overstimulation, diagnosis

Interventions/Rationale

- Prepare the child, as developmentally appropriate, and family for procedures. Tour the ICU preoperatively (for most school-aged children and older, with parents), talk with other patients and families, and use books and drawings. Modify the environment to reduce stimuli.

Knowing what to expect may help reduce anxiety and distress. Overstimulation may exacerbate anxiety.

- Assess the child's anxiety level and signs of anxiety (e.g., tachycardia, tachypnea, verbalizations, lack of eye contact, withdrawal).

Detecting anxiety allows interventions to be implemented.

- Involve parents to provide touch, distraction, comfort, and other interventions to reduce anxiety.

Parental presence provides the child with a sense of security; parents know best what may comfort child.

Expected Outcomes

- Child will demonstrate behaviors indicating decreased anxiety.

Nursing Diagnosis: Impaired parenting related to symbolic meaning of the heart, separation, lack of control and fear of the unknown, alterations in routine, overprotection of the child, financial and social constraints

Interventions/Rationale

- Allow parents to verbalize feelings; acknowledge and validate parental feelings.

Letting the parents know that the nurse has heard what they have said fosters trust and provides support.

- Encourage parental presence in hospital and interaction with the child. Support parental competence in assessing their child's needs and in caring for their child.

Parental support reinforces new behaviors and bolsters the parents' feelings of competence.

- Model developmentally appropriate communication and care techniques.

Modeling demonstrates skills and behaviors that the parents can learn and adopt.

NURSING PLAN OF CARE 15–1: THE CHILD WITH ALTERED CARDIOVASCULAR STATUS (CONTINUED)

- Use support resources (e.g., social worker, child life worker, support groups) to provide parents with additional mechanisms to share feelings and learn coping strategies.

An interdisciplinary team approach is necessary to enhance parental coping.

Expected Outcomes

- Parents will verbalize feelings regarding their child's illness.
- Parents will demonstrate appropriate bonding and attachment behaviors.

Nursing Diagnosis: Deficient knowledge: lack of information regarding cardiovascular condition and treatment

Interventions/Rationale

- Assess child and family's knowledge of the child's condition and current management, readiness to learn.

Assessment provides baseline information and focuses teaching topics.

- Arrange time and setting for teaching where child and family can focus on the information and skills to be learned.

Distraction impairs ability to focus and master content and skills.

- Teach child and family about condition and management, using materials and techniques appropriate for age and literacy level. Present information that is most important to the family first. Provide verbal and written instructions; use props as indicated (e.g., syringes to measure ordered medication dosage).

Selecting materials and information to meet the family's needs enhances understanding of and adherence to the management plan.

- Evaluate understanding of teaching provided.

May identify misunderstandings or topics that require further teaching.

- Assess family's ability to adhere to treatment plan; intervene as indicated.

Child and family may understand teaching, but factors such as lack of insurance, funds, transportation, or social support may interfere with adherence to management plan.

Expected Outcomes

- Child and family will accurately discuss child's condition.
- Child and family will manage child's condition to keep child as healthy as possible, and will demonstrate appropriate medication administration, as indicated.

Nursing Diagnosis: Deficient knowledge: Healthy lifestyle choices

Interventions/Rationale

- Assess family's nutrition and physical activity behaviors.

Family assessment provides baseline information and facilitates development of a plan that complements the family's lifestyle to promote healthy changes.

- Assess family's knowledge of healthy choices regarding nutrition and physical activity.

Information about the family's knowledge level assists in focusing teaching to family's needs.

- Discuss healthy food choices and the importance of physical activity (based on the child's age), and provide specific amounts of time to target for daily physical activity. Encourage parents to provide positive reinforcement for children with desirable activities (e.g., a trip to the park versus providing food incentives).

Food choices and activity instruction provide information for the family to set personal goals and activities.

- Discuss the consequences of sedentary lifestyle (including excessive screen time) and unhealthy food choices.

Lack of knowledge may contribute to negative lifestyle habits.

- Assist the family in identifying the goals for changes in lifestyle. Remain nonjudgmental, even if they do not desire change. Encourage realistic, incremental lifestyle changes.

The family, as a unit, must desire the change. Consideration of level of motivation is important to promote positive outcomes. Short-term goals are more readily achieved, promoting self-efficacy and demonstrating measurable results.

- Encourage family members to plan daily menus and acceptable activities together.

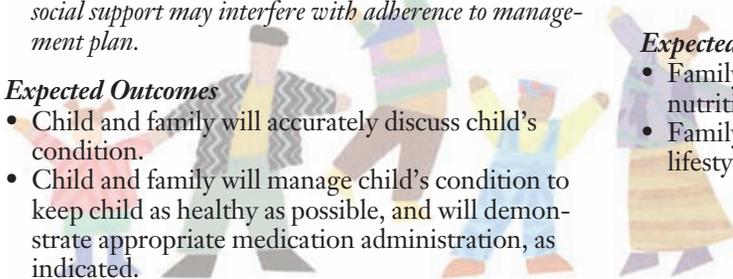

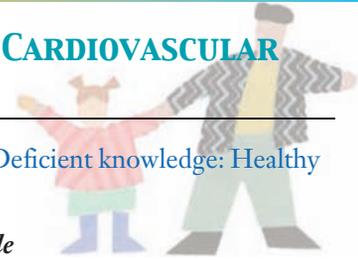

Involving all members of the family promotes adherence and implementation by all members.

- Assist the family to evaluate progress toward goals; revise goals and activities as indicated.

Evaluation helps to encourage modification of goals and activities to facilitate success.

Expected Outcomes

- Family will identify the importance of healthy nutrition and physical activity levels.
- Family will demonstrate incorporation of healthy lifestyle changes.

arrest and possibly necessitate surgical reexploration of the chest cavity. If this condition is not detected by early assessment, death may ensue.

Managing Arrhythmias

Arrhythmias may occur from surgical injury to the heart or fluid and electrolyte imbalances, primarily hypokalemia (see Chapter 17). Monitor and evaluate the ECG, which runs continuously; document the rhythm and any changes. If temporary pacing wires are present, they are connected to a temporary pacemaker according to hospital protocols. Antiarrhythmic agents are administered as ordered while the child is monitored for signs of side effects.

Managing Temporary Pacing Wires

Temporary pacing wires are placed in the heart muscle and are brought out through the chest at the end of an open-heart surgical case. In general, the wires on the right side of the chest are atrial wires, and the wires on the left side of the chest are ventricular wires. This arrangement may vary, however. For example, in patients with dextrocardia (congenital growth of heart inside the right side of the chest), wires will be reversed. The wires may be connected to an external temporary pacemaker (an emergency backup pacer used only if needed) that is placed next to the child. Connection to the temporary pacemaker is usually for 48 hours or until the child is out of danger for arrhythmia. Nursing interventions related to care of the child with pacing wires are discussed in Nursing Interventions 15–2.

Maintaining Fluid and Electrolyte Balance

As a response to surgery and cardiopulmonary bypass, aldosterone and antidiuretic hormone are secreted. These hormones increase sodium and water retention and potassium excretion. During the postoperative period, excess fluid, which has settled into the interstitial spaces, diffuses back into the systemic system. Because of excessive total body fluids, diuretics and fluid restrictions may be necessary.

Postoperatively, assess for hydration by palpating fontanels in infants, checking mucous membranes and skin turgor, and assessing for signs of edema. Edema is most evident in the hands, feet, sacrum, and periorbital areas. Fluid restrictions are calculated, and intake is adjusted to meet limitations. When children are stable, weigh them daily and closely monitor and document intake and output. Hypotensive episodes can be treated with small IV fluid volume boluses given as ordered. When the child can tolerate oral intake, fluid limits are advanced slowly.

Monitor urine output, which is an indicator of fluid volume status and of end organ perfusion, hourly while indwelling urinary catheters are in place. Renal failure is more likely to occur in children with heart disease associated with cyanosis and in those with periods of hypotension. Monitor the child's electrolytes as well as other pertinent laboratory values. Acid or base deficits may be

NURSING INTERVENTIONS 15–2

Caring for the Child With Temporary Pacing Wires

- Secure wires to the child's chest, avoiding tension on the wires and preventing them from dangling so they cannot be inadvertently pulled out.
- Mark the wires as either positive or ground and negative.
- Attach pacemaker control boxes to the bed with a safety pin. This minimizes the risk that the pacemaker could fall on the floor when a child is held or is up in the chair.
- If wires are disconnected from the pacemaker, place them in a finger cot or part of a disposable glove and tape the wires to the child's chest.
- Protect pacer wires from microshock. Avoid placing any electrical equipment on the bed, such as infusion pumps or tape recorders. Remove all liquids near electrical equipment or pacing wires.
- Temporary wires are pulled out at the bedside before discharge by the healthcare provider.
- After discontinuation of pacing wires, monitor the child for signs and symptoms of cardiac decompensation.

related to poor pulmonary function. Acidosis is also an indicator of poor cardiac output. Hypokalemia is treated with IV bolus doses of potassium while the child is in the ICU.

Promoting Respiratory Function

Ensure that chest tubes remain patent, and monitor and evaluate drainage, noting its consistency and color. Mediastinal chest tubes are discontinued after drainage subsides, which is usually by the second postoperative day. Although the procedure is quick, removing tape from dressings and skin is painful, and removal of chest tubes is uncomfortable. Medicate the child for pain well before the removal of chest tubes.

Alert! More than 1 mL/kg/hour chest tube drainage during the immediate postoperative period is considered excessive. If a coagulopathy is ruled out, too much bleeding may necessitate the child's return to surgery so that the surgeon can explore for potential bleeding vessels.

During cardiopulmonary bypass, the child's lungs are deflated, causing atelectasis. Also, cardiopulmonary bypass causes water and sodium retention and potassium depletion, so fluid settles in the interstitial spaces of the pleura, which increases body weight temporarily. Changes occur in the alveoli, and small pulmonary vessels become more permeable, resulting in interstitial pulmonary

edema. This edema causes leukocyte aggregation and sequestration in the lung, creating a mild decrease in lung compliance. Moreover, sternal pain can deter a patient from coughing and taking deep breaths to reexpand the lungs.

Perform pulmonary assessment and document changes as they occur. Note the child's general appearance and color. Mild tachypnea and decreased tidal volume usually occur postoperatively. Check for signs and symptoms of impaired pulmonary function, including dyspnea, tachycardia, tachypnea, pallor, diaphoresis, adventitious breath sounds, poor cough, and use of accessory muscles. Irritability, exhaustion, and an alarmed look can also be signs of respiratory distress. Cyanosis, abnormal arterial blood gas values, and low oxygen saturation levels can be normal in children with intracardiac mixing.

Most children are extubated within 24 hours of surgery, with some, such as older children and those who are predicted to be stable, being extubated during surgery. However, critically ill postoperative patients can require ventilation for cardiopulmonary support over many days. Perform endotracheal suctioning as needed, noting the character, amount, and consistency of pulmonary secretions.

After the child has been extubated, ensure that the airway is patent and monitor for stridor or wheezing. Assess chest wall rise and expansion, and respiratory rate and quality. Position infants in the "sniffing position," with the head slightly back and nose pointing up. Elevate the head of the bed to encourage lung expansion and ease the work of breathing. Administer supplemental oxygen and wean as tolerated. Perform pulmonary hygiene including coughing, deep breathing, breathing treatments, incentive spirometry, and nasotracheal suctioning. Chest physiotherapy is used to mobilize secretions and reinflate regions of atelectasis. Schedule nursing care and cluster tasks to prevent exhaustion and hypoxia. As the child tolerates it, encourage activity. Administer pain medication on a regular basis. Balance minimizing pain and maximizing alertness, so the patient can produce a strong cough.

Postoperative cardiac surgical patients are at risk for developing pleural effusions. Effusions can develop from an imbalance between filtration and reabsorption of pleural fluids. Chylothorax, a condition in which a characteristic type of lymph fluid called chyle accumulates in the chest cavity, may develop. The accumulation of chyle in the chest cavity leads to difficulty breathing, because the lungs cannot expand normally. Chylothorax may develop when a thoracic duct is injured and occurs most commonly after thoracotomy incisions. Chylothorax may be managed with ventilatory support, as indicated, and pleural fluid drainage. A fat-restricted diet supplemented with medium-chain triglycerides may be ordered to reduce chyle production. If so, explain the rationale for this to the child and parent, and encourage the child to select appropriate foods. Somatostatin or octreotide may be given intravenously or subcutaneously (Helin, Angeles, & Bhat, 2006); monitor for adverse effects including diarrhea, hypoglycemia, and hypotension.

Preventing Hemorrhage

Be alert for signs of acute bleeding, which may include increased heart rate, narrowing pulse pressures, and decreased perfusion and blood pressure. Bleeding can occur from the numerous suture lines in the heart and great vessels. Neonates with an immature liver and clotting system are at higher risk for bleeding. Cardiopulmonary bypass also traumatizes blood, from the mechanical actions of the blood passing through the pump and tubing. While on bypass, the patient is fully anticoagulated (heparinized) to keep blood from clotting in the pump tubing. Anticoagulation is reversed after the surgical repairs are complete, but can lead to clotting abnormalities postoperatively. Ensure that blood is readily available. Monitor the child's clotting factors, complete blood count, and platelets. Blood is replaced as necessary, but judiciously. Cardiac nursing units have an emergency sternotomy tray available and a protocol for reopening a chest incision in the ICU in the event of an emergency such as sudden or excessive bleeding.

Monitoring Neurologic Functioning

Neurologic insults may result from hypotensive states, hypoxia, or an embolic event. However, the causes are not always clear. Perform a neurologic examination including level of consciousness, pupillary response, movement of extremities, and responses to stimuli. Be alert for other changes that may indicate alterations in neurologic status such as irritability, a high-pitched cry, poor feeding, or rigidity. Subtle neurologic changes, such as poor eye focusing or confusion, are usually normal and transient. More severe changes include seizures, coma, and one-sided weakness.

Seizures that are related to neurologic dysfunction or electrolyte imbalances may occur. Seizures may be difficult to distinguish from normal jitteriness (see Table 14-4). Subtle signs of focal seizure activity might include chewing, eye deviation, or hypotonia. Anticonvulsant medications are administered to suppress seizure activity.

Preventing Infection

Children who are particularly debilitated pre- or postoperatively, who require prolonged ventilation, or who are undernourished are especially at risk for infection. Prophylactic antibiotics are usually administered for 48 hours or until invasive lines are removed.

Assess temperature and all dressings frequently and change dressings based on agency policy and procedures. Document the absence or presence of redness, exudate, edema, the approximation of the chest incision, and any invasive line insertion sites. Dress and secure pacing wires to the chest and label for easy access in case of an emergency (see Nursing Interventions 15-2). Monitor white blood count values daily.

Managing Sedation and Pain

While a child is critically ill, sedation can be a component of hemodynamic management. Because sedation reduces

systemic vascular resistance and pulmonary vascular resistance, sedation may improve cardiac performance. When a child is heavily sedated, the eyelids may not shut completely; provide eye care to prevent corneal damage.

Pain and anxiety are major issues for patients and families. After assessing for possible causes of pain and adequacy of pain control interventions, medicate the child appropriately (see Chapter 10). It is important for children to be comfortable enough to take deep breaths, cough, and be involved in activities between resting. Assess the child for signs and symptoms of pain, which include crying; restlessness; irritability; grimacing; splinting; rigid posture; and increased heart rate, respiration, or blood pressure. Position the child for comfort. Provide comfort measures such as bundling (for infants), placing the child in a particular position, or providing a pacifier. Use other noninvasive procedures to augment the effectiveness of opioid pain medications such as distractions like cartoons, music, favorite or new toys, or a soothing voice. Supplement opioid analgesia with acetaminophen. Administered on a regular basis, acetaminophen alleviates the general soreness of surgery, does not suppress respirations, and allows a child to be alert and interact.

Managing Nutrition

If a child is extubated; has active bowel sounds; is passing flatus; and has a soft, nondistended abdomen, the child may be ready to resume oral feeding.

Infants are started on a 5% dextrose solution or pediatric electrolyte solution. The older child is given ice chips and sips of water. When giving fluid, elevate the child's head 30 to 40 degrees; alternately, have the parent hold the child in his or her lap. Observe whether the suck-swallow reflex is normal. After the feeding, keep the child's head elevated for 30 minutes to prevent vomiting. As the child demonstrates tolerance of fluids by mouth, the volume of maintenance IV fluids is decreased. Calculate 24-hour fluid totals based on the ordered fluid limit and subtract the ordered IV therapy fluids to determine the remaining amount of fluid for oral intake per hour. Fluid limits are based on the child's "dry weight."

When the child is allowed to eat, document daily nutritional intake. Arrange a dietary consult if the child has the diagnosis of failure to thrive or demonstrates poor nutritional intake.

Feedings via a nasogastric tube may be needed for a critically ill neonate until he or she is strong enough to receive oral feedings. This process may take 1 to 2 months with the help of a feeding specialist.

Providing Psychosocial Support

After a child is extubated and is hemodynamically stable, the child may increase activity and sit up in a chair even before most invasive lines are discontinued. When lines are removed, children may ambulate and begin to participate in activities in the playroom. Part of a nurse's postoperative interaction is to boost confidence. Children may be afraid to move and walk because of fear and pain. Providing positive reinforcement and prodding a child to increase activity may help smooth recovery from surgery.

An important nursing intervention is to lessen the negative effects of surgery on the child's physical, emotional, and social well-being. Negative behavioral changes, such as clinging behavior, fear of uniforms, depression, or regression, are normal and to be expected. Uncooperative behaviors are self-protective and are an expression of anger. A combination of medications for pain, distraction techniques, comfort measures, prodding the child to advance activities, and accepting negative behaviors may help a child cope with the pain and stress of hospitalization.

KidKare ■ When a child is overwhelmed by multiple lines and tubes, he or she may choose one item about which to complain constantly, such as tape on an arm. The child may focus on something seemingly trivial because of the inability to fight all current stress and the lack of control over the situation. Reassure parents that this coping mechanism is normal.

Parents suffer greatly at the sight of ill children and their inability to protect them from pain. Parents usually protect and comfort their child continually in day-to-day life. Normally, a parent controls every aspect of a child's life and meets all physical and emotional needs. At home, parents decide when to feed, bathe, change, put down for naps, and plan activities. Suddenly, they are compelled to relinquish their child to strangers whom they allow to perform strange, painful, and unusual procedures in hopes of an improved future. This loss of control, although voluntary, may be overwhelming and may cause parents to feel guilty, saddened, and stressed.

Help by encouraging parents to express fears and concerns regarding their child's condition. Encourage families to participate in a child's care as often as they can and to do as much as they feel comfortable doing. Promote parents' touching and comforting of their child and allow them to hold the child as much as is practical. Explain all procedures to parents, while encouraging questions and enabling them to verbalize concerns. Parents benefit from continual updates on the child's status and progression. Also, nurses are instrumental in making referrals to support systems, when needed.

Community Care

Assess discharge planning needs in advance and provide follow-up referrals, if necessary. Discharge teaching includes postoperative expectations and written discharge instructions (TIP 15-2). To promote recovery, parents must be comfortable with activity restrictions for discharge.

Discharge instructions must include details about immunizations. Immunizations are avoided around the time of surgery. Otherwise, despite illnesses and hospitalizations, instruct families to maintain immunizations at scheduled times.

TIP 15–2 A Teaching Intervention Plan for the Child After Cardiac Surgery: Discharge Instructions

Nursing Diagnosis and Family Outcomes

- Deficient knowledge: Lack of information regarding postoperative care of the child at home

Outcomes

- Family will provide child with support, assistance, and encouragement to manage or master tasks related to postoperative care.
- Child, as age appropriate, and family will follow written discharge instructions, seeking assistance as needed to ensure safety and promote the well-being of the child.
- Child, as age appropriate, and family will demonstrate an understanding of the child's postoperative care needs.
- Child, as age appropriate, and family will verbalize measures to meet the child's needs.

Treatment of the Child

Medications

- Carry a list of your child's medications with you at all times (the name of each medication, the dosage, and how often it is taken).
- Always get your prescriptions filled before you run out.
- Never stop giving any medicine. Your cardiologist will determine when the medication is to be changed or stopped.
- Bring the medications and the list when you come in for your first follow-up visit.

Wound Care

- Only sponge bathe your child the first week. Do not apply lotions or powders to the incision site during the first 2 weeks after surgery.
- Keep the incision area clean and dry. If the incision area gets dirty or soiled, cleanse the area with mild soap and water.
- Do not remove Steri-Strips placed over the incision site. Occasionally, these strips become loose and fall off. Do not worry if they do.
- Observe the incision site daily for redness, swelling, or drainage.
- Be aware that tingling, itching, and numbness are normal sensations from the wound and will eventually go away.
- If there are areas of the incision that are constantly irritated by clothing or the chin rubbing, cover them with a Band-Aid to prevent irritation and to promote faster healing.
- Keep a shirt over the incision when your child is outside to protect it from the sunlight.

Activity

- Gradually encourage the child to increase activity each day. Generally, children recover quickly and

are able to participate in most of their normal activities. Activity level improves as the child recovers.

- Be aware that infants and children tend to pace themselves and will rest if they feel tired. Try to maintain a sensible balance of rest and exercise.
- Avoid lifting your child under the arms, because this may cause discomfort by placing stress on the surgical site. Instead, slide your hands under your child's buttocks and support the chest when lifting.
- To allow the breast bone to heal, for 6 weeks do not allow the child to engage in rough play or activities such as bicycling, climbing, skateboarding, or contact sports, and avoid activities that would put pressure on the child's chest, such as heavy lifting, or any activity that might cause a blow to the chest.
- Try to avoid large crowds and/or people with active infections for at least 2 weeks (e.g., birthday parties, church, school, shopping malls).
- Be alert for possible clinging behavior and/or sleep disturbances initially. Use positive reassurance and assist in returning to a normal routine.

Diet

- Allow your child to return to his or her normal diet with no restrictions.

Immunizations

- Expect immunizations to be delayed normally for 6 to 8 weeks after surgery.

Dental Care

- Whenever possible, delay routine dental care for 4 to 5 months after your child's surgery. Remember, some children with cardiac problems are required to take antibiotics for dental work to prevent an infection in the child's heart.

Discomfort

- Administer acetaminophen unless otherwise ordered by the healthcare provider for complaints of some incisional or chest discomfort after discharge.

Contact Your Healthcare Provider if:

You think there is a change in your child's behavior, which may or may not indicate illness. Watch for the following signs of illness:

- A change in feeding pattern
- Breathing harder or faster
- Puffiness of the hands, feet, or face, especially around the eyes
- Excessive sweating, especially evident on the forehead
- Weakness, irritability, weak cry in infant
- Cool, pale, mottled hands or feet
- Few wet diapers or poor urine output
- Temperature higher than 101 °F (38.4 °C)

MedicAlert bracelets are not considered necessary for all children with cardiac conditions but they are recommended for children with pacemakers, heart transplants, and automatic implantable cardioverter defibrillators (AICDs), and for those receiving anticoagulant therapy. Children who have a history of seizure activity after surgery may wear bracelets as recommended by the healthcare provider until they are seizure free for a specified time.

Neurologic growth and development are frequently impaired in children with CHD. Impairment is indicated by factors such as lower intelligence quotients, difficulty with practical reasoning tasks, language delays, hypotonia, poor eye–hand coordination, gross and fine motor delays, behavioral difficulties, and personal social difficulties (Majnemer et al., 2008). Referral to programs with physical, occupational, and speech and language therapy, plus educational and psychological support, may be indicated.

Pacemakers

Pacemakers can be used in children who have impaired impulse formation or conduction problems and are symptomatic. Bradycardia requiring pacemaker insertion in children is of primarily two types. One type, *sick sinus syndrome* or *sinus node dysfunction*, occurs when the heart's pacemaker functions normally but not fast enough to provide an adequate cardiac output. *Atrioventricular block*, the second category of bradycardia, occurs when the pacemaker functions appropriately, but the signal is not transmitted through to the atrioventricular node and ventricles. Atrioventricular block may be caused by a congenital heart block, medications, or a heart infection, or may occur as a postsurgical complication.

Most pacemakers are placed in the cardiac catheterization laboratory. In children, leads are placed on the external heart muscle of the atrium and ventricles; the generator is inserted in either the chest or abdominal space. The location of lead placement depends on the type of heart problem and size of the patient. If pacemaker placement is not successful in the cardiac catheterization laboratory, surgical placement involving a thoracotomy and abdominal incision is required. In the past, permanent pacemakers were too large to be placed in small children, but modern pacemakers are now small and lightweight enough that they have been used in infants. Provide routine postsedation or postoperative care as indicated.

Community Care

Children have their pacemakers checked as outpatients on a regular basis. A specialized computer and magnet that communicates through radiofrequency signals is placed over the pacemaker generator and is used to change settings and evaluate the pacemaker. It is a noninvasive way to check the activities of the pacemaker and battery usage.

As part of the pacemaker package, children are given a transtelephonic system to take home. This system enables them to periodically transmit ECGs to the clinic over

their home telephones. The placement of a pacemaker requires long-term follow-up and future surgeries. Periodically, minor surgery is required to replace the battery in the pacemaker. Lead wires can be fractured. Replacing lead wires involves a surgery that is more extensive than just battery replacement.

Psychosocial responses to pacemaker insertion depend on the personal responses of individual families. The child may have body image disturbance or self-concept changes caused by scars, activity restrictions, and continual follow-up (see Chapter 12 for nursing interventions).

Instruct parents of children with pacemakers to have the child avoid contact sports such as gymnastics and football. In addition, children must avoid highly magnetic areas, such as magnetic resonance imaging machines. Parents also need to know that high-voltage areas, such as those near high-tension wires, can also interfere with the function of a pacemaker. Emphasize to parents that modern microwave ovens do not affect pacemakers.

Cardiac Transplantation

Cardiac transplantation has become an option for extending the length and quality of life of children who have exhausted available medical treatment and palliative surgeries, and are no longer surviving well, as demonstrated by disabling cardiac symptoms or limited life expectancy. The diagnosis that most often leads to cardiac transplantation in older children is cardiomyopathy. Some of the congenital cardiac defects associated with cardiac transplantation are hypoplastic left heart syndrome (HLHS) and other complex single-ventricle hearts. Actuarial survival is 90% at 15 years (Ross et al., 2006).

Pediatric Donors

Although the list of infants and children waiting for transplantation is shorter than that for adults, the supply of donor pediatric hearts is extremely limited. Children on the waiting list outnumber the donor heart supply. Most pediatric donors die from sudden infant death syndrome, trauma, or birth asphyxia.

Determining when to place a child on the waiting list for an available heart is difficult. Decisions depend on the expected natural history of the particular underlying heart problem. Decisions regarding when the heart failure is terminal, coupled with the shortages of available donors, severely complicate the timing of transplantation surgeries.

For a child to be included on the waiting list, the possibility of any other systemic diseases that might rule out the viability of transplantation must be explored. Also, a psychosocial profile of the family that considers their resources and commitment to the program is developed. The depth of ethical decisions, the financial burden, the need for patient adherence to medications, and constant follow-up make the care of these children complex.

Once listed with the United Network for Organ Sharing on the national computer, patients and donors are matched based on blood type, body weight, length of time on the waiting list, and the child's medical stability.

After a heart transplant, the major challenge in caring for the child is maintaining the balance between immunosuppression and factors such as adverse medication side effects, infection, and rejection of the donor organ. For the child, side effects from and expense of immunosuppressive medications, and constant follow-up care are generally the areas of greatest concern. For the health-care practitioner, the largest issue is the balance between infection and rejection, which hinges on maintaining immunosuppression.

Rejection and Immunosuppression

Rejection of the foreign heart is attempted by all recipients' immune systems. The recipient's body never learns to accept the foreign tissue. Rejection occurs because of an incompatibility of cell surface antigen, which invokes a humoral and cellular immune response against the heart.

Management of rejection varies, but traditionally has included triple-medication therapy with cyclosporine, azathioprine (Imuran), and prednisone. Triple therapy is used so that the practitioner can prescribe lower dosages of each medicine, thus decreasing overall side effects. Susceptibility to infections is a complication of all the immunosuppressive medications used today.

Cyclosporine inhibits T-cell function, but exactly how it works is unclear. Cyclosporine is the immunosuppressive drug that has increased both rate and duration of survival among transplant recipients. Side effects include tremors, gum hyperplasia, hirsutism, flushing, nephrotoxicity, seizures, and hypertension.

Azathioprine (Imuran) is a suppressor of bone marrow function that inhibits purine synthesis and metabolism. The white blood cell count of children receiving this drug is followed closely to monitor for the side effect of depressed bone marrow function. Side effects may include high blood pressure, tremors, gum hyperplasia, hirsutism, and nephrotoxicity.

Prednisone, a corticosteroid, influences the immune system through its strong anti-inflammatory action and immunologic effect. Because of the severity of side effects of prednisone, transplant recipients with mild and few rejection episodes may be weaned off prednisone therapy. Side effects of corticosteroids include poor wound healing, ulcers, growth impairment, delayed sexual maturation, glucose intolerance, increased appetite, hyperlipidemia, cushingoid appearance, acne, and sun sensitivity. The development of a cushingoid appearance manifested by excessive weight, overgrowth of hair, and moon-shaped face can be a great source of stress for a school-aged child or adolescent, necessitating close monitoring for adherence. Usually, most of the symptoms subside in those children able to tolerate lower dosages of the immunosuppressive medications.

Serial myocardial biopsies are the most reliable predictor of rejection. They are performed in toddlers and children but are technically more difficult in infants. Children are also followed closely through noninvasive clinical evaluation including echocardiography, chest x-ray, and evidence of signs and symptoms. Episodes of

rejection may be managed by courses of IV steroid therapy or other strong immunosuppressive medications.

Over a life span, the long-term effects from immunosuppressive therapy on small children are unknown. Chronic usage of drugs for immunosuppression has led to renal dysfunction, malignancies, and hypertension. One important limiting factor for long-term survival of heart transplant recipients is cardiac allograft vasculopathy, which is an accelerated form of coronary artery disease. It occurs in 50% of patients during the first several years after surgery. The only definitive treatment is retransplantation.

Routine immunizations are still given to transplant recipients even though they are receiving immunosuppressant agents. However, no live viruses are used. Normal childhood infections in these children generally are well tolerated. Although transplantation has enabled many children to survive otherwise terminal diseases, it is not a panacea and is still an evolving field of care.

Psychological Stress

Children receiving heart transplants experience psychological stress, which may lead to anxiety, behavioral difficulties, depression, and other psychiatric problems. Normalizing the child's life as much as possible by providing routine, expectations for conduct, discipline, and developmentally appropriate activities may help diminish some of the negative effects of a chronic condition (see Chapter 12).

Supportive Care

When parents learn that their child has the diagnosis of a heart condition, substantial psychological and social consequences affect the family. The heart is viewed by many as an extremely important organ in the body that symbolizes the emotion of love. Parents usually need time to cope with the realities of having a child with a cardiac condition.

Parents of children with a correctable cardiac lesion may be just as anxious, if not more anxious, than those of a child with a very complex congenital lesion. Many children with cardiac lesions have no outward signs of cardiac disease. Specific symptoms that would cause the parents to feel that their child has a problem may not be evident. These parents may also experience fear and guilt about putting their otherwise "perfect" child through medical interventions. The parents may accept the child's condition more easily if the practitioner can point out some measurable feature, such as the echocardiogram results and the location of the lesion to assure them that the corrective intervention is essential. Seeing the chest radiograph of an enlarged heart with heart failure or comparing a poor growth curve may help parents appreciate and understand the existence of the heart defect.

Parental support groups or parent meetings with other families of children with CHD may be a source of support for parents, helping them to sort out the emotions and stresses of having a child diagnosed with CHD.

Parents of symptomatic children are often emotionally drained and have infrequent breaks from child care responsibilities. Baby-sitters are often fearful to take on the management of medication administration and the emotional burden of an ill child. Parents may be frightened and fearful of creating situations in which their child becomes symptomatic. The simple activities one normally does with an infant, such as feeding, can become tedious and painstaking events. Encourage parents to take personal time, alone or as a couple, and develop respite options.

Treatment options for a child with heart disease are not always clear and usually include expensive and invasive procedures. At times, families of children with complex heart disease are required to make choices for their child that will markedly alter the course of a child's life. Financial and religious factors may influence these decisions. For example, a parent may continue a job they may have otherwise quit, to maintain their health insurance benefits, or may refuse a job transfer so they can stay near a medical center where they are comfortable with the staff and facility. The needs of families in a world that can provide high-technology care are multifaceted, involving ethical, religious, financial, and emotional components.

Community Care

Most school-aged children with CHD are able to attend normal schools. If a child is being kept out of school, contact a social worker or the child's cardiologist to confirm that a medical need exists for the child to be denied access to school. Some parents may have inappropriate fears about the vulnerability of their child and may overprotect the child. Most children can be encouraged to participate in playground activities at their level of tolerance, but should not be pressured to exercise beyond their personal limits.

Children with severe cardiac lesions that need a more sedentary lifestyle that requires school programs to be modified on an individual basis. Such modifications enable the child to participate at a level the child can tolerate. For instance, a nap could be substituted for recess activities. Transportation to and from school could be arranged instead of having the child walk. If a period of school is missed, it is often associated with a procedure such as surgery or cardiac catheterization. Tell parents to encourage classmates to keep in contact with the ill child, perhaps visiting the child's home and sending cards to the hospital.

Children with minor cardiac issues or those whose lesions are repaired generally can travel without limitations. Extreme heat and sudden climate change can stress ill children and can cause venous pooling from vasodilation. Aggressive travel itineraries may overtax the endurance level of a child with limited reserve. Children with unrepaired lesions, heart failure, cyanosis, or the propensity for sudden illness or complications need to have ready access to appropriate emergency care. After cardiac transplantation, children are not allowed to travel to underdeveloped countries, where the risk of illness from water sources and limited medical care is greater.

If the family is traveling to a large metropolitan area, the child's cardiologist usually can locate a contact physician in the vacation area to call if necessary. Instruct parents to carry a list of emergency contact medical personnel and medications; and a short, written synopsis of the child's history.

Airplane travel or travel to areas of high altitude is restricted in children with heart disease that is associated with cyanosis, pulmonary hypertension, and severe heart failure. Higher elevations have a lower partial pressure of oxygen, which may further compromise the child's oxygen carrying capacity. Supplemental oxygen is used if high-altitude travel is necessary. Commercial airlines will not allow families to bring their own oxygen tanks. If oxygen support is necessary, arrangements must be made in advance with the airlines and with a medical supply company at the family's destination.

Well-child care and teaching must not be overlooked when caring for a child with a cardiac defect or problem. Historically, antibiotics were provided for routine dental care and medical interventions, as prophylaxis against infective endocarditis for most patients with heart lesions. The American Heart Association (Wilson et al., 2007) changed the antibiotic prophylaxis for dental procedures to include patients with cardiac conditions associated with the highest risk of adverse outcomes from endocarditis, including prosthetic cardiac valves, previous endocarditis, unrepaired CHD associated with cyanosis, 6 months' postcomplete repair of CHD disease with prosthetic material, or repaired CHD with prosthetic material and a residual defect. Antibiotic prophylaxis is not recommended for the placement, adjustment, or removal of orthodontic appliances for any cardiac patients. Antibiotic prophylaxis solely to prevent infective endocarditis is no longer recommended for any cardiac patient having a gastrointestinal or genitourinary procedure. A wallet card with the recommendations is available for the patient and family.

NURSING PLAN OF CARE FOR THE CHILD WITH ALTERED CARDIOVASCULAR STATUS

The effects of heart disease on the child and family are both acute and long term. When heart disease is suspected, the healthcare team acts rapidly to ensure that the child's physiologic status is as stable as possible. Nursing diagnoses during the early critical stages focus on oxygenation, cardiac output, and fluid volume concerns related to the child's specific condition (see Nursing Plan of Care 15-1).

Because the heart is vital to human existence, the presence of a cardiac condition is likely to cause considerable apprehension and fear for the parents and the family. The plan of care for the child with a cardiac condition must include interventions to help the parents cope so that they are able to deal with the facts related to their child's illness. An important role of the nurse is to assist the family in understanding the child's condition and the treatment plan.

Provide teaching and emotional support to children and their families. Prepare them for testing and procedures. Monitor the child on an ongoing basis, particularly during procedures. Protect the child from injury, while also maintaining readiness for any necessary emergency support in case the child becomes hemodynamically compromised.

Most children affected with CHD or an acquired heart condition are able to lead normal lives. Nursing care that addresses alterations in development, body image, and self-esteem concerns is indicated when the child's condition is severely limiting or disabling (see Chapter 12), or the child's life span is limited (see Chapter 13). Chapter 11 discusses nursing care of the child who is hospitalized or undergoing surgery. Chapter 10 provides an in-depth discussion of pain management.

ALTERATIONS IN CARDIAC STATUS

Heart disease in children can be classified as congenital or acquired. Heart failure or cyanosis may occur as a result of heart disease, regardless of the etiology. An understanding of both heart failure and cyanosis is critical to providing care to children with heart disease regardless of whether it is congenital or acquired. Each condition will be reviewed followed by discussion of congenital and acquired heart diseases.

Heart Failure

Heart failure is one of the major manifestations of cardiac disease. It is a clinical syndrome in which the heart's pumping ability is inadequate to meet the metabolic demands of the body. Heart failure is usually seen in infants, because most cardiac lesions are repaired or palliated during the first year of life. If a well child presents with heart failure beyond the first year of life, it may be the result of an acquired cardiac disease such as rheumatic fever, bacterial endocarditis, or viral cardiomyopathy. Older children may present with heart failure later in life because of the presence of a previously undiscovered lesion.

QUESTION: Based on Gabriella's current condition, would she be at risk for developing heart failure if her PDA goes untreated? Why or why not?

Pathophysiology

Heart failure may be a result of excessive circulation to the lungs, volume and/or pressure overloading, or poor myocardial function. Heart failure can be a right- or a left-sided heart problem, although children usually present in biventricular failure. Right ventricular dysfunction causes right ventricular end diastolic pressure to increase, leading to pulmonary venous engorgement. Left ventricular dysfunction causes left ventricular end diastolic pressure to increase, causing systemic engorgement. The ventricles dilate in response to elevated pressures.

The presence of a congenital heart defect is the most common reason for children to develop heart failure (Shaddy & Wernovsky, 2005). Lesions with left-to-right shunts typically result in volume overloading. For example, a child with a large VSD has shunting from the left side of the heart to the right. Because blood travels the path of least resistance, some blood crosses from the left ventricle to the right side without exiting the aorta and circulates to the lungs repeatedly, causing an extra load on the lungs. An obstructive lesion of the left heart may cause pressure overload. For example, in the case of aortic stenosis, the left ventricle is constantly pumping against a restricted valve. Depending on the stressors and severity of the stenosis, this obstruction could lead to failure of the left heart. Neonates with a severe left-sided obstruction may be without symptoms initially because their patent ductus is open; therefore, pressures may be relieved by shunting across the patent ductus. Symptoms appear as the ductus closes.

Nonstructural conditions such as a chronic heart rhythm disturbance or cardiomyopathy that is causing poor myocardial function may lead to heart failure. Arrhythmias that may cause heart failure include chronic supraventricular tachycardia, atrial fibrillation or flutter, and congenital heart block. Supraventricular tachycardia is the most common emergently presenting arrhythmia in the pediatric population. In dilated cardiomyopathy, the cardiac chambers are dilated and myocardial contraction is weakened, leading to heart failure.

Heart failure leads to pulmonary venous congestion, systemic venous congestion, and poor myocardial pumping (Chart 15–2). Increased pulmonary blood flow is the physiologic effect of the most common heart defects. Symptoms occur when the heart's compensatory mechanisms have exceeded the point of efficiency and cardiac output is diminished.

As the heart fails, the body uses available compensatory mechanisms in an attempt to meet the circulatory needs. Tachycardia, a compensatory response to decreased cardiac output, results from an increased release of catecholamines (epinephrine and norepinephrine) and causes rapid filling of stiff ventricles in an attempt to increase the force and rate of myocardial contraction. Tachycardia also increases oxygen consumption of the heart. Tachycardia that is too rapid decreases the heart's filling time and coronary perfusion. Although initially it has a compensatory advantage, excessive tachycardia may become destructive, ultimately impeding cardiac output.

Cardiomegaly occurs as a muscular response to the need to increase cardiac output. The heart dilates to increase the myocardial fiber stretch to improve the force of contraction. Stretching and dilation are advantageous, within limits, to increase cardiac output. Beyond a certain point, however, the increased myocardial stretch results in diminished pumping efficiency and fails.

Systemic Venous Congestion (Right-Sided Failure)

Elevation of right atrial filling pressures restricts the emptying of the vena cava into the right atrium. Blood

CHART 15–2 CLINICAL MANIFESTATIONS OF HEART FAILURE

Failure to thrive

pooling in the venous circulation raises systemic venous pressures, resulting in fluid sequestration to the interstitial spaces and hepatomegaly. Blood flow to the kidneys is diminished, and the renin–angiotensin–aldosterone system is stimulated, resulting in vasoconstriction and sodium and water retention, which further compounds fluid retention and decreases urine output.

Pulmonary Venous Congestion (Left-Sided Failure)

Imbalances between filtration and reabsorption of fluid in the pulmonary capillary bed caused by increased pulmonary capillary pressures can lead to respiratory symptoms arising from pulmonary congestion.

ANSWER: Gabriella's PDA results in pulmonary volume overload as a result of her left-to-right shunt. Over time, her respiratory status will further suffer because of the pulmonary congestion, her pulmonary vasculature will be damaged because of the increased pressure within the vasculature, and her cardiac musculature will be damaged as it compensates for the increased blood volume flowing to and from the lungs, resulting in heart failure.

Assessment

The diagnosis of heart failure typically is based on findings from the child's history, physical assessment, and diagnostic tests. When obtaining a history, ask whether the child fatigues easily or exhibits poor exercise tolerance. Parents may report that an infant tires with feedings and is anxious, irritable, and difficult to console. Failure to thrive, growth retardation, or poor weight gain that puts the child in the bottom percentile of the growth charts for weight despite normal height are suspicious signs, as are poor nutritional intake, nausea, failure to meet developmental milestones at a normal pace, and delays in gross motor skills.

During the physical assessment, note any abnormalities in the cardiac assessment. When the heart is auscultated, a gallop rhythm or extra heart sound (S3 gallop murmur) may be heard, resulting from excessive preload and ventricular dilation. On palpation, the pulses may be weak and thready. A hyperactive precordium noted when viewing the child's chest may indicate cardiac enlargement.

Note weight gain and swelling of soft tissue in dependent or sensitive areas, such as the sacrum, scrotum, or eyelids, indicating fluid retention of right-sided heart failure. Distended neck veins (despite sitting up) and ankle edema are other areas less commonly used to assess fluid retention in children. Hepatomegaly may indicate right-sided heart failure.

Tachypnea (shallow and rapid breathing) that worsens with feeding or activity can reflect pulmonary congestion and may indicate left-sided heart failure. Grunting, nasal flaring, and/or retractions that worsen in recumbent positions are manifestations of dyspnea or increased work of breathing.

Irritation from bronchial edema may cause a chronic, dry, hacking cough. Pulmonary obstruction, which causes edema of the bronchial mucosa from a distended airway, may cause wheezing. One of the late signs of heart failure is rales on auscultation. Rales occur from fluid settling into the alveolar spaces, causing pulmonary edema.

Diaphoresis, fatigue, and exercise intolerance are important signs. During feeding or physical activity, the infant or child with heart failure may be diaphoretic. Diaphoresis, usually seen as a cool sweat on the forehead, occurs because of an increased sympathetic response triggered by increasing cardiac output stimulating *baroreceptors* (stretch receptors that respond to changes in blood pressure) in the vessels.

Diagnostic Tests

No single diagnostic test can confirm the diagnosis of heart failure. A chest radiograph is commonly used as part of the decision-making process. A positive radiograph shows cardiomegaly and increased pulmonary vascular markings from excessive pulmonary blood flow.

Nursing Diagnoses and Outcomes

QUESTION: Which nursing diagnosis best describes Gabriella the morning of the case study?

In addition to those listed in Nursing Plan of Care 15–1, the following the nursing diagnoses and outcomes may apply to the child with heart failure:

Ineffective breathing pattern related to effects of excessive fluid in lung spaces, breathing difficulties from poor cardiac output, and increased respiratory rate required to compensate

Outcomes

- Child will exhibit normal respiratory rate and will perform normal work of breathing.
- Child will demonstrate clear breath sounds and oxygen saturation within normal limits for the child.

Imbalanced nutrition: Less than body requirements related to effects of increased work of feeding and increased calorie requirements

Outcomes

- Parents will verbally demonstrate understanding of feeding techniques and child's nutritional needs.
- Child will demonstrate growth curve appropriate for age.

ANSWER: Gabriella's nursing diagnosis is: *Ineffective breathing pattern related to effects of excessive fluid in lung spaces and increased respiratory rate required to compensate.* This explains why her symptoms are respiratory, but the problem is cardiovascular.

Interdisciplinary Interventions

When caring for a child with heart failure, direct interventions at conserving energy and decreasing metabolic demands on the weakened myocardium. Interventions are also directed toward removing excess accumulated fluids so that the pump has optimal preload (circulating blood volume). If coexisting illness, such as a viral infection, exacerbates symptoms of heart failure, it must be treated. To maximize oxygen-carrying capacity, if the child is cyanotic, blood products and fluids may be ordered to maintain hematocrit levels and blood values at normal levels.

Unstable patients in heart failure from arrhythmias require immediate IV adenosine or synchronized cardioversion. Complete heart block is rare. Emergency treatment includes medications and temporary or permanent pacemaker placement as indicated. Occasionally, these arrhythmias are detected in utero, and the fetus is treated via medications given to the mother.

Oxygen Therapy

Administer oxygen judiciously. Although full oxygen saturation decreases the work of breathing by increasing arterial oxygen levels, thereby relieving respiratory distress, oxygen can be detrimental, because it is also a pulmonary vasodilator. Pulmonary vasodilation can cause increased

tachypnea and fluid retention in the lung beds and worsen oxygenation, further exacerbating heart failure in cases in which the lungs are already overloaded. Therefore, children should not automatically be given oxygen to improve their respiratory status. Oxygen can actually worsen their symptoms over time. If oxygen is administered, monitor oxygen saturation levels to keep within limits appropriate for the child (see [thePoint](#) for Procedures: Oxygen Administration).

Pharmacologic Interventions

Pharmacologic methods of treatment aim to relieve symptoms and to improve the heart's pumping ability, including optimizing preload, afterload, and contractility. Improving cardiac output by manipulating preload and afterload may have a potent hemodynamic effect; monitor children closely for tolerance and negative effects.

Diuretics

Diuretics are medications given to lessen the workload on the heart by removing extra fluids the heart has to pump, ultimately decreasing preload. In heart failure, the renal tubular system tries to increase preload under the action of the renin–angiotensin–aldosterone system by retaining sodium and water to increase circulating volume. Diuretics are given to counteract this compensatory mechanism. Furosemide (Lasix), which inhibits electrolyte reabsorption at the loop of Henle, is the most commonly used diuretic, but it promotes loss of potassium as well as sodium. Spironolactone (Aldactone), a potassium-sparing diuretic, is therefore used with furosemide, to prevent excessive potassium loss.

Alert! Diminished cardiac output compromises perfusion to the kidneys, requiring close monitoring of renal function. Diuretics improve urine output but do not specifically help renal perfusion.

Positive Inotropic Agents

Positive inotropic agents are administered to improve myocardial contractility. Digoxin (Lanoxin) is a commonly used cardiac glycoside administered orally or intravenously as a positive inotrope. It decreases the workload of the heart and improves myocardial function. Dosages are given based on the child's weight. To avoid digoxin toxicity, ensure that blood levels, obtained periodically and when symptoms occur, are within normal limits.

caREminder

Digoxin toxicity is a serious complication of therapy in any age group. Signs and symptoms of digoxin toxicity in infants and children include nausea; vomiting; anorexia; and an irregular, low apical heart rate.

Teach parents to have the telephone number of a poison control center readily available in any household

should accidental ingestion or overdose of digoxin occur. Instruct parents to keep digoxin out of the reach of children at all times and to allow only those family members who have been carefully trained to administer this medication. Digoxin has a very narrow safety margin with a narrow gap between therapeutic levels and toxic levels.

Sympathomimetic agents—the rapidly acting catecholamines dopamine, dobutamine, and epinephrine—are positive inotropic drugs that are administered intravenously to improve myocardial contractility. These agents are used most often in critical care areas. Common side effects, particularly with increased dosages, are tachycardia and arrhythmia.

Vasodilators

Vasodilators enhance cardiac output by decreasing afterload, as measured by reduced left ventricular end diastolic volume and pulmonary capillary wedge pressure. Vasodila-

tors such as nitroglycerin dilate the systemic veins, leading to lowered blood pressure and reduced venous congestion, which in turn decreases preload. They also dilate the coronary arteries, improving myocardial blood flow. See a critical care pediatric text for elaboration of these concepts.

Captopril (Capoten) and enalapril (Vasotec) are angiotensin-converting enzyme inhibitors. They are used to block the conversion of angiotensin I to angiotensin II; this action results in vasodilation and increased sodium excretion. Another arterial vasodilator is sodium nitroprusside (Nipride), which also reduces afterload. The amount of medication given is titrated by slowly increasing dosages based on the child's weight, symptoms, and level of tolerance.

Energy Conservation

In the presence of impaired circulation and pulmonary congestion, limit the child's energy expenditure by promoting rest (Clinical Judgment 15–1). Rest lowers

CLINICAL JUDGMENT 15–1

A Child's Adaptation to Restrictions of Condition

Six-year-old Jenny G. was on bed rest at home because of recurrent heart failure caused by myocarditis. Despite the fact that anything more than quiet activity made her short of breath and often worsened her failure to the degree where she would be too tired to even eat the next day, she was always sneaking out of her room and playing actively in the hall. She talked about being bored and missing all her friends and activities at school.

Jenny's teacher worked with her mother to develop a special project to be completed in conjunction with her classmates. She was put in charge of updating the classroom's dinosaur display. A giant dinosaur had been placed on a bulletin board near the front of the room. Using a collection of dinosaur cut-out books, Jenny was to get pictures of all the types of dinosaurs they discussed each day. She was also asked to practice her writing skills by putting her classmates' names on the cut-out dinosaurs that were put on the big one. To practice her arithmetic, she kept track of the number of dinosaurs she made each day and how many she sent in to her classmates by way of her friend, who stopped by two or three times a week. Jenny had a great sense of pride in her accomplishment, along with quiet activity. Now that her friends have a reason to visit, they are more likely to stay to play a game after school, although they still want to play outdoors and the visits are still fairly brief. Jenny also got a 92 on her last math quiz.

Questions

1. Are these activities addressing the identified reason Jenny is not staying quiet?

2. What data from the vignette support your conclusion?
3. What other data would help confirm this conclusion?
4. What strategies would you use to promote Jenny's continued good health?
5. What outcomes would indicate that Jenny is doing well?

Answers

1. She reported feeling restless and bored and that she missed her friends from school. These activities give her something focused to accomplish each day and allow her to do the same activities as her classmates.
2. She is making the dinosaurs for the class, sending them in as requested, learning her math, and seeing her friends. She is also spending more quiet time at home as desired.
3. Her episodes of fatigue could be tracked. In addition, other physiologic parameters such as heart rate or blood pressure should indicate improvement.
4. Work with Jenny and her family to identify additional interventions such as this that can meet both her physiologic and psychosocial needs. Encourage Jenny to discuss her illness with her friends and to answer their questions.
5. Jenny is able to move back into the classroom easily with minimal loss of achievement as a result of her absence.

metabolic requirements and oxygen needs. Schedule nursing care so that activities are clustered and followed by long periods of undisturbed rest. Sedation may be provided for an acutely ill child with heart failure who is restless and irritable, to reduce oxygen demand. For toddlers and older children, television and video games provide an emotional distraction and encourage inactivity. Breathing and eating are strenuous activities for infants in heart failure, leaving no extra energy for play or motion. They tend to limit their own activity by falling asleep.

Learning to sit up and to walk and other gross motor activities require extra energy that a child with limited cardiac reserves may not have to spare. As the child's condition allows, encourage age-appropriate play to enhance cognitive and motor development. After surgical repair, when the child is no longer in heart failure, these children tend to catch up developmentally with their peers.

Positioning

In addition to receiving excessive circulation, the lungs in heart failure also have decreased compliance, requiring more work to expand the lungs. Small children may be propped up in an infant seat, ensuring that they are not slouched over, a position that causes pressure on the diaphragm and thus limits diaphragmatic excursion. An upright position also decreases pulmonary congestion by encouraging blood to pool in dependent areas, moving fluid away from the lungs and minimizing the work of breathing.

Nutritional Interventions

Feeding issues can be perplexing. Both the increased metabolic needs of the child's overworked heart and the extra work of breathing demand extra energy. The logical deduction is to encourage an infant to eat as much as possible. The drawback is that feeding takes energy, too. In addition, feeding distends the infant's abdomen, which exerts pressure on the diaphragm, decreasing lung expansion. Feeding also increases fluid levels in the circulatory system. Fluid restriction may be used for older children, but an infant's nutritional intake depends on fluids.

Because infants with heart failure fatigue easily, feedings may take longer than with healthy children. Small and frequent feedings are better tolerated and decrease the likelihood of vomiting. Formulas with increased calories and nutritional supplements are given to meet the greater caloric requirements.

Weigh the child daily and document intake and output meticulously to follow trends in nutritional stability and diuresis. Because scales vary, weigh the child on the same scale daily, at the same time before feeding. Fluid and sodium restrictions, although common for older children, vary by age and are individualized to the child.

Community Care

Teach parents the signs and symptoms of heart failure and the parameters for which they need to notify health-care providers. The term *heart failure* conjures up an image in the parents' mind of a terminal state, which

frightens families. Parents associate heart failure with the heart stopping suddenly. For many children, heart failure is a condition that can be medically managed and, if caused by a congenital heart defect, corrected with surgical repair. When teaching, include an explanation of the warning signs that indicate that a child's condition is deteriorating and that medical intervention is necessary. Give parents specific guidelines on how to administer medications, the rationale for each medication, and potential adverse reactions.

Heart Disease Associated With Cyanosis

Cyanosis is a sign of hypoxemia and is caused by circulating deoxygenated hemoglobin as reflected in a bluish hue to the skin, nail beds, and mucous membranes.

Pathophysiology

When oxygen saturation of hemoglobin is reduced, the circulation compensates by increasing the extraction of oxygen by peripheral tissues. Reasons other than cardiac issues can cause a child to appear cyanotic. Structural changes in the lungs, such as bronchopulmonary dysplasia, pulmonary edema, pulmonary arterial venous fistulas, and some neurologic abnormalities may cause cyanosis in a child. The nurse cannot assume that the child who appears dusky or cyanotic has a primary cardiac problem, because clinical assessment of hypoxemia is notoriously unreliable.

Cyanosis in CHD results mainly from two anatomic situations. The first is that pulmonary venous blood, rather than being delivered to the systemic circulation, is being redelivered to the pulmonary circulation, increasing pulmonary blood flow, as occurs in transposition of the great arteries and total anomalous pulmonary venous return (TAPVR). The second is restricted pulmonary blood flow (right-to-left shunts), as occurs in pulmonary atresia and tetralogy of Fallot. The severity of cyanosis depends on the volume of pulmonary blood flow or the degree of intracardiac mixing (shunting).

Hematologic problems associated with cyanotic heart disease include polycythemia, dehydration, bleeding, clubbing of nail beds, hypoxic spells, neurologic injury, and negative developmental outcomes. Polycythemia is caused by low arterial oxygen levels that trigger erythropoietin production in the kidneys, which stimulates the bone marrow to increase red blood cell production. Polycythemia is a compensatory mechanism in which the body attempts to have more hemoglobin available to increase oxygen-carrying capacity and thereby improve oxygenation to tissues. When the hematocrit value reaches a level of 65% or more, blood viscosity increases to such a degree that there is a risk of complications such as cerebrovascular accidents or strokes. Children may also be anemic if not enough iron is present to create the excess hemoglobin.

Chronic tissue hypoxia also stimulates increased red blood cell production, creating a condition of polycythemia. This compensation increases the amount of hemoglobin available to carry oxygen to tissue.

When a child who is polycythemic from cyanosis contracts a virus, especially one that causes vomiting or diarrhea, teach parents to monitor the child closely for dehydration, because the child is at greater risk for hemoconcentration.

Excessive hemoglobin limits space in the vascular bed for platelet and other coagulation factors. Therefore, children with chronic polycythemia tend to have abnormalities of hemostasis. These children may bleed postoperatively, bruise easily, or be prone to epistaxis (nosebleeds).

Clubbing is a thickening, widening, and flattening of the toenails and fingernails (Fig. 15–6). For unknown reasons, clubbing develops with chronic arterial desaturation and polycythemia. Clubbing is not seen solely in children with heart disease associated with cyanosis, but may be associated with other diseases, such as cirrhosis of the liver, chronic respiratory conditions, or hereditary nonspecific clubbing.

Children with tetralogy of Fallot and some other heart defects may have tetralogy or hypercyanotic spells, often called *tet spells*. These spells commonly occur when a child's heart has not yet been repaired, and changes in pulmonary outflow resistance and systemic vascular resistance result in sudden changes in the degree of right-to-left shunting. Hypercyanotic spells occur in young infants, most commonly at 2 to 4 months of age, may be precipitated by agitation, and are characterized by worsening cyanosis, disappearance or decrease in heart murmur intensity, hyperpnea, irritability or prolonged crying, limpness, fainting, and convulsions. These symptoms may be short-lived and subtle or may last for hours. A prolonged, severe spell may end in syncope, seizures, or cardiac arrest.

Alert! Tet spells may arise without warning or after a predictable precipitating event. To decide whether a child is having a tet spell, auscultate the heart. The intensity of the cardiac murmur decreases during a spell.

Substantial neurologic complications are a risk of chronic cyanosis. Chronic hypoxia and underperfusion

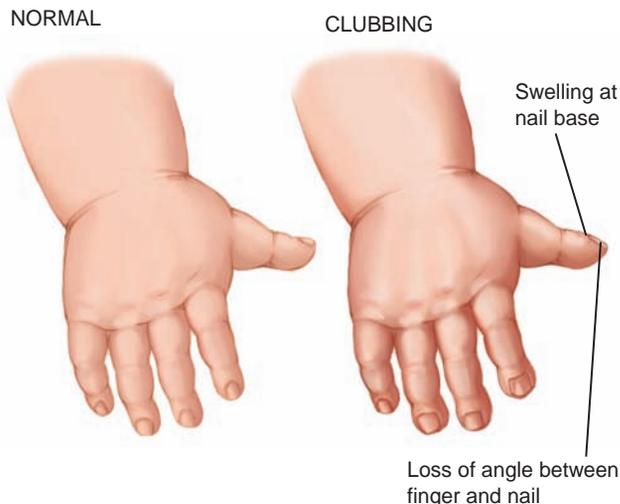

FIGURE 15–6. Clubbing of the nails.

put these children at elevated risk for stroke, meningitis, and brain abscesses. Hyperviscosity of blood from polycythemia increases the chances of thromboembolic events such as thrombus, brain abscesses, and abnormal neurologic development. With modern management techniques, more children with cardiac cyanosis are candidates for early surgical repair. Early intervention may lead to fewer neurologic complications from chronic cyanosis.

Assessment

History and physical assessment of cyanosis is discussed under the general assessment section at the beginning of this chapter.

Diagnostic Tests

Clinical determination of cyanosis is made by measuring the child's hemoglobin level. A child who is severely anemic and has a large left-to-right shunt may not appear cyanotic because the hemoglobin level may be too low for the child to appear blue. Further assessment, including a complete blood count, arterial blood gases, pulse oximetry, chest radiograph, and ECG, assists in developing an accurate diagnosis.

Oxygen is used in the diagnosis of CHD. When 100% oxygen is administered to an infant with intracardiac shunting from CHD or central cyanosis, arterial blood gas measurement may show only inconsequential improvements of partial pressure of serum oxygen concentration (PaO_2). Oxygen may actually destabilize some children with severe forms of CHD. However, an infant with an underlying pulmonary problem may improve considerably with supplemental oxygen. Also, children with intracardiac mixing may worsen their cyanosis with crying and activities, whereas the child who is cyanotic for other reasons, such as bronchopulmonary dysplasia, may improve with supplemental oxygen or crying.

Normal oxygen saturation of red blood cells is 95% to 100%. Depending on the heart defect, a child might have an expected saturation level ranging from 85% to 89% or less. A PaO_2 level of 80 to 100 mm Hg can be considered normal for a healthy child, but a cyanotic child may show a PaO_2 level around 45 mm Hg. Hypoxia is defined as reduced arterial PaO_2 and reduced oxygen saturation, leading to diminished tissue oxygenation.

Interdisciplinary Interventions

Treatment of tet or hypercyanotic spells is directed toward preventing conditions that may potentiate a cyanotic response, such as dehydration or crying. When a child has a known cyanotic condition, the practitioner must respond especially aggressively and quickly to childhood illnesses that may cause dehydration (Clinical Judgment 15–2). Because a high hematocrit level carries the risk that the child's blood will become too viscous, monitor the complete blood count closely in cyanotic children. In addition, assess these children for evidence of bruising, petechiae of the skin, or epistaxis.

CLINICAL JUDGMENT 15-2

Dehydration in the Child With Congenital Heart Disease

Eleven-month-old Rochelle presents at the clinic with what is described as 24 hours of vomiting and diarrhea. She is cyanotic, listless, tachypneic, and has a temperature of 101.5 °F (38.6 °C). The mother states that her child has a heart problem.

Questions

1. What historical data would be helpful to clarify the diagnosis?
2. What are potential complications of dehydration and diarrhea particular to this child that the nurse needs to consider in her nursing care?
3. Does Rochelle need to be admitted to the hospital?
4. What would be appropriate interventions?
5. What factors would indicate that Rochelle has recovered with no ill side effect from this dehydration episode?

Answers

1. Historical data would include asking the following questions: What is the actual cardiac diagnosis for the child? Is there a history of any cardiac surgery? Is the child normally cyanotic? How do past episodes compare with the current one? What is the child's normal oxygen saturation? What medications, if any, is the child taking? How many doses of the medications were missed? Has she been exposed to anyone with a history of vomiting
- and diarrhea? How many, and how large, were the stools the child had? When did she last urinate?
2. Children with heart disease that causes cyanosis may be at risk for hypercyanotic spells, and dehydration can be a triggering response. The complete blood count may be too high as a result of hemoconcentration. Also, cyanotic children are at increased risk for stroke and brain abscess.
3. Yes. Because Rochelle is listless and tachypneic, she is exhibiting clinical signs of deterioration from dehydration. Also, reasons for the vomiting and diarrhea, other than a virus, need to be ruled out.
4. Administer IV fluids, low-flow oxygen supplementation, antipyretics, and antiemetics, and begin a pulse oximetry monitor. If Rochelle was taking digoxin, a blood level should be obtained, because one symptom of an elevated or toxic digoxin level is vomiting. Notify Rochelle's pediatric cardiologist of the admission. Send stool cultures for evaluation. Routine laboratory values should include a blood culture with routine blood work (complete blood count and an electrolyte panel). Anemia and electrolyte imbalances need to be ruled out.
5. Rochelle has no vomiting or diarrhea. She is interacting playfully and tolerating oral intake, and her oxygen saturation levels on room air are at baseline.

In treating a cyanotic spell, interventions are aimed at raising the SVR. Provide calming and comforting measures to decrease oxygen demand and hyperventilation. Oxygen is administered, as well as morphine sulfate, to relax the right ventricular infundibulum, which increases pulmonary blood flow and therefore decreases the right-to-left shunt. During a cyanotic spell, place the child in the knee-chest position, which blocks blood flow to the legs and decreases venous return from the legs. These effects reduce left-to-right shunts, resulting in improved blood flow to the lungs. Although healthy, mobile toddlers may squat, and squatting is a normal position in some cultures, a cyanotic toddler may occasionally squat while playing, instinctively eliciting the same effect as does the knee-chest position.

Total repair of tetralogy of Fallot is commonly done before 1 year of age in the United States. Oral propranolol (Inderal) is useful in controlling spells by stabilizing the reactivity of the peripheral vasculature. During severe cyanotic spells, as the child becomes more hypoxic and pulmonary blood flow decreases, the child may develop metabolic acidosis. Acidosis necessitates immediate correction with sodium bicarbonate intravenously.

Collateral vessels develop in children with CHDs associated with cyanosis such as pulmonary atresia. These vessels are the body's attempt to improve oxygenation. They usually arise from the thoracic aorta and supply parts of the pulmonary system. These vessels tend to be fragile and tortuous. When a surgeon is correcting lesions to improve a child's oxygenation, these vessels are problematic, because they may be numerous and difficult to reach surgically. Many collaterals can be occluded in the catheterization laboratory with occlusion devices, such as coils, or ligated during surgery if they can be reached. Taking out collateral vessels can be laborious and may require repeat procedures.

For the child with CHD, palliative surgeries may be performed to improve cardiac mixing or increase blood flow to the lungs and thereby promote growth and development. A permanent cardiac repair, to remove areas of shunting and allow normal blood flow to the lungs, may definitively alleviate cyanosis and diminish compensatory responses. Cardiac transplantation may become the only option for a child with worsening symptoms who has received maximum medical management and for whom there are no other surgical options.

Teach parents of a cyanotic child how to differentiate between worsening blueness and cyanotic spells. It is not surprising to see a cyanotic infant who is obese. Parents fear the child crying and turning blue, so they may continually pacify the infant with a bottle. Another fear for parents is having their child turn more cyanotic with increased activity. Most cyanotic children limit their own activity levels. They may be as active as their peers, but do tend to fatigue sooner. When teaching, include a discussion of aggressively preventing dehydration to avoid an overly viscous blood volume; also teach parents ways to prevent obesity and alternative ways to handle their concerns about activity.

CONGENITAL HEART DEFECTS

Understanding a given child's precise cardiac defect is important, because management and health outcomes depend on the defect. Each lesion has its own natural history of adverse effects on pulmonary vascular resistance and on ventricles, valves, or other structures. With some defects, survival and preventing complications require prompt diagnosis and treatment during early infancy, whereas with other conditions, children may grow into adulthood before becoming symptomatic. Hospitalized children with cardiac diagnoses may be in various stages of repair, undergo surgical trauma, or have inadequate or disrupted surgical repairs.

QUESTION: Gabriella's PDA results in shunting. What are the blood flow and consequences of Gabriella's shunt?

Normally, oxygen-depleted blood drains from the venous system through the inferior and superior vena cava into the right heart. From there, blood is pumped to the lungs to pick up oxygen. The oxygen saturation of blood returning to the right heart and the pressures in the right chambers are normally low. The blood that enters the left atrium from the lungs is normally fully saturated and is pumped by the left ventricle under high pressure to the systemic circulation.

In some situations, shunting occurs. Blood pumped to the systemic circulation mixes with deoxygenated blood. This is called a *right-to-left shunt* and may cause cyanosis. Blood pumped to the systemic circulation that is not mixed with deoxygenated blood is called a *left-to-right shunt* and may cause overcirculation to the lungs, possibly resulting in heart failure. Either type of shunting can occur as a consequence of various CHDs.

ANSWER: During fetal circulation, the ductus arteriosus exists to shunt blood away from the lungs, which are not in use, and back into systemic circulation. For neonates, if the ductus arteriosus relaxes enough to permit blood flow, the higher systemic pressures and lower pulmonary pressures cause the blood flow to move in reverse of fetal circulation, flowing from the left side to the right and adding additional blood flow to the lungs.

CHDs can be classified as defects with increased pulmonary blood flow, defects with decreased pulmonary blood flow, obstructive defects, defects of the great vessels, and defects with a functional single ventricle.

Defects With Increased Pulmonary Blood Flow

Defects that increase pulmonary blood flow include PDA, ASD, VSD, and atrioventricular canal defect, also called *atrioventricular septal defect* or *endocardial cushion defect*.

PATENT DUCTUS ARTERIOSUS (PDA)

PDA is the persistence of the fetal structure that connects the aorta and the pulmonary artery. It is generally at the lesser curvature of the aortic arch distal to the subclavian artery and is connected to the left or main pulmonary artery.

Pathophysiology

At birth, the newborn's lungs expand, and the right side of the heart and pulmonary artery pressures decrease. When the umbilical cord is cut, systemic pressures increase, causing arterial blood to shunt from the aorta to the pulmonary artery. Oxygenated blood normally causes the ductus to constrict and close by 6 weeks of age; failure to close leaves the infant with a PDA. If the PDA remains open, blood flows from the high pressure in the aorta to the path of least resistance through the ductus, thus causing excessive blood flow to the lungs (Fig. 15-7).

The ductus arteriosus closes by 48 hours of life in 80% of term infants and in almost 100% of term infants by 96 hours of age (Agarwal, Deorari, & Paul, 2008). Slight flow from a small PDA may not clinically overstress a

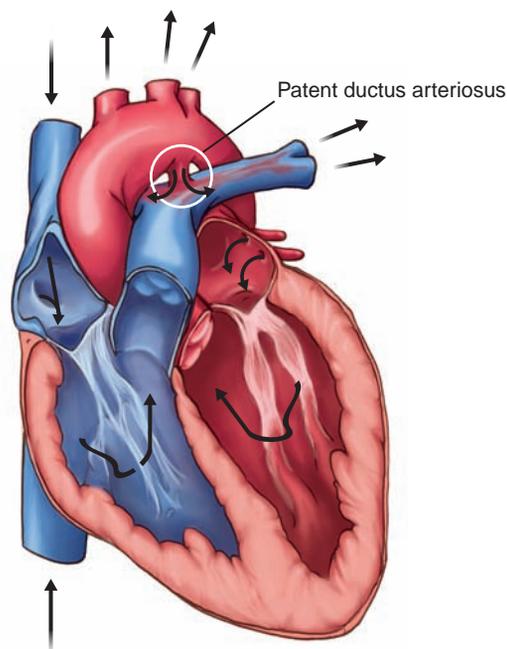

FIGURE 15-7. Patent ductus arteriosus.

heart, but the child is still at a greater risk than other children for air embolus, bacterial endocarditis, or clots. Also, if a PDA is left untreated, the rate of mortality increases with age as an adult. Over time, even a minor PDA puts the patient at risk for developing pulmonary hypertension.

In preterm infants, the incidence of PDA is inversely related to gestational age. The younger the infant's gestational age, the more likely the infant is to have a PDA. PDA affects 40% to 55% of infants born at less than 29 weeks' gestation or who have a birth weight less than 1,500 g (Mosalli & AlFaleh, 2008). A PDA in the premature infant is not considered a congenital lesion but a situational defect, because it occurs functionally as a result of the premature delivery. Premature infants with PDAs commonly are symptomatic.

Assessment

QUESTION: Is Gabriella's presentation of symptoms typical for a preterm infant?

Assessment findings that occur in the presence of a PDA vary, depending on the age of the child and the size of the shunt. In general, the larger the shunt, the greater the likelihood that the child will have symptoms of heart failure.

Obtain a thorough history. Typically, children whose initial diagnosis is made after the toddler years often are described by parents as having frequent pulmonary infections. They may be thinner than other children of the same age.

Auscultation reveals a continuous, machinerylike murmur, best heard at the second and third intercostal spaces. Peripheral pulses are bounding, from the runoff of blood (excess volume of blood) from the aorta to the pulmonary artery. These children also have widened pulse pressure. The diagnosis of PDA may be confirmed and treated through data obtained by radiograph, two-dimensional echocardiography, and color flow Doppler studies. The chest radiograph of a child diagnosed after toddlerhood may show an enlarged heart.

ANSWER: The presence of a murmur, bounding pulses, and pulmonary symptoms of heart failure are typical in a preterm infant.

Interdisciplinary Interventions

QUESTION: Will there be any long-lasting sequelae of Gabriella's PDA after her discharge from the hospital? Does it depend on whether the ductus is closed surgically or medically?

Interventions for PDA typically involve pharmacologic therapy or surgery to close the opening. In some cases,

medications are used to keep the ductus open to provide adequate circulation. Preterm infants without bleeding tendencies who have good renal function may receive orally administered indomethacin, a prostaglandin inhibitor, to encourage ductal closure. Success in closing PDAs with indomethacin varies (Malviya, Ohlsson, & Shah, 2003). Ibuprofen may also be used to encourage ductal closure (see Tradition or Science 15–1). Term infants typically undergo transcatheter closure of the PDA in the catheterization lab.

A PDA may be protective in an infant with a cardiac lesion such as HLHS that depends on an open ductus arteriosus to provide adequate circulation. The PDA acts as a natural shunt, allowing blood flow to mix and bypass an obstructed area. To ensure that the PDA remains patent, these infants receive an infusion of prostaglandin E₁ (PGE₁). This substance, found throughout the body, is involved in the regulation of virtually all organ systems. Given intravenously, it is a potent dilator of the ductus arteriosus and is used for left-sided obstructive lesions to improve systemic perfusion, acid–base balance, and urine output.

TRADITION OR SCIENCE 15–1

Is indomethacin the only medication effective in closing ductus arteriosus?

MORE INQUIRY NEEDED

Indomethacin has been used since 1976 to close PDA, but it has renal, gastrointestinal, and cerebral side effects. Both indomethacin and ibuprofen inhibit the synthesis of prostaglandin. Studies show that ibuprofen is as effective as indomethacin in PDA closure (Ohlsson, Walia, & Shah, 2008; Thomas, Parker, Van Overmeire et al., 2005; Witoslaw, Szymankiewicz, & Gadzinowski, 2005), but may not be as effective in infants with very low birth weight (Huning et al., 2005) and those younger than 27 weeks' gestation (Desfrere et al., 2005). Dani et al. (2008) found that infants with a gestational age of 26 to 27 weeks had a 17% risk of ibuprofen-resistant PDA, whereas those with a gestational age of 23 to 25 weeks has a risk of 62%.

A factor in determining treatment is the side effect profile of the treatment. Some research trials indicate that ibuprofen may cause less adverse effects on the kidneys, gut, and brain than indomethacin, but may increase the risk for chronic lung disease whereas indomethacin may reduce the risk of severe intraventricular hemorrhage and surgical duct ligation (Ohlsson et al., 2008; Sekar & Corff, 2008). Researchers are continuing to examine the efficacy and safety of ibuprofen versus indomethacin to close PDAs.

Prophylactic treatment with ibuprofen is not recommended to prevent PDAs because it unnecessarily exposes infants to potential side effects without conferring any important short-term benefits (Ohlsson & Shah, 2006).

Interventions, both surgical and in the catheterization laboratory, are low risk. In recent years, PDAs have been successfully occluded using devices in the catheterization laboratory. If the child is not a good candidate for PDA closure in the catheterization laboratory, surgical ligation is usually done during early childhood. The procedure is a nonpump case and is accomplished through a thoracotomy incision. Potential, but rare, complications include phrenic nerve damage, chylothorax, transient hypertension, and atrial flutter. As with any thoracotomy incision, the risk of chylothorax is increased. Nursing care postoperatively must include aggressive chest physiotherapy and pulmonary toilet. Ensure adequate pain management to discourage chest splinting (guarding) and encourage deep breathing.

ANSWER: No, timely ligation of the ductus stops the increased pulmonary blood flow and there are seldom cardiovascular sequelae. If the ductus is ligated surgically, it will not reopen. If it is closed with medication, there exists the possibility of it reopening, but this is still usually during the neonatal course and not after discharge.

ATRIAL SEPTAL DEFECT (ASD)

QUESTION: How is an ASD, VSD, or atrioventricular canal defect similar to a PDA, such as what Gabriella has?

An ASD is a communication between the right and left atria through the septum that persists beyond the newborn period. There are three classifications of ASD, which are based on the actual location of the defect in the atrial septum. If the opening in the atrial septum is high in the septum, it is called a *sinus venosus* defect. Sinus venosus ASDs are the second most common ASD and are located near the junction of the superior vena cava and the right atrium. These ASDs are often associated with anomalous pulmonary venous return, which is discussed later in this chapter.

The most common ASD, an *ostium secundum* defect, is located mid septum. These ASDs are located in the fossa ovalis center of the septum and can be closed in the cardiac catheterization laboratory. *Ostium primum* defects, the third classification of ASD, are located low in the septum. These ASDs lie inferiorly to the foramen ovale in the lowest portion of the septum. Ostium primum ASDs may also be associated with a cleft in the mitral valve and mitral insufficiency.

Pathophysiology

With ASD, blood shunts from the left atrium to the right atrium because pressures are greater on the left side of the heart. This left-to-right shunt may cause the mean pressure in the right atrium and left atrium to be similar. The amount of blood that shunts across the septum is

relative to the size of the defect. If the ASD is large enough, the shunt creates a burden on the right side of the heart from excess blood volume in the right heart circulation and the pulmonary bed (Fig. 15–8).

If an ASD is left unrepaired, the likelihood of right and left cardiac hypertrophy increases as time passes. As the atrium enlarges and stretches, the patient may have atrial arrhythmias. Chronic excessive pulmonary blood flow carries a risk of increased pulmonary vascular resistance, leading to pulmonary hypertension and an elevated risk of pulmonary emboli.

Assessment

In the fetus, the foramen ovale is naturally open; therefore, a diagnosis of ASD cannot be made in utero. Children with ASDs may be on the slender side with slight growth retardation. They may tire more easily than their peers during athletic activities. They may have a greater likelihood of repeat pulmonary infections. Because they generally lack any obvious symptoms, they are frequently identified during a physical examination only as having a murmur. If the ASD is not detected during early childhood, a child may remain asymptomatic until adulthood. ASDs are usually clearly delineated through the use of echocardiography.

Children are usually asymptomatic, but in severe cases may have heart failure. If the child is symptomatic, a chest radiograph may show cardiomegaly with an enlarged right atrium and right ventricle, and increased pulmonary blood flow. Assess for signs of a left-to-right shunt and heart failure.

Interdisciplinary Interventions

Treatment is provided during infancy if the child has heart failure. If the child is asymptomatic, the ASD is

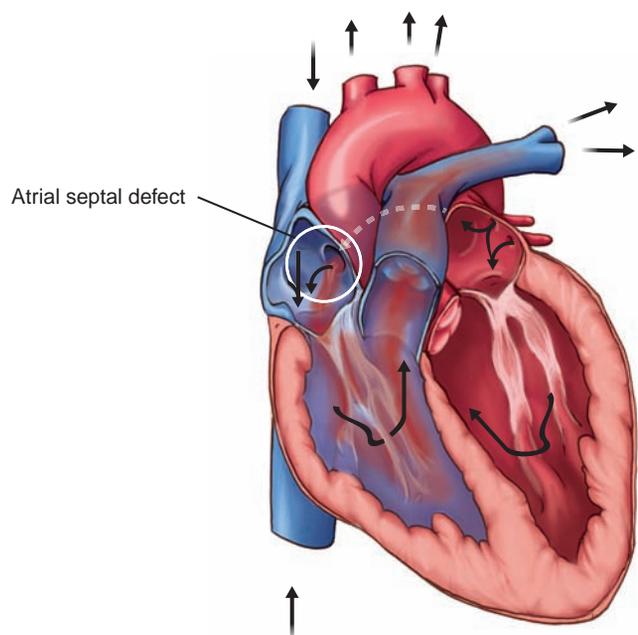

FIGURE 15–8. Atrial septal defect.

generally closed during early childhood, usually via cardiac catheterization. Spontaneous closure of the secundum type of ASD is 87% during the first 4 years of life (Park, 2008). Sinus venosus ASDs require a patch closure, and the surgeon must avoid damage to the sinoatrial node to prevent arrhythmias. Surgical repair is completed only if closure is not possible in the cardiac catheterization laboratory, through a median sternotomy incision, with the child on cardiopulmonary bypass. A rare surgical complication of repairing an ASD is complete heart block from suture damage that causes edema at the atrioventricular node and bundle of His. If partial anomalous venous return exists, the patch closure is placed so that it directs venous return to the left atrium with a baffle. Instead of the septum being repaired vertically, the patch angles over to envelop the oxygenated blood returning to the right atrium and directs it to the left atrium.

VENTRICULAR SEPTAL DEFECT (VSD)

A VSD—the most common CHD, accounting for 15% to 20% of all cases of isolated CHD—is an opening or communication in the septum, usually the membranous portion, between the right and left ventricles (Park, 2008). A VSD may be located in multiple and various places in the septum. Physiology of a VSD depends on the size and location of the defect and the effects on PVR (Fig. 15–9).

Three types of VSDs occur: membranous, muscular, and supracristal. The most common VSD (70%–80% of cases) is the *membranous* type, which occurs in the outflow tract of the left ventricle below the aortic valve. *Muscular* VSDs (25% of cases) are located entirely within the muscular septum. Muscular VSDs, found in approximately 5% of the population, commonly exist in multiple

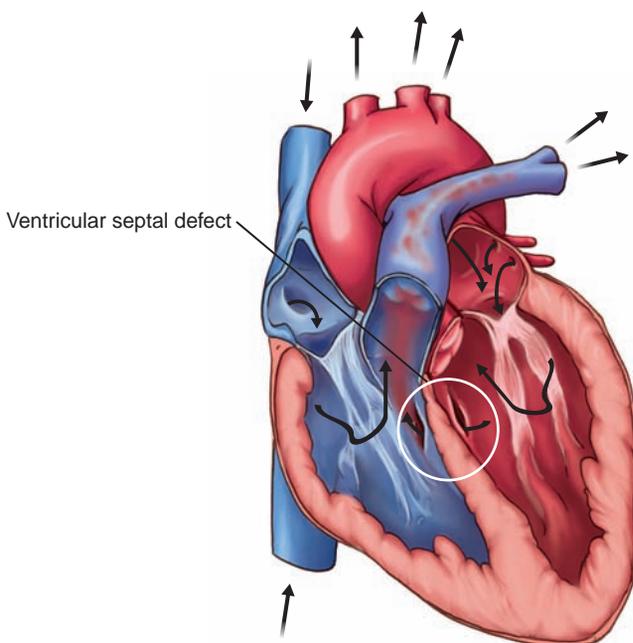

FIGURE 15–9. Ventricular septal defect.

locations, creating a Swiss cheese effect. The overlapping holes can limit the surgeon's ability to find the VSDs. *Supracristal* VSDs occur in the infundibular septum and can result in prolapsing aortic valve cusps.

Pathophysiology

The larger the VSD, the greater the amount of shunting that occurs. Large VSDs can rob the systemic circulation of a considerable portion of blood flow. Excessive flow through the right ventricle can overwork the ventricle and overcirculate the pulmonary bed.

To prevent lung disease and heart failure, repairing a VSD early in life is beneficial. Thirty to 40% of membranous and muscular VSDs, particularly small ones, may decrease in size or close spontaneously within the first 6 months of life (Park, 2008). Large defects also tend to become smaller over time. If a defect closes, it is most likely to occur within the 1 to 1½ years of life (Atalay et al., 2005; Miyake et al., 2004). Children with small VSDs have a very good prognosis.

If a moderate to large VSD is left untreated, PVR will eventually increase from constant excess flow to the pulmonary bed. Over time, as PVR increases, pressures in the right and left ventricles may change, causing higher pressures in the right ventricle than the left. When this pressure change occurs, the shunt reverses. PVR exceeding systemic pressure is called *Eisenmenger's complex*. Severe pulmonary hypertension may cause the condition to be inoperable. If the VSD is repaired in these circumstances, the sudden reduction of excessive blood flow to the lungs may prove fatal. Right-sided heart failure occurs because pulmonary vessels remain constricted postoperatively. The high pressure in the lungs overburdens the right ventricle, which no longer has the VSD to act as a release valve. Other defects that put patients at risk for pulmonary hypertension are atrioventricular canal defects and truncus arteriosus, described later in this chapter.

VSDs are the most common lesion to coexist with other cardiac anomalies. A VSD in combination with other lesions can have different effects on the heart. As with PDAs, depending on the specifics of the individual's combination of lesions, a VSD could be an asset that counters problems caused by another defect.

Assessment

In the presence of a small VSD, growth and development are normal, and the child lacks symptoms. To be classified as small, a VSD must be smaller than the orifice of the aortic valve, so that flow across it is restricted and the blood volume shunted is limited. A large VSD is one that is larger than the orifice of the aortic valve and is unobstructed; thus, pressure can equalize between the left and right ventricles.

An infant born with a VSD may not have an audible murmur until 6 to 8 weeks after birth, when PVR decreases and heart failure can develop. Children with moderate to large VSDs are prone to having decreased exercise tolerance, repeated pulmonary infections, slowed to impaired growth and development, and heart failure.

Chest radiograph results vary, depending on the amount of shunting, but can exhibit increased pulmonary vascular markings and cardiomegaly. Cyanosis and clubbing may indicate a reversed shunt caused by increased PVR. Assess for signs of a left-to-right shunt, decreased exercise tolerance, increased PVR resulting in a right-to-left shunt, and heart failure.

Interdisciplinary Interventions

Monitor children with a VSD for signs and symptoms of heart failure, poor growth and development, and poor feeding. In the presence of heart failure, standard treatment for VSD includes diuretics and digoxin (Lanoxin). Medical management includes antibiotics for prophylaxis against infective subacute bacterial endocarditis for all dental visits. The physician also may elect for surgical repair to alleviate the risk of infective endocarditis.

Infants with heart failure, failure to thrive, increasing PVR, or some combination of these factors require VSD repair. If the child is asymptomatic, repairs are scheduled early in life, most within the first 12 months of life. If the child is too small or ill but is in heart failure, then palliative pulmonary artery banding is done. Most children are able to avoid this additional procedure and undergo only one surgery to complete the repair (see [thePoint](#) for Care Path: Interdisciplinary Plan of Care for the Child With Surgical Repair of a VSD).

Surgery is completed through a median sternotomy incision with the child on cardiopulmonary bypass. A stitch closure is done for small VSDs; for larger defects, a patch is sewn over each hole. At some pediatric cardiac centers, VSDs from selective cases have been closed in the catheterization laboratory, but this technique is not yet approved by the Food and Drug Administration for general care.

Although most children tolerate surgery without complications, they do occur. Heart block is a potential complication, because septal sutures may cause edema in close proximity to the conduction system. Postoperative echocardiography and monitoring of mixed venous gases and oxygen saturation can help determine whether any residual VSDs are left after the repair is done. Inotropic medications are generally administered to support cardiac output during the immediate postoperative period. Postoperative pulmonary hypertension is now managed successfully in many patients previously considered high risk. Management in critical care includes sedation, hyperventilation, inotropic agents for right heart failure, and PGE₁ to decrease PVR. New inhalation therapies that decrease pulmonary blood flow, such as nitric oxide, assist in managing pulmonary hypertension.

ATRIOVENTRICULAR CANAL DEFECT

Another type of defect that increases pulmonary blood flow is an atrioventricular canal defect, also called *atrioventricular septal defects* or *endocardial cushion defects*.

Pathophysiology

Normally, in utero, the fetal endocardial cushions grow and separate into two openings that develop into the

tricuspid and mitral valves. The cushions also contribute to the development of both the atrial and ventricular septa (Park, 2008).

An atrioventricular canal consists of a large central hole, where the cushion did not develop properly, that allows blood to flow among all four chambers. Levels of shunting occur where the lower portion of the atrial septum and the upper portion of the ventricular septum do not meet in the middle (Fig. 15–10).

Along with the left-to-right shunting, at the atrial and ventricular levels, varying degrees of valve insufficiency exist. Valve insufficiency results from inadequate fusion of the centrally located endocardial cushion tissue. Both the septum and the mitral and tricuspid valve leaflets are underdeveloped.

Directions and pathways of flow between chambers depend on pulmonary and systemic resistance, pressure in chambers, and compliance of chambers. Because of the free flow of blood among the chambers, children are at risk for pulmonary hypertension and heart failure.

Without surgical intervention, these children generally die early in life. Their longevity depends on the size of the communication between chambers and the degree of atrioventricular valve incompetence. Early surgical correction can help prevent the development of pulmonary hypertension from excessive pulmonary blood flow.

Assessment

An atrioventricular canal defect can be diagnosed in utero by a level II fetal echocardiogram. If the defect is undiagnosed at birth, these children tend to present early in life with failure to thrive, repeated pulmonary infections, and heart failure. They may be underweight, tachypneic, and

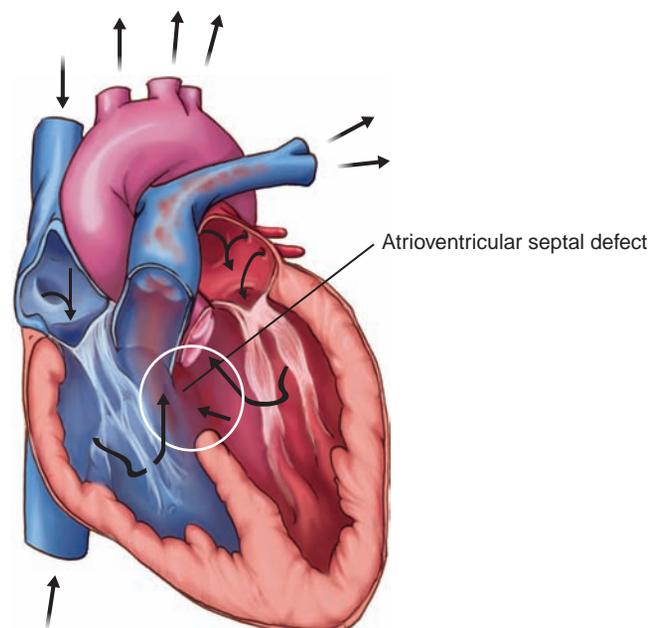

FIGURE 15–10. Atrioventricular canal defect.

tachycardic. Varying degrees of cyanosis are present that worsen with activity. The presence of this defect is frequently associated with Down syndrome and heterotaxy syndrome.

Interdisciplinary Interventions

With an incomplete or partial atrioventricular canal, differing degrees of partial fusion of the endocardial cushion result in varied atrial and ventricular valve abnormalities. If the atrioventricular canal defect is mild, it can be treated much like an ASD.

Medical management includes controlling heart failure by using diuretics and digoxin (Lanoxin). Caloric supplements are provided to support the increased metabolic demand by providing more calories per feeding and allowing the infant to expend less energy.

If the child is asymptomatic, repairs are scheduled early in life, usually toward the end of the first year. If the child is too small or too ill for surgery but is in heart failure, palliative pulmonary artery banding is done. Most children are able to avoid this additional procedure and have a complete surgical repair.

Surgical repair is done through a median sternotomy incision with the child on cardiopulmonary bypass. A Dacron patch is used to surgically close the septal defects. The mitral and tricuspid valves are reconstructed or replaced when necessary.

Complete heart block can occur as a consequence of edema after atrioventricular valve repair. Postoperatively, echocardiography is done to monitor for valvular dysfunction in the reconstructed valves. If pulmonary hypertension is present preoperatively, then postoperatively one can expect instability if the child has to do the work of breathing. Therefore, the child typically receives mechanical ventilation, being weaned from the ventilator slowly, over several days.

ANSWER: All three defects—an ASD, VSD, and atrioventricular canal defect—allow blood flow from the left side of the heart to the right side of the heart, resulting in increased pulmonary blood flow. If left untreated, all will result in pulmonary damage and heart failure.

Obstructive Defects

Obstructive defects include those defects that block the flow from the ventricles. These include coarctation of the aorta (or COA), aortic stenosis, and pulmonary stenosis.

COARCTATION OF THE AORTA (COA)

COA is a deformity that is created by localized constriction or narrowing of the aortic wall. This lesion is typically located at the junction of the aortic arch and descending aorta, distal to the origin of the left subclavian artery (Berstein, 2004). The COA location is the area directly opposite of that where the ductus arteriosus existed. Coarctation can be preductal (in which the area

of narrowing is proximal to the ductus) or postductal (in which the obstruction is distal to the ductus). Any length of the aorta may be obstructed, but obstruction usually occurs in the upper thoracic arch (Fig. 15–11).

Pathophysiology

Narrowing of the aorta mechanically obstructs the pumping of the left ventricle, thereby putting a strain on the left ventricle. When the aorta is obstructed or narrowed, pulmonary blood flow is normal and no areas of intracardiac mixing exist unless the child has a coexisting lesion. As blood is pumped out of the left ventricle to the aorta, some blood flows to the head and upper extremities at a high pressure. The rest of the blood meets the obstruction and is forced through the constricted area, but at a decreased flow as a result of the narrowing, traveling down the descending aorta. Therefore, upper extremity pressures are greater than normal and also greater than pressures in the lower extremities.

Children with coarctation develop hypertension; however, the actual mechanics of are unclear. Normal heart function produces a pulsatile flow to the organs. When an aortic coarctation is present, organs receive a nonpulsatile flow caused by the obstructed area. It is thought that nonpulsatile renal blood flow, by causing arterial vasoconstriction, stimulates the renin–angiotensin–aldosterone system.

Assessment

As with other defects, manifestations depend on the severity of the narrowing of the aorta. Assess for decreased or absent pulses in the lower extremities.

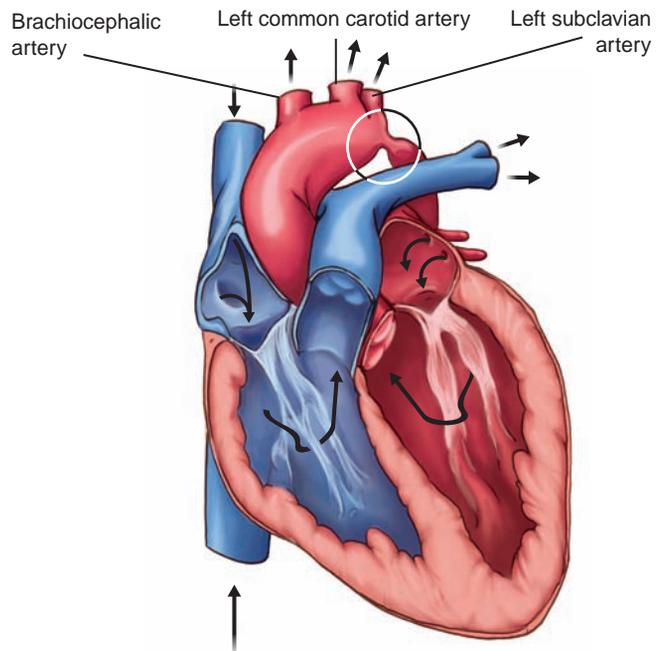

FIGURE 15–11. Coarctation of the aorta.

caREminder

Measure blood pressure in all four extremities to document the pressure gradient between the upper and lower extremities, which may indicate hypertension. Promptly report any finding of a pressure gradient more than 10 mm Hg in an infant.

Infants with moderate to severe aortic narrowing can have failure to thrive and heart failure. Adolescents have upper extremity hypertension. Infants with severe coarctation may have renal shutdown and early death from heart failure if not treated. Approximately 6% of patients with COA also have other defects. Thirty percent of patients with Turner's syndrome have COA (Park, 2008).

Interdisciplinary Interventions

Balloon angioplasty in the catheterization laboratory is an option for some COA lesions. These children can have excellent results while avoiding the more invasive, traumatic surgical repair. However, inadequate relief of the pressure gradient may occur, necessitating surgical repair.

If surgically repaired, the aorta is cross-clamped through a posterior lateral thoracotomy incision, so that the vessel can be repaired without the need for cardiopulmonary bypass. A COA can be surgically repaired in several ways, depending on the specifics of the lesion. The most common repair for COA in patients of all ages is the end-to-end anastomosis. Other less common methods may include patch angioplasty, Dacron conduit, or subclavian flap aortoplasty. Patch angioplasty uses a Dacron patch to widen the area of flow around the coarctation. The Dacron conduit is used as a bypass tube graft. The subclavian flap aortoplasty, done in infants, sacrifices the subclavian artery, which is used as a flap to patch the constriction of the aorta.

Monitor the child's blood pressure closely during the immediate postoperative period. The child's blood pressure is tightly controlled, being kept low, to avoid excessive pressure on the fresh suture lines of the aortic repair site. A child may have residual hypertension even after successful surgical repair. Complications, although uncommon, may include infection, hemorrhage, renal dysfunction, paralytic ileus, or spinal cord ischemia that produces paraplegia. These complications may occur from cross-clamping the aorta during the repair, which causes lack of blood flow below the aorta.

In children with complicated multiple lesions as well as COA, the coarctation is surgically repaired. This repair relieves obstruction to the heart's pumping action. Subsequently, other surgical cardiac repairs may be scheduled.

AORTIC STENOSIS

Aortic stenosis is a narrowing in the area of the aortic valve that obstructs left ventricular outflow. It can occur at the valve itself or it may be a discrete muscular area of obstruction. Three categories of aortic stenosis exist. In *valvular* aortic stenosis (the most common lesion), the

valve leaflets are abnormal, with features such as a small annulus or thickened cusps. The second most common lesion is *subvalvular*, in which a fibromuscular membrane is present below the valve. This membrane can be localized or long and tubular. The least common lesion is *supravalvular*, consisting of an annular constriction in which the aortic lumen is narrowed above the valve.

Pathophysiology

Aortic stenosis may be a result of a birth defect or rheumatic fever. Rheumatic fever damages the heart valves by causing lesions on the leaflets and scar formation over time. Aortic stenosis develops as the heart attempts to overcome resistance through the stenotic area. Resistance to ejection of blood through the heart can result in left ventricular hypertrophy.

In a normal valve, no measurable gradient exists when pressures are measured before and after the valve orifice. In a stenotic valve, pressures are higher before blood passes through the stenotic valve and lower after it passes through the valve. The ascending aorta dilates from the turbulent jet of blood shooting through the constricted area (Fig. 15–12) (Park, 2008).

Stenotic aortic valves may go undetected for many years or may present early in life with severe hemodynamic changes. Stenosis and calcification of valves tend to progressively worsen with age.

Assessment

The severity of signs and symptoms associated with aortic stenosis depends on the amount of valvular deformity and blockage. Children with mild to moderate aortic stenosis are usually asymptomatic but may have exercise intolerance. Older children with aortic stenosis are at risk

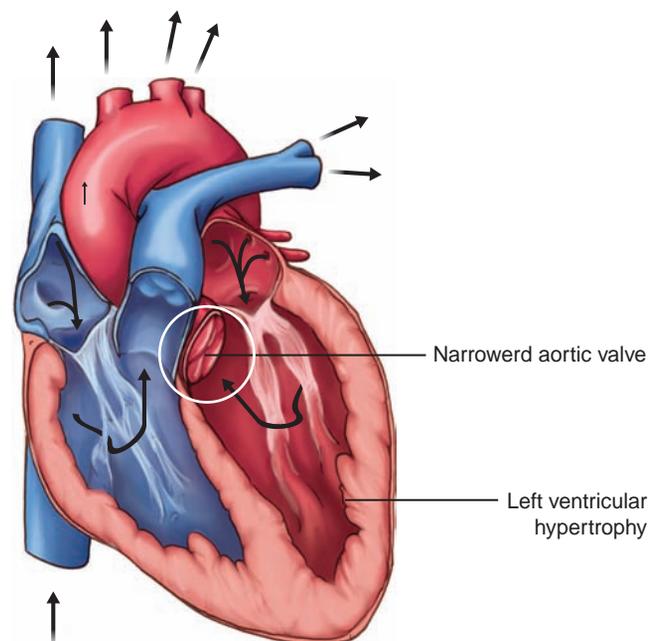

FIGURE 15–12. Aortic stenosis.

for exertional chest pain, easy fatigability, or syncope (Parks 2008).

Assess for symptoms of reduced cardiac output and heart failure. In severe cases, cardiac output is decreased from a poor left ventricular ejection fraction. Infants with critical aortic stenosis (obstruction of blood flow to the body resulting in severe left ventricular failure and shock; with dependency on patency of the ductus arteriosus for blood flow to the body—a true newborn emergency) have heart failure. Symptoms in older children with severe aortic stenosis may include angina, syncope, left ventricular heart failure, dyspnea, fatigue, and palpitations, so note any reports of such symptoms. Chest radiographs can show left ventricular enlargement with dilation of the ascending aorta.

Interdisciplinary Interventions

Instruct children with moderate to severe aortic stenosis to restrict exercise by avoiding sustained strenuous activity. Critically ill newborns may require management in the neonatal intensive care unit with oxygen and PGE₁. PGE₁ infusion maintains the patency of the ductus arteriosus, thus improving systemic blood flow and avoiding both acidosis and decreased perfusion to extremities and organs.

Balloon valvuloplasty can be performed in the cardiac catheterization laboratory. This procedure includes the risk of inducing aortic regurgitation, and the rate of early reintervention is high in neonates with critical aortic stenosis (Zain et al., 2006).

If the child is symptomatic and has severe left ventricular dilation and dysfunction, surgical repair is done through a sternal incision. The surgical procedure varies, depending on the type and severity of the lesion. Valvular repair may involve an aortic valve commissurotomy (dilating the valve and incising the commissures of the valve). Potential postoperative complications include residual stenosis and aortic insufficiency.

If the risk of aortic valve insufficiency is too great, the child may require an aortic valve replacement. Delaying valve replacement, if possible, until the child is large enough to receive an adult-sized valve is advantageous. The goal is to limit the total number of valve replacement surgeries required throughout a lifetime. If the valve is replaced with a metal valve, the child must receive long-term anticoagulant therapy.

Recently, the trend in valve replacement surgery is to use a pulmonary autograft, which enables some adolescents to avoid anticoagulant therapy. The stenotic aortic valve is removed, and the patient's own pulmonary valve is transplanted in its place. The root where the patient's own pulmonary valve was located is replaced with a *homograft* valve. Homograft tissue is tissue donated from a cadaver and preserved for later surgical insertion. Because of the high pressures on the left side of the heart, it is thought that the patient's own valve will last longer in the aortic position and function better than a homograft valve. However, this approach involves more complicated surgery, because two valves are replaced.

PULMONARY STENOSIS

Pulmonary stenosis is a narrowing at some location along the right ventricular outflow tract. Pulmonary valvular stenosis is the most common lesion producing obstruction to flow of the right ventricular systolic ejection. The cusps of the three-leafleted pulmonary valve may be thickened and fused, and the diameter of the opening varies (Fig. 15–13).

Pulmonary stenosis is classified into three types based on the location of the right ventricular outflow obstruction. *Subvalvular* or *infundibular* stenosis is uncommon and is located below the level of the pulmonary valve. *Supra-valvular* stenosis is located in the pulmonary arteries above the pulmonary valve. This condition is often associated with congenital rubella and Williams' syndrome, a genetic disorder. *Valvular* stenosis, characterized by dysplasia of the valve, makes up 90% of the cases (Park, 2008).

Pathophysiology

Pulmonary stenosis reduces blood flow to the lungs. Obstruction to the flow of the right ventricle leads to increased right ventricular pressure and right ventricular stroke volume workload. Over time, the extra workload may cause the right ventricle to fail and cause heart failure.

Assessment

Assessment findings associated with pulmonary stenosis are related to the severity of the obstruction. A child with mild stenosis may have no symptoms and thus may not require invasive interventions. Most children with pulmonary stenosis are acyanotic and have no activity restrictions.

For the child with moderate pulmonary stenosis, note how easily the child becomes fatigued and observe for

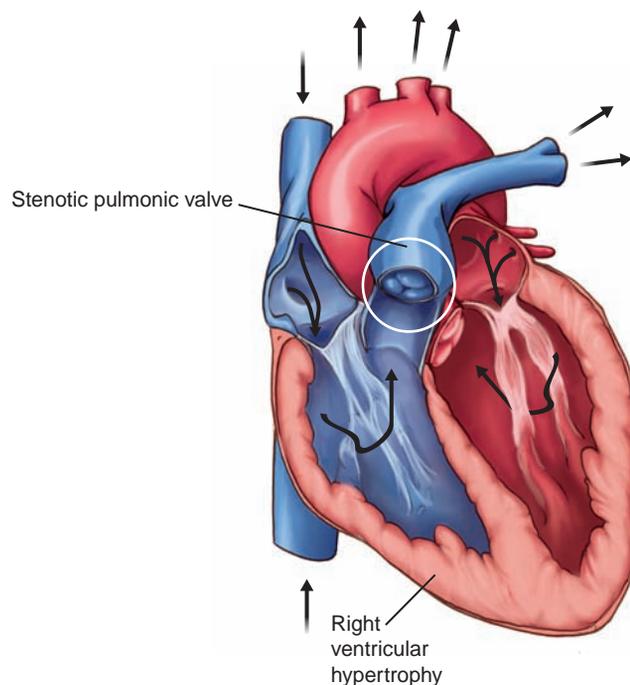

FIGURE 15–13. Pulmonic stenosis.

evidence of exertional dyspnea. In severe cases, an infant may be cyanotic and may have signs and symptoms of heart failure; assess for these signs. These infants may need urgent surgical repair or palliation. Some patients may benefit from dilatation in the cardiac catheterization laboratory. In severe cases, development of the peripheral pulmonary arteries may be affected by various areas of stenosis.

Interdisciplinary Interventions

A balloon valvuloplasty may be performed in the cardiac catheterization laboratory to dilate and rupture the deformed valve through circumferential stress. This intervention is the procedure of choice because it is less invasive than surgery, has low risks, and produces good outcomes.

Surgical repair involves pulmonary valvulotomy with resection of any muscle mass and patch widening of the pulmonary arteries as required. The surgery is completed through a sternal incision and sometimes requires the use of cardiopulmonary bypass. If the pulmonary arteries are stenotic, they may require patch widening or stent placement in the catheterization laboratory. After repair, the pulmonary valve is regurgitant, yet most patients are asymptomatic and merely require follow-up the rest of their lives.

Defects With Decreased Pulmonary Blood Flow

Defects with decreased pulmonary blood flow include tricuspid atresia, tetralogy of Fallot, and pulmonary atresia.

TRICUSPID ATRESIA

Tricuspid atresia is a cardiac lesion in which the tricuspid valve is missing, so no connection exists between the right atrium and the right ventricle (Fig. 15–14).

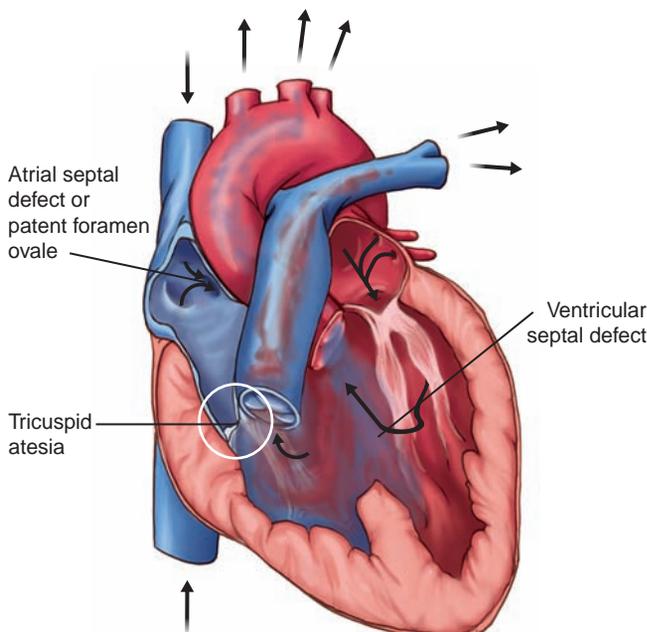

FIGURE 15–14. Tricuspid atresia.

Pathophysiology

In tricuspid atresia, blood cannot flow from the right atrium to the right ventricle; therefore, pulmonary blood flow is greatly reduced and dependent on other shunts. The right ventricle generally is hypoplastic, and the inflow portion of the right ventricle is missing. In infants, survival depends on the presence of an associated defect, such as an ASD, VSD, or PDA, that enables some cardiac mixing. Coexisting lesions associated with tricuspid atresia might include pulmonary stenosis, transposition of the great arteries, COA, and hypoplastic pulmonary arteries (Park, 2008).

Without intervention, children die early during infancy. These infants may require a shunt to increase pulmonary blood flow. Infants will likely grow and develop more slowly than the average baby because, until the completion of the staged repair, the amount of oxygen available for the body's needs is inadequate.

Assessment

Infants with tricuspid atresia are cyanotic from restricted pulmonary blood flow and can have hypoxic spells. Clinical manifestations include poor feeding and tachypnea. Chest radiograph shows a normal or slightly increased heart size with decreased pulmonary vascular markings.

Interdisciplinary Interventions

Palliation to increase pulmonary blood flow to the lungs can be provided by placing a Blalock-Taussig shunt. If the neonate has inadequate intracardiac mixing, a balloon atrial septostomy can be done to increase right-to-left shunting. Depending on the specifics of the particular lesion, some children have excessive pulmonary blood flow. In these cases, a pulmonary artery banding procedure is desirable to control heart failure, by limiting the excessive pulmonary blood flow.

Surgery for tricuspid atresia requires two procedures. A hemi-Fontan or bidirectional Glenn shunt is the preparatory surgery performed before the Fontan procedure. This procedure is essentially an anastomosis (connection) of the superior vena cava to the pulmonary artery. It redirects partial venous return straight to the lungs and decreases the workload on the single ventricle by approximately 20%.

The final repair is the Fontan procedure, which enables the single usable ventricle to act as the systemic pump. All the systemic venous return is directed to the lungs and bypasses the ventricle. This redirection is accomplished through a surgical connection between the right atrium and the pulmonary artery, and is known as an *intracardiac Fontan*. Some surgeons use an extracardiac Fontan, which involves the use of a Gore-Tex tube to connect the inferior vena cava directly to the right pulmonary artery. Some surgeons choose to leave a small fenestration, or opening, between the Fontan circuit and the right atrium that acts like an ASD. This opening allows a small amount of intracardiac mixing and relieves pressure in the right atrium. After the Fontan procedure, many children can experience improvements in growth and development.

TETRALOGY OF FALLOT (TOF)

Tetralogy of Fallot is the name given to a commonly occurring combination of four problems with manifestations and a course that are somewhat predictable. The child with tetralogy of Fallot has

- A large VSD
- Some degree of right ventricular outflow tract obstruction or pulmonary stenosis
- An aorta that is positioned such that it overrides the ventricular septum
- A right ventricle that becomes hypertrophic from continually pumping against the obstruction (Fig. 15–15)

Without treatment, most patients die by about 20 years of age. Complete repair of tetralogy of Fallot is associated with excellent survival (Lee et al., 2006). Pulmonary valve replacement is frequently needed after tetralogy of Fallot repair as an adult (Cesnjevar et al., 2004).

Pathophysiology

The VSD leads to shunting, the amount of which varies depending on the amount of obstruction to right ventricular outflow and the size of the VSD. These children have diminished blood flow to the lungs and excessive blood flow to the body of poorly oxygenated blood (Park, 2008).

Children with tetralogy of Fallot have varying degrees of pulmonary stenosis, with correlating proportions of cyanosis. Cyanosis may not be obvious in the neonate, but as early months pass, infundibular pulmonary stenosis increases, which in turn increases the right-to-left shunting through the VSD. Children with tetralogy of Fallot have normal growth and development, but if left untreated, they eventually suffer worsening cyanosis, clubbing, polycythemia, and exercise intolerance. When

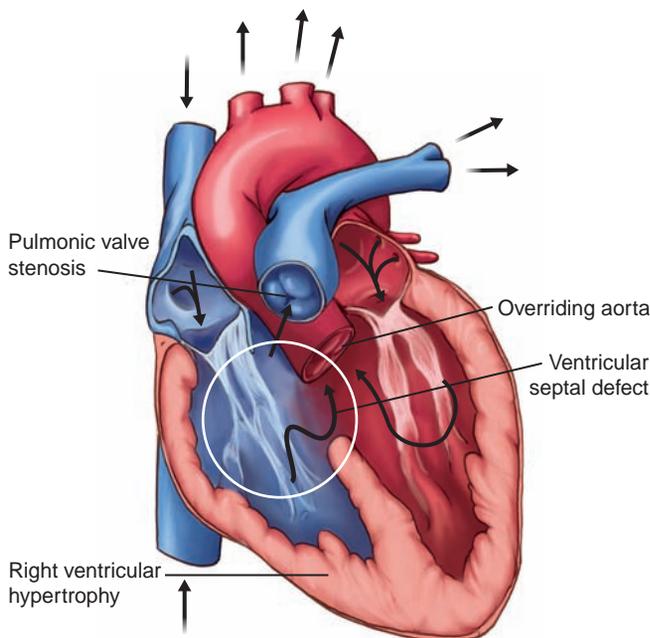

FIGURE 15–15. Tetralogy of Fallot.

the secondary lesion of pulmonary stenosis is present, with the right balance, it may act as a left ventricular outflow obstruction to decrease pulmonary blood flow from excessive shunting across the VSD. This circumstance may help prevent heart failure, but further complicates surgical repair of the heart.

Assessment

Assess for difficulty feeding, failure to gain weight, poor development, and symptoms of cyanosis (clubbing, dizziness, and loss of consciousness). These children are mildly cyanotic at rest and have increasing cyanosis with crying, activity, or straining (such as with a bowel movement). Children tend to limit their own activity levels relative to their level of hypoxic tolerance.

Some children with tetralogy of Fallot can be acyanotic. If, along with a large VSD, mild or moderate pulmonary stenosis is present that limits the amount of intracardiac mixing, a child may not be blue. Such children are often called *pink tet's*.

A chest radiograph of the child with tetralogy of Fallot shows decreased pulmonary blood flow and a normal heart size. The heart shows a boot-shaped silhouette from right ventricular hypertrophy pushing the heart apex upward (Park, 2008). Echocardiography can provide information that clearly defines the defect. If the coronary anatomy cannot be clearly delineated by echocardiography, a diagnostic heart catheterization is performed. Catheterization provides specific preoperative information about the direction and the amount of shunting, the coronary anatomy, and each portion of this heart defect.

Interdisciplinary Interventions

Medical management includes monitoring oxygen saturation to determine the degree of hypoxia, optimizing oxygenation, and recognizing and treating hypercyanotic spells (see the description of cyanosis and its management earlier in this chapter).

Some children require a palliative procedure to increase pulmonary blood flow. A Blalock-Taussig shunt can decrease cyanosis and eliminate tet spells. Children who may benefit from a shunt placement before total corrective surgery are those who are too ill or small for complete repair. Also, if the coronary artery crosses the right ventricular outflow tract, standard surgical repair may be ruled out. If a shunt is placed, it is removed at the time of the definitive surgical repair. At some cardiac centers, selected patients have undergone balloon dilatation of the outflow tract in the cardiac catheterization laboratory to widen the pulmonary artery and increase pulmonary blood flow before surgical repair.

Surgical repair is done through a median sternotomy incision with the child on cardiopulmonary bypass. The VSD is patched in such a way as to direct blood flow to include the overriding aorta toward the left ventricle. The right ventricular outflow tract is widened by resecting the infundibular tissue and placing a patch.

Most children survive surgery without long-term problems. Possible surgical complications include bleeding,

heart conduction problems, pulmonary valve regurgitation, residual VSD, and persistent right ventricular failure.

PULMONARY ATRESIA

Pulmonary atresia is a severe version of pulmonary stenosis. At birth, the only pulmonary blood flow is via the PDA. Without immediate medical intervention, these children have a very poor prognosis.

Pathophysiology

In pulmonary atresia, the pulmonary valve fails to develop, and the valve is imperforate. Generally, but not always, the right ventricle is also poorly developed and thus is unable to function effectively. Pulmonary atresia can occur with or without an intact ventricular septum (Fig. 15–16) (Park, 2008).

Assessment

These children present within the first day of life with severe cyanosis and tachypnea. Assess for and report breathing difficulties, irritability, lethargy, and evidence of cyanosis.

Interdisciplinary Interventions

As with most heart lesions, antibiotics are provided for routine dental care and medical interventions as prophylaxis against infective endocarditis. Goals of care are oriented toward minimizing cyanosis. In infancy, these children undergo heart catheterization to define anatomic and physiologic features. A balloon atrial septostomy may be done to improve shunting across the atria. In infancy, a systemic-to-pulmonary artery shunt procedure is performed to increase pulmonary artery blood flow by creating a left-to-right shunt.

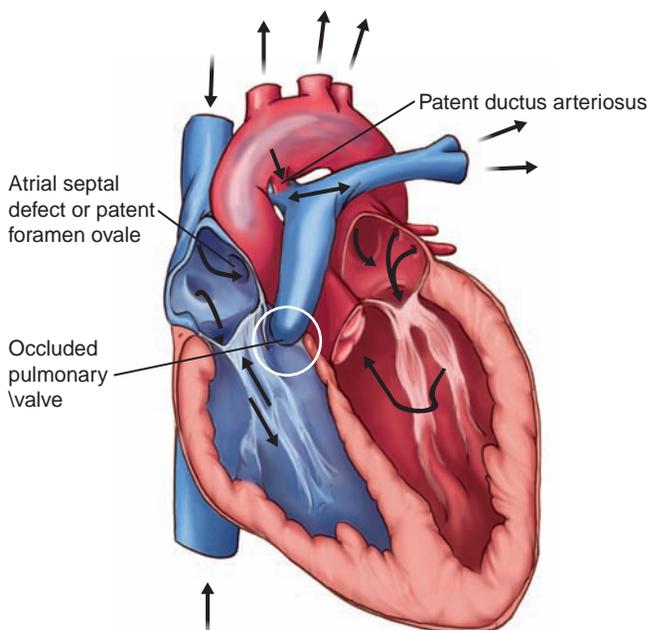

FIGURE 15–16. Pulmonary atresia.

After the child has grown and is a little older, and if the right ventricle is large enough, a valved conduit is placed, using a homograft, to provide circulation from the right ventricle to the pulmonary arteries (Rastelli procedure). This surgery enables biventricular function and separates the pulmonary and systemic circulations. When the right ventricle is hypoplastic, a modified Fontan procedure is used to provide separate pulmonary and systemic circulations.

Depending on the specific dynamic of the child's pulmonary arteries and a right ventricle of adequate size, some children benefit from a surgery that includes pulmonary valvulotomy and placement of a patch on the right ventricular outflow tract. This procedure opens communication between the right ventricle and pulmonary arteries. Blood passes through the right ventricle and pulmonary arteries, and can stimulate growth of those areas.

Children with pulmonary atresia and poor distal pulmonary artery development may still have a poor quality of life even after multiple heart catheterizations and surgeries.

Defects of the Great Vessels

Problems with placement or development of the blood vessels leading to or from the heart are termed *defects of the great vessels*. These include total anomalous pulmonary venous return, truncus arteriosus, and transposition of the great arteries.

TOTAL ANOMALOUS PULMONARY VENOUS RETURN (TAPVR)

In newborns with TAPVR, the pulmonary veins do not return to the left atrium; instead, they abnormally return to the right side of the heart. This blood returning back to the right side of the heart can go to the systemic venous circulation first and then to the right atrium, or just directly to the right atrium (Fig. 15–17). Partial anomalous pulmonary venous return occurs when one or more but not all of the pulmonary veins drain into the venous system.

The pulmonary veins are abnormally routed in different ways. The most common type of TAPVR is called *supracardiac*, in which the pulmonary veins drain directly into the superior vena cava. Another type is called *intracardiac*, in which the pulmonary veins drain into the coronary sinuses or flow directly into the right atrium. The supracardiac and intracardiac types of TAPVR are generally nonobstructive. With *infracardiac* TAPVR, the common pulmonary vein runs below the diaphragm into the portal system. A fourth type of TAPVR is a mixed combination of the other types.

Pathophysiology

The abnormal positioning of the pulmonary veins leads to mixing of systemic and pulmonary circulations resulting in cyanosis. The presence of an ASD is necessary for

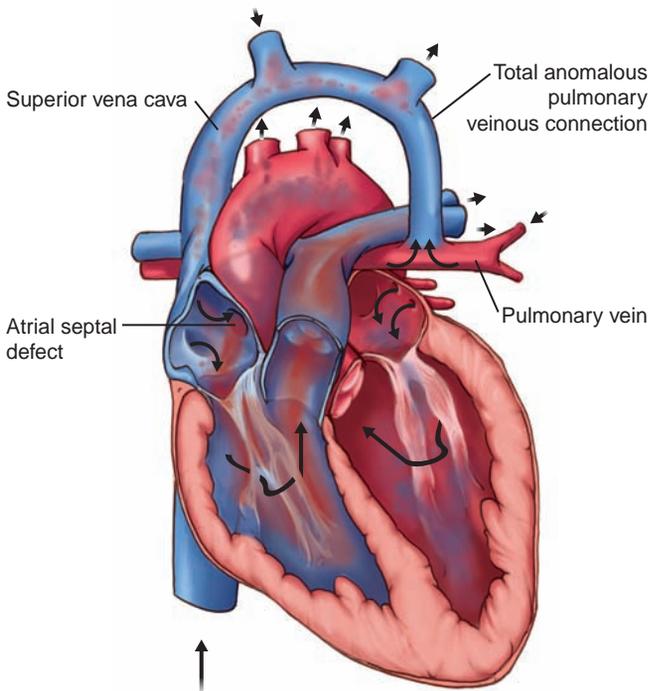

FIGURE 15–17. Total anomalous pulmonary venous return.

cardiac mixing and survival. In these children, the left atrium is relatively small from lack of blood flow and the right atrium may be distended from excessive blood flow.

Assessment

A newborn's degree of cyanosis depends on the adequacy of mixing through the foramen ovale and the extent to which flow is obstructed by the misdirected pulmonary veins themselves. Assess for signs and symptoms of cyanosis, heart failure, poor feeding, and failure to thrive. Chest radiograph shows cardiomegaly of the right atrium and right ventricle with increased pulmonary vascular markings. These children are also prone to repeat pulmonary infections.

Interdisciplinary Interventions

The clinical status of newborns with TAPVR can deteriorate quickly if the defect is left untreated. Medications to control heart failure, such as digitalis and diuretics, are administered. Some infants can benefit from a balloon atrial septostomy to encourage right-to-left shunting and to improve intracardiac mixing.

Surgical repair performed through a median sternotomy incision with the child on cardiopulmonary bypass is done during infancy. The mortality rate is high, and survivors have a prolonged postoperative recovery.

The type of surgical correction varies, depending on the location of the veins. For supracardiac lesions, the pulmonary veins are anastomosed to the left atrium, and the ASD is patched. For the intracardiac type of TAPVR, a communication is created between the coronary sinus and the left atrium, and the ASD is patched. For an infracar-

diac lesion, an anastomosis is created from the pulmonary veins and patched to the left atrium, and the pulmonary vein that extends below the diaphragm is ligated.

These children are sensitive to fluid volume loading because of the small left atrium. They may require a high right atrial pressure to ensure left atrial filling. Postoperative complications include atrial arrhythmias, pulmonary hypertension, and pulmonary vein obstruction.

Partial anomalous pulmonary venous return occurs when one or more, but not all, of the pulmonary veins drain into the venous system. If the veins drain into the right atrium, many of these defects can be repaired by simply widening the ASD patch to direct flow of the anomalous pulmonary veins toward the left atrium.

TRUNCUS ARTERIOSUS

In truncus arteriosus, the embryonic division of the primitive fetal truncus into the aorta and pulmonary artery fails to occur. At birth, a single large vessel, the common trunk, arises from both ventricles across a large VSD.

Four categories of truncus arteriosus exist. Type I is the most commonly occurring version of truncus, defined by a partial separation of the aorta and pulmonary artery. A short pulmonary trunk arises from the posterior aspect of the large truncus or aorta. Type II truncus occurs when two pulmonary arteries arise from the posterior aspect of the truncus. Each one is connected separately to the truncus instead of a main pulmonary artery. Therefore, no main pulmonary artery is present. Type III truncus is much like type II, except that the two pulmonary arteries arise separately from the lateral aspect of the truncus. In type IV, no pulmonary arteries exist. Only bronchial arteries arise from the descending aorta.

Pathophysiology

The opening of the common trunk has one valve with three to four leaflets. The common trunk leaves the heart and gives rise to the systemic and pulmonary circulations. Systemic and pulmonary blood mix completely (Fig. 15–18).

Assessment

Diagnosis of truncus arteriosus can be made in utero by a fetal cardiologist using echocardiography. Physical findings depend on the amount of pulmonary blood flow. The infant may exhibit cyanosis in varying degrees, and signs and symptoms of heart failure; assess for these. Note any history of frequent pulmonary infections, failure to thrive, or dyspnea with feeding. Chest radiographs show marked cardiomegaly with increased pulmonary vascular markings. Without surgical intervention, most children die of heart failure within 6 to 12 months (Park, 2008).

Interdisciplinary Interventions

Medical management includes measures to control heart failure, including digoxin and diuretics. A systemic-to-pulmonary artery shunt may be helpful for infants with severe cyanosis. Pulmonary artery bands have been

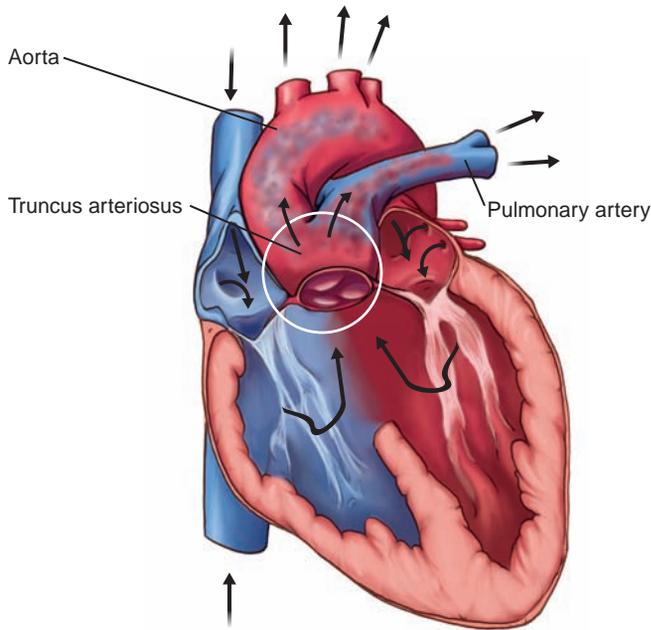

FIGURE 15-18. Truncus arteriosus.

placed in some infants, but this form of palliation is associated with high mortality.

The definitive surgical repair, the Rastelli operation, involves detaching the pulmonary trunk from the truncus so the truncus can pump the systemic circulation independently. Then a prosthetic or homograft valved conduit is connected to the right ventricle to direct flow to the pulmonary arteries. The VSD is closed, so that the left ventricle pumps exclusively to the aorta. Even though this surgery is complicated and associated with a high mortality rate, surgery is done during infancy because most children do not survive past that age without repair (Sun et al., 2005).

Repeat surgeries are done throughout the child's life to replace conduits that have been outgrown or that malfunction. Potential postoperative complications include arrhythmias, pulmonary problems, and persistent heart failure. Worsening regurgitation of the imperfect truncal valve may occur over time.

TRANSPOSITION OF THE GREAT ARTERIES

Transposition of the great arteries (TGA), also called *transposition of the great vessels*, is a malformation in which the aorta arises from the right ventricle and the pulmonary artery arises from the left ventricle (Fig. 15-19). TGA is the most common etiology for cyanotic CHD in the newborn. This lesion presents in about 5% of all patients with CHD (Bernstein, 2004).

Pathophysiology

With TGA, two parallel and separate circulations exist. One circulation system consists of the pulmonary veins traveling to the left atrium, left ventricle, pulmonary artery, and returning again to the pulmonary veins. The

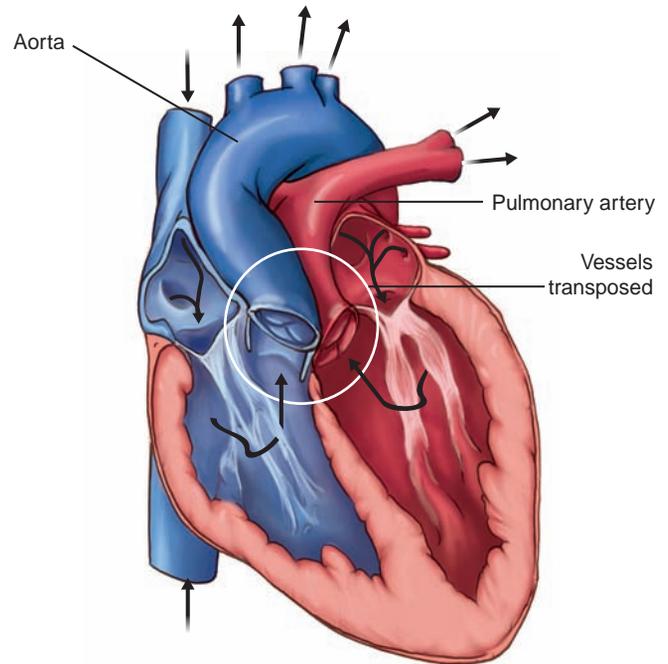

FIGURE 15-19. Transposition of the great arteries.

second system consists of blood flowing from the vena cavae, right atrium, right ventricle, then to the aorta and back again. Patient survival depends on adequate intracardiac mixing of blood between these two circulations via a PDA, a patent foramen ovale, or a VSD. Although the prognosis is variable, the overall survival rate in uncomplicated TGA exceeds 90% (Bernstein, 2004).

Assessment

Assessment findings at birth depend on the presence of associated lesions. Diagnosis of TGA can be made in utero by a fetal cardiologist using echocardiography. Infants with TGA are cyanotic at birth, although the cyanosis may be subtle. Heart failure develops during the first weeks of life. Assess for murmurs and signs and symptoms of cyanosis. These children present with hepatomegaly, feed poorly, and develop dyspnea. During infancy, progressive acidosis and hypoxemia occur unless adequate intracardiac mixing is established.

An accurate preoperative view of the coronary artery anatomy is necessary before treatment. In most cases, anatomy can be defined with echocardiography alone; otherwise, catheterization is required. Chest radiographs show cardiomegaly with increased pulmonary vascular markings on cardiac silhouette.

Interdisciplinary Interventions

Preoperatively, IV PGE₁ might be used to keep the PDA patent and to improve systemic arterial flow in children with inadequate intracardiac mixing. A palliative balloon atrial septostomy may be performed urgently in those children without a coexisting lesion. A coexisting lesion enables stabilization without PGE₁ infusion.

The arterial switch surgery is the surgical repair of choice for TGA and it corrects the parallel circulations. During the arterial switch surgery, the trunks of the aorta and the pulmonary artery are dissected and reversed onto their appropriate ventricular outflow tracts. Also, the coronary arteries are reimplanted into the stump of the new aorta. This surgical repair is frequently done during the first weeks of life, and long-term survival for these children exceeds 90% (Mussatto & Wernovsky, 2005). Complications include coronary artery occlusion and pulmonary artery stenosis.

Defects With a Functional Single Ventricle

In single-ventricle defects, only one of the two ventricles is of adequate functional size. Defects include HLHS and single ventricle. Tricuspid atresia, a condition associated with hypoplastic right ventricle, is discussed in Defects With Decreased Pulmonary Blood Flow.

HYPOPLASTIC LEFT HEART SYNDROME

HLHS is a diagnostic label given to a syndrome in which the entire left heart did not develop normally (Fig. 15–20).

Pathophysiology

HLHS includes hypoplasia of the left ventricle, mitral atresia, aortic atresia, and hypoplasia of the ascending aorta and aortic arch. The left ventricle and mitral valve may be entirely absent or poorly developed.

HLHS is fatal without intervention, usually within the first 2 weeks of life. Historically, limited numbers of children with HLHS survive through the final surgery. However, with recent increased experience in postoperative management by large centers, survival rates have improved considerably.

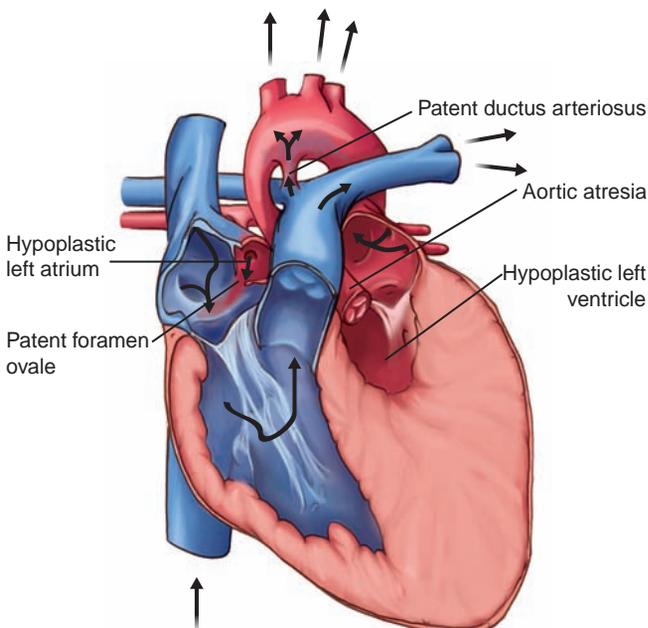

FIGURE 15–20. Hypoplastic left heart syndrome.

Assessment

HLHS can be detected prenatally with a level II fetal echocardiogram. At birth, assess for signs and symptoms of cyanosis. However, signs and symptoms may not be readily apparent during the initial newborn period, despite the severity of this condition. Chest radiographs show cardiomegaly, and generally these children do not have an audible murmur. An echocardiogram may provide enough information so that a cardiac catheterization may not be necessary.

Interdisciplinary Interventions

Historically, infants with HLHS died because no effective treatment interventions were available. Currently, two treatment options exist: palliative surgery or cardiac transplantation. Religious backgrounds and family interactions can affect the family's decision, and some may opt for no intervention (therefore, the infant will die). The healthcare team must be as realistic and honest as possible in allowing parents to express their feelings, and help them to comprehend the potential implications of each choice. Each option has its own medical, emotional, and economic burdens.

If parents choose not to provide any surgical intervention, they may leave the newborn in the hospital and visit with the baby at the bedside. Others have taken a relatively stable newborn home after medical interventions have been withdrawn and have allowed the child to die with family support at home. The choice of allowing the child to die is an extraordinary situation for nurses. The nurse must provide emotional support to a family during the grieving process and help them resolve any guilt or anger over their child's cardiac defect.

If the parents choose to stabilize the newborn for surgery, interventions focus on maintaining adequate systemic perfusion and a balanced pulmonary circulation. These include keeping the ductus open with an IV infusion of PGE₁, and low-dose dopamine to maintain adequate systemic perfusion and balance the pulmonary circulation. Usually, newborns receive mechanical ventilation until stabilized. Acidosis is treated aggressively with ventilation and sodium bicarbonate, and diuretics are administered to manage heart failure. Infants should be maintained on 25% to 35% oxygen to keep the PaO₂ level in the high 30s to low 40s mm Hg. This measure helps to balance pulmonary and systemic vascular resistance.

A newborn waiting for cardiac transplantation remains hospitalized. About 25% die waiting for a heart to become available for transplantation (Chrisant et al., 2005).

For those parents who select surgical palliation, their child receives a series of three surgical interventions, beginning with the Norwood procedure, followed by a hemi-Fontan or bidirectional Glenn shunt at about 4 months of age. Then, the Fontan procedure is done at a later time, usually around 2 to 4 years of age.

Stage I, the Norwood or the initial palliative surgery, is done to create an unobstructed and permanent flow from the right ventricle to the aorta. The right ventricle becomes the systemic ventricle by using the proximal

pulmonary artery and patches of pericardial or homograft tissue to reconstruct the aorta. Usually, an atrial septotomy is done to encourage adequate mixing. Also, the distal main pulmonary artery is attached to a shunt between the right ventricle and the pulmonary artery or to a modified Blalock-Taussig shunt.

When the child outgrows the Norwood shunt, the child is scheduled for the next surgery. Stage II consists of the hemi-Fontan procedure or a variation of the Glenn shunt, done to decrease the volume load on the right ventricle. This procedure is basically an anastomosis of the superior vena cava to the pulmonary artery and removal of the newborn shunt that was placed during the first surgery.

Stage III, the final surgery, involves the completion of the Fontan procedure, which separates the pulmonary and systemic circulations. This surgery connects venous return directly through the right atrium to the pulmonary artery. This connection leaves the systemic blood flow to be pumped by the single ventricle. Therefore, systemic flow is separated from the returning venous blood that goes directly to the lungs. A new approach for Fontan completion is to place a stent covered with a thin layer of Gore-Tex from the inferior vena cava to the hemi-Fontan baffle. This procedure can be performed in the catheterization laboratory and is associated with fewer postprocedure pleural effusions, lower mortality, and a shorter length of stay (Maher et al., 2004).

SINGLE VENTRICLE

The diagnosis of single ventricle denotes a condition in which both the right atrium and the left atrium empty into one ventricular chamber. The second ventricle may be a tiny chamber or may be a remnant of the one larger chamber (Fig. 15-21).

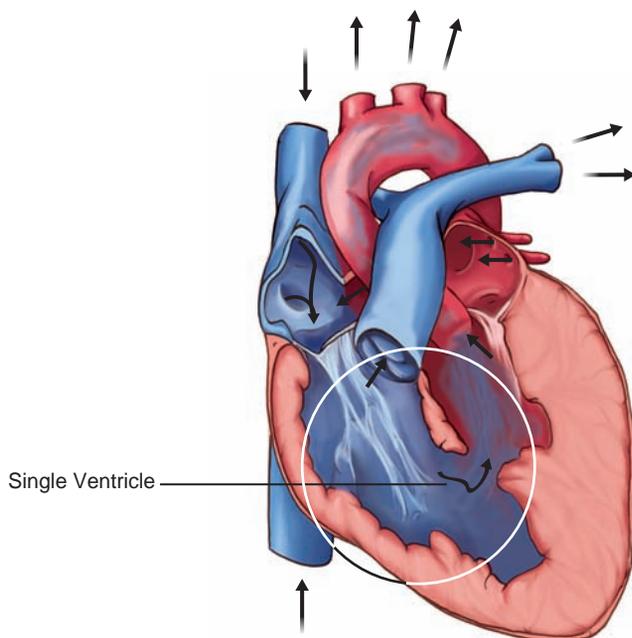

FIGURE 15-21. Single ventricle.

Pathophysiology

Both great vessels usually come off the single ventricle, so oxygenated and deoxygenated blood are completely mixed in the chamber. These children also have a high incidence of heterotaxy syndrome (Park, 2008).

Assessment

Clinical manifestations vary depending on the specific combination of problems. Cyanosis, failure to thrive, and difficulty fighting pulmonary infections are common manifestations.

Interdisciplinary Interventions

Palliative surgical interventions include a Blalock-Taussig shunt if pulmonary blood flow is restricted. When medical management of heart failure is not adequate, pulmonary artery banding may be used to restrict pulmonary blood flow. If cardiac dynamics allow, many of these children may benefit from a modified Fontan procedure.

ACQUIRED HEART DISEASE

Acquired heart disease refers to those disorders of the heart that are not present at birth. This category includes cardiac disorders other than anatomic defects, although some illnesses such as arrhythmias and cardiomyopathy can also have a congenital origin. Some acquired problems, such as arrhythmias, can develop as sequelae of CHD, surgery, or both.

Arrhythmias

Arrhythmia, sometimes called *dysrhythmia*, is a generic term for a variety of classifications of abnormal heart rhythms. Most are transient and benign, and rarely require treatment. However, these disturbances in rhythm do occur necessitating treatment.

Advances in care have enabled improved control and suppression of cardiac arrhythmias. Improvements in cardiac surgical techniques have promoted longer lives in children with complex heart disease. This progress has also increased the population of patients that has survived, but with an increased risk for arrhythmias.

During the immediate postoperative period, children who have had cardiac surgery are at particular risk for electrolyte imbalances, particularly potassium, magnesium, and calcium, and hemodynamic changes that can precipitate arrhythmias. For example, hypovolemia, hypoxia, fever, and hypothermia may be underlying causes. Anesthesia and medications may cause depression and irritability of the ventricles. Direct damage to the conduction system can occur from suture lines, dissection, and mechanical manipulation of the heart chambers. Other causes may include gastric dilation; chest trauma; sympathetic catecholamine release resulting from pain, fear, or anxiety; drug toxicity; and arrhythmogenic medications, including antiarrhythmics with proarrhythmic effects.

Sinus tachycardia is common after pediatric cardiac surgery. Other arrhythmias common in children include sinus bradycardia and supraventricular tachycardia (Chart 15–3).

QUESTION: Review the case study and identify the arrhythmia Gabriella experienced during the night. What may have caused the arrhythmia?

Assessment

Identify children at risk for cardiac arrhythmias. After a rhythm disturbance occurs, the arrhythmia must be identified and its clinical significance must be evaluated. Assess the child's blood pressure, urine output, peripheral pulses, temperature of extremities, skin color, capillary refill, and level of consciousness. Arrhythmias that affect cardiac output require prompt treatment. Continuously assess and monitor the child's response to the arrhythmia and treatments. Nursing care includes ruling out potential precipitating events and considering underlying causes before intervening (NIC 15–1).

Irregularities in cardiac rhythms may be documented and diagnosed through continuous ECG monitors, 12-lead ECG, Holter monitors, transesophageal probes, and electrophysiology studies (described earlier in this chapter).

Interdisciplinary Interventions

The therapies available for children with arrhythmias include pharmacologic management and suppression, ablative therapy, implantable antiarrhythmia devices, cardioversion, and pacemakers. The use of specific tools depends on the needs of each patient. Pacemakers are discussed earlier in the Treatment Modalities section of this chapter (Clinical Judgment 15–3).

Pharmacologic Interventions

Pharmacologic management is the simplest approach to controlling or suppressing arrhythmias. Drawbacks include nonadherence to the medication regimen (especially in the adolescent population), adverse effects, and failure of the medications to control the arrhythmia. The availability of a variety of drugs and advancements in pharmacotherapeutics are overshadowed by the lack of information about long-term efficacy of using antiarrhythmia medications in the growing child, with potentially toxic effects.

Electrophysiologic Interventions

Arrhythmias such as supraventricular tachycardias can also be managed by radiofrequency ablation (RFA). Reasons for using ablation in children include patient choice, arrhythmia refractory to conventional medical therapy, life-threatening arrhythmia, adverse antiarrhythmic drug effect, tachycardia-induced cardiomyopathy, and impending surgery.

Currently, no consensus exists among centers or practicing pediatric electrophysiologists regarding standard indications for or timing of the use of RFA for supraventricular tachycardia in young children. In some centers, RFA is used as a primary treatment in children age 1 to 4 years. Complications associated with the procedure include arterioventricular block (second or third degree), ventricular perforation, pericardial effusion, emboli, brachial plexus injury, and pneumothorax. A risk of death remains associated with RFA complications, and this fact must be presented and discussed with families in relation to the mortality risk associated with supraventricular tachycardia itself. Until follow-up data on outcomes are available, healthcare providers should monitor children who receive RFA for subsequent arrhythmias, valve dysfunction, or myocardial dysfunction.

Implantable Device Therapy

Arrhythmias have been managed by implanting devices such as automatic implantable cardiac defibrillators (or AICDs) and pacemakers. AICDs are used in a select group of patients for whom ablation and medical management have not controlled the arrhythmia. These devices are expensive, require implantation in the cardiac catheterization laboratory, and necessitate extensive follow-up. AICD is a system that senses the heart's rhythm and can provide defibrillation for ventricular tachycardia and ventricular fibrillation. The system consists of epicardial sensing leads attached to the heart to sense the rhythm, wire mesh patches on the epicardium for defibrillation, and a pulse generator placed in the chest or abdominal cavity. AICDs have had limited usage in the pediatric population. Unmanageable ventricular tachyarrhythmias have not been common in children, and the relative size of the device limits its placement in small children. Even though current use is low, the population of children who survive complex surgeries is increasing, so the population of older children who would benefit from the use of an AICD will also increase (see [thePoint](#), Supplemental Information: A Teaching Intervention Plan for the Child With an Automatic Implantable Cardiac Defibrillator: Discharge Instructions).

ANSWER: Gabriella experienced sinus bradycardia during her gavage feeding. She may have experienced stimulation of the vagus nerve as a result of the gavage feeding.

Cardiomyopathy

Cardiomyopathy is disease of the heart muscle that damages the muscle tone of the heart and reduces its ability to pump blood, resulting in heart failure. Cardiomyopathy is a leading cause of heart failure and is the most common reason for heart transplantation. Cardiomyopathy occurs in just over 1 per 100,000 children (Cox et al., 2006). Incidence is significantly higher in infants younger than 1 year than in children 1 to 18 years, in black

CHART 15-3 COMMON PEDIATRIC ARRHYTHMIAS

Arrhythmia	Description/Causes	Causes	Management
Sinus tachycardia	Normal configuration with rate faster than acceptable parameters for child's age Normal or abnormal depending on child's age and situation (i.e., fussy or crying infant's heart rate situationally faster than normal for the child's age but no medical intervention necessary)	Cardiac surgery Fever, sepsis Dehydration Pain, anxiety Hypotension Acidosis Anemia Drugs, catecholamines	Medical treatment rarely necessary. Interventions are focused toward treating the underlying causes, because sinus tachycardia is frequently a compensatory mechanism for an underlying problem.
Sinus bradycardia	Normal in configuration with rate too slow for the age of the child Common in preterm newborns	Immaturity of newborn conduction system Measures such as suctioning, feeding, or passing of a nasogastric tube resulting from increased susceptibility to stimulation of the vagus nerve (cranial nerve X) Cardiac surgery (damage to the sinoatrial node) In children without cardiac disease, may be a late sign of hemodynamic compromise	Requires immediate intervention; left untreated, may lead to death within a short period. Medications (e.g., atropine, epinephrine) Pacemaker
Supraventricular tachycardia	Most common form of symptomatic rhythm disturbance seen during the newborn period (Kothari & Skinner, 2006). Sudden burst of heart rate greater than 220 bpm in an infant and 180 bpm in a child, without variations in the pulse rate; possible compromise in cardiac output	Wolff Parkinson White syndrome: heart with an accessory pathway providing a reentry mechanism for impulses creating atrial tachycardia (heart structurally normal) VSDs, ASDs, and the Ebstein anomaly of the tricuspid valve (Kantoch, 2005)	May subside spontaneously. Vagal maneuvers if documented with a 12-lead ECG. To disrupt the rhythm, have the child gag, cough, or create the motion of holding one's breath as if to strain when having a bowel movement. Pacemaker (if the child has one): The rate can be increased to a rate much higher than the child's usual rate, to overdrive pace the abnormal rhythm while decreasing the heart rate to normal. Cardioversion Medications: digitalis, propranolol (Inderal), verapamil, and amiodarone. IV adenosine, used to break supraventricular tachycardia is rapid and short acting, and has minimal side effects.

NIC 15–1 Nursing Interventions Classification: Dysrhythmia Management

Definition: Preventing, recognizing, and facilitating treatment of abnormal cardiac rhythms

Activities:

Ascertain patient and family history of heart disease and dysrhythmias
 Monitor for and correct oxygen deficits, acid–base imbalances, and electrolyte imbalances, which may precipitate dysrhythmias
 Apply EKG electrodes and connect to a cardiac monitor
 Set alarm parameters on the EKG monitor
 Ensure ongoing monitoring of bedside EKG by qualified individuals
 Monitor EKG changes that increase risk of dysrhythmia development: prolonged QT interval, frequent premature ventricular contractions, and ectopy close to the T wave
 Facilitate acquisition of a 12-lead EKG, as appropriate
 Note activities associated with the onset of dysrhythmias
 Note frequency and duration of dysrhythmia
 Monitor hemodynamic response to the dysrhythmia
 Determine whether patient has chest pain or syncope associated with the dysrhythmia
 Ensure ready access of emergency dysrhythmia medications
 Initiate and maintain IV access, as appropriate

Administer advanced cardiac life support, as indicated
 Administer prescribed IV fluids and vasoconstrictor agents, as indicated, to facilitate tissue perfusion
 Assist with insertion of temporary transvenous or external pacemaker, as appropriate
 Teach patient and family the risks associated with the dysrhythmias
 Prepare patient and family for diagnostic studies (e.g., cardiac catheterization or electrical physiologic studies)
 Assist patient and family in understanding treatment options
 Teach patient and family about actions and side effects of prescribed medications
 Teach patient and family self-care behaviors associated with use of permanent pacemakers and AICD devices, as indicated
 Teach patient and family measures to decrease the risk of recurrence of the dysrhythmias
 Teach patient and family how to access the emergency medical system
 Teach a family member CPR, as appropriate

From Bulechek, G. M., Butcher, H. K., & Dochterman, J. M. (2008). *Nursing interventions classification (NIC)* (5th ed.). St. Louis, MO: Mosby. Reprinted with permission.

children more than in white children, and in boys more than in girls (Towbin et al., 2006).

Cardiomyopathy may be termed *ischemic* or *nonischemic*. Ischemic cardiomyopathy is disease that is caused by ischemia to the heart. Such cases often result from coronary artery disease. Nonischemic cardiomyopathy occurs because of structural damage or malfunction of the heart muscle. Nearly all cases of pediatric cardiomyopathy are nonischemic.

Cardiomyopathy may also be termed *primary* or *secondary*. Primary cardiomyopathy is independent of other disease or is a result of unknown causes (idiopathic). Approximately 57% to 68% of pediatric cardiomyopathy cases are idiopathic (Cox et al., 2006). Because the causes of primary cardiomyopathy are not fully understood, preventive education cannot be provided. Secondary cardiomyopathy occurs as a result of a known cause, such as heart muscle inflammation (myocarditis) caused by viral or bacterial infections. Acquired immune deficiency syndrome has also been associated with cardiomyopathy. Exposure to certain toxins, including cancer therapy with chemotherapeutic agents such as doxorubicin (Adriamycin), and certain disorders that affect the heart or other organ systems have been associated with cardiomyopathy.

The clinical course of patients varies. Death can be sudden (presumably from a lethal arrhythmia) or progressive, with slow deterioration of heart function and

worsening symptoms of heart failure. Yet, other children with the diagnosis of cardiomyopathy may have cardiac function that remains static for many years and can live a relatively active life (Nugent et al., 2005).

Pathophysiology

Cardiomyopathy in children falls into three functional classifications based on the mechanism of heart failure as systolic impairment or abnormal compliance:

1. **Dilated (congestive):** Cardiac dilation and enlargement of all four chambers, with progressive deterioration of cardiac output and heart failure. Decreased stroke volume and decreased cardiac output lead to systemic and pulmonary congestion, which are compensated for by increased heart rate, increased sympathetic stimulation, and dilated chambers.
2. **Hypertrophic:** Gross ventricular hypertrophy leading to impaired ventricular filling. Thickening of the ventricular wall narrows the ventricular cavity, restricting its ability to fill and causing abnormal stiffness of the left ventricle. Hypertrophic cardiomyopathy is most commonly noted during adolescence and early adulthood, after symptoms begin to express themselves.
3. **Restrictive:** Impaired diastolic ventricular filling related to excessive stiffness of the ventricular walls. Secondary factors that can cause restrictive cardiomyopathy

CLINICAL JUDGMENT 15–3

A Child With Altered Cardiovascular Status

Rick is a 14-year-old boy admitted to the emergency room after passing out while playing basketball with his brother in their backyard. He has a permanent cardiac pacemaker that was inserted 5 years earlier. Now Rick is awake and complaining about having to go to the hospital. His mother states he has been easily fatigued lately.

Questions

1. During your assessment, what other information would you elicit about Rick's current illness?
2. What are reasons for syncope in a child with a permanent pacemaker?
3. What would be your initial intervention?
4. What information might be gained by placing the patient on a cardiac monitor?
5. If Rick is currently hemodynamically stable and his rhythm on the monitor is normal, what further action is required?

Answers

1. What is his underlying cardiac problem? When was his last cardiac follow-up appointment? Does he take any antiarrhythmic medications? Did he miss any dosages? What are his previous cardiac surgeries? Is this his first episode of syncope? What are his pacemaker settings? What are his heart rate and blood pressure?
2. It is important to make sure Rick has been seen recently for a checkup, because the pacemaker battery is 5 years old and it may have reached its limits. He could be having an arrhythmia that is abnormal and faster than the pacemaker settings. He could have a cracked pacing lead, causing the pacemaker to malfunction. If he is taking antiarrhythmic medications to suppress a tachyarrhythmia and has been nonadherent in taking the medications, he could have a breakthrough arrhythmia.
3. Place Rick on the cardiac monitor to determine his current heart rhythm.
4. This will depend on the reason for his syncope. Information gained from a basic ECG will simply let you know if he is currently using his pacemaker and if his rhythm is normal at this time. It is also possible that his syncope was caused by a rhythm disturbance that occurred on exertion when playing basketball.
5. His cardiologist should be notified of his admission to the emergency room. Rick should be referred to his pacemaker clinic and placed on a 24-hour Holter monitor to determine his heart rhythm over this period of time. Also, if there was a lapse in taking his medications, teaching and behavior modification efforts should be used.

include glycogen deposits, neoplastic infiltrates, and iron deposits. Despite poor filling, contractile function is normal.

Assessment

The clinical presentation is the same regardless of the underlying cause. Assess for a murmur and for signs and symptoms of heart failure, such as hepatomegaly, tachycardia, jugular venous distention, fatigue, dyspnea on exertion, and orthopnea. As heart function worsens, the likelihood of arrhythmias increases. Common initial symptoms include shortness of breath, dyspnea on exertion, paroxysmal nocturnal dyspnea, peripheral edema, and history of syncope or palpitation.

The chest radiograph shows four-chamber enlargement and pulmonary congestion. This pulmonary congestion can lead to pulmonary hypertension and possible pleural effusions. An echocardiogram is the main diagnostic tool, which diagnoses as well as monitors changes in the size of the heart walls and cardiac output. Myocardial biopsy is done when cardiomyopathy is suspected. It can be useful to rule out myocarditis and some of the causes of cardiomyopathy, but generally does not add to the treatment plan.

Interdisciplinary Interventions

If a specific reason (such as a carotene deficiency) for the cardiomyopathy can be found, the child may benefit from interventions directed specifically to treat the origin of the illness. Otherwise, management is aimed at extending the length and improving quality of life for the child by minimizing symptoms and complications.

Medications given vary somewhat, depending on the type of cardiomyopathy. For dilated cardiomyopathy, pharmacologic therapy is the same as that for heart failure. For hypertrophic cardiomyopathy, beta blockers such as propranolol (Inderal) are administered to decrease outflow tract obstruction and to minimize arrhythmias. Calcium channel blockers, such as verapamil or nifedipine, may be used to improve diastolic filling. For restrictive cardiomyopathy, interventions include diuretics, but not digoxin, because systolic function is adequate. Steroids are administered to patients with known inflammatory disease. Children with cardiomyopathy are at risk for clot formation and benefit from anticoagulant medications such as aspirin or warfarin (Coumadin).

Activity restriction or bed rest is recommended to reduce the workload on the heart. As children become ill,

fatigue is the limiting factor on activities. As heart functions worsen, children are subjected to increasingly frequent hospital admissions for inotropic support such as IV dobutamine.

One of the more complicated features of caring for a child with cardiomyopathy is determining the proper timing for a heart transplant (see the earlier discussion of Cardiac Transplantation). For a child to die prematurely, when survival with transplantation was a wanted and practicable option, is tragic. Yet, the practitioner does not want to prematurely recommend transplantation for a child who could have maintained a relatively decent quality of life with cardiomyopathy.

Caregivers need to provide emotional support and strategic management of activities that are enjoyable to a child but do not overtax the heart. When increasing activity is a drain on energy reserves, appetites tend to decrease as well. Nutritional consultation and favorite foods that are nutritionally balanced can be beneficial.

Lipid Abnormalities

Dyslipidemia is abnormal (decreased or elevated) concentrations of cholesterol, triglycerides, or both; hyperlipidemia is elevated concentrations of cholesterol, triglycerides, or both. The atherosclerotic process begins during childhood in association with high blood cholesterol levels (McMahan et al., 2006). Individuals with abnormal lipid profiles during childhood have a much greater chance of developing atherosclerotic disease during adulthood. Educational promotions aimed at reducing serum cholesterol levels in children have been made in the hopes of establishing good childhood health habits that will extend into adulthood and reduce adult atherosclerotic disease.

Pathophysiology

Cells require cholesterol for survival. Cholesterol is used for the synthesis of cellular membranes and steroid production. Because the body has the ability to produce cholesterol, it is impossible to completely remove cholesterol through diet restriction.

Lipoproteins are protein-coated packages that carry cholesterol and fat in the blood. Low-density lipoprotein (LDL) cholesterol is the main transporter in the plasma of cholesterol to cells and is synthesized in the liver. Because LDL deposits cholesterol on the artery walls, promoting atherosclerosis, high levels are undesirable. High-density lipoprotein (HDL) cholesterol transports cholesterol from the bloodstream to the liver for secretion in the bile. This is desirable because it removes cholesterol from the body, thus it cannot build up on artery walls. *Triglycerides* are compounds of fatty acids synthesized from carbohydrates and are the main storage fuel for energy. Triglycerides are carried on *very low-density lipoprotein* molecules. The importance of elevated triglyceride levels measured during childhood to cardiovascular risk in adulthood is unknown.

There are three forms of lipoprotein abnormalities: genetic, disease related, and environmental. Genetic

causes of elevated lipoproteins are the primary form of the disease. Familial hypercholesterolemia is an autosomal-dominant condition (McCrindle et al., 2007). Thus, parents with familial lipid diseases have a 50% chance of passing the condition on to their children.

Several genetic disorders in children lead to dyslipidemia. In familial *hypercholesterolemia*, faulty gene coding of LDL receptors causes ineffective LDL clearance and results in elevated plasma levels. Familial hypercholesterolemia is a rare genetic disease that does not respond well to treatment and causes young children to develop coronary artery disease. In children, *hypertriglyceridemia* causes elevated triglyceride levels and, frequently, low HDL values. Another genetic disorder of lipids is familial *hypoalphalipoproteinemia*, which causes low HDL values. These children are at risk for developing early heart disease, especially if early interventions are not taken.

During childhood, some of the secondary disease-related causes of dyslipidemia include diabetes mellitus, hypertension, hypothyroidism, liver disease, and nephrotic syndrome. During infancy, dyslipidemia is usually related to glycogen storage diseases or congenital biliary atresia. Secondary environmental causes of dyslipidemia include obesity, inactivity, smoking, steroids, oral contraceptives, and, especially, a diet high in cholesterol and fats.

Assessment

In most individuals, atherosclerosis, or hardening of the arteries, is not diagnosed until adulthood, when they are already symptomatic and have substantial disease present. It can be assumed that this disease develops slowly throughout life, starting during childhood, and may be well underway by adolescence, but the child is asymptomatic.

Diagnostic Tests

Screening is recommended for children with a family history of premature cardiovascular disease or dyslipidemia, whose family history is unknown, or for those with risk factors for cardiovascular disease such as those who smoke, have hypertension, are overweight or obese, or have diabetes (Daniels, Greer, & Committee on Nutrition, 2008). Screening should take place after the age of 2 years, but no later than 10 years. If a child has values within the normal range, testing should be repeated in 3 to 5 years (Daniels et al.).

A lipid profile provides valuable information about total cholesterol, total triglycerides, HDL cholesterol, and LDL cholesterol. Desirable *total cholesterol* levels are less than 170 mg/dL, borderline levels are 170 to 199 mg/dL, and high levels are ≥ 200 mg/dL (Daniels et al., 2008). Plasma lipids are separated via a centrifuge and are grouped based on size and density. Blood is not drawn specifically to determine LDL levels; this information is calculated based on the levels of the three other components.

For *LDL cholesterol*, a value of less than 110 mg/dL is a desirable level. Borderline levels are 110 to 129 mg/dL, and high levels are ≥ 130 mg/dL (Daniels et al., 2008). Individuals with high levels of LDL cholesterol are at high risk for coronary heart disease.

For *HDL cholesterol*, a value of less than 35 mg/dL is a cardiac risk factor in children and adolescents (Daniels et al., 2008). High levels of HDL are considered to shield against vessel disease.

Triglyceride levels of more than 150 mg/dL are considered abnormal (Daniels et al., 2008).

Interdisciplinary Interventions

Modification of risk factors is the goal for all children with dyslipidemia. Because there have been no lifelong studies showing the results of childhood preventive measures to lower cholesterol levels, it can only be assumed that early treatment can minimize the risk of developing coronary artery disease as an adult.

Cholesterol-reducing medications should be considered for children who are more than 8 years old and who have high LDL concentrations (Daniels et al., 2008). Interventions for younger patients with elevated cholesterol readings should focus on weight reduction and increased activity in conjunction with nutritional counseling. Daniels et al. (2008) recommend the use of reduced-fat dairy products, such as 2% milk, for children as young as 1 year of age for whom overweight or obesity is a concern.

If diet therapy and exercise alone are not successful in controlling resistant cholesterol levels, drug therapies are administered judiciously. Two bile acid-binding resins—cholestyramine resin and colestipol—are the recommended drugs for pediatric patients. They work by binding bile acids in the intestines; they are excreted in the feces and therefore are not absorbed systematically. Occasionally, niacin is taken alone or as adjunct therapy with resin binders. High doses of niacin suppress production of LDL cholesterol by the liver. Liver function tests must be ordered routinely during niacin treatment, because it can cause hepatic inflammation. Statins, such as lovastatin or simvastatin, may also be used in children. Generally, statins should not be started before the onset of menses in girls and before the age of 10 years in boys (McCrinkle et al., 2007).

Community Care

Modification of risk factors requires education about nutrition therapy and weight management, such as the American Heart Association—National Cholesterol Education Program diets, low-fat diets high in soluble fiber, diets with plant stanol ester-containing margarines, and diets containing fish oils (omega-3 fatty acids). Regular physical activity and smoking cessation are also important, and pharmacotherapy may be indicated.

Nutritional education includes teaching about a diet low in total fat, cholesterol, and saturated fat for children older than 2 years of age (Tradition or Science 15–2). A recommended dietary program is one that derives 28% of energy from total fat, with less than 8% from saturated fat, up to 9% from polyunsaturated fat, and less than 75 mg/4,200 kJ cholesterol (not to exceed 150 mg/day [Van Horn et al., 2005]).

Obesity education focuses on achieving a proper weight ratio for height, age, and body structure. Obese children tend to come from obese families. In those cases,

TRADITION OR SCIENCE 15–2

Does a low-fat diet interfere with growth or nutritional adequacy in children?

EVIDENCE-BASED PRACTICE

Dietary fat is an important component of balanced nutrition. Dietary fat intake is particularly important in young children, because it is essential for normal development, especially myelination of the nervous system. Reducing fat intake is an important component of managing dyslipidemia in adults, but for children, some still voice concerns about long-term consequences of fat-modified, cholesterol-lowering diets on adequate nutrition and growth, and about potential adverse psychological effects. Reducing total fat intake to the levels in the Step II diet is safe and does not interfere with growth, sexual maturation, or nutritional adequacy in preadolescents (Lauer et al., 2000; Obarzanek et al., 2001). Several studies have shown that fat intake is not associated with growth of young children (Boulton & Magarey, 1995; Jacobson et al., 1998; Lagstrom et al., 1999; Niinikoski et al., 1997; Shea et al., 1993). Studies have shown no adverse effect on neurologic development (Rask-Nissilä et al., 2002) or academic functioning, psychological symptoms, or family functioning (Lavigne et al., 1999). The evidence demonstrates that reduced-fat diets for children are safe. Children receiving dietary intervention are significantly more likely to make healthy food choices (Van Horn et al., 2005). Teach children and families how to eat a healthy diet and be more physically active (see American Heart Association et al. [2006] and Williams et al. [2002] for specific interventions).

behavior modification and education have to meet the needs of the family as a whole. If an obese child is living in a family of normal weight individuals, overeating habits may have an emotional component, and those problems, as well as dietary adjustments, must be addressed. Nutritional education has to emphasize that eating habits must change for a lifetime.

The current culture of our society popularizes sedentary activities such as watching television, using computers, and playing video games. Maintaining cardiovascular fitness requires regular physical activity. To increase awareness, it may be helpful for a family to document the hours they spend participating in sedentary activities and compare them with the hours spent on physical activities.

Smoking habits generally begin during the adolescent years. If a teenager is diagnosed with dyslipidemia, and the parents deny that the child smokes, counsel the child separately. Preemptive education of children can help alleviate the potential problem of smoking.

Through behavior modification, most individuals are able to regulate their blood cholesterol levels. A thorough understanding of dyslipidemia, risk factors, and preventive care is important. Cholesterol awareness and education is an important teaching tool in all aspects of nursing care.

Hypertension

In children, high blood pressure is defined as a systolic and/or diastolic blood pressure greater than or equal to the 95th percentile for the child's age, height, and gender on three or more occasions (National High Blood Pressure Education Program Working Group on Hypertension Control in Children and Adolescents, 2004).

Currently, hypertension in children is classified into four groups (National High Blood Pressure Education Program Working Group on Hypertension Control in Children and Adolescents, 2004):

1. Normal: Systolic/diastolic less than 90th percentile
2. Prehypertension: More than 90th and less than 95th percentile, or blood pressure exceeding 120/80 mm Hg
3. Stage 1: Blood pressure between the 95th percentile and 5 mm Hg more than the 99th percentile
4. Stage 2: Blood pressure more than the 99th percentile plus 5 mm Hg

Hypertension is further classified as *primary* (essential), if no cause can be found for the elevated blood pressure, or *secondary*, if it results from other pathology such as renal disease, heart or vascular disease (PDA, COA), endocrinopathy, or central nervous system changes. If hypertension is caused by underlying pathology, that pathology should be treated to reduce the blood pressure. This discussion focuses on primary hypertension.

An estimated 1.8% to 4.5% of children worldwide are hypertensive (Sorof et al., 2004; Stergiou et al., 2005). Another 2% have white-coat hypertension, in which blood pressure is elevated when taken in a healthcare setting but normal outside a clinical setting, and 3.8% have masked hypertension, in which blood pressure is normal in a healthcare setting but elevated when out of a clinical situation (Stergiou et al., 2005). Although primary hypertension is far more common among adults, the rate among children is rising—a trend that researchers link to the increase in childhood obesity (Falkner et al., 2006). Familial predisposition and elevated body mass index are risk factors for primary hypertension (Robinson et al., 2005). In one study, 30% of children with a family history of essential hypertension had a diastolic blood pressure in the more than 95th percentile (Surekha et al., 2003).

Pathophysiology

When a child has high blood pressure, the heart must pump harder and the arteries are under greater strain as they carry blood. Over time, high blood pressure can damage the heart, kidneys, and brain. Hypertension puts a child at higher risk for stroke, heart attack, kidney failure, loss of vision, and atherosclerosis. Left ventricular hypertrophy is present in about 20% to 40% of hypertensive children, with obesity being the primary risk factor for left ventricular hypertrophy (Hanevold et al., 2004; National High Blood Pressure Education Program Working Group on Hypertension Control in Children and Adolescents, 2004). Hypertensive children tend to have other medical problems, such as obesity, high blood lipids, diabetes mellitus, or some combination of these

factors. Childhood hypertension is a predictor for adult hypertension.

Assessment

The history, physical examination, and laboratory evaluation of hypertensive children and adolescents should include assessment for additional risk factors for other problems, particularly for cardiovascular disease. Elicit information about family history of hypertension; hyperlipidemia; diabetes; obesity; and cardiovascular, renal, or endocrine disease. Ask about the child's diet and habits (smoking, alcohol intake) and sleep history, because snoring, abnormal sleep patterns, or sleep-disordered breathing may be associated with higher blood pressure (Amin et al., 2004; Kwok, Ng, and Cheung, 2003).

For health maintenance, blood pressure should be measured

- When a child older than 3 years of age is seen in a medical setting
- In a child younger than 3 years of age with a history of a neonatal condition requiring intensive care; symptoms of hypertension, hypotension, elevated intracranial pressure, recurrent urinary tract infections, renal or cardiac disease; malignancy or transplant (solid organ, bone marrow); treatment with medications known to affect blood pressure

Auscultation is the preferred method of measuring blood pressure in children, because automated devices require frequent calibration, and established reference standards for children are lacking. Automated devices are acceptable when auscultation is difficult (e.g., in young children) or when frequent measurements are required. The cuff width should be 40% of the circumference of the arm as measured midway between the olecranon and acromion, and the cuff bladder length should cover 80% to 100% of the circumference of the arm. If a cuff is too small, use the next larger size. Explain to the child and family why monitoring is important, how it is done, and what equipment is used (see [thePoint](#) for Procedures: Vital Signs: Blood Pressure).

KidKare ■ ■ Use language that is appropriate for developmental level. For example, "I'm going to see how your heart is working. You will feel like your arm is getting a hug."

Have the child rest quietly for 5 minutes before measuring blood pressure. Use the right arm whenever possible for consistent measurement and comparison with standard norms. When deflating the cuff, note Korotkoff (K) sounds. Note K1, the onset of the beating or tapping sound, as the systolic reading (systolic blood pressure). Note K5, the disappearance of Korotkoff sounds, as the diastolic reading (diastolic blood pressure). If sounds can be heard to 0 mm Hg, repeat the measurement, using less pressure on the head of the stethoscope. If the very low K5 measurement persists, use K4, muffling of the sound,

as the diastolic blood pressure (National High Blood Pressure Education Program Working Group on Hypertension Control in Children and Adolescents, 2004).

Compare the child's blood pressure with previous readings and age-appropriate norms (see Appendix D) to detect changes in status and potential pathology. Blood pressure is typically equal in the upper and lower extremities until about 6 to 9 months of age. At that time, blood pressure in the lower extremities is higher than in the upper extremities.

If the child's blood pressure is more than the 90th percentile, repeat the measurement twice at the same visit and use an average of the readings for systolic blood pressure and diastolic blood pressure (National High Blood Pressure Education Program Working Group on Hypertension Control in Children and Adolescents, 2004). If the child's blood pressure is more than or equal to the 95th percentile, repeat the measurement on at least two additional occasions to confirm the diagnosis (National High Blood Pressure Education Program Working Group on Hypertension Control in Children and Adolescents, 2004).

Clinic measurements may be unreliable for assessing a child's hypertensive status, because the child may be stressed by the visit or, because blood pressure constantly fluctuates, the reading may not capture hypertensive periods. Ambulatory blood pressure monitoring, typically over 24 hours, enables more comprehensive blood pressure assessment and may be performed in children for whom more information on blood pressure patterns is needed (Lurbe, Sorof, and Daniels, 2004).

Assess for signs and symptoms of hypertension, including headache, bounding pulse, visual changes, dizziness, nosebleeds, heart palpitations, and nausea. In infants and toddlers, the symptoms of hypertension may be irritability, excessive crying, poor feeding, or failure to gain weight. Although a child may not demonstrate symptoms, high blood pressure still puts the child at risk for long-term health problems.

Diagnostic Tests

Laboratory screening for hypertensive children also commonly includes urinalysis and culture, complete blood cell count with platelets, blood urea nitrogen, creatinine, electrolytes, fasting glucose, and lipid panel. A renal ultrasound is performed to evaluate kidney function.

Interdisciplinary Interventions

Management of the child with hypertension involves non-pharmacologic and pharmacologic interventions. Non-pharmacologic interventions are indicated for children with blood pressure in the more than 90th percentile.

Nonpharmacologic Interventions

The first line of treatment should be family-based therapeutic lifestyle modifications that focus on diet and exercise. Encourage a diet that is high in fresh fruits and vegetables, and low in salt. The National High Blood Pressure Education Program Working Group on Hypertension

Control in Children and Adolescents (2004) salt-restriction recommendations are a sodium intake of less than 1.2 g/day for 4- to 8-year-olds and 1.5 g/day for older children. Teach children and families to avoid adding salt to their food, to avoid processed foods and salty snacks such as chips and pretzels, and to review school menus for sodium content.

Physical activity is key to weight, blood pressure control, and cardiovascular fitness. The National High Blood Pressure Education Program Working Group on Hypertension Control in Children and Adolescents (2004) recommends regular, moderate aerobic activity for 30 to 60 minutes on most days and limiting sedentary activities to less than 2 hours per day. Children who have uncontrolled stage 2 hypertension should not participate in competitive sports until their blood pressure is under control.

If the child is overweight, teach methods of weight reduction. Diet therapy, as discussed earlier in Lipid Abnormalities, can help with weight reduction.

Encourage children and families to practice stress reduction and relaxation techniques, and to limit caffeine intake, which may also help lower blood pressure. Children with hypertension should also quit, or never start, smoking, which can worsen the long-term associated heart problems. Alcohol intake can also increase the risk for hypertension and should be discouraged.

Pharmacologic Interventions

If the child has symptomatic hypertension, established hypertensive target organ damage, or mild hypertension unimproved by 6 months of lifestyle changes, medications are indicated (National High Blood Pressure Education Program Working Group on Hypertension Control in Children and Adolescents, 2004). Angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, beta blockers, calcium channel blockers, and diuretics may be prescribed. The goal of pharmacologic therapy is to reduce blood pressure to less than the 95th percentile, unless concurrent conditions are present; if so, the goal is to reduce blood pressure to less than the 90th percentile (National High Blood Pressure Education Program Working Group on Hypertension Control in Children and Adolescents, 2004). Educate the child and family about the effects and side effects of prescribed medications, and caution them not to discontinue the medications without direction from their healthcare provider, even if they feel better and have no symptoms of hypertension.

Community Care

Managing hypertension requires a long-term commitment to healthy lifestyle habits. Teach and reinforce the nonpharmacologic interventions discussed here. Advocate for increased physical activity and healthy food choices at schools. Actions such as removing vending machines or replacing sodas and candy with healthier choices; pricing healthy food choices lower than unhealthy choices; and limiting sales of cookies, doughnuts, and candy as fundraisers may have a positive effect on children's intake.

Although severe hypertension is rare in children, even mild to moderate hypertension over time can damage the heart, kidneys, and blood vessels. Therefore, taking clinical measures to reduce these risks and optimize health outcomes is important.

Infective Endocarditis

Children with heart defects may develop endocarditis, a serious infection of the endocardial surface of the heart. A bloodstream infection is believed to be more likely to lodge in the heart as a complication of having CHD or, in the rare case of a child with Kawasaki disease or rheumatic heart disease, with valve dysfunction. Endocarditis can also occur in a child without any heart disease and is often associated with central indwelling venous catheters. This infection usually involves the aortic or mitral valve.

Pathophysiology

In children with CHD or valve dysfunction, bacteria or other pathogens attach to endocardial surfaces because these children have areas in their heart where the cardiac endothelium is damaged or interrupted by an abnormal flow, turbulence, or artificial materials and is therefore susceptible. Infectious organisms that are most likely to be found in a positive blood culture in the presence of endocarditis are *Staphylococcus aureus*, *Streptococcus*, and *Candida* (Baddour et al., 2005; Hickey et al., 2009). Pathogens that cause endocarditis are introduced into the bloodstream by dissemination from infected tissue or by procedures that damage mucosal surfaces. Bacteria may enter the bloodstream from the mouth after dental procedures or after an infection in the throat, ears, or chest. Indwelling vascular catheters and intestinal, urinary tract, and vaginal procedures or surgeries also are events that put the child at increased risk for endocarditis. Improved cardiac surgical repair techniques, repairing pediatric conditions at an earlier age, and giving prophylactic antibiotics have improved outcomes for patients at risk for endocarditis.

Damage to the endothelial tissue of the heart chambers or valves stimulates platelet deposition and localized thrombosis. This process eventually results in sterile clumps of platelets, fibrin, and, occasionally, red blood cells; these clumps are called *vegetations*. Invading organisms can adhere to vegetations and promote further thrombosis.

Assessment

Signs and symptoms of endocarditis can be elusive. Symptoms might include fever, decreased activity level, a new murmur or changes in an existing one, and neurologic symptoms such as seizures. Laboratory values showing decreased hemoglobin, increased sedimentation rate, and hematuria can help in making the diagnosis. Skin changes such as petechiae (minute hemorrhages from fragile capillaries) are rare in children and are probably caused by microemboli from vegetations.

Diagnostic Tests

When endocarditis is suspected, a definitive diagnosis is achieved through blood cultures drawn from two separate sites. A negative blood culture does not rule out endocarditis; it just indicates a lesser likelihood that it is present.

Routine chest radiographs, echocardiography, and transesophageal echocardiography are tools used to aid in the diagnosis of endocarditis by locating vegetation within the heart. However, negative findings (no vegetation) do not rule out endocarditis.

Interdisciplinary Interventions

If the diagnosis of bacterial endocarditis is suspected, antibiotics are administered after blood cultures are drawn. Antibiotic selection is based on culture and sensitivity results. Antibiotics are administered intravenously over a 4- to 6-week period.

The most therapeutic and cost-effective treatment of endocarditis is preventive therapy with antibiotics. The American Heart Association (Wilson et al., 2007) recommendations include oral amoxicillin for prophylaxis with some routine dental work for cardiac patients at highest risk. Clindamycin or erythromycin is taken if the patient is unable to take amoxicillin. Antibiotics are recommended to be taken 1 hour before a procedure.

Preventing endocarditis is important. Teach parents the importance of notifying any healthcare provider, including dentists, about the child's condition and potential need for prophylactic antibiotic therapy. The American Heart Association produces several patient education pamphlets with complete guidelines that can be given to patients who are at risk for endocarditis. Be proactive in counseling parents of high-risk children who could benefit from prophylactic antibiotics. In addition, teach the child and parents about signs and symptoms of bacterial endocarditis, including those that warrant a call to their healthcare providers.

Kawasaki Disease

Kawasaki disease is a generalized vasculitis that is an acute, usually self-limiting, multiple-organ system disease of childhood. This disease was first described by Kawasaki (1967) as mucocutaneous lymph node syndrome. The etiology of the disease is unknown but may involve an infectious agent. Kawasaki disease occurs most frequently in Japan and in children of Japanese and Pacific Island heritage. Black and Hispanic children are at intermediate risk, and white children are at lowest risk (Newburger et al., 2004). Kawasaki disease most commonly occurs in winter and spring, and affects children younger than 5 years of age (Pinna et al., 2008). The incidence of Kawasaki disease varies worldwide. Japan has the highest incidence, at 134 per 100,000; incidence in the United States is 17.1 per 100,000 (Pinna et al., 2008).

Approximately 20% of children with Kawasaki disease develop coronary artery abnormalities, which lead to

ischemia, myocardial infarction, and death in some children. Kawasaki disease is the leading cause of acquired heart disease in children (Pinna et al., 2008); therefore, follow-up care in community settings is an important piece in the continuum of care for this disease.

Pathophysiology

Kawasaki disease is generally regarded as a triphasic disease comprising acute, subacute, and convalescent stages. The acute phase (1–11 days) is characterized by progressive inflammation of the small vessels, and complications may include early arthritis, uveitis, meningitis, perivasculitis, myocarditis, pericarditis, mitral insufficiency, and heart failure. During the subacute phase (11–21 days), inflammation of the medium-sized muscular arteries leaves the patient at risk for coronary artery aneurysm and at greatest risk for serious cardiovascular complications, as well as late-onset arthritis, gallbladder hydrops, fingertip and toe desquamation, thrombocytosis, mitral insufficiency, and coronary artery thrombosis. The convalescent phase (21–60 days) begins as the walls of the vessels begin to heal inward. Complications of this phase may include the persistence of arthritis; aneurysms may persist and long-term scarring may form in affected vessels. The children at greatest risk are children with prolonged fever (Newburger et al., 2004).

Assessment

Assess for signs and symptoms of infection and inflammation. The diagnosis is confirmed if the child has been febrile for at least 5 days and demonstrates at least four of the clinical criteria as shown in Chart 15–4. Children are often very irritable, perhaps as a result of cerebral vasculitis and aseptic meningitis.

CHART 15–4 CLINICAL CRITERIA FOR KAWASAKI DISEASE*

- Fever that persists for 5 days or more
- At least four of the following:
 - Bilateral conjunctivitis (without exudate)
 - Oral mucosal changes (dry, cracked lips and tongue, strawberry tongue, diffuse reddening of the oral and pharyngeal mucosa)
 - Changes in the extremities (edema of the hands and feet, reddening of the palms and soles, membranous desquamation of the fingertips and toes)
 - Erythematous rash, often in the perineal area
 - Nonpurulent swelling of cervical lymph nodes more than or equal to 1.5 cm in diameter

*Kawasaki disease can be diagnosed in children with fever for more than 5 days and less than four other features when coronary artery abnormalities are detected by two-dimensional echocardiography or angiography.

Diagnostic Tests

Laboratory features associated with Kawasaki disease include a leukocyte count of more than 15,000 leukocytes/ μL with left shift, an elevated erythrocyte sedimentation rate and C-reactive protein level of 770 mg/L, a platelet count of 500,000 to 1,000,000 platelets/ mm^3 , and sterile pyuria (Newburger et al., 2004).

Interdisciplinary Interventions

Children with Kawasaki disease may need hospitalization for diagnostic purposes, for medical indications, or for initiation of therapy. An echocardiogram is obtained at baseline and at regular intervals throughout the disease course and convalescence to monitor myocardial and coronary artery status. Monitor the child closely for signs of heart failure, such as increased respiratory rate, increased heart rate, dyspnea, rales, and abdominal distention.

Comfort Measures

Joint pain may limit a child's mobility and may require comfort measures. Frequent oral care and a clear-liquid diet are provided to minimize mucous membrane pain. Assess mobility and consider passive range-of-motion exercise and elevating affected limbs if arthralgia develops.

Environmental modification may reduce irritability; these modifications may include dim lighting and noise control. Provide age-appropriate bed rest activities to minimize the child's activity and irritability; child life and volunteer services may be very useful in providing diversional activities.

Pharmacologic Interventions

Intravenous gamma globulin (IVIG) is administered in conjunction with high-dose aspirin during the acute phase to reduce the risk of coronary artery abnormalities. Current recommendations indicate that a single infusion of IVIG is ideal. Therapy should be instituted within the first 10 days of illness and, whenever possible, between days 5 and 7 (Newburger et al., 2004). The high-dose aspirin in conjunction with the IVIG appears to provide an additive anti-inflammatory effect. The aspirin dose is adjusted to low-dose administration anywhere from day 3 to day 14 after administration of IVIG. Aspirin is used for its antiplatelet effects. Aspirin therapy usually continues for a minimum of 6 to 8 weeks; if coronary arterial abnormalities develop, it may be continued indefinitely (Newburger et al., 2004). Children who are on chronic aspirin therapy for its antiplatelet effect should not use ibuprofen, because it antagonizes the irreversible platelet inhibition that is induced by aspirin (Newburger et al., 2004).

Monitoring of children receiving IVIG is similar to that for any patient receiving a blood product, including frequent observation for signs of allergic reaction. Particularly while high-dose aspirin therapy is delivered, be alert to signs and symptoms of bleeding caused by aspirin's

anticoagulant effect, such as tarry stools, excessive bruising, altered mental status, or excessive bleeding from the gums.

Community Care

Care in the community focuses on follow-up, instruction in CPR if cardiac damage has occurred, and signs of heart failure. Home care includes teaching about potential cardiac sequelae and the importance of adhering to therapy. Teach parents to monitor the child's temperature for several days after the return home, and report any fever. The family needs to understand that the disease is not spread from person to person. Except for measles and varicella vaccines, immunizations may be given at their scheduled times. To reduce the risk of Reye syndrome, which is associated with varicella or influenza infection that occurs concurrently with aspirin therapy, it is recommended that the child have an annual influenza vaccine. The healthcare provider may substitute another antiplatelet medication for aspirin during the first 6 weeks after varicella vaccination (Newburger et al., 2004).

caREminder

Measles and varicella vaccines should not be administered for 11 months after high-dose IVIG therapy because of the potential that neutralizing antibodies will diminish the effectiveness of live vaccines. If the child is at high risk of exposure to measles, immunization can occur earlier, with reimmunization 11 months or more after IVIG (Newburger et al., 2004).

Encourage families to obtain schoolwork for the child to do at home and facilitate the return to school when the child is cleared by the healthcare provider. The school nurse needs to be alerted to any limitation or necessary follow-up. Provide written discharge instructions so that they are available for future reference.

Frequent follow-up visits occur during the first 2 months after hospitalization. The child is assessed for cardiac arrhythmias, heart failure, valvular problems, and myocarditis. Serial ECGs and echocardiograms are used to assess for these conditions. All other symptoms of Kawasaki disease are self-limiting and will resolve within 6 to 8 weeks.

Acute Rheumatic Fever

Acute rheumatic fever is a sequela of group A beta hemolytic streptococcal respiratory infections. It is a multisystem disorder that may involve the heart, joints, central nervous system, and the skin. A latency period of about 20 days intervenes between a reported incidence of pharyngitis and the onset of symptoms of acute rheumatic fever. During the latency period, patients are asymptomatic.

The incidence of rheumatic fever in the United States has dropped dramatically during the past 50 years (Shulman et al., 2006), decreasing from 50 per 100,000 to 0.5 per 100,000 (Gerber, 2004). Improved socioeconomic conditions in the United States have been a major factor in reducing the incidence of this disease. Additionally, aggressive treatment of streptococcal pharyngitis with antibiotics and the initiation of long-term prophylactic therapy for those children who have had a prior episode of rheumatic fever have contributed to the reduction in incidence and severity.

WORLDVIEW: Acute rheumatic fever remains prevalent in socially and economically deprived population groups in which widespread poverty and overcrowding exist. Children need to be considered at risk if their living situation is characterized by poor sanitation practices and crowding. When the child presents with a cold or any of the clinical manifestations noted in the Jones criteria, the current or past presence of a streptococcal infection must be determined.

The increased incidence of streptococcal infections during fall, winter, and early spring is associated with an increased incidence of acute rheumatic fever during these same periods. Children age 5 to 15 years are more susceptible than others to group A streptococcal infections and, therefore, are also more susceptible to acute rheumatic fever. However, the condition has also been noted in older age groups where close personal quarters are maintained (e.g., the military services) (Gerber, 2004). The disease is slightly more common in girls than in boys and is now seen more in blacks than in other ethnic groups.

Recent outbreaks of rheumatic fever have not led to an overall increase in the incidence rate. Unlike previous outbreaks, in which overcrowding and poor sanitation were important predisposing conditions, the new outbreaks have occurred in middle-income and rural populations in which adverse socioeconomic conditions could not be implicated. Investigators have speculated that virulence factors associated with particular strains of group A beta hemolytic streptococcus may have played a greater role in these incidents.

Pathophysiology

Group A beta hemolytic streptococcal infection of the respiratory tract acts as a trigger for acute rheumatic fever in predisposed individuals. Host susceptibility to acute rheumatic fever implicates immune response genes, which are present in approximately 15% of the population. The immune response triggered by colonization of the pharynx with group A streptococci consists of

- Sensitization of B lymphocytes by streptococci antigens
- Formation of immune complexes that cross-react with cardiac sarcolemma antigens
- Myocardial and valvular inflammatory response

The disease involves the heart, joints, central nervous system, skin, and subcutaneous tissues. Acute

rheumatic fever is characterized by an exudative and proliferative inflammatory process of the connective tissue.

Assessment

The diagnosis of acute rheumatic fever is made by clinical criteria, because no single laboratory test is diagnostic. The *Jones criteria* provide a guideline in establishing the diagnosis of acute rheumatic fever (Chart 15–5). Traditionally, two major or one major and two minor criteria (plus supporting evidence of streptococcal infection) justified the diagnosis of rheumatic fever. However, physical findings may be so subtle and transient that the child's symptoms are marginal with respect to the standards of the criteria.

Assess for regurgitant murmurs, cardiomegaly, heart failure, pericardial friction rubs, and choreas. If rheumatic fever appears likely on the basis of appropriate evaluation but does not fully meet the revised Jones criteria, a diagnosis of suspected acute rheumatic fever is appropriate, resulting from the serious consequences of missing the diagnosis.

The most serious manifestation of acute rheumatic fever is carditis. It is the only manifestation that can cause mortality during the acute stage of the illness or that may result in long-term sequelae. Rheumatic carditis affects the endocardium and the pericardium. Overall,

endocarditis is the most important manifestation, because it is the only finding that results in residual chronic cardiac disease. Acute rheumatic carditis has four main clinical signs:

1. Regurgitant murmur
2. Cardiomegaly
3. Heart failure
4. Pericardial friction rubs

The absence of a murmur makes the diagnosis of rheumatic carditis unlikely. Carefully and frequently examine the child for the presence of a new murmur. The most common murmur is one of mitral regurgitation and generally occurs early during the acute attack. The murmur is holosystolic, is heard best at apex, and radiates to the left axilla. The murmur also has a high-pitched, blowing quality; is unchanged by position; and has an intensity of two or greater on a scale of six.

If the rheumatic process affects the central nervous system, the child will exhibit chorea (Sydenham's chorea, chorea minor, St. Vitus' dance). The latency period for chorea is from 1 to 6 months after an upper respiratory infection. Chorea is characterized by purposeless, involuntary movements; emotional lability; and muscular incoordination. The onset of the disease is usually insidious. Initially, the child is more clumsy than usual and may have a shortened attention span, which may lead to school-related problems.

CHART 15–5 JONES CRITERIA (REVISED)

Major Manifestations

Carditis

Polyarthritis (two or more joints with heat, pain, redness, and tenderness and swelling)

Sydenham's chorea

Erythema marginatum (macular erythematous rash with a circinate border on trunk and extremities)

Subcutaneous nodules (nontender, movable on scalp, over joints, and spinal column)

Minor Manifestations

Polyarthralgia (pain in two or more joints without heat, swelling, and tenderness)

Fever (low grade)

Previous rheumatic or heart disease

Acute Phase

Elevated erythrocyte sedimentation rate

C-reactive protein

Leukocytosis

Prolonged PR interval on ECG

Interdisciplinary Interventions

Treatment of acute rheumatic fever must match the manifestations and severity of the attack. Supportive management of carditis includes inotropic agents, diuretics, vasodilators, and, occasionally, corticosteroids. A definitive diagnosis is essential before aspirin or corticosteroids are administered, because these anti-inflammatory agents can mask other diagnoses, such as septic arthritis. Chorea is treated with sedatives and minor tranquilizers, and a quiet environment, as required.

Community Care

Prevention of acute rheumatic fever must be a priority for all healthcare providers working with children. All children older than 3 years of age with the symptoms of fever and sore throat need to be cultured for streptococcus, and those with positive cultures need to be treated with penicillin. Include this preventive teaching in anticipatory guidance discussions for parents, starting when the child is of preschool age, stressing the importance of contacting the physician for sore throat and fever that lasts for 24 hours, or rash. Also, mention the importance of notifying the physician when another child with strep throat is reported in school. Most schools send notification of potential contact with such illnesses home to the parents.

See [thePoint](#) for a summary of Key Concepts.

The Child With Altered Respiratory Status

Case History

Do you remember the Diaz family from Chapter 9, in which Jose has trouble taking his asthma medication, and in Chapter 4, in which Jose's little sister, Lela, expresses her personality even as a newborn? Jose is 4 years old and was diagnosed with asthma this past fall, about 6 months ago. Since that time Claudia, his mother, has noticed several factors that trigger his asthma including getting sick, pollen, and cold air.

One evening following a warm early-spring day, Jose is outside playing as the sun sets and the air cools. When he comes inside he begins to cough. Claudia sets up his nebulizer and gives him a treatment of albuterol, which lessens his coughing. Within an hour, Jose is coughing constantly again and wheezing. After one hard coughing fit, Jose has a hard time catching his breath; he looks pale and ashen, and his wheezing is very pronounced. Claudia tells her husband, Ignacio, that she thinks they should go to the emergency room. They

leave Lela, the baby sister, with Claudia's mother, Selma, and head to the hospital.

At the hospital the emergency department nurse observes Jose sitting cross-legged and leaning forward on his hands. His mouth is open and he is breathing hard with an easily audible inspiratory wheeze. He is using his subclavicular accessory muscles with each breath. His respiratory rate is 32 breaths per minute, his pulse is 112 beats per minutes, and he is afebrile. Claudia explains that he was fine; he was outside running and playing, and then came in and began coughing and wheezing, and she gave him an albuterol treatment. The nurse places a pulse oximeter probe on his finger, which takes a few minutes to establish reliability but settles down, vacillating between 89% to 90%. After reporting her assessment and receiving orders, the nurse adjusts the oxygen flow to 30% and places a simple oxygen face mask on Jose.

CHAPTER OBJECTIVES

1. Describe the developmental and biologic variances in children's respiratory systems that predispose them to respiratory problems.
2. Describe the common alterations in health patterns within the respiratory system in children in terms of etiology, pathophysiology, clinical manifestations, and interdisciplinary interventions.
3. Describe the nursing assessment of the child with compromised respiratory function.
4. Discuss the nursing care responsibilities associated with diagnosis of respiratory difficulties in children.
5. Select the treatments that are most effective for specific respiratory conditions.
6. Select nursing care interventions to support the child with an acute or chronic respiratory illness.

See [thePoint](#) for a list of Key Terms.

Respiratory conditions, both acute and chronic, are the leading causes of morbidity in children. Compromises to the respiratory system are the most common types of problem encountered by the nurse caring for infants, children, and youth. Respiratory conditions during childhood can be acute or chronic, life threatening, and can present as either the primary clinical problem or a secondary complication (also called a *comorbid condition*). Respiratory infectious conditions, such as influenza, are widely recognized as major causes of respiratory mortality and morbidity for young healthy children.

Growth and maturation of the respiratory system during childhood is characterized by changes in its physiologic and anatomic features. The physiologic processes of respiratory control and gas exchange in children, although immature, are determined by respiratory mechanisms similar to those of adults. However, anatomic structural variations in the respiratory tracts of infants and young children from those of adults result in substantial differences in the manifestations of respiratory disturbances. A key aspect of providing respiratory care in pediatric patients is recognizing these similarities and differences. Note these variations when identifying normal versus abnormal symptoms.

Assessment of the respiratory system is critical in pediatric care. Key functions of the nurse in the acute or ambulatory healthcare settings involve identifying changes in respiratory status and quickly instituting corrective measures if needed. In respiratory care, developing and refining assessment skills is essential to providing age-appropriate care for children. Therefore, the skilled nurse must have an excellent working knowledge and a keen understanding of the clinical importance of these unique anatomic and physiologic features of children's respiratory systems. Because respiratory system infections are relatively common in children and are a leading etiology in respiratory morbidity, understanding how infections can affect the respiratory system is important.

Knowledge of both acute and chronic respiratory conditions helps the nurse provide appropriate care throughout the child's life span.

DEVELOPMENTAL AND BIOLOGIC VARIANCES

QUESTION: How is it possible the Jose could "out-grow" his asthma as he gets older?

The child's respiratory system differs in many ways from that of the mature adult. The child is physically smaller and functionally immature; thus, the pediatric respiratory system has much less reserve capacity. Children are more vulnerable to respiratory illnesses and complications than adults. Infants and children develop **respiratory distress** (impaired respiratory function) and **respiratory failure** (respiratory impairment in which the arterial oxygen tension falls below 60 mm Hg, carbon dioxide tension rises to more than 50 mm Hg, and the arterial pH drops to less than 7.35) much more readily. Unique differences in the size, structure, and function of the respiratory system in children are shown in Figure 16–1.

This section summarizes variances in major structures and provides suggestions regarding ways to modify assessment skills and intervention techniques to provide optimal care to the child with altered respiratory status.

Central Nervous System Control

Respiratory rate and depth are controlled by central and peripheral chemoreceptors located in the circulatory system. Although these receptors are present at birth, fewer exist in the infant and young child than in the mature adult. Term infants and young children respond to **hypoxemia** (inadequate oxygen in the blood) and **hypercarbia** (excessive carbon dioxide in the blood) as an adult does, by increasing the rate and depth of respiration to normalize blood gas concentrations of oxygen and carbon dioxide. The premature infant, however, may respond to low blood oxygen levels initially with an increased rate of respiration, followed by a slowing respiratory rate, apnea, or both. Conditions such as bronchopulmonary dysplasia (BPD), pneumonia, and bronchiolitis put premature infants at especially high risk for developing hypoxia and apnea, so nursing care must focus on careful monitoring of blood gases.

Airways

The pediatric airway is much smaller in diameter and shorter in length than the adult airway. During childhood, the airways continue to grow in both diameter and length. For example, in newborns the trachea is 4 cm long, and in 18-month-old infants it is 7 cm long. In adults, it is 12 cm long. Airway inflammation or a small amount of mucus can produce a critical decrease

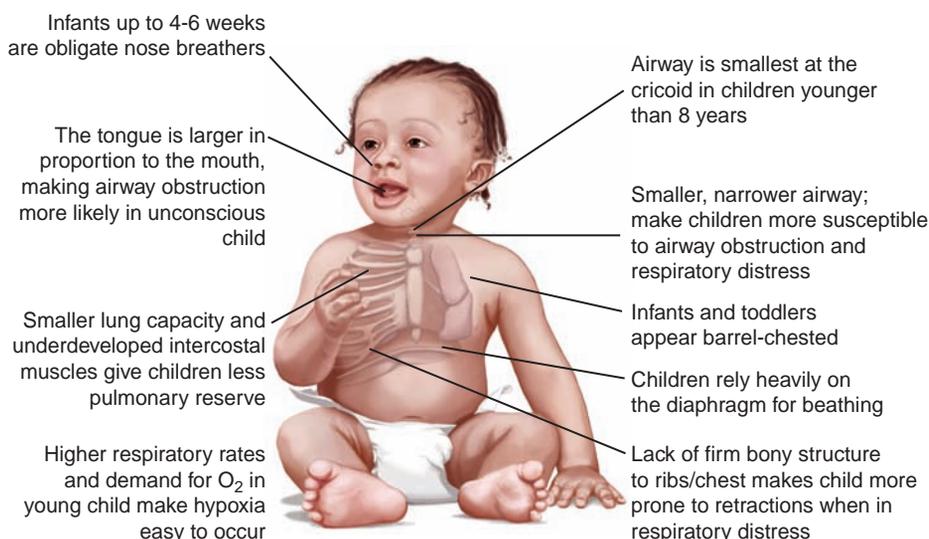

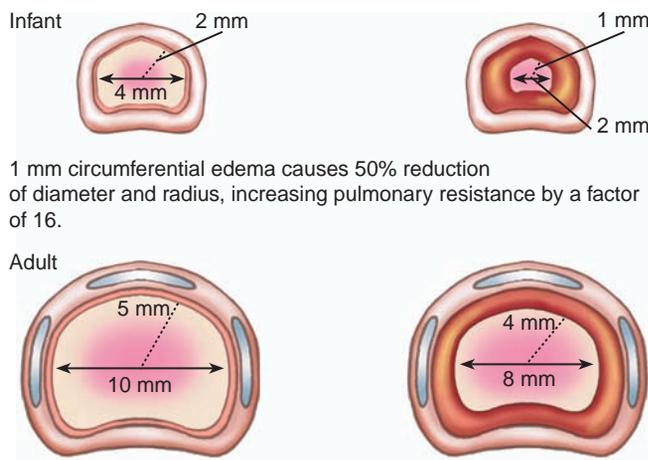

FIGURE 16-1. Developmental and biologic variances: respiratory.

in the airway diameter and increases the resistance to airflow dramatically, leading to substantial respiratory distress or even failure (Fig. 16-2). The pediatric tongue is larger in proportion to other structures than the adult tongue, and therefore causes airway obstruction more readily.

The pediatric larynx is funnel shaped because of a narrowing at the cricoid cartilage, with the narrowest portion at the level of the cricoid ring (Fig. 16-3).

caREminder

The child younger than age 8 who requires intubation usually does not need a cuffed endotracheal tube. The child's narrow cricoid provides a "natural physiologic cuff" around the uncuffed or straight tube.

1 mm circumferential edema causes 20% reduction of diameter and radius, increasing pulmonary resistance by a factor of 2.4.

FIGURE 16-2. A small amount of mucus can produce significant obstruction of the pediatric airway.

The cartilage surrounding the entire larynx is quite soft and can be compressed easily, subsequently causing airway occlusion when the neck is flexed or hyperextended. Maintaining an optimal neck position (sometimes called the *sniffing position*) by placing a towel under the occipital area of the head is an important nursing consideration for the pediatric patient. The right mainstem bronchus, a common location for aspirated foreign bodies, arises from the trachea at a wide angle in children (versus the much sharper angle of the left mainstem bronchus).

Chest Wall and Respiratory Muscles

The cartilaginous chest wall is twice as compliant and flexible as the bony chest wall of the adult. Thus, with respiratory difficulty, children may display chest **retractions**, a visible clinical phenomenon in which the bones

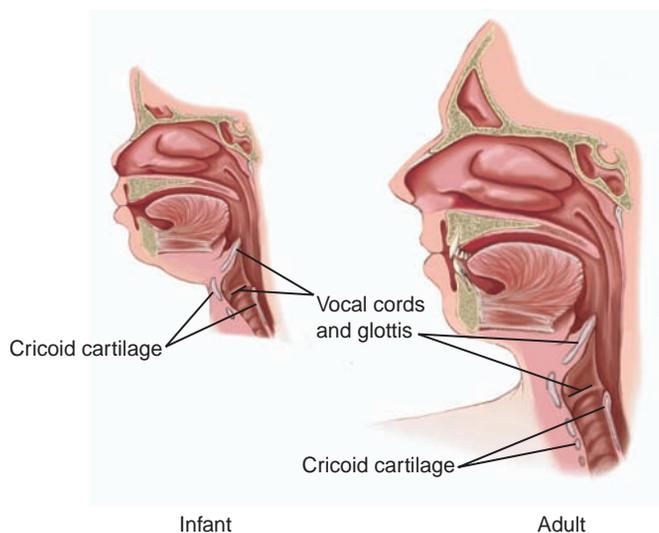

FIGURE 16-3. Differences in the upper airway between a child and an adult. The infant's larynx is funnel shaped, with the narrowest part of the airway at the cricoid cartilage. The adult airway is cylinder shaped, with the narrowest portion of the airway at the glottis.

and cartilage structures of the chest become more prominent with inspirations (see Fig. 8–8). Chest retractions increase the work of breathing and reduce the efficiency of ventilation.

The shape of the chest and the angle of rib articulation relative to the sternum and vertebrae are other anatomic variations of the chest wall that adversely affect the mechanical efficiency of breathing in the infant and young child. Until the child reaches 7 or 8 years of age, the ribs are horizontal in orientation, in contrast to the 45-degree angle present in the older child and adult. This orientation accounts for the barrel-shaped appearance of the chest in the infant and young child. Because of this horizontal orientation of the ribs, the intercostal muscles do not have the leverage necessary to lift the ribs and aid in chest expansion during respiration. Young infants and children with diagnoses such as pneumonia must be assessed carefully and frequently for the development of respiratory fatigue and subsequent respiratory failure as a result of these variations.

The muscles important for efficient and effective respirations include the diaphragm, the intercostal muscles, and the muscles supporting the head and the upper and lower airways. These muscles are relatively underdeveloped in pediatric patients. They lack the tone, strength, and coordination necessary to prevent and effectively manage episodes of respiratory distress.

The diaphragm, which is the main muscle of respiration in patients of all ages, is located higher in the thorax in infants and young children and is inserted horizontally, versus obliquely, as in adults. Any condition that impedes diaphragmatic movement, such as abdominal distention caused by accumulation of air or fluid, can substantially compromise respiratory status. In addition, the intercostal muscles are underdeveloped and function only to stabilize, rather than actually lift, the chest wall. Because of these important variations in the respiratory muscles, children with neuromuscular weakness or paralysis secondary to disorders such as muscular dystrophy or Werdnig-Hoffmann syndrome may exhibit respiratory compromise or distress as one of the first presenting symptoms of their disease.

Lung Tissue

The ability of lung tissue to inflate and deflate gradually increases throughout childhood, as the tissue grows and matures. Many factors affect lung tissue in individuals of all age groups. For example, the presence or absence of *surfactant* (a material secreted by the alveoli), and the number and character of elastic fibers in the lung tissue can affect the ability of the lung tissue to expand and deflate. Infants born prematurely lack surfactant, which develops relatively late during intrauterine development and contributes to the stability of the alveolar surfaces. Without surfactant, the lung tissue's ability to inflate and deflate is greatly decreased, and lack of surfactant leads to severe respiratory distress and even death.

Children also have less elastic tissue in the alveoli than adults. This variation tends to cause the alveoli to lose

patency, leading to higher incidences of pulmonary edema, pneumomediastinum, and pneumothorax. Minimal elastic recoil properties cause a higher incidence of **atelectasis** (partial or complete pulmonary collapse) in pediatric patients than in adults. In addition, poorly developed pathways of collateral ventilation can lead to rapid small airway obstruction and significant respiratory distress. Because of all these variations, neonates are especially susceptible to the development of pulmonary edema.

ANSWER: As Jose gets older, larger, and stronger, his symptoms may decline. He may continue to have some reactive airway disease, but his larger airways, stronger musculature, and more mature lung tissue will result in less dramatic symptoms.

ASSESSMENT OF THE CHILD WITH ALTERED RESPIRATORY STATUS

Collecting the health history and performing the physical assessment of the child with a respiratory system disturbance is the first step in the nursing process. During the history, the child and family have an opportunity to tell their story about the illness and what prompted them to seek care from the healthcare team. Make the assessment a more positive experience by allaying the child's fears and discomfort, and establishing a relationship of trust and communication with the child and parents.

Focused Health History

QUESTION: Review Focused Health History 16–1. Analyze the information in the case study and identify the information regarding the Diaz family that is missing. Integrate the information you have about the Diaz family. What are some unique characteristics of the Diaz family that you will incorporate into your collection of a health history?

When taking a history, begin with the reason for the visit or hospitalization. When possible, use the child's or parents' own words to document all descriptions of the child's symptoms (Focused Health History 16–1). When taking a history of a respiratory system problem, follow general history-taking guidelines (see Chapter 8), but also include questions about the environment—things that make the symptoms worse (sometimes called *triggers*)—and potential comorbid conditions or symptoms. As with general history taking, remember that clear and detailed information about the current illness as well as other factors (environment, family, and so forth) helps you to formulate an initial plan of care and directs further questioning to confirm or refute any hypothesis regarding diagnosis.

FOCUSED HEALTH HISTORY 16–1

The Child With Altered Respiratory Status*

Current history	<p>Chest pain with breathing Shortness of breath relative to activity level Difficulty eating Cough (duration, onset, intermittent or continuous, paroxysmal, worse at night, production of sputum) Nasal congestion Runny nose (color of mucus) Sore throat Airway noise (barking cough, dry cough, stridor, or wheeze) Easy fatigability Other persons in the household who are ill Allergies (animals, plants, other allergens or irritants, foods, medicines)</p> <p>Current Medications Medications (including over-the-counter medications) or complementary and alternative medical practices and home remedies related to current treatment of any current or chronic respiratory problems Medications (including any of those listed earlier) unrelated to current or chronic respiratory problems</p>
Past medical history	<p>Prenatal/Neonatal History Apgar score, spontaneous breathing at birth Meconium-stained amniotic fluid Prematurity Required mechanical ventilation Prenatal maternal infections (e.g., chlamydia or herpes simplex) Maternal smoking history; marijuana, heroin, cocaine use</p> <p>Previous Health Challenges History of respiratory illness such as strep throat, tonsillitis Number of colds per year including “typical course”; coughing, wheezing, or other noisy breathing associated with colds History of otitis media History of tuberculosis History of previous respiratory diseases (asthma), frequency of colds History of known allergies or asthma</p> <p>Immunizations Status of current immunizations (including influenza) Date of past tuberculosis test and results</p>
Nutritional assessment	<p>Weight loss Failure to gain weight between office visits Decrease in physical activity Decrease in appetite Changes in bowel patterns and appearance of feces</p>
Family medical history	<p>Family history of allergies, asthma, tuberculosis, pertussis, cystic fibrosis Focus on sibling history of respiratory illness</p>
Social history	<p>Cultural (any customs that may affect treatment) Number of persons living in the household and whom Child’s primary caregiver</p>
Environmental history	<p>Home environment (age and type of dwelling, condition of home [water damage may indicate mold exposure], sources of heating/cooling) Types of household products used (e.g., chemicals, pesticides, cleaning supplies, paint fumes, hobby supplies) Environmental exposures such as plant allergens, animal allergens (pets, rodents, insects), powders, aerosols, household irritants</p>

(Continued)

FOCUSED HEALTH HISTORY 16–1

The Child With Altered Respiratory Status* (Continued)

Growth and development

Outdoor air exposures (e.g., levels of air pollution in local community)
 Smoking behaviors of other household members or visitors to home
 Parental occupational exposure (parents' clothing from work may be a source of exposure to heavy metals or chemicals)
 Physical milestones
 Developmental milestones
 Habits: play, sleep
 School attendance and performance

*This history focuses on the respiratory system. See chapter 8 for a comprehensive health history.

The child's past medical history, including birth history, previous health problems, childhood illnesses, immunizations (routine and yearly, including yearly flu vaccines), and allergies, helps put the current illness into perspective. For example, a child presenting with paroxysmal coughing episodes may cause the nurse to consider foreign body aspiration (FBA), croup, bronchitis, or pneumonia, depending on the presence of other accompanying symptoms. However, if the child was never immunized against pertussis, has not been screened recently for tuberculosis, or has recently visited or lived in another country, additional possibilities for the symptoms must be considered. Focus on birth weight, gestational age, and any complications involved with the child's birth. Lungs develop in utero; therefore, premature infants, whose lungs do not have time to develop fully, may have respiratory complications throughout the life span.

Ensure that family medical history includes any inherited (e.g., genetically linked), chronic, or infectious respiratory conditions. Also include a careful environmental assessment, taking into account where the child usually resides (home) and other places in the child's daily environment (e.g., school, child care setting, and relatives' home). Using the environmental history, you can examine relationships between known exposures and symptoms, provide anticipatory guidance to prevent further exposure, empower parents to seek information about environmental issues, and give parents the knowledge and skills to advocate for their children's health and well-being.

caREminder

Children often spend large amounts of time away from their usual home setting (e.g., school, relative's home, babysitter's, child care setting). When taking a history about environmental risks, consider the child's daily environment in addition to the regular home setting.

Assess nutrition and general growth and development factors. Growth impairment caused by chronic hypoxia and poor nutritional intake is sometimes the first sign of

decompensation in the child with chronic respiratory problems.

ANSWER: The case study does not include information regarding Jose's birth history, his immunization history, and nutritional assessment; as well as family, social, and environmental history. His medications are covered in more depth in the Chapter 9 case study. The Diaz family is Mexican American and, although both parents are bilingual, there may be aspects of the health history that the couple struggle to explain adequately in English and could relay with more accuracy and detail in Spanish. Be attuned to the potential need for a medical translator. It is also appropriate to ask if any cultural remedies have been used with Jose.

Focused Physical Assessment

QUESTION: Which techniques has the nurse used to assess Jose? What additional information do you anticipate the nurse will identify as the physical assessment is completed?

Use the techniques of observation, inspection, auscultation, palpation, and percussion when performing a physical assessment of the respiratory system in infants, children, and youth. Focused Physical Assessment 16–1 summarizes possible physical assessment findings and highlights abnormalities and their implications.

Note the shape, size, and symmetry of the thoracic cavity. Notice the type and quality of breathing, and the depth and regularity of respirations. In the child younger than 7 years, respirations are diaphragmatic, and the abdomen rises with inspiration; later, the breathing becomes thoracic. Note respiratory effort and appearance of retractions, nasal flaring, and use of accessory muscles. Breathing should be quiet and nonlabored, at a respiratory rate normal for age (see Appendix D), with an inspiratory phase

FOCUSED PHYSICAL ASSESSMENT 16–1

The Child With Altered Respiratory Status

Assessment Parameter	Alterations/Clinical Significance
General appearance	<p>Fretting, lethargy, agitation, distress, or weakness is common with hypoxia. Presence of tachypnea, dyspnea, or orthopnea indicates respiratory compromise.</p> <p>Underweight, linear growth below average, frequently is the result of growth retardation with chronic respiratory conditions (e.g., cystic fibrosis).</p> <p>Unusual positioning: Position of comfort with head elevated may indicate hypoxia; refusal to lie flat because of respiratory compromise in that position.</p> <p>Fever may indicate bacterial or viral illness.</p>
Integumentary system (skin, hair, nails)	<p>Observe color at rest.</p> <p>Cyanosis indicates inadequate oxygenation.</p> <p>Mottling of the chest may indicate severe hypoxemia.</p> <p>Mottling and cyanosis may also be related to vasoconstriction or polycythemia.</p> <p>Digital clubbing (tissue proliferation on terminal phalanx) indicates chronic hypoxemia (commonly seen in children with cystic fibrosis).</p>
Head and neck Face, nose, and oral cavity	<p>Tenderness, swollen glands indicate infection.</p> <p>Nasal flaring (bilateral widening on respiration) is associated with the child's attempt to improve oxygenation.</p> <p>Tenderness upon palpation of sinuses indicates sinusitis.</p> <p>Exudate on the tonsillar surface, hypertrophy of tonsils, or substantial erythema is seen in tonsillitis.</p> <p>Erythema in back of throat is seen with sore throat.</p>
Thorax and lungs	<p>Observe the shape, size, and symmetry of the thoracic cavity. Palpate chest for chest expansion, tenderness, pulsations, and masses.</p> <p>A round chest in an older child usually indicates chronic lung disease.</p> <p>Observe breathing pattern, rate, and exertion.</p> <ul style="list-style-type: none"> • Abdominal breathing in an older child may indicate a respiratory disorder or a fractured rib. • Prolonged expiratory phase may indicate an obstructive respiratory disorder, such as asthma. • Prolonged inspiratory phase may indicate an upper airway obstruction, such as croup. • Retractions are associated with both obstructive and restrictive lung diseases. • Absent or diminished breath sounds are associated with obstruction or pneumothorax. • Adventitious breath sounds, including rales, rhonchi, and wheezes, are associated with fluid, secretions, obstruction or narrowing of the airway, pulmonary edema, inflammation, exudate, tumors, and foreign bodies.
Cardiovascular system	<p>Tachycardia is noted in respiratory distress.</p> <p>Capillary refill longer than 3 seconds may indicate cardiovascular compromise.</p>
Abdomen	<p>Distended abdomen may occur if child is breathing rapidly and swallowing air.</p>
Musculoskeletal system	<p>Pectus excavatum or pectus carinatum (asymmetric deformities of the chest) may compromise lung expansion.</p>
Neurologic system (behavior and development, reflexes, motor and sensory)	<p>Decreased sensorium may indicate hypoxia.</p> <p>When the child assumes the “tripod” position, refuses to lie down, prefers to sit upright, and leans forward indicate epiglottitis or acute asthma attack.</p>

slightly longer than or equal to the expiratory phase. Count the respiratory rate for a full minute, ideally when the child is asleep or quiet. **Tachypnea** (rapid breathing or panting) may be observed in the presence of fever, anxiety, or stress. Prolonged tachypnea may be an indicator of respiratory distress.

The color of the face, trunk, nail beds (and the shape of the nail beds) also can provide clues to respiratory status. Skin and mucous membranes should be pink. Nail beds should be pale or pink, and the nails should be flat, with the angle between the nail and the nail base at approximately 160 degrees.

While observing respiratory status, assess also for speech patterns (shortness of breath can be seen in quick, short sentences) and activity level.

During auscultation, assess the quality and intensity of the breath sounds as well as noting the area of the chest where they are heard (see Table 8–6). *Vesicular* breath sounds are low-pitched, soft sounds (heard more during inspiration than during expiration) audible throughout lung field. *Bronchovesicular* breath sounds are moderately pitched, harsh sounds (inspiration = expiration) heard over the manubrium. *Bronchotubular* breath sounds are high-pitched, hollow sounds (inspiratory sounds greater than expiratory sounds) heard over the trachea. Adventitious (abnormal) breath sounds that can be auscultated

include wheezes, crackles (rales), and rhonchi (Focused Physical Assessment 16–2).

Listen for audible abnormalities including stridor and grunting. Stridor is a harsh, grating, whistling sound heard on inspiration and is produced by turbulent airflow through laryngeal or tracheal obstruction. It is usually more pronounced when the child is crying or agitated. Grunting is a noise the infant may make as he or she attempts to provide a self-induced positive end-expiratory pressure. By grunting, the infant closes the glottis and applies positive pressure to the airway to increase the resting volume of the lung.

Alert! Grunting is usually an ominous sign and may indicate impending respiratory failure in the infant or young child. Other clinical signs of respiratory distress and impending respiratory failure that require immediate attention include increased work of breathing (severe retractions and grunting), diminished or absent breath sounds, development of hypoventilation (apnea or gasping respirations), altered level of consciousness (lethargy or inability to be consoled by parents), poor systemic perfusion (capillary refill of more than 2 seconds, mottling, or both), tachycardia, and bradycardia (late sign).

Palpate the chest to assess for chest expansion, tenderness, pulsations, and masses in the thoracic region. **Subcutaneous emphysema** (crepitus) is a manifestation of

FOCUSED PHYSICAL ASSESSMENT 16–2

Adventitious Breath Sounds

Sound	Description	Pathology and Examples
Crackles		
Fine	Intermittent, high-pitched, soft popping sounds. Heard late in inspiration. Sound similar to hair rolling between fingers. Not cleared by coughing.	Fluid in alveoli (pneumonia)
Medium	Intermittent and medium-pitched sounds that are loud and coarse sounding. Heard early or during mid inspiration.	Fluid in bronchioles and bronchi (pulmonary edema)
Coarse	Loud, bubbling, low-pitched sounds. Heard on expiration. Cleared by coughing.	Fluid in bronchioles and bronchi that is resolving (bronchitis)
Friction rub	Superficial, coarse, low-pitched, grating sound. Sounds similar to two pieces of leather rubbing together. Heard on inspiration and expiration.	Pleural inflammation from loss of normal lubricating fluid (pleuritis)
Rhonchus		
Sonorous	Continuous, snoring, low-pitched, moaning, vibrating sound that clears with coughing. Heard throughout respiratory cycle.	Air flow obstruction (mucus) in large bronchi and trachea (bronchitis, upper respiratory tract infection)
Wheezes		
Sibilant	Continuous, high-pitched, musical, hissing sound. Heard predominantly during mid to late expiration.	Air flow through narrowed passageway because of inflammation, collapse, secretions, or tumors (asthma)
Audible without stethoscope: inspiratory	Sonorous, musical sounds are heard on inspiration.	High obstruction (croup)
Audible without stethoscope: expiratory	Whistling, sighing sounds are heard on expiration.	Low obstruction (bronchial foreign body)

free air that has leaked from the respiratory system into the subcutaneous tissue, most commonly resulting from a pneumomediastinum or pneumothorax. It can usually be palpated over the neck, shoulders, and upper chest. Assess and palpate for symmetry of chest wall excursions, especially in a child in whom trauma is suspected. Trauma to the rib cage can result in fractures and a “flail chest” (nonsymmetric movement of the chest) with decreased movement of the affected side. The position of the trachea may deviate from the normal midline in the presence of atelectasis and with pneumothorax, so palpating this structure is important.

Use percussion to identify areas of consolidation or other internal changes within the lung. Percuss with a gentle motion to achieve sufficient tones, keeping in mind that the pediatric patient’s thinner chest wall will produce a more resonant tone. A normal percussion finding includes dullness over the heart and resonance over the lung fields. If a consolidation such as pneumonia is present, the resonance over the lungs will change to a dull sound.

ANSWER: The nurse has used inspection but not auscultation. Did you anticipate that Jose’s breath sounds may be difficult to assess because of the loud inspiratory stridor? The nurse does not hear air moving well in the lower lobes, but is not certain if the sound is masked by the stridor or if Jose is truly not moving air well.

Diagnostic Criteria

QUESTION: Of the four groups of diagnostic tests identified in the following pages, three are typically used to evaluate a child’s condition with asthma. One is already in use: the pulse oximeter. Which diagnostic test will most fully reflect the respiratory status of the child?

Four major groups of diagnostic tests and procedures used in the evaluation of the respiratory system and respiratory disorders in children include (1) measurement of lung volumes and flow rates (pulmonary function tests and peak flow measurement), (2) direct or indirect blood and body fluid analysis (arterial blood gases, fluid cultures, sweat chloride test), (3) imaging techniques (radiographs, fluoroscopy, bronchography, computed tomographic scan, scintigraphy, magnetic resonance imaging), and (4) direct visualization of the respiratory tree (laryngoscopy, bronchoscopy). These diagnostic tests, used alone or in combination with others, may yield information necessary in the diagnosis and treatment of acute and chronic lung disease. Tests and Procedures 16–1 describes the purpose, findings, and indications of individual diagnostic tests, as well as the specific responsibilities and considerations for the healthcare provider.

Measurement of arterial blood gases is considered one of the most useful diagnostic tests when a child presents with respiratory distress, impending cardiopulmonary

failure, or both. Therefore, knowing normal arterial blood gas values for children is important for the nurse assessing and evaluating the child (Tests and Procedures 16–2). Pulse oximetry and apnea monitors are examples of noninvasive and portable methods to detect respiratory compromise in the pediatric patient. Pulse oximetry is primarily used in inpatient and outpatient clinical settings by healthcare providers (Fig. 16–4). Apnea monitors are used in both clinical and home settings as both a diagnostic tool to assess for apnea and a system to alert care providers that a child is experiencing an apneic event and intervention may be warranted (see [thePoint](#) for Procedures: Pulse Oximetry and Apnea Monitoring for supplemental information).

ANSWER: Pulse oximetry can read the oxygen saturation of Jose’s hemoglobin, but it cannot detect an increase in carbon dioxide or pH changes. An arterial blood gas measurement, although invasive, relays information that cannot be obtained readily through a noninvasive alternative.

TREATMENT MODALITIES

Respiratory illnesses in children, both acute and chronic conditions, require aggressive and immediate intervention. Respiratory failure is one of the leading causes of cardiopulmonary arrest in children (American Heart Association, 2005). A thorough assessment of the child’s status, followed by quick actions that support oxygenation and ventilation, can serve to avert an impending arrest situation. In the case of acute respiratory problems, children generally respond well and promptly to the simple administration of oxygen and medications. For children with a chronic respiratory condition, oxygen, medications, airway clearance techniques (ACTs), and nutritional support can assist them through exacerbations of the illness and provide them with the strength to maintain a high level of wellness despite their chronic conditions. Some conditions may require use of artificial airways, mechanical ventilation, or tracheostomy.

Administration of Oxygen

QUESTION: Examine the various modes that oxygen can be delivered in Nursing Interventions 16–2. Why was a simple mask used to deliver oxygen to Jose instead of nasal cannula?

Oxygen is indicated for the treatment of hypoxemia and can be the most dramatic, life-saving intervention for that condition. Although oxygen is important, assess patency of the airway first. Oxygen is indicated for the presence of or risk of low arterial oxygen (PaO_2) levels and is also indicated to improve oxygenation when cardiac output is low, to decrease pulmonary vascular resistance, to

Tests and Procedures 16–1 Evaluating Respiratory Status

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Responsibilities
Pulmonary function tests (spirometry, gas dilution, and body plethysmography)	<p>Measures airway function, lung volumes, and gas exchange.</p> <p>Used to determine the presence, nature, and extent of pulmonary disease. Does not indicate the cause of the dysfunction.</p>	<p>Abnormalities of particular measurements may occur in different diseases.</p> <p>Restrictive diseases cause decreased VC and TLC.</p> <p>Obstructive diseases may cause an increase in TLC and RV, decreased VC, and decrease in FEV₁ and forced expiratory flow between 25% and 75% VC (FEF_{25%–75%}).</p>	<p>Most results are effort dependent.</p> <p>Emphasize the need for maximum cooperation during the test to achieve valid results.</p> <p>Some tests require that the child's nose be clamped.</p> <p>Child should not have eaten immediately prior to examination: coughing required during the test sometimes stimulates vomiting.</p> <p>Test may be performed before and after bronchodilator therapy.</p>
Bronchoprovocation tests	<p>Used as an attempt to provoke mild bronchospasm in patients in a controlled setting.</p> <p>Substances such as histamine and methacholine are introduced to determine whether the child's airways constrict.</p>	<p>Positive test is diagnostic for airway hyperresponsiveness (a characteristic feature of asthma) and can determine severity of asthma. Negative test may help rule out asthma.</p>	<p>The morning of the test the child should not take any asthma medications and should avoid caffeinated beverages, chocolate, extremely hot or cold environments and exercise. The child should be free of any respiratory illnesses at time of tests. At the end of the test, a bronchodilator may be given to reverse any constriction of the airways.</p> <p>Test must be performed by a trained individual.</p>
Peak flow measurement	<p>Used to measure the greatest flow velocity during a forced expiration.</p> <p>Child exhales forcefully and quickly into the meter while taking maximal deep inhalation (TLC).</p>	<p>Peak flow rate decreases as airway obstruction increases.</p> <p>Values should be compared with the individual child's baseline or "personal best" vs. average predicted normal values.</p>	<p>Child must be developmentally able to follow instructions (generally older than 4 years of age).</p> <p>May not be appropriate if child is in severe respiratory distress.</p> <p>Accurate peak flow measurement is effort dependent.</p>
Arterial blood gases	<p>Used to measure and analyze PaO₂, PaCO₂ retention, and alterations in the pH.</p>	<p>The PaCO₂ measurements indicates adequacy of ventilation.</p> <p>PaO₂ is used to detect altered gas exchange.</p> <p>pH indicates whether hypo- or hyperventilation is chronic or acute.</p>	<p>Air should not be allowed to enter the syringe with the sample; doing so can alter the findings.</p> <p>Firm pressure should be applied to the puncture site for 5 minutes after draw to prevent hematoma or bleeding.</p> <p>Most reliable when obtained from an indwelling arterial catheter.</p> <p>Arterial puncture is painful and may be associated with altered findings if child has been crying or screaming for a prolonged period.</p>

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Responsibilities
Pulse oximetry	Monitors oxygen saturation (SaO ₂). Can also detect and provide a digital display of the pulse rate.	SaO ₂ can be used to estimate PaO ₂ using the oxyhemoglobin dissociation curve. Used to evaluate respiratory function and check for hypoxemia. Healthy children have a saturation of 98% to 100%.	Information enables continuous monitoring and evaluation of SaO ₂ (see thePoint for Procedures: Pulse Oximetry).
Apnea monitor	Used to detect pauses of breathing lasting 5 to 20 seconds.	May indicate child has apnea of prematurity, apnea of infancy, or an apparent life-threatening event.	Unless otherwise ordered, the apnea monitor should be used continuously, except during bathing or at times when the infant is involved in interactive activities with the caregiver (see thePoint for Procedures: Apnea Monitors).
Sputum culture/tracheal aspiration	Used to detect presence of and identify bacterial, viral, fungal, or other respiratory pathogens.	Presence of pathogens usually indicates infection. Observe sputum for color, consistency, and odor. Thick yellow or green sputum indicates infection. Infection with <i>Pseudomonas aeruginosa</i> causes the sputum to have a distinct “sweet” odor.	Specimen should be collected within 3 to 7 days after onset of signs and symptoms and before antimicrobial therapy is initiated, unless the culture is being completed to examine the effectiveness of therapy. The specimen should be placed in a sterile container for culture or a tube with appropriate medium. Specimen must be from bronchial tree, not just saliva from mouth. Specimens should not be frozen and should be transported as soon as possible.
Throat culture (throat swab)	Used to determine viral or bacterial cause in pharyngitis. Reliable method to differentiate infection with group A beta-hemolytic <i>Streptococcus pyogenes</i> from infection with viral organisms.	Positive throat culture for <i>S. pyogenes</i> indicates “strep throat.”	Specimens should be obtained from the posterior pharynx and each tonsillar area. Any white patch or inflamed area should be cultured. Results take 24 to 48 hours to obtain. Special test kits are available for strep throat that can yield results in 7 minutes.
Nasal and nasopharyngeal culture or washing	Preferred method used to detect bacterial, viral, and other respiratory pathogens, because large number of ciliated epithelial cells are essential for optimal recovery of the pathogens.	Able to detect <i>Bordetella pertussis</i> , <i>Candida albicans</i> , <i>Corynebacterium diphtheriae</i> , <i>Neisseria meningitidis</i> , <i>Haemophilus influenzae</i> , and others. Coagulase-positive staphylococcus may be present in 50% of people who have nasopharyngeal cultures done.	For a culture, the flexible swab should be inserted into the nose and rotated against the anterior hairs for a good specimen. For a washing, normal saline should be instilled into the nostril and then immediately suctioned with a catheter into a specimen container.

(Continued)

Tests and Procedures 16–1 Evaluating Respiratory Status (Continued)

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Responsibilities
Sweat chloride test	Used in diagnosis of cystic fibrosis. Measures amount of sodium and chloride content in the sweat.	Sweat chloride of >60 mEq/L indicates positive test for cystic fibrosis. Levels of 40 to 60 mEq/L are highly likely to be positive.	Test takes about an hour for enough sweat to be collected. A positive reading requires the sweat test to be performed at an approved cystic fibrosis center.
Lung biopsy and/or thoracentesis	A needle is inserted through an intercostal space into lung tissue to obtain a lung aspirate specimen for histology and culture.	Purulent fluid indicates infection (empyema). Presence of lymphocytes with chyle indicates chylothorax. Presence of lymphocytes may indicate malignancy, and bloody fluid may indicate hemothorax.	Bleeding and pneumothorax are potential complications.
Chest radiograph	The best initial imaging technique to detect abnormalities of the pulmonary, mediastinal, and musculoskeletal structures of the thorax.	Air or fluid in the pleural space indicates a pleural effusion or pneumothorax. Hyperinflation often implies air trapping seen in bronchiolitis or asthma. Atelectasis, infiltrates, or both may indicate pneumonia.	Determine whether adolescent female patients may be pregnant. Anteroposterior view more appropriate for children younger than 2 years.
Fluoroscopy	Related to chest radiographs, but image is continuous on a television monitor and enables continuous observation of chest movements during inspiration and expiration.	Useful in assessing diaphragmatic movement. Can detect air trapping and presence of pulsation in intrathoracic masses.	Child should be immobilized. Determine whether adolescent female patients may be pregnant. Lead shields are used to protect radiosensitive areas, such as gonads and thyroid gland.
Bronchography	Uses a contrast medium instilled directly into the tracheobronchial tree to visualize the bronchi for narrowing, obstruction, dilation, or malformation of the bronchial tree.	Provides information about the most peripheral bronchioles. Chronic distal bronchial obstruction and dilation indicate bronchiectasis.	Signed consent required. Child must be NPO 6 to 12 hours before test and after test until gag reflex returns. Important to check whether child has any loose teeth prior to test. Usually performed with child under general anesthesia.
Computed tomographic scan	A sequence of radiographs that show a cross-sectional view of the thorax. Used to detect masses or locate lesions.	Presence of mediastinal mass may indicate tumor; hilar adenopathy may indicate infection with tuberculosis.	Sedation or immobilization of child usually required. NPO 3 to 4 hours prior to examination because IV contrast media may be used to further visualize cardiac chambers and vessels.
Radionuclide scintigraphy, lung scan (V/Q scan)	A nuclear medicine scan performed to detect alterations or defects in perfusion (Q), inequalities in ventilation (V), or both.	Scintigraphy is able to detect noninfectious inflammatory diseases, presence of pulmonary emboli, pulmonary complications of HIV infection, and tumors.	Signed consent required for injection of radionuclides intravenously. Young or uncooperative child may be sedated and thus should be NPO 4 hours before procedure. If sedation is not used, it is not necessary to keep child NPO.

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Responsibilities
Magnetic resonance imaging	Uses magnetic waves to provide two- and three-dimensional views on the transaxial, coronal, and sagittal planes.	Easily detects abnormalities of soft tissues, presence of solid masses, chest wall deformities, and vascular abnormalities.	Child must be able to cooperate and lie still; the younger child may need sedation. Any clothing with metal snaps or metal items, such as barrettes, should be removed.
Laryngoscopy/bronchoscopy; rigid or flexible fiberoptic	Procedure similar to insertion of an endotracheal tube used to provide direct visualization of the airways using a lighted laryngoscope.	Aids in diagnosing cause of upper airway obstructions (including foreign bodies), abnormalities in major airways, aspiration of thick mucous plugs; obtaining secretions for bronchial lavage and cultures, aspiration of thick mucus; and obtaining secretions for cultures. Flexible equipment affords more detailed visualization of mucosa; rigid equipment can remove foreign bodies from major airways.	Signed consent necessary. Suction equipment and oxygen should be ready and available at bedside. Sedation required for flexible bronchoscopy; general anesthesia required for rigid bronchoscopy.

FEV₁, forced expiratory volume in 1 second; IV, intravenous; NPO, nothing by mouth; PaCO₂, arterial carbon dioxide; PaO₂, arterial oxygen levels; RV, residual volume; SaO₂, arterial hemoglobin saturation; TLC, total lung capacity; VC, vital capacity.

enhance elimination of carbon dioxide, or to accelerate removal of nitrogen from air-containing spaces such as a pneumothorax.

Oxygen can be delivered by mask (Fig. 16–5), nasal cannula, oxygen hood, oxygen tent, or mechanical ventilation (see [thePoint](#) for Procedures: Oxygen Administration for supplemental information). The mode of oxygen delivery used is based on the concentration or percentage of oxygen desired and on the child's ability to cooperate with therapy. To ensure patient safety, measure and monitor the concentration of inspired oxygen carefully and document response during oxygen therapy. Oxygen therapy in children should use the least amount of oxygen required to normalize PaO₂ (more than 60–80 mm Hg) and arterial hemoglobin saturation (SaO₂) (more than 93%). When oxygen is administered through an artificial airway such as an endotracheal tube or a tracheostomy tube, the gas must be artificially heated and humidified.

caREminder

To decrease the risk of mucociliary dysfunction, injury to the respiratory epithelium, and thickening of secretions, children receiving oxygen therapy through an artificial airway for more than 1 to 2 hours should receive warmed, humidified oxygen.

The use of oxygen therapy in the home is becoming more prevalent. Teaching Intervention Plan (TIP) 16–1

describes care of the child receiving home oxygen therapy and the educational needs of the family.

ANSWER: Jose is breathing primarily through his open mouth. For a nasal cannula to be an appropriate mode of delivery, the child must keep his or her mouth closed and breathe through the nose.

Medications

Medications are an important component of treating respiratory disorders in children. Routes of administration are oral, inhaled, intravenous, and injectable (subcutaneous or intramuscular). Inhaled medications are used most often to increase respiratory tract absorption and to decrease systemic absorption.

Classes of Medications

The main classes of medications used for respiratory disorders include bronchodilators, corticosteroids, and leukotriene modifiers/mast cell stabilizers. Other groups of medications often used in conjunction with these include, but are not limited to, antibiotics, antivirals, mucolytics and expectorants, decongestants, antihistamines, and diuretics. The pharmaceutical agents used for particular respiratory disorders are addressed in the appropriate sections. Principles of inhalation therapy and aerosolized medications are addressed here.

Tests and Procedures 16–2 Pediatric Arterial Blood Gases

	pH	PaCO ₂ (mm Hg)	PaO ₂ (mm Hg)	HCO ₃ (mEq/L)	Causes of Imbalance
Normal Values					
Preterm infant	7.11–7.36	27–40	55–85	21–28	
Term infant	7.35–7.45	27–41	54–95	21–28	
Child	7.35–7.45	35–45	80–100	21–28	
Abnormal Values					
Respiratory acidosis (acute alveolar hypoventilation)	<7.30	>50	WNL or <80	WNL	Chronic lung disease (chronic bronchitis, asthma), respiratory depression from drugs or anesthesia, pneumonia, respiratory distress
Respiratory alkalosis (acute alveolar hyperventilation)	>7.50	<30	WNL	WNL	Anxiety, fear, pain, improperly adjusted ventilator (overventilation), salicylate toxicity, fever, hyperventilation, hypoxia, tetany, head trauma, gram-negative septicemia
Metabolic acidosis	<7.30	WNL	WNL	<21	Severe diarrhea, kidney failure, diabetic ketoacidosis, shock, burns, malnutrition, ingestion of salicylates
Metabolic alkalosis	>7.50	WNL	WNL	>28	Loss of HCO ₃ by intestines, severe vomiting, cystic fibrosis, gastric suctioning, severe diarrhea, renal failure, diuretics
Respiratory acidosis with compensation (chronic alveolar hypoventilation)	WNL	>50	WNL or <80		Kidneys try to retain more HCO ₃ by increasing retention
Respiratory alkalosis with compensation (chronic alveolar hyperventilation)	WNL	<30	WNL		Kidneys try to reduce HCO ₃ by increasing excretion
Metabolic acidosis with compensation	WNL	<30	WNL		Lungs try to reduce PCO ₂ by increasing ventilation
Metabolic alkalosis with compensation	WNL	>50	WNL		Lungs try to increase PCO ₂ slightly by hypoventilation

HCO₃, bicarbonate; PaCO₂, arterial carbon dioxide; PaO₂, arterial oxygen pressure; WNL, within normal limits.

Aerosol Therapy

QUESTION: Jose uses a nebulizer at home. Evaluate the other methods of aerosol therapy. What supportive rationale can you offer for why this method of medication delivery is an appropriate choice for Jose?

Bronchodilators, corticosteroids, and mast cell stabilizer medications are delivered by inhalers or nebulizers. However, bronchodilators and corticosteroids are also available in oral and intravenous forms. Administering medications by inhalation is effective, because the medication reaches the small airways and works directly on the lungs. Medications are nebulized or aerosolized by using compressed air or oxygen. A variety of machines (compressors) are

FIGURE 16–4. Child with a pulse oximeter. The finger probe has a red sensor light that fascinates some children.

available for use with a handheld nebulizer, often for use in the home. The handheld nebulizer has the advantages of being able to aerosolize almost any drug available in liquid form, allowing modification of dose volume and concentration, and requiring minimal patient coordination. The child or infant usually uses a mask attached to the nebulizer cup, which is held over the nose and mouth. The medication is dispersed as a mist. Older children can use the mouthpiece and should be instructed to take slow, deep breaths through the mouth during the treatment (Fig. 16–6). Nebulizers are effective for most children younger than 5 years of age and older children who have difficulty coordinating a metered dose inhaler (MDI).

KidKare ■ Allow the child to hold the mask up to his or her face instead of using the elastic strap around the head. When the child is getting the treatment, he or she may like to have “teddy” or “dolly” wear a mask and “get a treatment,” too.

FIGURE 16–5. Child receiving oxygen via a face mask.

The MDI is a simple, portable, self-contained handheld canister that delivers a predetermined amount of the specified medication to the patient. Most bronchodilators, corticosteroids, and mast cell inhibitors are available in an MDI. Although MDIs have the advantage of being very portable and can provide efficient drug delivery with rapid preparation and administration time, they do have the disadvantage of being difficult to coordinate and use correctly. A spacer device should be used with MDIs regardless of age (Fig. 16–7). Use of a spacer allows time for the propellant to remain suspended and achieve smaller particle size. The spacer device may have a mouthpiece or face mask. Using spacers with mouthpieces requires coordination of breathing and drug dispersal, so spacers with masks may facilitate dosage in younger children.

Another device for inhalation is the drug–powder inhaler. The drug–powder inhaler, which is similar to the MDI, consists of a suspension of microfine, solid particles of drug contained in a small MDI-sized device with a mouthpiece.

A third type of device for administering inhaled medications is breath-activated inhalers. With these devices, medication is delivered as the patient takes a breath. The child must seal their lips around the device before inhaling and should hold their breath for 10 seconds. Evaluate the child’s ability to perform this technique properly before he or she uses the device on a daily basis.

If the infant or child is receiving aerosol or inhalation therapy, assess response to the treatment. Assess breath sounds and respiratory effort before and after the treatment for effectiveness. For the child receiving bronchodilators (beta-adrenergic agents), assessing the heart rate is also important, because tachycardia is a common side effect of these medications.

caREminder

Be sure to have the child rinse out the mouth or wash the face after using an inhaled corticosteroid to decrease the chance of systemic absorption and side effects related to the medications.

ANSWER: Jose is 4 years old. The nebulizer is very simple to use and requires no special skills. Simply breathing in and out deeply will allow the medication to work directly on the lung tissue.

Airway Clearance Techniques (ACTs)

The airway clearance process may be dysfunctional, leading to retained secretions, or there may be hypersecretion of mucus in the airways. Accumulation of secretions in the airways leads to partial or total obstruction. Ventilation and gas exchange are altered, producing a favorable environment for infection. For example, children with conditions such as cystic fibrosis (CF), bronchiectasis, or dysfunctional motility of cilia; those receiving mechanical ventilation; and those with acute problems after general anesthesia can benefit from ACTs.

TIP 16–1 A Teaching Intervention Plan for the Child on Home Oxygen Therapy

Nursing diagnoses and outcomes

Deficient knowledge

- Home management with oxygen therapy

Outcome

- Parents/caregivers will verbalize the need for oxygen, care of the infant/child while receiving oxygen therapy and safety precautions; parents/caregivers will demonstrate care of the child and use of the oxygen.
- Risk for injury related to use of oxygen in the home and fire hazards

Outcome

- Family shall remain free of injury, and the potential for fire or explosion shall be minimized.
- Impaired gas exchange related to underlying respiratory disease process

Outcome

- Infant/child will exhibit adequate oxygenation and ventilation as evidenced by normal (for age and child) respiratory rate and effort and color of child.

Teach the Child/Family

Physiology and Need for Oxygen

- Discuss with parents/caregivers how oxygen enters the body and how it is used by the body. Explain the need/rationale for oxygen for their child.

Use of Oxygen

- Explain and demonstrate how to place/change the nasal cannula under the nose and over the ears, with the portion with the holes positioned under the nose, and how to attach the cannula to the flowmeter on the tank.
- Show parents/caregivers how to open the oxygen device and how to regulate the flow (depends on device being used in the home).

Physical Care

- Provide appropriate skin care on the face. Use hypoallergenic tape or skin protectant on the areas where the cannula is secured on the face.
- Provide humidity with oxygen if flow is more than 1 L/minute, or instill normal saline drops to nares, as needed; oxygen can be drying to the nares.

- Provide nasopharyngeal suctioning to nares with bulb syringe as needed to keep nares patent and to allow adequate flow of oxygen to child.
- Do not use petroleum-based creams or ointments or oil-based products on the child (they are combustible).

Health Maintenance

- Describe and have parents/caregivers identify “normal” color and respiratory status for their infant/child.
- Teach parents/caregivers how to detect changes in color (blueness of lips/nail beds, pale, or dusky) and respiratory status (retractions, nasal flaring, accessory muscle use, and increased respiratory rate). Instruct caregivers on need to notify physician if these changes are present.
- Stress importance of regular follow-up visits with healthcare provider.

Home safety and modifications

- Ensure that family has the following available in the home:
 - Notification sticker (OXYGEN IN HOME) for fire department (place on front window where easily visible)
 - Fire extinguisher and label for area where kept
 - Smoke detector
 - Battery-operated flashlight on hand in child’s room in event of power failure
 - List of emergency numbers posted by all phones
- Do not allow smoking in the home. Post NO SMOKING signs. Do not burn incense, candles, or fires in the home. Keep the oxygen tank more than 5 feet away from the heater or any other heat sources.
- Reduce static electricity of clothes by using fabric softener.
- Keep oxygen source upright and secured in holder at all times.
- If traveling, keep portable oxygen source in upright position and secure at all times. Keep window open slightly in car to allow ventilation. Avoid places that allow smoking.

Contact the Healthcare Provider if:

- Child experiences respiratory distress

FIGURE 16–6. Child receiving treatment with a nebulizer.

Suctioning the trachea and nasopharyngeal airway is a method to enhance airway clearance by removing secretions that cannot be removed by the child's spontaneous cough. Suctioning may also be used to obtain secretions for diagnostic purposes (see [thePoint](#) for Procedures: Nasotracheal Suctioning for supplemental information).

Traditionally, chest physiotherapy (also called *postural drainage* and *percussion*) has been the primary intervention for pulmonary conditions with hypersecretion or retained bronchial secretions. However, more therapy options for airway clearance exist now than were available in the recent past. Ongoing research to match the most effective therapy with the individual will improve quality of life in this rapidly expanding area. Nursing Interventions 16–1 summarizes information on these techniques as well as traditional ACTs. Advantages and disadvantages of the new techniques are also addressed, along with age indicators.

Determining the appropriateness of these newer interventions for a particular patient requires assessing the severity and type of lung disease, physical ability to perform the technique, effectiveness of the particular technique, and age. Other psychosocial factors to be considered are motivation to learn, adherence to treatment, cost, and payer or reimbursement. These techniques should be performed 30 minutes before mealtimes, as a safety measure to avoid vomiting and aspiration, and to promote comfort (Fig. 16–8).

FIGURE 16–7. Commercial spacer device.

caREminder

Supplemental continuous gastrostomy tube or nasogastric tube feedings must be discontinued for at least 30 minutes before postural drainage and percussion.

Artificial Airways and Mechanical Ventilation

Noninvasive measures such as oxygen therapy and ACTs may sometimes not meet the needs of all children who require oxygenation and ventilation. When respiratory effort is increased but inadequate to maintain gas exchange because of airway obstruction, intrapulmonary pathophysiology, neuromuscular disease, or other factors, artificial or mechanical ventilation may become necessary.

Several methods are available to provide artificial ventilation. A bag-and-mask unit, or Ambu bag, is used to manually ventilate a child who has not been intubated (had an endotracheal tube placed). Effective bag-and-mask ventilation is best provided with a self-inflating bag and a mask that fits properly over the child's nose and mouth.

To provide an open airway, extend the infant's or child's neck slightly in the sniffing position and lift the jaw (Fig. 16–9). The jaw thrust maneuver is used in the pediatric trauma victim with possible spinal injury or in infants for whom overextending the neck can occlude the airway. Place the mask, held in your nondominant hand, over the nose and mouth to create a seal. With your dominant hand, compress the bag rhythmically and in synchrony (or slightly faster) with the child's spontaneous respiratory efforts, if present, compressing the bag only enough to make the chest rise and fall. Aggressive ventilating will lead to gastric distention. Ensure that the bag is connected to an oxygen source, with oxygen delivered at a flow rate of 10 to 15 L/minute.

When prolonged artificial ventilation is needed because of respiratory failure or anesthesia, or when the airway is obstructed, intubation—placement of an artificial airway—is necessary, and mechanical ventilation is provided. Endotracheal intubation is the insertion of an artificial airway (an endotracheal tube) through either the nose (nasotracheal) or the mouth (orotracheal) into the trachea (Fig. 16–10). Another less invasive device for mechanical ventilation (used most commonly in the operating room) is the laryngeal mask airway.

Mechanical ventilation replaces the work of breathing and involves inflating the lungs with compressed gas, applied by either positive or negative pressure. Positive-pressure ventilators are more commonly used than negative-pressure machines. They work by creating pressure at the airway opening that is greater than the intra-alveolar pressure, thus forcing pressurized gas into the lungs. This flow of compressed gas improves gas exchange and inflation of poorly ventilated portions of the lungs. Negative-pressure machines are more cumbersome and are primarily used for long-term ventilation in persons with respiratory failure caused by neuromuscular diseases. The machine works by creating intermittent negative pressure around the thorax, causing the chest to be drawn outward and inspiration to occur. Negative-pressure

NURSING INTERVENTIONS 16–1

Airway Clearance Techniques (ACTs)

Airway Clearance Technique and Description	Benefits/Advantages	Disadvantages/Problems
<p>Postural drainage and percussion: Mobilizes secretions by using dependent positioning, gravity, and percussion Vibration with expiration can be used Mechanical percussor can be used (instead of cupped hands)</p>	<p>Gold standard Localize therapy to involved segment Can be assisted with mechanical percussor Used for all ages, especially infants, toddlers, and preschool children who may be unable to cooperate with the controlled breathing techniques</p>	<p>Time-consuming Usually needs another person to do all lobes Difficult to apply in some settings Difficult to tolerate with oxygen dependency, gastroesophageal reflux, and implanted venous access devices Head-down position contraindicated for infants because of the risk for increased gastroesophageal reflux Monitor oxygen saturation levels, particularly with the Trendelenburg position, which may be poorly tolerated by children with respiratory compromise Does not foster independence Adherence problems Carpal tunnel syndrome reported by some caregivers</p>
<p>Autogenic drainage (self-drainage): Controlled method of breathing using three different lung volumes Active cycle of breathing technique: Breathing technique that combines three methods: thoracic expansion exercises, breathing control, and forced expiratory techniques in a set cycle</p>	<p>Effective Needs no external devices Enables independence Enables independence Absence of desaturation or compromise during therapy No costly equipment</p>	<p>Labor- and time-intensive to teach and learn Must be able to take directions Child must be older than 12 years Not useful for infants and young children</p>
<p>Positive expiratory pressure: Child breathes out 10 to 20 times through a flow resistor, creating positive pressure in airway to about 15 to 20 cm H₂O during exhalation, followed by two to three “huff” coughs Cycle repeated up to 20 minutes</p>	<p>Enables independence Not reported to cause compromise with desaturation Can be done by children older than 3 years</p>	<p>Potential complication of pneumothorax</p>
<p>High-frequency chest compression: High-frequency oscillation to chest wall delivered by a vest</p>	<p>Enables older children to be independent Possible future application for younger children</p>	<p>Trial time needed to determine effectiveness before rental or purchase Patients may not tolerate the feeling from the compression Equipment must be rented or purchased Requires storage space Requires concentration May be uncomfortable if child has venous access device that is being used during the respiratory treatment</p>

Airway Clearance Technique and Description	Benefits/Advantages	Disadvantages/Problems
<p>Exercise: Any activity that requires physical exertion, endurance, and upper body strengthening</p>	<p>May not cost anything May apply in many situations Socially acceptable May also improve cardiovascular fitness, self-esteem, and general health</p>	<p>May cost for membership to clubs or gyms; depends on climate Limited to physical ability Children with preexisting conditions such as asthma (with exercise component) may need to observe special precautions when exercising (e.g., premedicate)</p>
<p>Flutter valve: Small pipelike device with a metal ball rotating freely within pipe Patients inhale and actively exhale through the pipe, which generates positive pressure to about 15 to 25 cm H₂O. Oscillations are transmitted to airways. Done for 5 to 15 breaths, followed by two to three huffs through flutter until lungs are clear, or for 20 minutes.</p>	<p>Enables independence Requires cooperation</p>	<p>Requires purchase of the device</p>

machines do not require an artificial airway. Another mode of providing mechanical ventilation is called high-frequency ventilation. This machine works by delivering oxygen under high pressures at a rapidly cycling rate.

Closely monitor the respiratory and cardiovascular status of the child receiving mechanical ventilation. Many children are sedated while intubated and all will have a nasogastric tube in place to decompress the stomach (see Tradition or Science 16–1). Perform suctioning based on the presence of adventitious breath sounds, increased respiratory effort or distress, or both. Chest physiotherapy may be ordered to further promote removal of secretions. Provide oral care and ensure the intubation tube is not causing skin irritation around the mouth or nares. Ensure the ventilator alarms are on and set within acceptable parameters to provide early notification of distress. Assist the family and, as appropriate, the child to understand

FIGURE 16–8. Postural drainage and percussion is used to assist with expulsion of mucus from the airway.

FIGURE 16–9. Child being ventilated using the bag-and-mask technique.

FIGURE 16–10. An intubated child. The tube has not yet been secured in place.

the rationale for the use of mechanical ventilation. As appropriate, provide medications to help the child remain calm and quiet while being ventilated, which will ensure optimal respiratory outcomes.

Tracheostomy

A tracheostomy consists of the surgical placement of an artificial airway directly into the trachea below the larynx. Many conditions that can cause upper airway obstruction, respiratory failure, or prolonged intubation in children may have to be managed by placing a tracheostomy tube. Emergencies such as epiglottitis or foreign

body aspiration (FBA) may require a tracheostomy for more short-term management. In some clinical conditions such as laryngotracheomalacia, subglottic stenosis, or vocal cord paralysis, the tracheostomy may be long term, until the condition is outgrown or corrected. Moreover, with some cases, such as in chronic respiratory failure with long-term mechanical ventilation, the tracheostomy may be permanent.

Tracheostomy tubes are made of Silastic, silicone, or metal and are available in various sizes and lengths. The appropriate size is determined by patient age and size. Single-cannula tracheostomy tubes are most commonly used in pediatric patients, because they have a smaller inner diameter and are usually made of Silastic, which conforms better than other materials to the shape of the trachea. For older children, a tracheostomy tube with an inner cannula may be used. The inner cannula is removed for cleaning, while the outer cannula is left in place. Additionally, some tracheostomy tubes have external cuffs. Most pediatric tubes do not have an external cuff because of the child's small airway diameter and the increased risk of trauma to the airway caused by the cuff. Because cuffless single-cannula tracheostomy tubes are used in most children, explanation of the nursing care focuses on these.

While the child is hospitalized, nursing care involves preparing child and family preoperatively, providing skilled nursing care and observation postoperatively, and facilitating a successful discharge plan for home management if the tracheostomy will be long term. Preoperatively, explain to the child and parents why the tracheostomy tube is needed, what the basic anatomy and physiology of the airway are, how breathing will be different, what to expect postoperatively, and how the child will look when he or she returns from surgery. If possible, allow the family to see a tracheostomy tube and supplies to help decrease anxiety about what to expect.

Focus postoperative nursing care on close observation to maintain a patent airway and to monitor for possible complications such as hemorrhage, edema, subcutaneous emphysema, pneumothorax, and accidental decannulation. Because infants and children are at greater risk for tracheostomy obstruction related to the relatively smaller airway, they should be initially managed in an intensive care or close observation unit postoperatively.

TRADITION OR SCIENCE 16–1

Does infant position affect outcomes of newborn infants receiving mechanical ventilation?

MORE INQUIRY NEEDED

In patients of different ages undergoing mechanical ventilation, research has indicated that particular positions, such as the prone position, may improve respiratory parameters. Clinical trials assessing the position of neonates receiving mechanical ventilation have not substantiated that any particular body position during mechanical ventilation produces sustained and relevant improvements in oxygenation. The prone position has been found to slightly improve oxygenation in neonates receiving mechanical ventilation; however, more research is needed to determine the various risks and benefits associated with different laying positions for this population of ventilated patients (Balguer, Escribano, & Roque, 2003).

Alert! All children with a tracheostomy should have an extra tracheostomy tube of the same size available at the bedside in case the tube in place is dislodged or becomes obstructed and cannot be cleared.

Respiratory assessments include vital signs and examination of the child's color, respiratory rate and effort, breath sounds, and type and amount of secretions. For the first 5 to 6 days, until the tracheocutaneous tract is well formed, long sutures (stay sutures) attached to the trachea are taped to the chest. The sutures can be used to

keep the stoma open in the event of an accidental decannulation. The surgeon removes the sutures when the tract in the trachea is formed.

The airway must remain patent to prevent obstruction and possible complications. The child may require frequent suctioning for several hours immediately after the procedure, because excessive and sometimes bloody secretions are common. Provide suctioning on an as-needed basis thereafter to prevent occlusion of the tracheostomy tube by secretions and mucous plugs. To prevent complications of suctioning, such as hypoxemia, hypotension, bradycardia (vasovagal responses), laryngospasm, bronchospasm, atelectasis, and trauma to the airway, gauge the suction pressure (should be 80–100 mm Hg), limit the time for suctioning (no longer than 4–5 seconds) and the number of suction passes, monitor the depth of the suction catheter ($\frac{1}{4}$ – $\frac{1}{2}$ inch [.635 to 1.27 cm] beyond the tip of the length of the airway), and provide manual ventilation with oxygen, rest time between suction passes, or both.

caREminder

Do not instill saline prior to suctioning. Studies do not demonstrate the efficacy of normal saline in thinning mucus secretions. Studies have shown that instilling saline before suctioning has an adverse effect on oxygen saturation, which may last up to 5 minutes. Also, instilling saline during suctioning dislodges bacteria into the lower airway.

The functions of warming, filtering, and humidifying inspired air that the upper respiratory tract normally performs are bypassed in a child with a tracheostomy. Therefore, the inspired air must be humidified and warmed to maintain loose secretions, prevent occlusion of the tube by secretions, and prevent drying of the tracheal mucosa. Nursing care is directed toward maintaining appropriate humidification via a mist collar. In addition, promoting adequate fluid intake to keep the child well hydrated is important. To prevent infection and irritation of the skin around the tracheostomy tube, provide stoma care to keep the skin clean and dry. Gently remove the secretions around the stoma, using gauze pads soaked with half-strength hydrogen peroxide followed by gauze pads soaked with sterile water. Keep the tracheostomy ties clean and dry, and change them daily and as needed when soiled.

The schedule of tracheostomy tube changes varies depending on the institution or physician preference. The first tube change usually is done by the surgeon about 5 days after the tracheotomy is performed. Subsequent tube changes are generally performed once a week in the child with a well-healed tracheostomy stoma, usually before a feeding or meal to avoid stimulation that could cause emesis.

Because many children go home with tracheostomy tubes, it has become necessary to teach parents or other primary caregivers how to care for the child at home (Fig. 16–11). TIP 16–2 outlines a teaching plan for the

FIGURE 16–11. Caregivers should be given ample opportunity to take care of the child's tracheostomy before the child is discharged.

child who has had a tracheostomy tube placed. It is also helpful to ensure that visiting nursing is provided after discharge to assist the family with routine care.

NURSING PLAN OF CARE FOR THE CHILD WITH ALTERED RESPIRATORY STATUS

QUESTION: One nursing diagnosis for Jose is: Ineffective breathing pattern related to respiratory disease process. Based on the information in the case study, what is another important nursing diagnosis?

Health promotion and disease prevention activities are essential for infants, children, and adolescents with acute and chronic respiratory conditions. These activities should focus on promoting a child's growth and development, and on adequate home management. Preventive care, monitoring and early detection of symptoms, adequate management (home vs. hospital), and health education are critical components of respiratory care for children. For example, sedentary lifestyles and obesity have grown to epidemic proportions in this country. Health promotion and disease prevention activities that focus on developing and encouraging healthy lifestyles can lead to improvements in overall health, as well as specifically enhancing respiratory functioning. Therefore, nursing care in these areas can reduce the risk for complications, exacerbations of respiratory conditions (e.g., asthma attacks), morbidity (e.g., hospitalizations, emergency room visits, school days missed), and development of comorbid conditions related to the child's preexisting condition. It can also reduce or prevent the recurrence of respiratory illnesses.

Multiple nursing diagnoses may be used to address altered respiratory function and status (Nursing Plan of Care 16–1). For example, ineffective breathing pattern

TIP 16–2 A Teaching Intervention Plan for the Child Receiving Home Tracheostomy Care

Nursing diagnoses and outcomes

- Risk for injury related to management of tracheostomy

Outcome

- Family will verbalize and identify factors in handling an airway emergency with a tracheostomy.

Deficient knowledge

- Home maintenance management of tracheostomy

Outcome

- Family will identify and demonstrate all aspects of home care of the child prior to discharge.

Teach the Child/Family

Suctioning

- Identify need for suctioning, such as sound of mucus in the tracheostomy tube, breathing sounds “rattled,” child is restless or appears anxious, child’s color is pale or dusky, or there is difficulty feeding.
- Wash hands thoroughly before and after each suctioning procedure. Alcohol or disinfectant foam is an acceptable substitute when soap and water are not available. Nonsterile gloves should be worn for the protection of the caregiver who is not a family member or by anyone who is concerned about infection.
- Connect suction catheter to suction tubing and be careful not to touch tip of catheter. Insert the suction catheter to the predetermined depth (depending on tracheostomy tube size) and place thumb over port to apply suction. Pull back catheter while twirling catheter between thumb and index finger.
- Rinse mucus from catheter with sterile saline, and repeat as necessary.
- Clean the catheters.
 - Wash and flush used catheters with hot, soapy water.
 - Disinfect catheters by soaking in vinegar and water solution or commercial disinfectant.
 - Rinse catheters inside and out with clean water and allow to air dry.

Stoma Care

- Perform daily site care and observe for signs of infection, skin breakdown, or complications around the tube site and the neck.

- Keep skin and stoma site clean and dry. Gently clean skin and stoma with a clean, wet washcloth. Use half-strength hydrogen peroxide to remove thicker, crusted secretions if necessary.
- Change tracheostomy ties daily and as needed when soiled or wet.

Daily care and home environment

Tracheostomy Tube Change

- Perform routine tracheostomy tube change once a week or more often as needed or ordered by the physician.
- Gather all supplies, wash hands thoroughly, and prepare child for procedure. Have a second person to assist with positioning of the child. Position child with neck slightly extended; may use a towel roll placed under the shoulders.
- Suction child to minimize secretions. Cut old ties while holding tracheostomy tube in place. Remove old tube from stoma and gently insert new tracheostomy tube with obturator into the stoma using a downward and forward motion following the curve of the trachea.
- Quickly remove the obturator, assess for adequacy of ventilation, and secure the tracheostomy ties.
- Take caution when feeding the infant or child so that food or formula does not get into the tracheostomy. If this should occur, suction the tracheostomy immediately. Never prop a bottle or leave the infant or child unattended while feeding.
- Bathe the child in a tub, being sure to keep the water shallow and not allowing water to get into the tracheostomy tube. Never leave the child unattended in the tub, and do not put the child in a shower. Avoid use of talcum and baby powders on the infant or child.
- Encourage normal play both indoors and outdoors as much as possible. Avoid toys that are fuzzy or have small, removable parts. On cold and windy days outside, cover the tracheostomy with a mask or 100% cotton scarf. Avoid playing in sandboxes or in or around pools, lakes, and oceans; and avoid participating in rough contact sports.
- Avoid buying clothes with high, tight necklines that may cover the tracheostomy opening.
- Do not permit smoking in the child’s home or around the child.

Safety and emergency care

- Change or replace the tracheostomy tube immediately if accidental dislodgment or occlusion of the tube should occur.
- Keep all emergency telephone numbers by the telephone and a copy with the family at all times.
- Have all necessary equipment (e.g., extra tracheostomy tube with ties, suction machine, catheters, Ambu bag) with child when traveling or going on “outings” outside the home.
- Keep flashlight handy in case of power failure, and notify electric and telephone companies that there is a child with special healthcare life-sustaining needs in the home.
- Keep all immunizations up to date.
- Check tension on tracheostomy ties daily. Tracheostomy ties should be tight enough to allow the smallest finger to be slipped underneath. T will tape tracheostomy ties can stretch after being initially secured, so recheck in 1 to 2 hours for appropriate tightness.

- Place tracheostomy tie knots on the side of the neck to prevent skin breakdown on the back of the neck.

Contact Healthcare Provider if:

- Child develops fever more than 101 °F (38.3 °C)
- Child is having difficulty breathing or the breathing pattern changes
- Child’s lips or nail beds become bluish or dusky
- Child has increase in secretions or change in color, odor, or consistency of the secretions
- Blood (greater than a teaspoon) is leaking from the tracheostomy
- There is difficulty inserting the tube with a routine tracheostomy tube change
- There is a rash, drainage, or unusual odor around the tracheostomy stoma, or food or formula is coming through the tracheostomy tube

may be used to describe a child in respiratory distress related to an asthma exacerbation (asthma attack). Respiratory distress in children also may lead to correlating problems in other body systems (e.g., cardiac, immune). In addition, many respiratory conditions are chronic. Refer back to Nursing Plan of Care 12–1 for a summary of the diagnosis and care interventions for the child with a chronic condition. The nurse’s plan of care should encompass all primary and secondary effects of the child’s respiratory illness.

ANSWER: Based on the information that Jose’s oxygen saturation is between 89% to 90%, another nursing diagnosis is: Impaired gas exchange related to underlying respiratory disease process.

ALTERATIONS IN RESPIRATORY STATUS

Respiratory conditions are among the most common maladies affecting children, ranging from those that develop in utero, such as malformations of the palate and trachea, to chronic conditions such as asthma. Respiratory health directly affects children’s stamina and their ability to engage in activities in settings that are conducive to safe air exchange. The nurse plays a primary role in educating children and their families about ways to safeguard their respiratory health. In addition, the nurse plays a critical role in determining if and when a child’s respiratory condition may place other children at

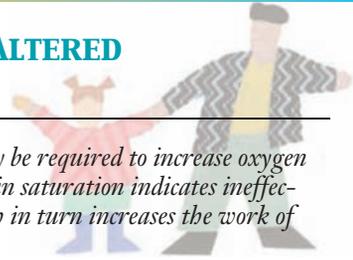

risk for infection. Thus, the role of the nurse is both to collaborate in improving the health of children with a respiratory condition and to protect the health of children who may be exposed to contagious respiratory conditions.

CONGENITAL ABNORMALITIES OF THE RESPIRATORY SYSTEM

Congenital abnormalities or malformations of the respiratory systems are fortunately rare. These disorders result in respiratory dysfunction primarily caused by airway obstructions or collapse. Congenital conditions include choanal atresia (a unilateral or bilateral bony or membranous septum between the nose and pharynx), Pierre Robin syndrome (abnormally small jaw with upper airway obstruction [resulting from tongue prolapse into the pharyngeal airway] and cleft palate; Fig. 16–12), laryngomalacia (weakness and poor tone of the larynx), and tracheomalacia (weakness and poor tone of the trachea).

These abnormalities are generally diagnosed at birth or shortly thereafter, when the child exhibits varying degrees of respiratory distress. The presence of **cyanosis** (bluish skin color caused by inadequate oxygenation of the blood) is a key finding. The treatment is largely supportive; the primary goal of treatment is to maintain a patent airway. Surgical interventions to relieve the obstruction (such as for choanal atresia) or structurally support the airway (such as for severe tracheomalacia) may be necessary. Adequate nutritional support to promote

NURSING PLAN OF CARE 16–1: CARE OF THE CHILD WITH ALTERED RESPIRATORY STATUS

Nursing Diagnosis: Ineffective airway clearance related to excess thick secretions, obstruction, or infection

Interventions/Rationale

- Conduct a complete respiratory assessment with each routine vital sign check and as indicated by the child's condition.
Enables early detection and correction of abnormalities. Thick secretions increase hypoxia and will be reflected by changes in respiratory status. Colored or odorous secretions may indicate bleeding or infections.
- Encourage child to cough, especially after respiratory treatments. Teach effective cough techniques.
Ineffective cough may be caused by respiratory muscle fatigue, severe bronchospasm, and/or thick, tenacious secretions.
- Provide humidified oxygen as ordered.
Decreases viscosity of secretions.
- Encourage increased fluid intake (clear liquids; avoid dairy products) if no contraindications, such as cardiac or renal disease, are present.
Fluid intake prevents dehydration from insensible losses through mouth breathing and increased respiratory rate. Assists to decrease viscosity of secretions and increase ciliary action to remove secretions.
- Administer prescribed medications and intravenous fluids, monitor for response and side effects.
Intravenous fluids help to maintain adequate hydration. Mucolytic agents, bronchodilators, and antibiotics may be used to increase effectiveness of cough, enhance work of breathing, and treat infections that may cause thick, tenacious secretions.

Expected Outcomes

- Child's airway will be free of secretions, as evidenced by normal or improved breathing, normal arterial blood gases, and/or oxygen saturation 92% or greater on pulse oximetry.

Nursing Diagnosis: Ineffective breathing pattern related to effects of respiratory disease process

Interventions/Rationale

- Conduct a complete respiratory assessment with each routine vital sign check and as indicated by the child's condition.
Enables early detection and correction of abnormalities. Hypoxemia, hypercapnia, and hypocapnia will cause breathing pattern changes as the autonomic nervous system attempts to maintain homeostasis.
- Provide oxygen as needed to the child to maintain oxygen saturation at more than 92% or within parameters defined as child's personal best.

Oxygen therapy may be required to increase oxygen saturation. A decrease in saturation indicates ineffective oxygenation, which in turn increases the work of breathing.

- Place child in an upright position to optimize ventilation.
Partial pressure of arterial oxygen may increase in the prone position.
- Provide reassurance to the child and allay anxiety. Keep child as calm as possible.
Increased restlessness and anxiety indicate insufficient oxygenation. Increased work of breathing can lead to fatigue. Energy expenditures increase the child's oxygen demands.
- Administer prescribed medications and intravenous fluids; monitor for response and side effects.
Steroids may help reduce bronchial inflammation, antibiotics may be used to treat infection or sepsis, and bronchodilators may be useful to enhance airway clearance.

Expected Outcomes

- Child will demonstrate an effective respiratory rate, rhythm, and effort, and will experience improved gas exchange in the lungs, as evidenced by blood gases within child's normal parameters.
- Child will verbalize ability to breathe comfortably without sensations of dyspnea and related feelings of fear or anxiety resulting from shortness of breath.

Nursing Diagnosis: Impaired gas exchange related to consequences of underlying respiratory disease process

Interventions/Rationale

- Conduct a complete respiratory assessment with each routine vital sign check and as indicated by the child's condition.
Signs of hypoxia, such as changes in level of consciousness, cyanosis, effortful breathing, ventilation (rate, quality, pattern, and depth), and vital signs indicate impaired gas exchange and compensatory efforts to manage these physiologic changes.
- Closely monitor oxygen saturation levels via pulse oximetry and arterial blood gases, and note changes.
Pulse oximetry provides an estimate of oxygen saturation; blood gases (arterial or capillary) are objective indications of oxygenation status. Progressive hypoxemia is apparent on serial blood gases despite increased concentrations of inspired oxygen.
- Provide oxygen as needed to the child to maintain oxygen saturation at more than 92% or in parameters defined as child's personal best.

Oxygen therapy may be required to increase oxygen saturation. A decrease in saturation indicates ineffective oxygenation, which may indicate that the child's condition is worsening.

- Anticipate the need for intubation and mechanical ventilation. Assist with these procedures as needed.

Intubation is indicated in the presence of impending respiratory failure. Mechanical ventilation provides supportive care to maintain adequate oxygenation and ventilation parameters to the child.

Expected Outcomes

- Child will demonstrate improved gas exchange in the lungs, as evidenced by blood gases within child's normal parameters and an alert, responsive mental status or no further reduction in mental status.

Nursing Diagnosis: Decreased cardiac output related to consequences of respiratory distress and failure

Interventions/Rationale

- Perform a complete assessment of cardiovascular status including vital signs, hemodynamic pressures, urine output, skin temperature, peripheral pulses, and respiratory effort.

Decreasing cardiac output will be reflected by changes in blood pressure, decreasing strength of peripheral pulses, decreased urine output, cool extremities, and changes in ventilation that may necessitate changes in positive end-expiratory pressure.

- Administer prescribed medications and intravenous fluids; monitor for response and side effects.

Inotropic agents may be used to increase cardiac output. Sedatives and analgesics are used to relieve pain and agitation. Neuromuscular blocking agents may be needed if the child is ventilated, to promote synchronous breathing. Intravenous fluids are administered to maintain fluid balance without causing edema.

Expected Outcomes

- Child will demonstrate adequate cardiac output, as evidenced by strong peripheral pulses; normal vital signs; urine output greater than 2 mL/kg/hour; and warm, pink, dry skin.

Nursing Diagnosis: Risk for infection related to pooling of lung secretions, ineffective cough and contagious nature of condition

Interventions/Rationale

- Conduct a complete assessment to monitor for respiratory infection, including auscultating breath sounds; evaluating for changes in sputum; and observing for fever, chills, increase in cough, shortness of breath, nausea, vomiting, diarrhea, and decreased appetite.

Early assessment of signs of infection will facilitate early intervention. Bronchial breath sounds and rales may indicate pneumonia. Sputum changes such as an

increase in production, changes in consistency, and changes in color may indicate presence of infection.

- Evaluate child's and family's understanding of techniques to prevent infection, such as careful hand hygiene, adequate rest and nutrition, avoiding contact with sick individuals, and so forth. Provide additional education as needed.

Increased knowledge and subsequent implementation of activities to prevent infection will reduce infection risk.

- Follow standard infection control precautions during all contact with the child.

Standard precautions reduces the risk of transmission of microorganisms.

- Encourage child to cough and expectorate secretions frequently. Encourage strict handwashing and infection control practices for the child, family members, and all care providers.

Retained secretions provide an environment for bacterial growth.

Expected Outcomes

- Child will be free from infection, and the parents will demonstrate adequate knowledge of risk for infection, signs/symptoms of infection, and measures to reduce infection risks.

Nursing Diagnosis: Imbalanced nutrition: Less than body requirements related to underlying chronic lung disease and increased work of breathing

Interventions/Rationale

- Assess child's nutritional status, including height, weight, body mass index percentile, diet history, child's ability to eat, and possible causes for poor appetite.

Assessment provides baseline data to assist in determining interventions. Increased metabolic needs caused by increased work of breathing will require greater caloric intake. Work of breathing may leave little energy for other activities, including eating.

- Assist child/parents to plan well-balanced meals that incorporate child's food preferences and dietary limitations imposed by disease process (e.g., low-to-moderate fat, high-protein, high-calorie meals for the child with cystic fibrosis). Encourage small feedings of nutritious soft foods and liquids. Add nutritional supplements as ordered.

These measures minimize metabolic expenditures while providing nutritious high-calorie foods that are appealing and easy to digest.

- Ensure frequent oral care is provided.

Dry mucous membranes and poor oral hygiene may contribute to decreased appetite and worsening nutritional status.

Expected Outcomes

- Child will demonstrate adequate nutritional intake for age, and parents will identify steps to achieve and maintain ideal body weight.

FIGURE 16–12. In the child with Pierre Robin syndrome, malformation of the mandible makes the chin appear recessed and restricts the tongue to a posterior position, causing easy occlusion of the airway. A tracheostomy is necessary to maintain an open airway.

optimal weight gain is a key intervention. These conditions improve with growth, and in the absence of other congenital anomalies, the prognosis for normal respiratory function is good.

Alert! The infant with Pierre Robin syndrome must be maintained in the prone position as much as possible to prevent the tongue from obstructing the pharynx and causing respiratory distress. Improper positioning can quickly result in complete obstruction and death.

Early and ongoing support and education of the parents is of utmost importance. A diagnosis of a congenital anomaly creates a crisis for the family. Reinforce the concept that in most cases the cause of the defect is unknown and not the fault of the parents. Also educate the family about appropriate positioning and feeding techniques to ensure adequate intake of formula or breast milk (either by actual breast-feeding or breast milk expressed into a bottle) and solid foods as the infant reaches the appropriate age for introducing them. Routine infant healthcare is administered. Parents need to be informed that the infant's symptoms may worsen during respiratory illnesses. If they have any concern about worsening respiratory distress, instruct them to seek assistance from their healthcare professional. Parents should also be instructed in CPR.

UPPER RESPIRATORY INFECTIONS AND OBSTRUCTIONS

Upper respiratory tract infections are extremely common in infants and young children. The upper respiratory tract, or upper airway, consists primarily of the nose, mouth, and oropharynx. For purposes of this book, infections of the epiglottis, larynx, and trachea are considered in the upper respiratory tract as well. Infections of this area of the respiratory system are usually viral and self-limiting. Although the respiratory tract is equipped with several natural defense mechanisms, invading organisms frequently gain access to these structures, resulting in

respiratory conditions that range from mild to life threatening. When infection occurs, organisms travel freely among the structures of the upper airway, including through the eustachian tubes to the inner and middle ears. The severity of resulting illness depends on age, organism, and the integrity of the child's immune response. Some infections can lead to inflammation or obstructions of the airway; obstruction can also result from noninfectious causes. Most upper respiratory conditions are treated in the home or in ambulatory care settings.

Allergic Rhinitis

QUESTION! As described in the Chapter 9 case study, Jose has seasonal allergies that trigger his asthma. Summarize the relationship between children with allergic rhinitis and children with asthma.

Allergic rhinitis is a condition characterized by sneezing; nasal itching; thin, watery rhinorrhea; and nasal congestion. The conjunctivae and posterior pharynx may also be involved. Allergic rhinitis may be seasonal, with symptoms that correspond to specific pollen peaks in the spring or fall, or may be perennial (year-round symptoms). Some children have perennial symptoms with additional flares during pollen seasons. Allergic rhinitis is the most common of all allergic disorders, affecting 10% to 20% of the population. Allergic rhinitis accounts for 2 million days lost from school, 28 million days of restricted activity, and a cost of more than \$3.3 billion for physician visits annually (Blaiss, 2004; Gleason et al., 2006, Hayden, 2007, Salib et al., 2008). The prognosis for allergic rhinitis is good if symptoms are controlled with treatment.

Pathophysiology

Airborne allergens come into contact with mast cells and basophils at mucosal surfaces. Mast cells have immunoglobulin E (IgE) receptors on their membrane surfaces that bind to IgE in serum. Exposure to the appropriate airborne allergens cross-links the mast cell IgE receptors and triggers the release of chemical mediators. This mediator release causes an immediate reaction, which includes sneezing, itching, nasal congestion, and mucus secretion accompanied by nasal mucosa edema. Four to 12 hours later, a late-phase reaction occurs, causing a second, more prolonged period of nasal congestion.

Assessment

Diagnosis of allergic rhinitis is based on clinical history, family history, physical findings, and laboratory (skin test) evaluation. Assess for complaints of nasal congestion, pruritus, clear rhinorrhea, and paroxysms of sneezing. The nasal congestion may be bilateral, unilateral, or variable and is often worse at night. Chronic rhinitis symptoms may lead to irritability and fatigue, which can cause inattentiveness and difficulty concentrating in school. Parents may tell you that their children sniff,

snort, and frequently clear their throats. They may also twitch, pick or rub their nose, and have episodes of repetitive sneezing. In conjunction with nasal symptoms, the eyes may itch and water. Bronchospasm with coughing, shortness of breath, or chest tightness may occur in children who also have asthma. Other symptoms may include fatigue, irritability, headache, depression, and anorexia.

A predisposition to allergic rhinitis is often familial; therefore, determining whether other family members (parents, siblings, or grandparents) have a history of hay fever or allergies can help make the diagnosis.

On physical examination, look for certain characteristic features that distinguish allergic rhinitis from the common cold (rhinitis) (Table 16–1). The child may have bluish discoloration of the infraorbital area (called *allergic shiners*), caused by increased venous flow related to the local allergic vigor. The child may have a transverse crease across the lower third of the nose caused by rubbing the nose (called the *allergic salute*). Examination of the nasal cavity using a nasal speculum may reveal edematous mucosa, with swollen, boggy, and pale-pink to blue-gray turbinates. Nasal secretions are generally clear, watery, or white.

Microscopic examination of the nasal secretions reveals abundant eosinophils. Skin testing for sensitivity to allergens believed to contribute to the nasal symptoms may help establish specific triggers for the allergy symptoms (e.g., dust mite, cat, dog, trees, grass, or ragweed).

Interdisciplinary Interventions

The mainstay of treatment for allergic rhinitis is avoiding the offending allergens. Environmental control measures that can help relieve symptoms by limiting exposure to common indoor allergens are shown in Community Care 16–1. Parents of children with seasonal (pollen-induced) allergic rhinitis must be cautioned that pollen counts are highest in the mornings between 5 and 10 AM. Environmental measures to reduce allergen exposure should include wet-mop dusting, closing household windows at least during the allergy season, and frequently changing ventilation filters. One may be able to further limit exposure by limiting household pets and making the home smoke free.

TABLE 16–1

Differences Between Allergic Rhinitis and the Common Cold

Symptoms	Allergic Rhinitis	Common Cold
Family history of atopy	Yes	No
Conjunctival pruritus	Yes	No
Fever	No	Yes
Pharyngitis/laryngitis	No	Yes
Purulent secretions	No	Yes
Sinus pain	Yes	No

Medical management involves the use of oral or intranasal antihistamines, decongestants, intranasal corticosteroids, leukotriene modifiers, mast cell stabilizers, and allergen-specific immunotherapy (Blaiss, 2004; Gleason et al., 2006). Antihistamines are used to block histamine from binding at its H₁ receptor site, thereby preventing the vasodilatation, sneezing, and hypersecretion it causes. Decongestants may be helpful in reducing nasal obstruction through vasoconstriction, but the suitability of over-the-counter preparations for the younger child should be verified through the healthcare professional. Nasal corticosteroids are used to decrease inflammation in the nasal passages. For moderate to severe cases of allergic rhinitis, leukotriene modifiers and mast cell stabilizers may be used. In children with more severe symptoms, immunotherapy may be used (Berger, 2004; Blaiss, 2004).

As with any medication, educate parents and children regarding the uses and side effects of these medications. Medications for rhinitis include sedating and nonsedating forms. The availability of over-the-counter cold preparations for children changes; therefore, instruct parents to read the package label carefully.

ANSWER: Although not all children who have allergic rhinitis also have asthma, a significant portion of children who do have asthma also have allergies. The allergies can act as a trigger for their asthma, and therefore controlling their allergic response also helps to control their asthma. What is difficult for many families is maintaining a preventative medication regime when the child does appear sick.

Sinusitis

Sinusitis in children is usually seen as a viral or bacterial infection in the paranasal sinus structures. On the average, children have about six to eight colds per year and, of these, 0.5% to 5% will develop into acute sinusitis (Ramaden, 2004). Sinusitis characteristically responds well to antibiotic therapy, although prolonged courses may be required. Complications can occur as a result of local extension of the disease, such as orbital cellulitis. Intracranial infection, with associated neurologic symptoms, is also a potential sequela of sinusitis. Prompt, appropriate antibiotic therapy usually prevents the onset of these potentially life-threatening ophthalmologic and neurologic complications.

Pathophysiology

The paranasal sinuses, which encompass the ethmoid, maxillary, sphenoid, and frontal sinuses, are hollow areas in the skull beneath the turbinates in the nasopharynx. Ethmoid and maxillary sinuses are present at birth. The sphenoid sinuses are formed by 5 years of age, and frontal sinuses continue developing until adolescence (Figure 16–13). The various functions of the sinuses include warming and humidifying inspired air, trapping inspired particles, secreting mucus, and reducing the weight of the skull.

COMMUNITY CARE 16–1

Home and School Environmental Control of Allergies

Suggestions for eliminating or reducing triggers can be provided to families, and may include

Home

- Do not allow smoking in the home or car; encourage smokers to always smoke outside. Refer family members who are smokers to local smoking cessation programs (e.g., American Lung Association, American Cancer Society, Local Smoking Quitline).
- Encase mattresses, box springs, and pillows with airtight hypoallergenic covers. The child should avoid sleeping or lying on rugs or upholstered furniture. Use synthetic materials for all bedding, and wash bed linens weekly in hot water (130 °F[54.4°C]). Place stuffed toys in the clothes dryer (on air fluff) at least once a week to reduce dust mites.
- Remove clutter (dust collectors) including knick-knacks, pictures, wall hangings, trophies, and stuffed toys from the child's bedroom. Wet dust and clean the child's bedroom twice a week.
- Use shades, vertical blinds, or curtains that are washable in hot water (130 °F[54.4°C]). Wash curtains every 1 to 2 weeks.
- Hardwood floors are preferable to carpeting. If able, remove carpeting from the child's room. If unable, vacuum twice a week with the windows open to increase ventilation and reduce dust collection. The child should be out of the room or house during vacuuming.
- Do not allow pets, particularly dogs and cats, in the child's bedroom. Wash the pet weekly. Ideally, the pet should be kept outdoors.
- Avoid painting or using cleaning products around the child. The child should not be in the house when these chemicals are being used. Consider using natural cleaning products like dilute white vinegar, useful in removing mold, mineral deposits, and crayon marks; baking soda can be used as a general cleaner; and club soda is a good spot remover. Avoid perfumes, powders, aerosol sprays and hairsprays around child.
- Clean and dust the kitchen floor and cabinets 1 to 2 times a week to remove cockroach allergen present in house dust (especially in apartment buildings).

Keep brown paper grocery bags, cardboard boxes, and newspapers outside.

- Avoid using humidifiers in the house, because they promote the growth of dust mites and can harbor fungi and molds if not cleaned properly. Ideally, the humidity level in the house should be kept at 25% to 40%.
- Other strategies to reduce home environmental allergens and pollutants can be found at the Environmental Protection Agency (EPA) website (<http://www.epa.gov/iaq/asthma/triggers.html>).

School

- Ensure cleaning of chalkboards when students are not in the classroom; clean erasers outside.
- Replace paint and marker caps when they are not in use to control strong fumes.
- If possible, include nonfur-bearing pets such as fish or snakes, which are preferable in classrooms to reduce allergen exposure from furry pets. Wet-dust bookshelves weekly.
- Avoid upholstered furniture. Furniture should be made of vinyl, leather, or wood.
- Bare wood or tile floors are best. If possible, remove rugs and keep floors clean.
- Consider placing small rugs and carpets (without rubber backs) in clothes dryer (on air fluff) at least weekly to reduce dust mites and soil collection. Carpets can trap dust and soil.
- Opening windows to allow fresh air exchange is good, but check pollen and pollution levels first.
- Wet-dust fan blades and air exchange vents at least monthly.
- Clean or change window air conditioner filters at least monthly.
- Use air conditioners or a dehumidifier to keep relative classroom humidity at 35% to 45%.
- Have teachers and staff avoid perfumes, scented talcum powder, and hairsprays.
- Use liquid rather than bar soap (mild or unscented) for handwashing.
- More EPA guidelines and strategies for healthy school environments can be found at <http://www.epa.gov/schools/>

The sinuses are prone to infection most frequently after a viral upper respiratory tract infection because the sinus cavities in children are smaller in area than in the adult. Inflammation and edema of the mucous membranes during an upper respiratory tract infection can lead quickly to obstruction of the opening to the nasopharynx. The nor-

mally sterile sinus cavity is then invaded by bacteria. Bacterial pathogens in acute sinusitis are the same as those found in acute otitis media, with *Streptococcus pneumoniae* and *Haemophilus influenzae* predominating. *Moraxella catarrhalis* is also a common cause of acute sinusitis in children (American Academy of Pediatrics, 2001; Lindbaek, 2004).

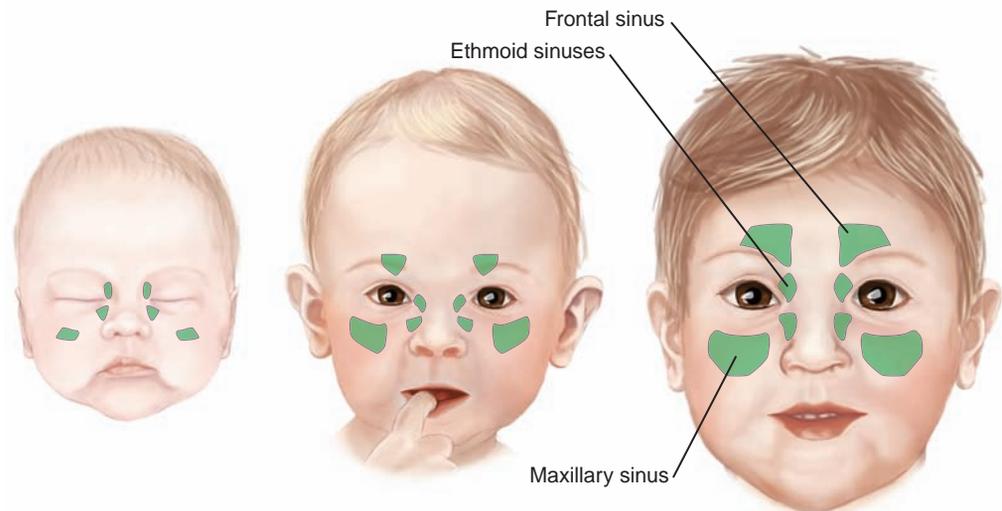

FIGURE 16-13. Development of the frontal, ethmoid, and maxillary sinuses.

Assessment

Children with sinusitis have various clinical manifestations and histories. Ask questions to elicit any evidence of the two most common symptoms of sinusitis: headache and toothache. The infant or younger child may exhibit fever and irritability after a viral upper respiratory tract infection. The older child may have symptoms such as purulent rhinorrhea, malodorous breath, headache, anorexia, sore throat, a feeling of fullness or pain in the face (especially over the sinuses), cough, and a disturbed sense of smell.

History of symptoms and physical examination are needed to diagnose sinusitis in children younger than 6 years. A positive history for sinusitis would include symptoms that last more than 10 days without evidence of improvement.

Clinical diagnostic testing (e.g., radiography, computed tomography) for sinusitis is usually not indicated in children younger than 6 years of age. For older children, history of symptoms, physical examination, and clinical diagnostic testing (radiography, computed tomography, and cultures) are required.

Interdisciplinary Interventions

Antimicrobial therapy and symptomatic relief measures are the main interventions for sinusitis. Antibiotics are usually given orally, and in complicated cases may be required for as long as 6 weeks. Hospitalization for sinusitis is rarely required, although on rare occasions, children with sinusitis may develop an advanced infection or complication that requires hospitalization for more intense neurologic monitoring and parenteral antibiotic therapy. Decongestants and antihistamines, although their use is not supported by research (American Academy of Pediatrics, 2001; Lindbaek, 2004), have been used to promote drainage from the sinuses. Encourage parents to administer additional clear liquids during the acute phase to promote hydration and sinus drainage.

Alert! The Food and Drug Administration has recommended that over-the-counter products such as decongestants, expectorants, antihistamines, and cough suppressants not be used to treat infants and children younger than 4 years because of serious and potentially life-threatening side effects.

Nasopharyngitis and Pharyngitis

Nasopharyngitis (common cold) and pharyngitis (throat infections) are among the most frequently encountered complaints in the pediatric ambulatory care setting. One group of researchers reported that during the first years of life, daycare attendance and having siblings significantly increased the likelihood of contracting respiratory syncytial virus (RSV) and rhinovirus, and increased the risk of rhinovirus-induced wheezing (Copenhaver et al., 2004). These inflammatory syndromes of the nasopharynx and oropharynx are attributed predominantly to infectious agents or, less commonly, to secondary involvement in systemic or noninfectious illnesses.

Pathophysiology

The nasopharynx and oropharynx consist of mucous membrane layers composed of stratified squamous epithelium; the inflammatory process is initiated in these structures by viruses or bacterial pathogens. The lymphatic drainage system is involved secondarily. Excessive drying of the mucous membranes during the winter months and passive or active smoking are other potential contributing factors, because they irritate the mucous membranes and increase susceptibility to infection. The virulence of viral or bacterial pathogens depends on mucosal cell wall antigens. Viral particles are transmitted by air, by direct contact, and sometimes by food-borne transmission (Anon, 2003; Park et al., 2006).

When the mucous membranes are involved, infection can spread through the lymphatic drainage system and

saliva to other parts of the oral cavity and respiratory tract. The uvula and epiglottis may become inflamed. Unresolved nasopharyngitis and pharyngitis, combined with fever, decreased appetite, and reduced fluid intake, can dehydrate an infant rapidly. Complications such as otitis media, lymphadenitis, and peritonsillar abscess may also occur if the infection is not self-resolved (for viral conditions) or treated effectively with antibiotics (for bacterial infections).

Viral upper respiratory infections constitute nearly all cases of pharyngitis and nasopharyngitis. Rhinovirus, respiratory syncytial virus, coronavirus, and adenovirus are the most common pathogens in children younger than 3 years of age. Influenza, parainfluenza, Epstein-Barr virus, and coxsackievirus A are among the more prevalent causative agents in older children and adolescents. Pharyngitis is most commonly attributed to group A beta-hemolytic streptococci (GABHS). Other etiologic agents include *Corynebacterium diphtheriae*. Infection with diphtheria was common at the turn of the century; immigrant and other nonimmunized populations in the United States remain at risk for contracting this organism today. *Mycoplasma pneumoniae* can also cause pharyngitis that is clinically indistinguishable from GABHS, most commonly in the adolescent population. Gonococcal pharyngitis may be seen in sexually active or sexually abused children. Table 16–2 compares pharyngitis caused by viral versus bacterial agents.

Assessment

Observe for the hallmark symptoms of nasopharyngitis: clear rhinorrhea, nasal stuffiness, cough (usually worse at night because of postnasal drip), generalized malaise, and irritability. Extreme throat discomfort is the chief complaint in most cases of pharyngitis (Fig. 16–14). With GABHS, white exudate, petechiae, or both may be visible on the posterior palate and tonsils. High fever, scarlet fever rash, and tender cervical lymphadenopathy may also be present in bacterial pharyngitis. Dysphasia, hoarseness, and laryngitis may accompany either pharyngitis or nasal pharyngitis.

Interdisciplinary Interventions

Pharyngitis and nasal pharyngitis are treated in the home by the parents, often in collaboration with the healthcare professional. Bacterial pathogens can be identified by throat culture and treated with the appropriate antibiotics. Parents need instructions to monitor carefully for signs of complications or disease progression and to seek medical attention promptly if they occur. Parents may also be advised to position the infant in an infant seat or with the head of the bed elevated for comfort and to facilitate drainage of nasal secretions. A bulb syringe may also be used to clear nasal passages before feedings, especially for infants, to promote feeding and nipping.

TABLE 16–2

Comparison of Viral and Bacterial Pharyngitis

	Viral Pharyngitis	Streptococcal Pharyngitis
Signs and symptoms	WBC usually normal Gradual onset Headache, low-grade fever Rhinitis, cough, and hoarseness common; abdominal discomfort uncommon Slightly red pharynx with moderately enlarged tonsils Absent marked cervical lymphadenopathy	WBC count elevated (15,000–20,000/mm ³) Abrupt onset Headache, fever up to 104 °F(40°C) Common complaints are sore throat, abdominal discomfort, and trouble swallowing; rhinitis, cough, and hoarseness uncommon Erythema and enlargement of tonsils with white exudate on posterior pharynx and tonsils Firm, tender cervical lymph nodes present
Treatment	Symptomatic treatment only	Antibiotics to eradicate organisms, either penicillin or erythromycin for 10 days, plus symptomatic treatment
Complications	Few complications	Complications include otitis media, sinusitis, peritonsillar abscesses, acute cervical adenitis, rheumatic fever, meningitis, and acute glomerulonephritis
Duration	Usually self-limiting, lasting 5 to 7 days	Without antibiotics, child may be acutely ill for 2 weeks. If left untreated, group B streptococcus may lead to further complications, including rheumatic fever, acute poststreptococcal glomerulonephritis

WBC, white blood cell count.

FIGURE 16-14. Pharyngitis. Note the redness of the pharynx, tonsillar exudate, and white strawberry tongue coating.

FIGURE 16-15. “Kissing tonsils” occur when the tonsils are so enlarged that they touch the uvula and/or each other, greatly narrowing the airway.

Community Care

Supportive care, including rest, nutritious foods, and cool fluids, is the primary intervention. General fever reduction methods should be used for children with temperatures higher than 101 °F (38.3 °C). Acetaminophen, the drug of choice for reducing fever, may be alternated with nonsteroidal anti-inflammatory drugs for temperatures more than 102.2 °F (39.0 °C) in children older than 3 years of age. Comfort measures such as cool fluids and ice pops may be given, and warm saline throat irrigations (saltwater gargle) may be comforting for the older, cooperative child. The most common carrier of infection is the human hands. Frequent hand-washing by the child and caregiver is needed to reduce spread of the infection. Symptoms generally resolve in 5 to 7 days.

Tonsillitis

Tonsils and adenoids are important to the normal development of the body's immune system, because they serve as part of the body's defense against infection, but they may become a site of acute or chronic infection (tonsillitis). The tonsils are located on either side of the pharyngeal cavity. The palatine, or faucial, tonsils enlarge when infected and are readily seen behind the faucial pillars at the sides of the oropharynx. Adenoids are the nasopharyngeal tonsils, which are located adjacent to the palatine tonsils on the posterior wall of the nasopharynx. Tonsillar tissue increases in size during childhood as a result of acute nasopharyngeal infections that commonly occur in the school-aged child (Fig. 16-15). Tonsils reach their maximum size between 8 and 12 years of age and then begin to involute, or shrink, during adolescence.

Tonsillitis most often affects school-aged children. About 7 per 1,000 people are estimated to be managing symptoms of tonsillitis at any one time. The condition is not limited to the pediatric population.

Pathophysiology

Repeated acute infections centered in lymphoid tissue such as the tonsils draw the body's defenses to that location, causing the tissue to swell. The acute infectious process inflames the tissues of the tonsils and may cause exudate to form on the tonsils. Enlarged tonsils and adenoids impinge on the pharyngeal opening of the eustachian tube, preventing it from ventilating and draining the middle ear, thus contributing to incidence of otitis media as a sequela to tonsillitis. Other symptoms include reddened pharynx and tonsils, sore throat, dysphagia, fever, and swollen lymph nodes in the neck region.

Acute tonsillar infection is thought to result largely from infection with group A beta-hemolytic streptococci (GABHS), although other organisms can cause tonsillitis, including *H. influenzae*, pneumococcal infection, and viral agents. GABHS is particularly problematic because it cannot be identified by rapid strep test. GABHS may be obtained by throat culture, although cultures are difficult to obtain and are at times inconclusive. Children generally recover from tonsillitis, but if it is caused by GABHS that is not completely eradicated, sequelae such as rheumatic fever or acute glomerulonephritis may occur.

Chronic tonsillitis is a common affliction of childhood; however, its exact incidence is unknown.

Assessment

Children with acute or chronic tonsillitis present with clinical signs and symptoms similar to those of pharyngitis.

Inspect for inflammation of the tonsils and surrounding tissues, accompanied by varying degrees of soreness of the mucosa. This soreness may cause the child to refuse to eat or drink because of discomfort on swallowing. Additional clinical manifestations include exudate on the tonsillar surface, substantial erythema, recurrent or persistent sore throat, and possible obstruction to swallowing or breathing caused by hypertrophied tonsils or adenoids. Occasionally, the throat may be dry and irritated, and the breath may be offensive. If the tonsils and adenoids are hypertrophied, determine whether they are obstructing the upper airway. This complication, although rare, can cause respiratory distress, with chronic hypoxia and the development of pulmonary hypertension. Children with tonsils or adenoids that are so enlarged that they partially obstruct the upper airway often present as “mouth breathers” and often snore during sleep. Consider a sleep apnea evaluation for such children.

Hypertrophy or acute infection of the tonsils must be carefully evaluated. Many apparently enlarged tonsils are, in fact, normal in size. The misinterpretation arises from the fact that, because of frequent nasopharyngeal infections, tonsils are normally larger during early childhood years than later in life. Tonsils may virtually meet in the midline in some normal, asymptomatic children, especially when the child gags. Ascertain whether hypertrophy, if present, is chronic or the result of a recent acute infection. Tonsils can increase in size tremendously with an acute infection and recede after the infection subsides.

Inspect an older child’s tonsils simply by asking the child to say “aahh.” If the child is unable to hold the tongue down, use a tongue blade lightly to help. Younger children consider the examination of the mouth and throat intrusive and may be uncooperative. Infants and young children whose cooperation cannot be gained will usually open their mouths during crying to allow a good view of the oropharynx. If a tongue blade is needed, use it cautiously and quickly.

Interdisciplinary Interventions

When tonsillitis is present, it is necessary to screen for GABHS by culturing the tonsillar surface that may contain the exudate. A throat culture can be best obtained using the same techniques as those for inspecting the throat. Identifying the causative organism is helpful in determining the antibiotic course that will be used. The recommended treatment for acute tonsillitis secondary to GABHS is usually penicillin, unless a contraindication (i.e., penicillin allergy) exists. In cases of penicillin allergy, cephalosporins may be used. Antibiotics are generally administered orally or intramuscularly; the oral dose should be given for 10 days. Teach the parent that administering the complete course of antibiotic is essential because, although symptoms may subside in 24 to 72 hours, the full course is necessary to prevent complications such as rheumatic fever and glomerulonephritis.

Tonsillectomy and adenoidectomy are controversial surgical interventions for chronic tonsillitis. Recurrent

throat infections (documented with positive throat cultures) remain one of the leading indications for surgery. Tonsillectomy has been documented to decrease the number of infections in children with recurrent tonsillitis; however, the number of throat infections also declines in many children who have not had tonsillectomies. Chronic upper airway obstruction is also a major indication for surgery. Symptoms of upper airway obstruction are more prominent during sleep and include mouth breathing, loud snoring, and, in extreme cases, apnea. The child with upper airway obstruction extensive enough to warrant tonsillectomy may also exhibit sleep disturbances and enuresis. Patients with severe obstruction improve after surgery; many patients with mild to moderate symptoms improve without it. Before considering tonsillectomy, healthcare professionals, in collaboration with parents, should carefully document that sore throats are caused by GABHS and are frequent (more than five per year), symptomatic (fever, exudate, erythema, adenitis), and costly in terms of missed school and work days and medical expenses.

Tonsillectomy and adenoidectomy surgeries usually are performed on an outpatient basis 2 to 3 weeks after acute infection. The nurse prepares the child and family for the surgery, and teaches both child and family the postoperative care protocol.

Observe for potential hemorrhage during the postoperative period. An ice collar is applied externally around the neck. As soon as the child is awake, he or she may suck on ice chips. The most comfortable and safe position is prone (on the abdomen) with the head turned to the side so that mouth drainage can be observed. Small amounts of bright-red blood may be present soon after the surgery. It is normal for the child to have one emesis of old blood after the surgery and small amounts of blood-streaked mucus within the first few hours after the surgery.

caREminder

Perform any needed suctioning with caution, to avoid trauma to the oropharynx and surgical site. Instruct the child to avoid coughing, talking, clearing the throat, or blowing the nose after surgery, to prevent disturbing the surgical site.

If the child spits up bright-red blood frequently or has repeated emesis of old blood from the stomach, or if he or she becomes tachycardic (heart rate >120 beats per minute), pale, and restless, notify the surgeon immediately. Occasionally, it may be necessary for the child to return to surgery to ligate a bleeding vessel. If no bleeding occurs, ice chips and water may be given soon after surgery, after the child is fully alert. Advance the diet from clear liquids to full liquids, as tolerated. Give pain medication, in the form of a liquid or syrup if available, within the first 2 hours after surgery. The child should receive pain medication every 4 hours during the first 24 to 48 hours to control pain and to make swallowing fluids more comfortable.

TIP 16–3 A Teaching Interventional Plan for the Child After Tonsillectomy or Adenoidectomy

Nursing diagnoses and outcomes

- Acute pain related to effects of surgical procedure

Outcome:

- Child will demonstrate indicators of comfort and will receive adequate periods of rest.
- Deficient fluid volume related to decreased intake of fluids and loss of fluids (vomiting, secretions)

Outcome:

- Child will have adequate fluid intake with minimal fluid losses.
- Deficient knowledge: signs of postoperative complications

Outcome:

- Family/caregiver verbalizes and describes home treatment and early signs of postoperative complications.

Teach the Child/Family

Home Management of the Child

- Allow the child to engage in quiet activity for the first week after surgery. The child may return to school in 1 to 2 weeks or after the follow-up appointment.

- Give analgesics for pain every 4 to 6 hours as needed. Use acetaminophen for pain relief; avoid aspirin and ibuprofen because these may increase bleeding tendencies.
- Apply an ice collar to the child's neck, which may help with pain management.
- Be aware that halitosis is common for 1 to 2 weeks after surgery. Provide mouth care by using mouth rinses, instructing the child not to gargle.
- Encourage the child to drink plenty of fluids (1–1½ quarts) daily.
- Offer tepid fluids or slow-melting fluids such as ice pops or Italian ices, and offer a soft diet, avoiding spicy, rough, or coarse foods for the first 7 to 10 days.
- Use caution with straws; utensils; and sharp, pointed toys that may be put in the mouth and injure the surgical site.
- Avoid crowds and protect the child from contact with persons who are ill.
- Emphasize the importance of the surgical follow-up appointment, usually 1 to 2 weeks after surgery.

Contact Healthcare Provider if:

- Persistent bleeding, frequent swallowing, coughing, or blood in vomitus
- Child complains of an earache
- Child has a fever more than 101 °F (38.3 °C)

The child may be discharged on the day of surgery or the following day, but should convalesce at home for several days. TIP 16–3 highlights key instructions for care of the child at home.

Community Care

The child with uncomplicated acute tonsillitis is usually managed on an ambulatory basis. The symptoms of a sore throat may be treated in the home with acetaminophen (nonsteroidal anti-inflammatory drugs for children older than 6 months), throat lozenges or hard candies, cool fluids, ice chips or ice pops, and saltwater gargles to keep the throat moist. Discourage the use of topical anesthetic sprays, because their efficacy in young children is unproved and because of the risk of systemic absorption and allergic sensitization. Stress the importance of clear liquids to encourage hydration (diary products should be avoided, because they promote thickening of mucous).

Occasionally, the throat swelling is severe, symptoms indicate epiglottitis, or the child may become severely dehydrated and therefore require hospitalization for treatment with intravenous fluids, parenteral antibiotics, and emergency equipment available in case of airway obstruction.

Croup

Croup is one of the most common acute respiratory conditions seen during early childhood (6 months–6 years of age) and the most common cause of upper airway obstruction (Cherry, 2005; Leung, Keller & Johnson, 2004). The term *croup* represents several distinct disorders that cause a characteristic clinical syndrome of hoarseness, inspiratory stridor, a “croupy” or barking cough, and varying degrees of respiratory distress.

Croup syndromes are generally more common in boys than in girls and occur more often in the late autumn through early winter months. Although croup is generally a benign condition resulting in minimal airway obstruction, some forms of croup can be life threatening, resulting in respiratory failure. Young children are particularly at risk, because inflammation and narrowing in their small airways can easily result in obstruction. Croup syndromes are usually described according to the primary anatomic area of inflammation: acute epiglottitis (supraglottitis), laryngotracheobronchitis (LTB; inflammation of one or more of the following structures: vocal cords, larynx, subglottic tissue, trachea, bronchi, bronchioles), spasmodic croup (larynx), and bacterial tracheitis (trachea).

Croup syndromes may be infectious or noninfectious. Noninfectious croup syndromes, such as spasmodic croup, may be caused by asthma or allergic reactions, or they may follow endotracheal extubation or foreign body aspiration (FBA). This section focuses on croup syndromes with infectious etiologies.

Acute Epiglottitis (Supraglottitis)

Epiglottitis is a rare, acute inflammation of the supraglottic structures, the epiglottis and aryepiglottic folds. It characteristically does not involve the subglottic and tracheal regions. Epiglottitis constitutes one of the true pediatric emergencies. If treatment is delayed, it may rapidly progress to complete airway obstruction, cardiopulmonary arrest, and a potentially fatal outcome. When prompt diagnosis and coordinated, well-organized management occur, the prognosis for full and uncomplicated recovery is excellent.

The incidence of epiglottitis is unknown. Although has been estimated to be fewer than 10 per 10,000 pediatric hospital admissions. Epiglottitis is commonly seen in children in all age groups, including infants, but occurs most often in children 2 to 7 years of age, with 80% of the cases occurring before 5 years of age (Leung, Kellner, & Johnson, 2004). It occurs year-round, but is more common during winter and early spring.

Epiglottitis most commonly results from infection of the supraglottic structures by *H. influenzae* type B (HIB). GABHS, *S. pneumoniae*, and, rarely, other bacteria and some viruses have also been reported. The infecting organism can be isolated from the upper airway as well as from the blood. Direct invasion by HIB causes inflammation of the supraglottic structures, with subsequent edematous swelling of these structures and bacteremia. Since 1985, with the licensing of the HIB vaccines, the incidence of disease caused by *H. influenzae* has declined. Still, pediatric health professionals should not dismiss the risks of epiglottitis and its consequences, however, because organisms such as streptococci have risen as causes of epiglottitis (Faden, 2006). All patients who have the clinical picture of this disease must be managed with the same cautious approach.

Assessment

Diagnosis of epiglottitis is made primarily from clinical signs. Consider epiglottitis in any child with acute upper airway obstruction and respiratory distress, including stridor, of sudden onset (developing over a few hours) accompanied by high fever (more than 102.2 °F [39 °C]), sore throat, hoarseness, dysphagia, and drooling. Often these symptoms are preceded by symptoms of an upper respiratory infection. Epiglottitis seldom causes the “barking” cough characteristic of other croup syndromes. Agitation, characterized by irritability and restlessness, is almost always present. Observe whether the child assumes the “tripod” position, the hallmark of epiglottitis—the child refuses to lie down, preferring to sit upright and lean forward, mouth open, to attain the best airway possible and to allow secretions to run out of the mouth. As the

obstruction increases, cyanosis may occur and retractions of the supraclavicular and substernal area may be present. Parents are usually very fearful and anxious as they witness and describe rapid onset of symptoms.

Never attempt direct visualization of the upper airway in any child with symptoms of epiglottitis. Direct visualization of the upper airway may precipitate complete airway obstruction and respiratory arrest. It should be attempted only by a person skilled in intubation and with all necessary equipment present at the bedside. Upon visualization, the epiglottis is cherry red, and it and the surrounding tissues are extremely swollen. The laryngeal orifice may be severely narrowed, and pooling of mucous secretions often occurs.

Alert! Do not use tongue blades or other instrumentation to visualize the epiglottis. Such actions can cause the epiglottis to spasm and totally occlude the airway.

A lateral neck radiograph is a useful diagnostic technique. It shows the epiglottis as a large, rounded soft mass below the base of the tongue.

Interdisciplinary Interventions

Skilled pediatric personnel should carefully monitor children for whom the diagnosis of epiglottitis is suspected at all times and in a controlled medical environment (e.g., hospital room or emergency room with airway equipment appropriately sized for pediatric use). The child and the parents are usually extremely anxious, and the most important interdisciplinary intervention is keeping the child quiet and undisturbed until endotracheal intubation is performed. Minimize episodes of crying by allowing the child, if possible, to sit upright in the parent's arms. Never force the child into a supine position, because this position may cause the inflamed epiglottis to obstruct the airway, compromise diaphragmatic excursion and air movement, or enable the child to choke on swallowed secretions.

Respiratory status, including rate and depth of respirations and the presence of retractions, nasal flaring, and stridor, must be carefully monitored. Give humidified oxygen by face mask and keep the head of the bed elevated at all times. Monitor SaO₂ levels using pulse oximetry. Intravenous antibiotics (usually ampicillin or cefuroxime) must be given as soon as possible. Upon strong suspicion or confirmation of the diagnosis, intubation should be performed, ideally in the operating room under general anesthesia. Intubation sometimes is not possible because of laryngospasm or severe swelling, and in these cases, placement of a tracheostomy is required (see Treatment Modalities earlier in the chapter).

Other important interventions include administering and monitoring sedative medication, because the risk of accidental extubation is high. Mild sedation also allows the child to breathe spontaneously, making mechanical ventilation unnecessary. Assess for possible respiratory complications, monitor body temperature, and provide

adequate fluid and calorie intake. The child must have nothing by mouth during the acute phase of the illness, and oral fluids and soft foods should not be provided until the child has demonstrated ability to tolerate extubation (Clinical Judgment 16–1).

As with any hospitalization, parental anxiety is high, especially if the child is admitted in acute respiratory distress. During this period, provide calm, factual, step-by-step information. Repeat this information as the family's stress level decreases and they are able to formulate questions. Initial information should include the course of events in the immediate future—for example, when and where the child will be intubated; where the family may wait; when they may first visit the child after airway management is accomplished; how the child will be given nutrition, hydration, and medication; and how long they should expect he or she will need to remain intubated and sedated.

Recovery from epiglottitis is usually rapid, with endotracheal extubation occurring in 2 to 3 days as the fever dissipates, the child can handle secretions, and airway narrowing is resolved. Reassuring and supporting the parents is key during this recovery phase, because the rapid progression and critical nature of this disorder render it extremely frightening. Nurses and social workers can assist families by providing frequent, accurate education and updates on the child's condition, and allowing parental visitation or "rooming in" as much as

possible. Tell parents when they should expect the child to resume normal dietary habits and when discharge from the hospital is expected. Begin teaching about administration of oral antibiotics at home (to complete a 7-day course) when the intravenous line is discontinued.

Community Care

Urge immunization with the HIB capsular polysaccharide vaccine for the patient and all siblings of appropriate age (see Chapter 8), if they are not already immunized. Prophylaxis with rifampin by mouth is recommended for all household contacts, if at least one contact is younger than 4 years, regardless of immunization status. Daycare and nursery school contact groups should be managed on an individual basis. The HIB vaccine and rifampin prophylaxis can both be obtained from the county public health agency in many states.

Laryngotracheobronchitis (LTB)

LTB is the most common type of croup syndrome. The peak incidence of this illness is in the 6-month to 3-year-old age group, but LTB can be seen in children as young as 3 months and as old as 15 years of age (Leung, Keller, & Johnson, 2004). LTB usually occurs during the fall and winter months.

CLINICAL JUDGMENT 16–1

The Drooling Child

Jimmy, a 5-year-old child, presents in the emergency room with respiratory stridor upon inspiration and a temperature of 102.5 °F (39.2°C). He is drooling and prefers to sit forward with his chin slightly protruded. His mother states that he developed the difficulty breathing "so suddenly," and both mother and child appear anxious.

Questions

1. What additional data would you collect during your initial assessment?
2. Is this an upper or lower respiratory problem?
3. What actions would your initial interventions include?
4. Is obtaining a throat culture indicated at this time? Why or why not?
5. What interventions should be implemented to maintain a patent airway in this child?

Answers

1. Heart rate, duration of fever, and other signs of respiratory illness. Is the child voiding? When did he last eat or drink (to assess for dehydration and

shock)? No visual inspection of the oral cavity is ever indicated if epiglottitis is suspected.

2. An upper respiratory problem, as distinguished by inspiratory stridor resulting from an obstruction. In this case, the obstruction is a swollen cherry-red epiglottitis.
3. Interventions include establishing and maintaining an airway. Keep the child with his mother to help reduce anxiousness and allow him to remain in the "tripod position," because this helps maintain an open airway. Provide oxygen via mask or blow-by oxygen. If respiratory distress becomes severe, ventilate with a bag-valve mask.
4. A throat culture should not be obtained, because manipulation of the oropharynx for visualization or when obtaining a culture may precipitate airway (trachea) spasm and obstruction from the swollen epiglottitis.
5. The primary therapy is to maintain the airway. Therefore, provide oxygen support via face mask or bag-valve mask ventilation as needed until the physician is ready to intubate the child.

Infectious agents associated with LTB croup are usually viral and affect the subglottic region. Parainfluenza 1 and 2 account for many cases of LTB. Other viral agents associated with LTB include influenza, respiratory syncytial virus (RSV), adenovirus, rhinovirus, enterovirus, and, more rarely, measles virus and herpes simplex virus (Braden, 2006; Leung, Keller, & Johnson, 2004).

Pathophysiology

The underlying pathophysiology of LTB is inflammation and edema of the larynx, trachea, and bronchi; laryngeal muscle spasm; and production of mucus that further obstruct the airway. Inflammation in LTB narrows the subglottic region, the smallest portion of the upper airway in children, thus producing the classic symptoms of upper airway obstruction found in children with croup. Hoarseness occurs because the vocal cords swell; the barking cough is caused by inflammation of the larynx tissues.

Assessment

The incubation period for LTB is usually 2 to 6 days and is typically preceded by a mild upper respiratory infection with symptoms of rhinorrhea, mild cough, and low-grade fever. Children presenting with LTB look ill and appear to be in acute respiratory distress. Listen for hoarseness, inspiratory stridor, and the characteristic “barking” or brassy cough. The history typically reveals a mild upper respiratory infection, followed within 2 to 6 days by symptoms of LTB. Clinical signs, depending on the severity of airway obstruction, may include suprasternal, substernal, and intercostal retractions; intermittent cyanosis during coughing; and altered mental status related to hypoxia and carbon dioxide retention. A thorough respiratory assessment is important, because the child with upper airway obstruction with mild hypoxia develops muscle fatigue and hypoventilation that can result in severe hypoxemia and hypercapnia. Rarely, endotracheal intubation is necessary because of complete airway obstruction or respiratory distress.

A characteristic concern in children with LTB is parental anxiety, which is usually high. However, the degree of anxiety depends on many factors, including parental experience with previous croup episodes, lack of sleep from child’s “barking,” and the severity of the child’s respiratory distress and degree of anxiety and irritability.

Interdisciplinary Interventions

Treatment of children with LTB depends on its severity and may include general supportive care, corticosteroids, nebulized epinephrine, supplemental oxygen, or some combination of these therapies. Rarely, emergency measures for ventilation (endotracheal intubation) are required. General supportive measures for the child include hydration, fever reduction measures, and maintaining a calm and reassuring atmosphere for the parents. As with any respiratory condition, hydration is an important nursing action. Encourage clear fluids, particularly fluids the child prefers, unless respiratory distress is severe, in which case

the child should have nothing by mouth and should be hydrated intravenously. Give antipyretics if the child is febrile (fever higher than 101 °F [38.3 °C]). Ensure that parents understand the distinction between bacterial and viral illnesses, so they are not distressed when antibiotics are not prescribed. LTB is generally a self-limiting illness in which children’s symptoms subside in 3 to 5 days, and full recovery without complications is the norm.

Children who present with respiratory distress symptoms such as cyanosis and who are severely hypoxic, fatigued, in respiratory distress, or unable to drink sufficient fluids are hospitalized to receive intravenous fluid, oxygen, and airway support. Observe for any deterioration of respiratory status and monitor vital signs, including rate, rhythm, and depth of respirations, and cardiac rate and rhythm. Tachycardia, cardiac arrhythmias, or both may be seen with hypoxia. Ensure that equipment for intubation and tracheostomy is readily available.

Mist therapy (croup/mist tents or mist via mask or nasal cannula), widely used in the past, has questionable efficacy for treating LTB (Bradin, 2006). Current therapy relies on aerosol inhalation therapy with medications such as racemic epinephrine. Racemic epinephrine is believed to work via topical alpha-adrenergic stimulation, which causes mucosal vasoconstriction and leads to decreased edema in the subglottic region. Facilitate the administration of respiratory inhalation treatments at the prescribed frequency, to disrupt regular feeding and sleep patterns as little as possible.

Community Care

Two of the most important interventions are to minimize anxiety and maximize opportunities for rest. Providing a comfortable environment free from noxious stimuli lessens respiratory distress. Encourage children to engage in quiet play that provides diversion and reduces anxiety. Coloring books, watching favorite videos and DVDs, listening to music, reading stories, and doing puzzles are some examples.

Nutritional supports for children with croup are generally short term. Encourage oral intake of clear fluids, especially fluids the child prefers. Dairy products should be avoided until respiratory status is stable. When solid food is resumed, the child may find frequent, small nutritious snacks more appealing than an entire meal.

Teach parents and other caregivers about medications, respiratory inhalation treatments, and ways to assess their child’s respiratory status. Although most children recover without complications, caregivers must be able to recognize and describe signs of impending respiratory failure and know how to access emergency services. A home health referral may be indicated if the parent’s assessment ability is in question and the child’s condition does not warrant hospitalization. The child should be afebrile and free from cough before returning to school or daycare.

During the acute phase of the illness, parental anxiety may be very high. Provide information and support, emphasizing the short-lived nature of the illness. For the child who remains at home, help the parents to mobilize their extended family and community resources, to

relieve them of some care responsibilities and provide them opportunities for adequate rest.

Bacterial Tracheitis

Bacterial tracheitis is an uncommon, but potentially life-threatening, acute bacterial infection of the mucosa of the upper trachea. It is also called *membranous laryngotracheitis* or *membranous croup*. Although it is a very rare disease, it may be seen in children between 1 month and 5 years of age; the peak incidence is in the fall and winter months (Cha et al., 2006). This condition is unrelated to ethnicity, gender, or socioeconomic status. Bacterial tracheitis is a serious cause of airway obstruction, severe enough to cause respiratory arrest. The overall mortality rate is 4%. With early recognition and treatment, outcomes are generally very good. The most common causative organisms are *Staphylococcus aureus*, *H. influenza*, *Streptococcus pyogenes*, and other anaerobic bacteria (Cha et al., 2006).

Assessment

The child with bacterial tracheitis usually appears quite ill and presents with a history of a prior upper respiratory tract infection, viral croup, or both, followed by a high fever, cough, and increasing inspiratory stridor unaffected by position. The trachea is inflamed and appears erythematous and edematous, with thick, tenacious, purulent secretions. Respiratory distress is a key symptom in bacterial tracheitis and requires immediate medical attention. The physician uses laryngoscopy or bronchoscopy to confirm the diagnosis. Tracheal cultures are obtained during the endoscopic procedure (Cha et al., 2006).

Interdisciplinary Interventions

Vigorous management, including early recognition of bacterial tracheitis and prompt attention to the airway, is necessary to prevent the airway from being obstructed by the thick secretions. The child should be hospitalized, and appropriate emergency airway management equipment should be available. Frequent tracheal suctioning is necessary to keep the airway patent, and often the child has an artificial airway (endotracheal tube) in place. This management is especially important in the younger child, who is at risk for abrupt airway obstruction. Additionally, the child requires humidified oxygen, parenteral broad-spectrum antibiotics (for 10–14 days), and antipyretics for fever and discomfort.

Apnea

Apnea is cessation of airflow in to and out of the lungs. Apneic episodes lasting longer than 20 seconds, and shorter respiratory pauses associated with cyanosis, bradycardia, **pallor** (paleness), or limpness, are considered pathologic apnea. This definition is simply a description of a characteristic clinical syndrome, not a specific disease process. Three general types of apnea occur:

1. *Central apnea* is an impairment of the mechanisms that control breathing, which results in absence of nasal airflow and ventilatory effort.
2. *Obstructive apnea* is usually caused by anatomic abnormalities and occurs when nasal airflow is absent despite normal or exaggerated respiratory effort. Obstructive apneas include *obstructive sleep apnea* (OSA), which is the most common type of sleep apnea.
3. *Mixed apnea* includes central and obstructive components and may require multiple treatment methods.

Although apnea can occur at any age, the premature infant is at a greater risk. The incidence of apnea among children younger than 1 year of age has been estimated at between 0.5% to 6% (Hall & Zalman, 2005). Normal respiratory system development is such that the lungs and respiratory center of the brain are designed to breathe and control respiration at term, although they are capable of breathing air by 23 weeks' gestation. Therefore, the lungs and respiratory center of the premature infant have not fully matured, leading to disruptions in the regularity of respiration.

Apnea of prematurity (AOP) is the occurrence of pathologic apnea and periodic breathing in an infant of less than 37 weeks' gestation. AOP is a common, natural consequence of immaturity and need not be viewed as a disease (Stokowski, 2005).

Apnea of infancy (AOI) describes episodes of breathing cessation or respiratory pauses in a previously healthy infant of at least 37 weeks' gestation.

Apparent life-threatening events (ALTEs) is the current term for more severe disturbances of a frighteningly serious nature. These episodes have been formerly called *near-miss sudden infant death syndrome (SIDS) episodes*; however, the term *ALTE* is believed to more accurately describe the occurrence. An ALTE is defined as an event in which an infant has a convincing history of an episode of apnea that is sudden in onset, considered frightening to the observer, and is characterized by color change (cyanosis, pallor, or erythema), marked change in muscular tone (limpness, rarely stiffness), and choking, gagging, or both. It requires substantial intervention (vigorous shaking, mouth-to-mouth breathing, or full CPR) to revive the infant and restore normal breathing (American Academy of Pediatrics, 2003).

Studies of sudden infant death syndrome (SIDS) have indicated that AOP or AOI is not a precursor or predictor of subsequent SIDS death (American Academy of Pediatrics, 2003). Healthcare professionals should promote preventive practices to decrease the risk of SIDS. Specific interventions include supine positioning for sleep, safe sleeping environments, and elimination of smoke exposure.

Acute apneic episodes with cyanosis in term infants can have a variety of treatable causes including seizures; infection; breath-holding spells; congenital heart disease; cardiac dysrhythmia; electrolyte imbalances; congenital central hypoventilation syndrome; brain stem compression; anemia; or exposure to alcohol, sedatives, and narcotics. ALTE can also be the result of a profound central nervous system insult or depression involving structural damage to the brain stem (as in trauma, infection, or

edema) or interference with cerebral metabolic function (e.g., drug overdose, hypotension, severe hypoxia). The prognosis for these infants depends on the etiology and treatment of the underlying cause.

Assessment

Apnea may present simply as a parental report of prolonged asymptomatic respiratory pauses during sleep or as dramatically as a witnessed complete cessation of breathing and absence of a heart rate. Because apneic episodes, regardless of their severity, typically occur away from the view of the medical team, the significance of the event is based largely on the caregiver's recollection of the event. A single mild episode that required little or no intervention does not necessitate an extensive diagnostic evaluation or aggressive therapy and has little prognostic importance. The healthy infant who presents with a history of AOI or an ALTE for whom the obvious treatable causes have been ruled out presents a greater challenge in evaluation and management.

Infants usually appear entirely normal by the time they reach medical attention after an ALTE. The most important element of assessment is, therefore, to obtain a careful history from the person who witnessed the event. Interview the witness to determine the color of the child when found (pale, or blue/cyanotic), whether the child had any respirations, and whether the child was limp. Determine whether there was evidence of vomiting. Ascertain whether the apneic episode occurred when the child was asleep or awake. Collaborate with other healthcare personnel to gain as much detail as possible about the event itself, the physical condition of the infant before and after the event, and circumstances surrounding its occurrence. Assess the reliability of the historian and look for any signs of child abuse or neglect; also evaluate the potential for sepsis.

OSA may occur in children of any age. Symptoms include snoring, periods of observed apnea, heavy breathing, broken or restless sleep, bad dreams, and failure to grow or thrive. Sequelae of OSA may include inattentiveness, developmental disorders, mood disorders, or excessive daytime sleepiness.

One of the primary diagnostic tests in apnea is the polysomnographic study (PSG, or sleep study). Other diagnostic tests may include but are not limited to arterial or capillary blood gases (persistent acidosis indicates a severe event or a chronic metabolic disorder); complete blood counts (anemia may precipitate apnea, polycythemia reflects chronic hypoxia, elevated white blood cell count indicates infection); and serum electrolyte, glucose, and blood urea nitrogen levels (numerous abnormalities, such as hypocalcemia and hypoglycemia, may contribute to the development of apnea).

The primary diagnostic test for OSA is the nocturnal PSG. Many healthcare professionals diagnose OSA based on physical examination and nocturnal pulse oximetry.

Interdisciplinary Interventions

Optimal care of infants who have had an episode of apnea accompanied by color change or who present with a seri-

ous ALTE includes hospitalization for observation, monitoring by healthcare personnel, a thorough evaluation for possible causes, and parent training (see [thePoint](#) for Care Paths: An Interdisciplinary Plan of Care for the Child With Apnea). Continuous cardiorespiratory monitoring and frequent assessment of color, breathing patterns and effort, and tone are appropriate healthcare interventions.

Alert! Numerous studies have demonstrated that infants in whom no treatable cause for an ALTE is found have a risk that is 15 times greater than that of the general population for subsequent death from SIDS (Edner, Erikson, Milerad, & Katz-Salamon, 2002; Horemuzova, Katz-Salamon, & Milerad, 2002; Mitchell & Thompson, 2001).

The preterm infant who continues to exhibit symptomatic apnea during the hospital stay should also be evaluated carefully for hypoxia or anemia, which can cause apnea in the premature infant. In the absence of hypoxia or anemia, preterm infants who are still having clinical episodes of apnea can be discharged with home apnea and bradycardia monitoring equipment.

Agents such as theophylline, aminophylline, or caffeine are sometimes useful in decreasing the severity and frequency of apneic episodes. These medications are central nervous system stimulants that act on the respiratory center of the brain and therefore are sometimes effective in treating central apnea only. Besides stimulating the respiratory center, these drugs also act on the kidney, heart, and skeletal and smooth muscles. Side effects include tachycardia and increased diuresis. Parents and caregivers must be taught to draw up and administer the medications and observe for toxic side effects (tachycardia, vomiting, excessive irritability). Teach them to monitor for therapeutic drug levels and to report toxic levels.

Treatment of OSA primarily focuses on tonsillectomy, adenoidectomy, or both. Other options include weight reduction, inhaled corticosteroids, or positive-pressure airway breathing (including continuous positive airway pressure).

Community Care

Parental anxiety is characteristically the foremost psychosocial issue challenging nurses and other members of the healthcare team in working with the infant and family after admission to the hospital with an apneic episode or after an ALTE. Much guidance and reassurance is needed, in conjunction with education, to increase parental confidence and problem-solving skills.

Because no specific treatment currently exists for infants with AOI or ALTE of unknown etiology, home apnea and bradycardia monitoring is the primary therapy. Ongoing therapy can be equally anxiety producing as the initial ALTE for parents and families. Home monitors serve only to alert the caregiver that an apneic episode is occurring. The parent or caregiver must then respond and act to evaluate and terminate the apneic episode. Most parents feel the need to use the monitor at all times when the infant is

not being directly observed. Home apnea monitoring often adversely affects parents' ability to work, socialize, nurture their other children, and generally maintain their former life functions because of their obsessive focus on the monitor and its every nuance.

Before initiating home apnea monitoring, and while the infant is still hospitalized, conduct a thorough review of the family's living arrangements and verify that appropriate resources are present to successfully support a home apnea monitoring program. Minimum environmental requirements include electricity, a telephone in the home, and availability of caregivers trained to respond to the apnea alarm. This inpatient evaluation of the family system is crucial in determining the teaching plan and coordinating follow-up. It may be necessary to contact community resources when appropriate, according to the family's needs.

Parental education for home apnea and bradycardia monitoring includes information on monitor use, alarms, indications for help, and CPR. Parents and caregivers are also taught to keep a log or diary of all apnea and bradycardia alarms, especially those requiring any intervention. If both parents work outside the home, alternative caregivers (extended family members, daycare providers, and so on) must also receive this education (see [thePoint](#) for Care Paths: An Interdisciplinary Plan of Care for the Child with Apnea).

Most infants with ALTE require 4 to 6 months of home monitoring. The decision to discontinue the apnea monitor should be made jointly between the family and the healthcare professionals. If the decision is made to end monitoring, give the parents a clear statement of the status of the problem and explain that it appears to have resolved, and that the infant can be expected to grow and progress normally. Monitoring is discontinued using a similar protocol as that used in persistent AOP, in that the monitor may be safely discontinued after 2 to 3 months without apnea or bradycardia spells that require intervention (American Academy of Pediatrics, 2003). Because of the diligence required for successful home monitoring, many parents find it difficult to stop home monitoring when it is no longer required for their infant. The caregiver has learned to rely on the monitor to provide a comforting reassurance that the child is well.

Foreign Body Aspiration (FBA)

FBA remains a persistent problem and an important cause of morbidity and mortality in the pediatric age group. Foreign bodies retained in the airway can be potentially life threatening and can produce severe lung damage.

Quantifying the overall incidence of FBA is difficult, because nearly all foreign bodies aspirated into the respiratory tract are probably expelled immediately by spontaneous coughing and never require medical intervention. However, FBA remains a common cause of mortality and morbidity among children during the first 3 to 4 years of life.

Most episodes occur during eating or play. Commonly aspirated objects include foods such as hot dogs, peanuts, other nuts and seeds, grapes, popcorn, and carrots as well

as items such as small plastic toys, marbles, buttons, earrings, and latex balloons. Factors related to a young child's physical and developmental status predispose him or her to the risk of FBA (see Chapters 4 and 5). Young children (particularly those 6 months–2 years of age) explore the environment by putting objects in their mouth and are at highest risk for aspiration. They also have insufficient size and number of teeth to thoroughly chew foods. In addition, they may seek relief from the teething process by chewing on hard objects. Exposure to certain foods thus may be inappropriate for a young child's cognitive and dental stage of development, and may lead to choking and aspiration.

Pathophysiology

The pathophysiology of FBA varies depending on the size of the foreign body, the location of the object in the respiratory tract, and the acute or chronic nature of the condition. If an object is too large or of a shape that does not allow it to be expelled by coughing, respiratory symptoms result. Foreign bodies in the upper airway often cause a mechanical or partial obstruction that results in non-specific respiratory signs and symptoms such as cough, wheeze, stridor, **dyspnea** (labored or difficult breathing resulting from air hunger), voice changes, cyanosis, retractions, and **hemoptysis** (coughing blood). At times, a carefully assessed history reveals an episode of coughing, choking, or breathing difficulty that can be traced back to an aspiration event, but on many occasions, the discovery of an FBA is made without ever obtaining such a history.

Assessment

The location of the foreign body is a key factor in determining the signs, symptoms, and physical assessment findings (Table 16–3). Although nearly all children who have aspirated a foreign body exhibit a chronic cough, a history of an acute coughing episode, or both, other symptoms vary according to where in the respiratory tract the object is lodged.

Perform a respiratory assessment. The child with a foreign body that lodges in the upper airway, such as the larynx or trachea, usually presents with an acute and rather fierce onset of stridor and respiratory distress necessitating immediate intervention to dislodge the foreign body. A foreign body lodged in the bronchus may act as a ball valve, obstructing the airway perhaps partially on inspiration and completely on expiration. Wheezing localized to one side of the chest on inspiration and diminished breath sounds on expiration result. In children with an esophageal foreign body, the distended esophagus compresses the nearby trachea, thus causing respiratory distress. Physical assessment findings may reveal asymmetry of chest wall movement, and wheezing or diminished breath sounds in a localized area of the lungs. If the obstruction is located in the upper airway, stridor is common.

Radiographs may be normal, may allow clear visualization of the presence of a foreign body, or may show changes related to the foreign body directly or caused by secondary inflammatory changes. Abnormalities are less likely to be noted on chest radiograph for foreign bodies

TABLE 16-3

Locations of Foreign Body Aspirates and Associated Findings

Location of Foreign Body	Clinical Findings
Supraglottic	Cough, dyspnea, drooling, gagging, changes in phonation
Larynx	Cough, stridor, changes in phonation; at times, severe respiratory distress
Trachea, intrathoracic	Expiratory wheeze, inspiratory noise
Trachea, extrathoracic	Inspiratory stridor, expiratory noise
Bronchi	Cough, asymmetric breath sounds or wheeze, hyperresonance
Esophageal	Drooling, dysphagia, stridor, respiratory distress

located above the bifurcation of the mainstem bronchus. Lateral neck films are obtained when this location is suspected.

“Chronically” retained foreign bodies can lead to a marked inflammatory response in the respiratory tract and, possibly, death. The right mainstem bronchus is a common site for foreign body lodgment because of its angle. Airway inflammation and narrowing secondary to edema often occurs. Materials such as nuts, which contain fats, cause an especially intense inflammatory response. Recurrent infections such as lipoid pneumonia or a lung abscess may ensue. Chronic obstruction of air exchange to the alveoli could mimic obstructive emphysema on chest radiographs. Foreign bodies that have been dislodged by coughing can lead to involvement as described here in different lung segments.

Interdisciplinary Interventions

Emergency treatment for the choking child includes the use of abdominal thrusts (the Heimlich maneuver) in the child older than 1 year of age and use of back blows and chest thrusts in the infant younger than 1 year. Use these methods in situations in which the aspiration was witnessed or strongly suspected and the child has an ineffective cough with increasing stridor and respiratory distress or has become unconscious and apneic.

In many cases, the object is not coughed up spontaneously and is lodged farther down in the respiratory tree; therefore, the foreign body has to be removed as soon as possible to prevent further airway damage. Rigid bronchoscopy to remove the foreign body after aspiration is the most common medical intervention. This procedure is very safe and effective when carried out by an experienced physician. Rigid bronchoscopy enables removal of the object and any associated inflammatory material; it also provides a means of assessing the condition of the airway.

Nursing care responsibilities for the infant or child undergoing rigid bronchoscopy focus on preoperative preparation and postoperative monitoring. Explain the reason for the procedure to the family. Intravenous hydration, emptying of stomach contents, and preoperative assessment of respiratory status are fundamental nursing interventions. Postoperatively, frequently assess

quality and symmetry of breath sounds, vital signs, color, and respiratory effort. Atelectasis, bronchospasm, and pneumothorax all are possible postbronchoscopy complications.

Community Care

The psychosocial consequences of an FBA incident vary in intensity, depending on the severity of the event. The most dramatic scenario involves the infant or child with a complete airway obstruction who is experiencing respiratory arrest and requires immediate resuscitation. This experience is extremely terrifying for both the child and the caregivers. Asphyxiation with subsequent brain damage or even death may occur. The grief and guilt that parents and caregivers experience in this situation are tremendous and often incapacitating. Extensive support and counseling services are crucial for these families. Less severe episodes of FBA may also raise feelings of guilt or embarrassment about inadequate supervision or about not recognizing symptoms.

The most effective “therapy” for FBA is prevention. Anyone who works with children should be certified in CPR, including airway obstruction management. Education for parents and other caregivers of infants and young children regarding aspiration risk factors is an essential role for all pediatric healthcare providers. Information on common items aspirated, age groups especially at risk, and developmental and environmental considerations can help parents be more aware of potential dangers and take proper precautions.

Environmental factors such as a high degree of distraction during play and mealtimes, and insufficient adult supervision may also contribute to FBA. Remind parents that watching television during meals can be a dangerous distraction to young children and should be avoided. Caregivers of children at play must be cautioned about being vigilant with small children, to keep them from putting objects in their mouths. Visitors to the home should place purses and other personal items out of reach of the small child. Last, products containing any small, cylindrical components should bear labels discouraging use around young children and should detail the age groups particularly affected.

LOWER RESPIRATORY INFECTIONS AND OBSTRUCTIONS

Lower respiratory infections and obstructions include influenza, bronchiolitis, bronchitis, and pneumonia.

QUESTION: Because Jose has a preexisting condition (asthma), he is at greater risk from respiratory infections. Jose will go to kindergarten next year. What information can the nurse share with Claudia to help her keep Jose from catching lower respiratory infections?

Influenza

Influenza illnesses have been described and defined epidemiologically for centuries. Influenza viral agents were the first proved to be respiratory tract pathogens. Consequently, the terms *flu* and *influenza* are perhaps the most overused diagnostic labels for nondescript infectious conditions in both medical and lay circles. This confusion is probably increased by influenza's broad range of clinical manifestations and its wide prevalence in the community.

Influenza infection often occurs in epidemics that sweep throughout a community in a matter of 6 to 8 weeks. Thousands of individuals die from influenza infections in the United States each year. Morbidity is highest in susceptible populations, such as infants and persons older than 65 years of age. Children with preexisting conditions such as bronchopulmonary dysplasia (BPD), cystic fibrosis (CF), asthma, and congenital respiratory conditions (e.g., Pierre Robin syndrome) are at increased risk for morbidity and mortality associated with the flu. It is imperative to recognize the elevated vulnerability of this population. The incidence of infection is highest, however, in children of school age.

Pathophysiology

The influenza viruses are large, single-stranded RNA viruses. Influenza viruses have a high affinity for epithelial cells of the respiratory tract mucosa. The virus causes a lytic infection of the respiratory epithelium with a loss of ciliary function, decreased mucus production, and desquamation of the epithelial layer. The incubation period for influenza virus can be as short as 2 to 3 days, and viral replication usually continues for 10 to 14 days after primary infection.

There are three influenza virus types, specific in their protein and antigen composition: influenza A, B, and C. Influenza A and B cause seasonal outbreaks and epidemics. Influenza A causes pandemics (Goldrick & Goetz, 2007). Literally hundreds of subtypes of these categories "shift" their complement of antigens on a regular basis. These mutations largely account for the ability of influenza to produce serious epidemics in populations of people who have been previously immunized or have experienced influenza infection. This regular antigenic shift makes the preparation and distribution of influenza vaccines necessary on an annual basis.

Assessment

Infections with influenza viruses may be manifested by mild, moderate, or severe clinical symptoms. Generally, a child with influenza infection has a more sudden onset of these symptoms than do children with parainfluenza, Respiratory Syncytial Virus or adenovirus infections. Look for fever of sudden onset accompanied by a flushed face, dry throat and nasal mucous membranes with dry cough, sore throat, muscle pain, headache, and malaise. During the acute phase of the illness, the child may be quite ill and require hospitalization if dehydrated or if a secondary infection develops. Fever, sore throat, and headache normally subside in 3 to 5 days, whereas other symptoms, such as fatigue and malaise, may persist for several weeks. Provide supportive interaction to parents to allay anxiety regarding progression of the illness and complications. Children are often disappointed at missing important events and activities, yet they do not have the strength to participate.

Influenza is difficult to distinguish from other respiratory illnesses in children. Most recently, commercial rapid diagnostic tests have been developed that can detect influenza viruses within 30 minutes (Schrag et al., 2006). Diagnostic tests for influenza also include viral culture, serology, rapid antigen testing, polymerase chain reaction, and immunofluorescence assay.

Interdisciplinary Interventions

Community Care 16–2 lists the recommendations for use of inactivated influenza vaccine to prevent influenza in children. The only specific contraindication for the use

COMMUNITY CARE 16–2

Recommendations for Administering the Influenza Vaccine to Children Who Are at High Risk

All Children Age 6 Months to 23 Months

Children with acute or chronic conditions such as

- Chronic pulmonary disease (cystic fibrosis, asthma, bronchopulmonary dysplasia)
- Congenital heart diseases and hemodynamically significant diseases
- Immunosuppression
- Sickle cell disease and other hemoglobinopathies
- Diabetes and other chronic metabolic diseases
- Chronic renal disease
- Symptomatic HIV infection
- Children with cognitive impairments, seizure disorders or neuromuscular conditions

Source: Centers for Disease Control, 2005.

of this inactivated vaccine is anaphylactic hypersensitivity to eggs.

Interventions for children with influenza include supportive care to alleviate or minimize symptoms. Antiviral agents such as zanamivir and oseltamivir may also be used for influenza A or B within certain populations. These agents have shown effectiveness by reducing the influenza course by 1 to 3 days when an early diagnosis is made (Schrage et al., 2006). Administration of acetaminophen every 4 to 6 hours for fever and muscle aches is also beneficial.

 **Alert!** Never treat children 18 years of age or younger with aspirin or other salicylate derivatives, because of the relationship among viral syndromes, aspirin, and Reye syndrome.

Other antipyretic therapies include undressing the child with a persistent fever to permit radiant heat loss and giving tepid sponge baths.

caREminder

Do not bathe a shivering child, because the child likely will shiver more and remain febrile.

Teach parents the signs and symptoms of respiratory deterioration, the signs of dehydration and ways of preventing and treating it, and the reason that aspirin administration is contraindicated in children.

Clear liquids for children and oral rehydration formulas for infants replace losses from fever, tachypnea, and vomiting. Parents should offer oral fluids in small amounts (30–60 mL) on a frequent basis. If the child becomes dehydrated and requires hospitalization, he or she should receive parenteral fluids. Bed rest is important and should be encouraged for the first 3 to 5 days. If the child is home, teach the parents or caregiver what to watch for, such as increased lethargy, excessive vomiting, or respiratory distress that may indicate that the child needs to be seen by a healthcare professional.

 **Alert!** Supplemental oxygen may be needed for chronically ill children with an influenza infection because of their poor respiratory reserves and increased propensity to develop hypoxemia.

 **ANSWER:** The nurse should share that it is important that Jose receive the flu vaccine each fall. Additional teaching may be needed to explain why this vaccine is unlike his other childhood immunizations and a vaccination is needed each fall. In addition, teaching Jose good hand hygiene techniques and emphasizing the importance of hand hygiene may well prevent him from catching influenza and other viruses.

Bronchiolitis

QUESTION: How are Jose's symptoms different from a child with bronchiolitis or bronchitis? Examine Table 16–4 for more information.

Bronchiolitis is an acute inflammation and obstruction of the bronchioles, the smallest, most distal sections of the respiratory airway network. It generally occurs during the first 2 years of life, with a peak incidence between 2 and 6 months of age. Infant susceptibility may be attributable to the loss of full maternal antibody protection that is universally present at birth and for the first few months of life (Christakis et al., 2005). Premature infants, immunodeficient infants, and those with underlying comorbid conditions such as BPD, CF, or congenital heart disease are extremely vulnerable to respiratory failure and other severe complications of bronchiolitis. Many infants can be managed at home; a few may require hospitalization.

Pathophysiology

In bronchiolitis, the bronchioles become narrowed, and some even become totally occluded as a result of the inflammatory process, edema of the airway wall, accumulation of mucus and cellular debris, and smooth muscle spasm. It may also cause thickening of the muscular wall and destruction of ciliated cells. This narrowing of the airway lumen can profoundly decrease airflow. Impaired clearance of secretions and decreased airflow lead to bronchiolar obstruction, atelectasis, and hyperinflation, causing impaired gas exchange that results in hypoxemia. Carbon dioxide retention occurs in the severely affected infant. The illness is self-limiting and generally resolves with adequate intervention.

Acute bronchiolitis most often has a viral cause. In some areas of the United States, bronchiolitis is the most common cause for hospitalization among infants younger than 1 year (Christakis et al., 2005). RSV, which has a high affinity for the respiratory tract mucosa, is the most common cause of bronchiolitis (Cooper, Banasiak, & Allen, 2003; Yorita et al., 2007). This virus is highly contagious and extremely prevalent in communities during the winter and spring months. Nearly all children have been infected with RSV by the age of 2 (Yorita et al., 2007). Respiratory syncytial virus (RSV) is transmitted by direct contact with infected secretions via hands and respiratory droplets. Adults as well as children are infected with RSV disease; thus, the source of viral infection in an infant is usually a family member with a mild respiratory illness. Infections with other viruses, primarily adenovirus, parainfluenza, and influenza, have been associated with bronchiolitis in smaller numbers of cases. In a small percentage of infants with bronchiolitis, suprainfection with a bacterial pathogen can occur.

Assessment

Diagnosis of bronchiolitis is made by history and physical examination. Diagnostic criteria include exposure to ill

persons, seasonal timing, and upper respiratory symptoms. The infant with bronchiolitis has typically had an upper respiratory infection for 2 to 3 days. Parents report sneezing and nasal discharge initially, and then the infant develops a harsh, dry cough and low-grade fever. Listen for wheezing on auscultation. The infant may develop increasingly distressed breathing and tachypnea. Inquire about feeding difficulties or loss of appetite caused by nasal congestion and the increased work required to breathe.

Because a major consequence of airway obstruction is impaired gas exchange, the child with bronchiolitis has many of the signs and symptoms of hypoxia and respiratory distress. Note the respiratory rate, which is commonly more than 60 breaths per minute and may be as high as 100 breaths per minute. Look for chest retractions; rhonchi and wheezes or crackles are generally heard in all lung fields. Check for dehydration, which can be severe because respiratory distress often prevents adequate oral fluid intake. In addition, the elevated respiratory rate causes insensible fluid loss (see Chapter 17). When the infant becomes ill during winter months, dry air may further exacerbate the condition. Hypoxia and hypercarbia result in restlessness and irritability, making the child difficult to console, even by parents.

A nasal swab may assist in an RSV diagnosis. A chest radiograph may be done if the child is hypoxic.

Interdisciplinary Interventions

The care of a child with bronchiolitis involves respiratory, pharmacologic, and nutritional support (see [thePoint](#) for Care Paths: An Interdisciplinary Plan of Care for the Child With Bronchiolitis). Infants with moderate to severe respiratory distress caused by bronchiolitis or children experiencing respiratory distress with feeding difficulties are usually hospitalized. Others may require only supportive care at home, although oxygen and bronchodilators may promote ease of breathing.

Hospitalized infants with RSV bronchiolitis are at high risk for respiratory failure and may require mechanical ventilation during the acute phase of the illness. Clinical indications for mechanical ventilation include worsening respiratory distress with increased work of breathing, increased heart rate, poor peripheral perfusion, apnea, bradycardia, and hypercarbia. Generally, the most critical phase of the disease is the first 24 to 72 hours.

Because RSV and other causative agents are shed in high titers for days after the onset of the illness, contact isolation to prevent infecting other patients, staff, and family members is strongly recommended. RSV is easily transmitted on hands, clothing, equipment, cribs, and so forth. Limiting child-to-child contact, washing toys between children's use of them, and careful handwashing are the most effective methods of preventing nosocomial infections.

Respiratory Support

Oxygen should be administered to infants with all but the mildest cases of bronchiolitis. The oxygen is optimally

humidified and of a concentration sufficient to maintain SaO_2 at more than or equal to 92%. The child can be weaned from the oxygen when oxygen saturation levels remain higher than 94% (Cincinnati Children's Hospital Medical Center, 2006). Continuous pulse oximetry is recommended for infants in acute distress. Take care to document oxygen saturations when the child is awake during quiet time, asleep, and with crying. Desaturations to less than 90% with crying are likely; therefore, close monitoring until saturations return to baseline (more than 92%) is essential. The infant should be suctioned when clinically indicated before feedings, prior to inhalation therapy, and as needed. The use of chest physiotherapy, cool-mist therapy, and aerosol therapy with saline have not been found to be helpful (Cincinnati Children's Hospital Medical Center, 2006).

Pharmacologic Support

Although treatment of bronchiolitis focuses on supportive therapy, pharmacologic interventions may prove effective in certain individuals. These medications include antiviral agents, bronchodilators, and possibly corticosteroids.

Ribavirin (Virazole) is an antiviral agent (also used to treat hepatitis C) that has been demonstrated to reduce the severity of bronchiolitis caused by RSV when administered early during the course of the illness. The drug can be used on the intubated, mechanically ventilated patient as well as the nonintubated patient. In mechanically ventilated infants, most of whom were previously healthy and had no underlying conditions, ribavirin treatment has been demonstrated to be safe and was associated with a reduced need for mechanical ventilation and supplemental oxygen, shorter duration of hospitalization, and cost-effectiveness (Cooper et al., 2003). Other candidates for ribavirin therapy include infants at increased risk for respiratory complications and respiratory failure because of underlying cardiac, lung, or immunodeficiency disease.

caREminder

Nurses and respiratory therapists administering ribavirin should wear a specially designed mask to prevent exposure to ribavirin particles released into the air. Although no studies link ribavirin use to defects in human embryos, it is recommended that pregnant personnel wear a mask when in the room of the child receiving ribavirin.

Bronchodilators and corticosteroids have limited effects on a child with bronchiolitis. However, this pharmacologic therapy may assist with respiratory benefits, such as ease of breathing, improved oxygenation, and increased respiratory drive.

Preventive therapies for bronchiolitis are used in limited populations. Children with bronchopulmonary dysplasia (BPD) and congenital heart disease should receive monthly Synagis vaccines during the RSV season.

Nutrition and Rest

Nutritional care for the infant with bronchiolitis includes supportive fluid and electrolyte replacement. Close monitoring of fluid and electrolyte status, including accurate measurement of intake and output with urine specific gravities, is essential to assess for dehydration.

caREminder

In the case of severe respiratory distress or a respiratory rate of 60 breaths per minute or more, the infant should have nothing by mouth, and fluid should be given intravenously.

Infants hospitalized with acute bronchiolitis are using all their energy to breathe. These infants are too uncomfortable to respond to the social stimuli they are accustomed to, such as television or interaction with siblings. Minimizing energy expenditure and oxygen consumption should remain a primary goal of therapy until oxygen saturation levels are continuously within normal limits. Soothing activities, such as play with musical toys and holding and rocking by parents, will help the infant relax. As the child's condition improves, quiet play activities may be gradually reintroduced.

Respiratory distress or air hunger creates anxiety in both infant and parents. The irritable, crying, inconsolable infant is unable to drink fluids and is exhausting to care for. Parents are often suffering from frustration and worry, as well as being completely exhausted at the time of admission to the hospital. These parents need the opportunity to express their feelings and receive support. Nurses or social service personnel are the ideal members of the healthcare team to provide these interventions to the family of an ill infant.

Community Care

Caregivers play an active role in health management, because most children are not hospitalized and do not require 24-hour care by the healthcare team. Parental or caregiver education is essential, especially if the child is not hospitalized and is cared for at home. Teach the parents to recognize the signs of increasing respiratory distress, such as grunting, retractions, pallor, and cyanosis, and state appropriate actions to take. Also instruct how to count the respiratory rate for a full minute, during both sleep and awake times. Encourage parents to promote fluid intake, to measure and record the infant's oral intake during the illness, and to observe for signs of dehydration. Other issues relevant to the care of the infant with bronchiolitis in the home include positioning with the head of the bed elevated for comfort and to facilitate removal of secretions, and quiet play activities as the child's energy level permits. Encourage parents to call their healthcare provider if they have any doubts about their infant's respiratory status. Teach families respiratory infection control measures, such as washing hands, avoiding exposure to illness, and staying current with routine immunizations. Additional preventive measures include eliminating exposure to cigarette smoke and lim-

iting contact with crowded areas and other children (e.g., daycare).

Bronchitis

Bronchitis is defined as a transient inflammatory process involving the distal trachea and major bronchi. The pharynx and nasopharynx may also be involved; the laryngeal and subglottic regions are not. Bronchitis can be acute, chronic, or recurrent.

As with most viral respiratory infections, the peak incidence is in winter and early spring. The disease appears to be more common in younger children and in males. In the child with a competent immune system, bronchitis usually has a viral cause.

Pathophysiology

Most episodes of acute bronchitis caused by bacteria occur as secondary infections while airways are vulnerable after a prior viral attack or other insult. Although exposure to irritants such as gastric acid or passive smoke and environmental pollutants can produce acute symptoms, these insults contribute more commonly to symptoms in children with reactive airways (see Asthma).

Chronic and recurrent bronchitis in children are conditions that are not clearly understood. Viral or bacterial agents attack the airway mucosa. Pathologic changes commonly seen in chronic bronchitis in childhood include thickened bronchial walls, mucous gland hypertrophy, and chronic inflammation. The ciliated epithelium becomes damaged, mucous gland activity increases, and neutrophils infiltrate the airway wall and lumen. This process accounts for what sometimes appears to be purulent sputum, in the absence of a bacterial infection. Mucociliary transport is disrupted, and this stasis contributes to secondary bacterial infection. Because these characteristics are commonly seen in asthmatic patients as well, a pathologic link between the two conditions is suspected (Table 16-4) (Jartti, Mäkelä, Vanto, & Ruuskanen, 2005).

Chronic bronchitis in children may be a symptom of an underlying pulmonary disorder and may be an important factor in predisposing the child to chronic respiratory symptoms and lung dysfunction even into the adult years.

Assessment

Take a careful history. The onset of viral bronchitis is generally gradual, beginning with upper respiratory symptoms such as rhinitis and a minimal cough. Three to 4 days later, the cough becomes more pronounced. Note the quality of the cough; a bronchial cough begins as dry and nonproductive, and progresses to become looser and more productive. Auscultation of the chest may be unremarkable during the early stages; rhonchi and wheezing may be heard as the cough progresses. Low-grade fever (<101 °F [38.3 °C]) is common. Young children generally swallow the mucus, often resulting in vomiting and paroxysmal coughing. During the recovery phase of the last 7 to 10 days, the cough subsides, and the fever resolves. If

TABLE 16-4
Characteristics of Acute Bronchitis, Bronchiolitis, and Asthma

	Acute Bronchitis	Bronchiolitis	Asthma
Etiology	Viral or bacterial infection	Usually viral infection	Bronchial hyperreactivity Hereditary component Allergic component Exacerbated by infections
Pathology	Transient inflammation of lower airways from trachea to bronchi Sloughing of respiratory mucosa and mucosal congestion No decrease in airflow or gas exchange	Infectious inflammation of small bronchioles Sloughing of respiratory epithelium into airway Tissue edema and mucus production Leads to decreased airflow and decreased gas exchange	Recurrent airway inflammation in response to allergens or irritants Airflow decrease as a result of bronchoconstriction; leads to decreased gas exchange Mucus plugging occurring in the airways
Clinical symptoms	Primary symptom is cough, which may be loose and productive Low-grade fever lasts 3 to 5 days Rhinitis Some wheezing possible on expiration Severe hypoxia uncommon	Starts with upper airway infection of 1–3 days' duration Progresses to tachypnea (>60 breaths/minute), retractions, rales and cough Fever Wheezing variable Severe hypoxia can occur	Episodic expiratory wheezing (sometimes inspiratory wheeze if severe) can be brief or prolonged Nonproductive cough Severe hypoxemia common
Treatment	Bronchodilators if wheezing Antibiotics for documented bacterial infection Avoidance of irritants	Oxygen therapy Fluid support Respiratory support with bronchodilator therapy Corticosteroids rarely helpful Antiviral agents	Bronchodilators and corticosteroids Respiratory support if respiratory failure imminent Preventive and environmental control measures Education stressing prevention and/or early detection and treatment

the cough or fever persists beyond 2 weeks, suspect a secondary bacterial infection and refer the child for appropriate medical treatment.

Interdisciplinary Interventions

Treatment for acute bronchitis is largely supportive. Adequate rest and humidification of room air improve comfort. Exposure to irritants such as cigarette smoke should be strictly avoided. A productive cough is common. Therefore, the use of cough suppressants should be discouraged to enable the child to cough and expectorate. Reserve antibiotics for conditions in which a bacterial infection has been confirmed by culture. Acetaminophen may be administered to help reduce the fever. Bronchodilators, such as albuterol, corticosteroids, or both may be considered to reduce airway inflammation and constriction, and to improve ease of breathing.

Comfort the child with acute bronchitis and monitor for respiratory distress. Focus nutritional support on maintaining adequate hydration. Encourage the child to drink plenty of fluids and eat foods such as ice pops, fruit

ices, broth, and Jell-O to prevent dehydration. The child's appetite for foods is usually diminished, and post-tussive emesis is common. Small frequent feedings (or clear liquids if vomiting is frequent) are appropriate for the acute phase of the illness. As cough diminishes, regular diet may be gradually resumed.

Community Care

Quiet activities such as watching television, playing with puzzles, and reading books are recommended for the toddler or school-aged child while recovering from bronchitis. Allowing for adequate rest is an important consideration, because frequent coughing may disrupt sleep. After the first few days, when the child is feeling better, school homework should be resumed. The child may return to school when he or she receives adequate rest at night, is not coughing, and is afebrile. Normal energy level may not be restored for several days to weeks. Teach parents and caregivers that the child must be protected from passive smoke and other environmental pollutants, because such conditions may lead to a

repeated bronchitis episode. Dust and allergy proofing the home environment, especially sleeping quarters, helps prevent subsequent recurrences (see Community Care 16–2).

ANSWER: Cough is one of the presenting symptoms with bronchiolitis, bronchitis, and asthma. However, Jose is afebrile and wheezing, which are solely symptoms of asthma.

Pneumonia

The term *pneumonia* describes any inflammatory condition of the lung parenchyma, resulting most frequently from infection, in which the alveoli are filled with fluid, blood cells, or both, and oxygen exchange is impaired. Pneumonia can be a primary illness (often called *community-acquired pneumonia* or *CAP*) or can develop as a complication of another respiratory infection or underlying illness. It is distinguished from the more common upper respiratory tract infections by the presence of lower respiratory tract signs and symptoms such as tachypnea, rales, and associated areas of infiltration on chest radiographs.

The annual incidence of pneumonia is 34 to 40 cases per 1,000 in children younger than 5 years of age (Taylor, 2003). Although this incidence is not high, pneumonia is a major cause of morbidity and mortality in children worldwide. Most deaths from pneumonia occur in third world countries, yet pneumonia also remains an important factor in morbidity in developed countries, especially among the chronically ill pediatric population.

The causes of pneumonia in children vary depending on the season and the child's age and health status. Pneumonia most likely develops when the body is unable to defend against infectious agents. Infectious agents may be

viruses, bacteria (Chart 16–1), mycoplasma, fungi, chemicals, foreign substances, or various other organisms or materials. Newborn infants acquire pneumonia pathogens by several means. Transplacental infection, aspiration of organisms during passage through the birth canal, and contact with humans or contaminated equipment immediately after birth are the most common mechanisms. After 1 month of age, viruses become the most common cause of pneumonia. Bacterial pneumonias occur year-round but are most common during the winter months (Cooper, Banasiak, & Allen, 2003).

Children with chronic illnesses, such as asthma, BPD, or CF, often develop recurrent or persistent pneumonias because of respiratory compromise. Immunodeficiencies, congenital heart disease, neuromuscular diseases, and various hematologic and oncologic diseases all are conditions that can render the child compromised in the ability to fight pneumonias and other infections.

Not all inflammation of the lung is infectious in origin. Pneumonia can be caused by aspiration of foreign substances. Gastroesophageal reflux with aspiration, smoke inhalation, hydrocarbon ingestion, aspiration of baby talcum powder, near-drowning, and some autoimmune processes (such as pulmonary hemosiderosis) all can result in a pneumonialike syndrome.

Pathophysiology

Although the term *pneumonia* refers to a multitude of disorders that differ widely depending on causative agent, each involves an inflammatory response. The respiratory tract is normally equipped with a variety of natural mechanisms to guard the lungs against infection. The nose filters air, the cough reflex expels objects or organisms in the laryngeal airway, and cilia in the walls of the trachea and bronchi trap small particles and remove them in mucus. When any of these defenses is impaired, pathogens invade and initiate the inflammatory response.

CHART 16–1 COMMON VIRAL AND BACTERIAL CAUSES OF PNEUMONIA

Causative Agent	Age	Season
Viral		
Respiratory syncytial virus	Infants, young preschool	Winter
Parainfluenza viruses 1 and 2	Preschool	Fall
Parainfluenza virus 3	Infants and preschool	Spring
Influenza viruses A and B	Preschool, school age	Winter
Adenoviruses	All ages	Year-round
Bacterial		
<i>Chlamydia pneumoniae</i>	Acquired during birthing process All ages	Year-round
<i>Mycoplasma pneumoniae</i>	School age	Year-round with peaks in fall and early winter
<i>Streptococcus pneumoniae</i>	Acquired during birthing process All ages	Year-round

Viral pathogens enter the upper respiratory tract and spread through the airways. The severity of the inflammatory response and the associated pathophysiology vary. Characteristic features include loss of alveolar cell wall integrity, resulting in accumulation and stasis of fluid and mucus, and smooth muscle contraction. These changes obstruct airflow and cause **ventilation–perfusion mismatch**, a condition in which the diminished alveolar–capillary gas exchange is no longer adequate for the blood supply, thus resulting in hypoxia and hypercapnia.

Bacteria are introduced into the lungs through the inhalation of infectious droplets or through the bloodstream. Alveolar involvement in bacterial pneumonia is characteristically more intense than that seen in viral infections. The alveoli can fill rapidly with proteinaceous fluid, causing ventilation–perfusion mismatch, or bacterial agents can cause necrosis of intra-alveolar septa, causing abscesses and destruction of lung architecture.

Similar processes occur in aspiration pneumonia. When gastric contents, secretions, blood, or volatile chemical compounds enter the lung, the presence of one or more of these irritants initiates the characteristic inflammatory response. Gastroesophageal reflux is associated with pneumonia when the acidic contents enter the pharynx, where, if protective mechanisms fail, it is aspirated. Baby talcum powder and other fine-particle materials inhaled into the pharynx and lower airways precipitate tissue inflammation. Hydrocarbons (organic solvents found in gasoline, furniture polish, cleaning compounds, lighter fluid, paint thinner, kerosene, and other substances) aspirated into the alveolar space dissolve surfactant lipids and impair surface tension, thereby reducing activity of surfactant. Atelectasis, alveolar cell damage, edema, granulocyte infiltration, hemorrhage, and necrosis can result. Smoke inhalation also can cause chemical irritation, depending on the source of the smoke.

Assessment

Pneumonia, regardless of etiology, is generally distinguished from less severe respiratory tract infections by the type of cough (sputum producing, rather than dry and hacking) and by tachypnea, crackles, and cyanosis. Although distinguishing viral from bacterial pneumonia by clinical manifestations alone usually is not possible, understanding the characteristic presentation of each is important.

Viral pneumonia typically has a gradual onset, beginning with an upper respiratory tract infection of 3 to 4 days' duration. This initial illness may include low-grade fever and rhinorrhea, with a gradual development of cough and increasing respiratory distress. The child in respiratory distress may manifest cyanosis, grunting respirations, retractions, coarse crackles, or wheezing.

Bacterial pneumonia has a more acute pattern of onset. Suspect bacterial pneumonia in a child with the symptoms already listed, plus a cough that produces thick green, yellow, or blood-tinged sputum, and an overall appearance of lethargy and malaise. Chest pain may also be present. Fever and increased respiratory rate are hallmark manifestations of bacterial pneumonia. Check for dehydration stemming from poor oral intake and increased insensible fluid losses from fever and tachypnea.

Tachycardia, hypotension, and poor perfusion may indicate sepsis and early shock.

The young child with fever, retractions, tachypnea, or grunting will be irritable and difficult to console. Hypoxia and hypercarbia result in decreased level of consciousness in a child of any age. Be ready to help parents cope with anxiety related to the often severe acute onset of respiratory symptoms.

Families of children with chronic conditions live with constant concerns regarding exposure to a potentially fatal infection and may exhibit and act on feelings of guilt and anger upon diagnosis of pneumonia. Counseling and support for these families during acute illness episodes is imperative.

Culture confirms the diagnosis of bacterial pneumonia. Common bacterial pathogens include *S. pneumoniae*, *H. influenzae*, *S. aureus*, group B streptococci, *Chlamydia pneumoniae*, and *M. pneumoniae*. Chest radiographs may be used to determine the lung fields affected by the pneumonia or if additional problems exist (e.g., atelectasis, pleural effusions).

Interdisciplinary Interventions

Interventions for pneumonia involve careful assessment of respiratory status and general supportive care (see [thePoint](#) for Care Paths: An Interdisciplinary Plan of Care for the Child With Pneumonia). Whether a child with pneumonia requires hospitalization depends on age, general health status, and the suspected organism. Because infants readily develop respiratory distress with accompanying hypoxia, apnea, poor feeding, and dehydration, hospitalization is common.

For the hospitalized child, careful and frequent respiratory assessment, including evaluation of respiratory rate and effort, color, presence and location of retractions, breath sounds, and oxygen saturation levels, is required for the infant or child with pneumonia. Report changes in respiratory status immediately for further medical evaluation. Supplemental oxygen may be needed to keep saturation levels more than or equal to 92%. For some children, continuous pulse oximetry is indicated. Implement chest physiotherapy (percussion, vibration, and postural drainage) to facilitate clearing of secretions, with special attention paid to any identified areas of involvement or infiltration on the chest radiograph (see Treatment Modalities earlier in this chapter).

In most viral pneumonia cases, especially in infants, antibiotics are given because secondary bacterial involvement cannot be ruled out. Many experts consider this approach the safest and most practical, although it may not alter the course of the illness. Infants are generally treated with broad-spectrum antibiotics such as ampicillin and an aminoglycoside. Specific antiviral therapy for RSV (ribavirin) is considered for infants and children with chronic illnesses (see Bronchiolitis).

caREminder

Children in severe respiratory distress should receive nothing by mouth because of the increased work of breathing and the risk of aspiration.

Fluids and medications are administered by the intravenous route. Fever and tachypnea result in insensible fluid loss; thus, the child with pneumonia is at risk for dehydration. Intake and urine output, and urine specific gravity are measured frequently, and skin turgor is assessed to monitor hydration status. Body temperature is monitored, and fevers are treated with acetaminophen, because a high body temperature can increase oxygen requirements and exacerbate insensible fluid loss. As respiratory status improves, the diet can be advanced from clear liquids to regular diet as tolerated. For recurrent aspiration pneumonia, suck and swallow coordination and gastroesophageal reflux may be evaluated to identify risk for aspiration before full oral feedings are resumed. If oral intake is allowed, feedings should be given with caution, to avoid aspiration.

The child and family require constant information and support from all health professionals during an acute pneumonia episode. Social services may provide counseling services or referrals in the event of life-threatening or chronic illness. After the child's condition becomes more stable, parents, nurses, and child life specialists should collaborate in planning quiet diversionary activities appropriate for age.

Community Care

Home health support for parents who must learn to perform respiratory assessment and administer medication is an option for the older child being treated at home. Children with pneumonia are usually evaluated in an ambulatory care setting 2 to 3 weeks after treatment is completed, to ensure that their respiratory symptoms are fully resolved or, if a chronic condition exists, to ensure that they are being managed effectively at home. Repeat chest radiographs may be completed to evaluate persistent symptoms or confirm complete recovery.

CHRONIC CONDITIONS OF THE RESPIRATORY SYSTEM

Chronic conditions of the respiratory system can have a serious affect on children and adolescents, and may substantially alter their quality of life and physical and social development (see Chapter 12 for a more extensive discussion of the affect of chronic conditions on the child and the family). Such conditions can affect all other aspects of the child's and family's physical and emotional health, and can lead to development of comorbid conditions, increased risks for morbidity, and, at times, early death. The most common chronic conditions seen in childhood and adolescence are asthma, BPD, and CF. Chronic pulmonary conditions during childhood and adolescence are characterized by periods of relative wellness interspersed with periods of acute exacerbation, often necessitating healthcare interventions (e.g., ambulatory care visits, emergency room visits, or hospitalization). Although no "cures" exist for these chronic conditions, self-care management is essential. Extensive child and family education is required, related to prevention, recognition of symptoms, early and ongoing medical treatments, and optimization of self-care and home care strategies.

Asthma

Asthma is defined by the National Heart, Lung and Blood Institute (2007) as the following:

A chronic inflammatory disorder of the airways in which many cells and cellular elements play a role; in particular, mast cells, eosinophils, neutrophils (especially in sudden onset, fatal exacerbations, occupational asthma, and patients who smoke), T lymphocytes, macrophages, and epithelial cells. In susceptible individuals, this inflammatory process causes recurrent episodes of coughing (particularly at night or early in the morning), wheezing, breathlessness, and chest tightness. These episodes are usually associated with widespread but variable airflow obstruction that is often reversible either spontaneously or with treatment. (p. 9)

During childhood and adolescence, pediatric asthma can have a profound effect on growth and development, and on the daily lives of families. During the past few decades, assessment, management, and self-care strategies for children and adolescents with asthma have resulted in increased longevity, along with an increased shift from hospital to home care. Significant advances in evidenced-based management guidelines, pharmacologic products, and durable medical equipment have resulted in improved disease outcomes and quality of life for these children and their families. Comprehensive asthma management programs that address important issues such as accurate diagnosis, patient and family education, environmental control, and early treatment of asthma exacerbations have been shown to significantly improve the overall health of children with asthma (Liu and National Institutes of Health, 2004; National Heart, Lung and Blood Institute, 2007). The following discussion of asthma incorporates the most recent management guidelines provided by the National Heart, Lung and Blood Institute. A complete version of the guidelines is available at <http://www.nhlbi.nih.gov/guidelines/asthma>. The four components of care presented in the guidelines and discussed in this section include

1. Assessment and monitoring
2. Education
3. Control of environmental factors and comorbid conditions
4. Medications

QUESTION: In following discussion, does Jose represent the typical incidence and prevalence of asthma in children?

Pediatric asthma is the single largest public health burden, with more than 6.5 million children and adolescents with asthma in the United States (National Heart, Lung and Blood Institute, 2007). Asthma is the third leading cause of hospitalization among children younger than 15 years of age. It is the leading cause of school absenteeism caused by a chronic condition (Asthma and Allergy Foundation of America, 2008).

WORLDVIEW: Social disparities play a large role in pediatric asthma prevalence, morbidity, and mortality. Populations from low socioeconomic and urban, inner city areas have high rates of asthma and asthma-related morbidity and mortality. Prevalence of asthma among African American children is high (38% higher than among whites and 95% higher than among Hispanics). Compared with nonminority peers, African American adolescents are more likely to have poorly controlled asthma, to experience restrictions in activity, to be hospitalized, and to report severe functional disability because of their asthma. In addition, African American children covered by Medicaid have worse asthma and use less preventive asthma medications than other children in the same managed Medicaid population (American Lung Association, 2005).

ANSWER: Jose is Mexican American, lives in a suburban environment, and thus does not represent the prevalence of asthma among inner city African American children. However, Jose is typical in that he does have seasonal allergies and his allergies are a trigger for his asthma.

Pathophysiology

The pathology of asthma is best described as a condition characterized by reversible (in most cases) changes in the airway that lead to bronchoconstriction, airway hyperresponsiveness, and airway edema. At a cellular level, mast cells in the airways release inflammatory and chemotactic mediators, such as histamine, causing smooth muscle contraction and bronchoconstriction. Increased mucus secretion by goblet cells causes epithelial damage. The increase in mucus secretion then leads to increased permeability and sensitivity to inhaled allergens, irritants, and inflammatory mediators. The result is airway edema, mucus hypersecretion and plugging, and substantial airway narrowing, leading to rapid airway obstruction (Fig. 16–16). This acute reaction, called the *early asthmatic*

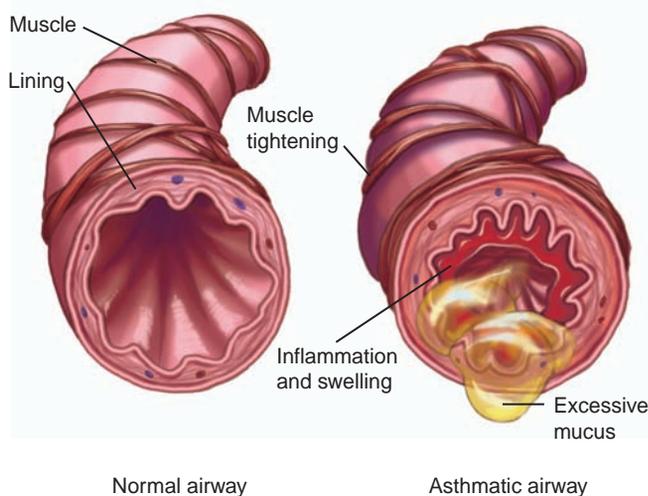

FIGURE 16–16. Asthmatic airway compared with a normal airway.

response, generally resolves with bronchodilator treatment within 1 to 3 hours.

“Remodeling” or permanent changes in the airway may occur. Persistent changes in the airway structure, such as subbasement fibrosis, mucous hypersecretion, injury to epithelial cells, smooth muscle hypertrophy, and angiogenesis, may occur (National Heart, Lung and Blood Institute, 2007, p. 9).

The physiologic changes that occur during an acute episode contribute to the clinical findings characteristic of asthma exacerbation. Air becomes trapped behind the narrowed airways and the functional residual capacity increases, causing hyperinflation of the lungs, which can be seen on a chest radiograph. This hyperinflation helps keep the airways open that are already narrowed from bronchoconstriction, mucosal edema, and mucus. The accessory muscles of respiration help to maintain the lungs in a hyperinflated state; therefore, the child has chest retractions. Hypoxemia results from ventilation–perfusion mismatch, because areas of the lung are not being well ventilated.

A key development in the study of asthma has been the recognition that a late asthmatic response also occurs. Mediator release from the mast cells causes direct migration and activation of inflammatory infiltrates, predominantly eosinophils and neutrophils, and mast cell degranulation causes the release of leukotrienes and prostaglandins, which leads to further inflammation. Airway response in the form of obstruction can occur 4 to 6 hours later and can last 24 hours or more. The late asthmatic response has a number of features characteristic of chronic asthma: reduced responsiveness to bronchodilators, increased mucus secretion, heightened airway responsiveness, and the development of airway inflammation. With the onset of the late asthmatic response, a vicious self-perpetuating cycle of asthma symptoms ensues.

The precise cause of the inflammatory response seen in asthma is yet to be discovered. Three potential causes include innate immunity, genetics, and environmental factors. Innate immunity refers to the balance between Th1-type and Th2-type cytokine responses in early life. Numerous factors are believed to affect this balance and potentially lead to immune changes in which the Th1 immune response that fights infection is dominated by Th2 cells, leading to the expression of allergic diseases and asthma. It is hypothesized that exposure to other children, less frequent use of antibiotics, and “country living” are factors that enhance the Th1 response and lower the incidence of asthma (National Heart, Lung and Blood Institute, 2007, p. 10).

Scientific evidence exists that asthma is partly hereditary. Studies have shown that the risk of having an asthmatic child is significantly greater when one or both parents have asthma than if neither parent is affected (Ober, 2005). **Atopy** (an increased predisposition to form antibodies on exposure to common environmental antigens) is present in most patients with asthma. Atopy is at least partially hereditary, although exposure to certain allergens early in life (e.g., pollens, animal dander) may influence the development of asthma in a child who is genetically predisposed.

Food allergens, however, are rarely responsible for airway reactions in children. Although the link between asthma and atopy is not completely clear, exposure to allergens may cause airway inflammation and may lead to increased airway responsiveness.

Other factors felt to be involved in the development of airway reactivity and asthma include respiratory infections and environmental pollutants (many which may be seasonal in nature; see Tradition or Science 16–2). RSV bronchiolitis, for example, has been causally linked to enhanced airway reactivity, especially in children with a family history of atopy. Indoor air pollutants play a major role in asthma exacerbations, and outdoor air pollutants have been found to reduce lung function in children in cities with high levels of outdoor air pollution (Gauderman et al., 2004).

Assessment

QUESTION: The peak expiratory flow rate (PEFR) is an important assessment tool. Why would the nurse assessing Jose in the emergency department not obtain a PEFR?

According to National Heart, Lung and Blood Institute (2007) guidelines, a careful history is one of most important elements in evaluating the child. Historical data can identify possible high-risk patients and assist in planning

TRADITION OR SCIENCE 16–2

Does secondhand smoke exacerbate asthma symptoms?

EVIDENCE-BASED PRACTICE

Environmental pollutants such as tobacco smoke have been clearly linked to asthma exacerbations in children (Centers for Disease Control, 2006; Institute of Medicine Committee on the Assessment of Asthma and Indoor Air, Division of Health Promotion and Disease Prevention, 2000). In children with asthma, parental (particularly maternal) smoking has been associated with increases in symptom severity and hospitalizations. Exposure rates among children are high, with approximately 60% of children age 3 to 11 years in the United States exposed to secondhand smoke (Centers for Disease Control, 2006). In 2002, the Centers for Disease Control estimated that more than \$1.57 billion in annual economic costs and more than 440,000 premature deaths were attributable to secondhand smoke. The relationship of secondhand smoke exposure to the development of asthma is less well defined; however, some research has suggested that maternal smoking may cause alteration in the developing lung before birth (Institute of Medicine Committee on the Assessment of Asthma and Indoor Air, Division of Health Promotion and Disease Prevention, 2000).

for appropriate interventions. The key information to compile is listed in Focused Health History 16–2. The history can help to rule out other conditions that may present with cough, wheezing, and shortness of breath. Additionally, if the child presents with recurring episodes, the history can identify possible precipitating factors and treatments that have been effective in the past.

Suspect asthma in a child with wheezing and varying degrees of respiratory distress. And, for many children a history of chronic cough (worse at night) is a classic symptom. The hallmark manifestation of asthma is the result of airway obstruction. The child may present with a worsening cough and wheezing, and may complain of chest tightness (Clinical Judgment 16–2). Because of bronchospasm, airway inflammation, and mucous plugging, expiration becomes increasingly difficult, and there is air trapping. The child with a persistent asthma exacerbation may be unable or unwilling to lie flat because breathing is more difficult in this position.

The National Heart, Lung and Blood Institute (2007) guidelines suggest using multiple measures of the child's level of current impairment (frequency and intensity of symptoms, low lung function, and limitations of daily activities) and future risk (risk of exacerbations, progressive loss of lung function, or adverse side effects from medications) to assess the child's status. Some children can be at high risk for frequent exacerbations even if they have few day-to-day effects of asthma. Some children may have early or prodromal signs and symptoms hours to days before an asthma exacerbation.

Alert! Pay special attention to children at high risk of asthma-related death. Children with a history of the following events are at increased risk:

- Prior admission to an intensive care unit for asthma (with or without intubation)
- Two or more hospitalizations for asthma, three or more emergency room visits for asthma, or both, during the past year
- Hospitalization or emergency room visit for asthma during the past month
- Current use of or recent withdrawal from systemic corticosteroids
- History of psychiatric disease or psychosocial issues
- History of nonadherence to asthma treatment plan (National Heart, Lung and Blood Institute, 2007)

Focus the physical examination on general health, including growth and development, hydration status, and any signs of drug-related side effects.

Hypoxemia is universal in the child with moderate to severe symptoms. Monitor blood gases. Carbon dioxide retention is also a common finding. Hypoxemia and hypercarbia result from air trapping in the alveoli and ventilation–perfusion mismatch. A PaCO₂ level more than 50 mm Hg indicates ventilatory failure unless the child has a preexisting chronic lung disease. Review radiograph reports. Typical radiograph findings in the child with extensive asthma symptoms are hyperexpansion, atelectasis, and a flattened diaphragm. Younger children are particularly prone to develop atelectasis because of their small airways and underdeveloped collateral ventilation. Infiltrates and pneumothoraces are uncommon findings.

FOCUSED HEALTH HISTORY 16–2

The Child With Asthma

Nature of symptoms	Shortness of breath, wheeze, cough, chest tightness, rhinorrhea, conditions such as sinusitis, eczema
Pattern of symptoms	Frequency (daily, weekly, monthly), timing (morning vs. nighttime), onset and duration, severity, seasonal, perennial, diurnal variation, associated with physical activity
Aggravating factors or triggers	Upper respiratory infections, environmental allergens and irritants (dust mites, mold, inhalants, chemicals, pollens), secondhand smoke exposure or smoke, strong emotional expressions (crying, laughing hard), exercise, weather changes, pets, air pollution, foods or medications, menstruation cycle, stress
Typical exacerbation	Prodromal signs and symptoms, temporal progress, and usual management and response to treatment
Previous and current drug therapy	Dosage, mode of delivery, response, side effects
Development of disease	Age at onset, age at diagnosis, progress of disease, previous evaluations, treatments, and response to current management
Effect of disease	Number of emergency room visits, hospitalizations and intensive care unit admissions in past year, school attendance and performance, activity limitations and exercise tolerance, sleep disturbances, child's growth and development, child's behavior, effect on siblings, economic impact
Living situation/environment	Presence of smokers in home, pets, housing conditions, home age, heating/air conditioning, carpeting, humidifier, cockroaches
Family and patient perception of asthma	Knowledge of and belief in chronic nature of asthma, coping styles, family support systems, capacity to recognize exacerbation, economic resources
General medical history	Presence of or history of allergic disorders (allergic rhinitis, atopic dermatitis), recurrent respiratory tract infections, birth history (early injury to lung tissue), symptoms of gastroesophageal reflux, detailed review of systems
History of allergies	History of adverse reactions to medications, food, or allergens (pollen, mold, pets)
Family medical history	History of IgE-mediated allergy in close relatives, asthma in close relatives

Monitor blood pressure. Pulsus paradoxus (a decrease in systemic blood pressure with inspiration) occurs because the negative pleural pressures become more negative as a result of lung hyperinflation. A decrease of 12 mm Hg or more in systolic blood pressure with inspiration rather than with expiration indicates moderate distress. A decrease of 20 mm Hg or more occurs in severe asthma exacerbations. Pulsus paradoxus may be difficult to assess in the young child because of rapid heart and respiratory rates. In the preverbal child, also evaluate the quality of the cry (weak vs. lusty).

Diagnostic studies helpful in evaluating the child with asthma symptoms include spirometry, PEFr, pulmonary function tests, bronchoprovocation (with methacholine, histamine, cold air, or exercise), arterial blood gases, pulse oximetry, and chest radiographs (see Tests and Procedures 16–1 earlier in this chapter). In addition, examination of biomarkers of inflammation are demonstrating

promise as useful tools for diagnosis and assessment of asthma. Biomarker assessment includes total and differential cell count; and mediator assays of sputum, blood, urine, and exhaled air (National Heart, Lung and Blood Institute, 2007, p. 12).

Spirometry is used to obtain objective measures of lung function. During the initial assessment, spirometry helps to establish a diagnosis of asthma. Spirometry is also recommended after treatment is initiated and peak inspiratory function is stabilized, during periods of progressive or prolonged loss of asthma control, and finally, as an assessment tool every 1 to 2 years to evaluate response to therapy.

In contrast, peak flow meters are used to measure PEFr and are designed for monitoring purposes rather than diagnostic purposes. PEFr is considered a valuable measurement in assessing asthma severity and in evaluating response to therapy. PEFr is the greatest velocity of

CLINICAL JUDGMENT 16–2

The Child in Respiratory Distress

Six-year-old Danielle comes to the community health clinic with her mother. The child presents with a history of onset of wheezing, shortness of breath, chest tightness, and cough that developed the previous night. Danielle is lethargic and pale, and her skin is cool and clammy. She is sitting in a tripod position; her eyes are open wide with a fearful countenance.

Questions

1. What historical data would help to clarify the diagnosis?
2. Is this an upper or lower respiratory problem?
3. Is the child in respiratory distress?
4. What would be your initial intervention?
5. How would you determine whether oxygen therapy and bronchodilators are effective in relieving the child's respiratory problems?

Answers

1. Number of similar occurrences of these respiratory signs the child has had in the past year; family history of asthma; introduction of new animals,

- products, or other environmental factors at home or school; occurrence of respiratory illness in other family or friends at this time
2. Lower respiratory, as distinguished by wheezing and chest tightness resulting from bronchial constriction
3. Yes. Respiratory distress occurs when there is an inadequate ability to meet the oxygenation needs of the body. Signs of respiratory distress include nasal flaring, retractions, poor chest expansion, cool extremities, poor peripheral pulses, and changes in level of consciousness.
4. Provide oxygenation to the child—100% oxygen at 6 L—given via face mask or nasal cannula. Do not have her lie down; let her assume a position of comfort.
5. The signs and symptoms of respiratory distress would be alleviated. The child would become more alert and pink, and would appear calm and able to verbalize that the tightness in her chest has diminished or that she is able to breathe easier.

flow that can be generated in forced expiration, starting with fully inflated lungs. Evaluate PEFR in a serial manner using a peak flow meter and compare it with the baseline or “personal best” for the individual, rather than with normal values. PEFR decreases as airway obstruction and inflammation worsen (Fig. 16–17). Children younger than 5 years of age are generally not able to perform PEFR tests, and they may be too stressful for the child in severe distress, potentially worsening his or her

status (see [thePoint](#) for Procedures: Use and Care of Peak Flow Meters and Spacers).

ANSWER: Two rationales support the nurse's decision not to try to obtain a PEFR. One is Jose's level of respiratory distress and the other is Jose's age. Jose is working very hard just to ventilate himself. Asking him to focus on a diagnostic procedure could precipitate a worsening of his respiratory distress. As a 4-year-old, Jose may be able to provide baseline PEFR values on a good day, and this may be a valuable daily activity for his mother to track. During a stressful event, children rely on earlier coping skills and asking a preschooler to perform a complex task at a very stressful time is unlikely to be successful.

FIGURE 16–17. The child may use a peak flow meter and chart to monitor peak expiratory flow rate.

Interdisciplinary Interventions

The National Heart, Lung and Blood Institute (2007, p. 4) has identified the two primary goals of asthma therapy as

- Reduce impairment (prevent chronic symptoms, require infrequent use of short-acting beta₂ agonist, maintain [near-] normal lung function and normal activity levels)
- Reduce risk (prevent exacerbations, minimize need for emergency care or hospitalization, prevent loss of lung function, prevent reduced lung growth [for children], have minimal or no adverse effects of therapy)

As previously mentioned, these goals are accomplished through an interdisciplinary plan that includes assessment and monitoring, education, control of environmental factors, and careful selection of medication and delivery devices to meet the child's needs and individual circumstances. The following section discusses these care components as well as the management and treatment of exacerbations.

Effective asthma management enables children to pursue active lifestyles both at home and at school, and to enjoy sleep uninterrupted by asthma symptoms. However, attaining this goal requires special attention to children's unique physiologic states (different from the adult), growth and development, and maturing self-care abilities in light of the tasks of effective asthma management. These tasks must also be continued while in other environments, such as the school or recreational activity settings.

Assessment and Monitoring

QUESTION: Does the case study regarding Jose in Chapter 10 provide enough information to classify the severity of his asthma?

Assessment for purposes of diagnosis are discussed in the preceding section. This section discusses the ongoing assessment and monitoring of the child with asthma. Activities associated with assessment and monitoring include assessing the asthma severity to initiate treatment, assessing asthma control and adjusting therapy as needed, and ensuring the child is periodically monitored by the healthcare provider.

Severity classification of asthma is based on symptom frequency, nighttime symptoms, character and frequency of exacerbations, and lung function variability before treatment. When asthma is well controlled, the child's overall asthma severity is classified as intermittent or persistent (mild, moderate, or severe) and a "stepwise" approach to managing asthma is used to adjust therapy. Therapy is initiated depending on the child's age group and the assessed degree of impairment and risk. Impairment refers to the frequency and intensity of symptoms and functional limitations being experienced by the child. Risk refers to the likelihood of asthma exacerbations, progressive decline in lung function, or risk of adverse effects of medication (National Heart, Lung and Blood Institute, 2007). Tables 16–5 to 16–10 provide an overview, by age (0–4 years, 5–11 years, and youths ≥ 12 years) of the National Heart, Lung and Blood Institute guidelines for initiating therapy and adjusting therapy. In addition, the tables provide the stepwise approach to increase therapy (stepped up) or decrease therapy (stepped down) as indicated by the child's condition.

Assessment of the child with asthma begins by classifying asthma severity. If the child is presenting with symptoms, identify the precipitating factors for the current episodic symptoms (e.g., child was exercising at school, child spent night at friend's house where cats are

present). Determine whether comorbid conditions exist that may affect asthma management, such as sinusitis, obesity, or stress. Last, assess the child's knowledge and skills for self-management (National Heart, Lung and Blood Institute, 2007).

Monitoring of the child includes an evaluation of the child's daily peak flow monitoring records and using spirometry to assess current status. Samples of peak flow monitoring charts are provided by National Heart, Lung and Blood Institute or makers of peak flow meters, and can be downloaded from the Internet.

Schedule follow-up visits for the child. The child is seen at 2- to 6-week intervals while gaining control of asthma symptoms, at 1 to 6 months after asthma control is achieved and to ensure control is maintained, and at 3-month intervals if a step-down therapy is anticipated (National Heart, Lung and Blood Institute, 2007).

ANSWER: Jose is on albuterol and cromolyn sodium morning and evening. In addition, he has another recent episode of an exacerbation of his asthma. However, we still do not have a clear picture of his incidence of daytime and nighttime symptoms.

Education

QUESTION: What is the role of the nurse regarding the education about Jose's asthma?

A primary goal of asthma management is to ensure the child and the family have the tools and knowledge to self-monitor and manage the child's condition. Education focuses on promoting optimal physical growth and function by minimizing airway obstruction, maximizing physical function despite airway obstruction, and preventing and treating exacerbations and complications of asthma and its therapy. The child should also achieve and maintain normal psychosocial growth and function by maintaining optimal psychosocial development and maximal participation in his or her own healthcare. To promote optimal family functioning, these interventions are integrated into the normal daily lifestyle of the family.

Child and family education must be an integral part of asthma care. Parents and children with asthma often have a poor or incomplete understanding of the disease and its management, and this lack of knowledge may lead to increased need for hospitalization and increased healthcare costs. Self-care management in children and adolescents depends on the individual's cognitive abilities, maturity, and fine and gross motor skills to manage the daily responsibilities of asthma care. Cognitive and language abilities will affect how well the child is able to perceive and communicate changes in breathing patterns. Both the parents and the child should assess daily for asthma symptoms, such as increased cough, wheezing, shortness of breath, or irritability, then initiate additional therapy as instructed. Beginning in the preschool years,

Classifying Asthma Severity and Initiating Therapy in Children

Components of Severity	Classifying Asthma Severity and Initiating Therapy in Children						
	Intermittent		Mild		Persistent		
	Ages 0-4	Ages 5-11	Ages 0-4	Ages 5-11	Ages 0-4	Ages 5-11	Severe
Symptoms	≤2 days/week	≤2 days/week	>2, days/week but not daily	3-4x/month	Daily	Throughout the day	
Nighttime awakenings	0	≤2x/month	1-2x/month	3-4x/month	>1x/week but not nightly	>1x/week	Often 7x/week
Short-acting beta ₂ -agonist use for symptom control	≤2 days/week	≤2 days/week	>2, days/week but not daily	3-4x/month	Daily	Several times per day	
Interference with normal activity	None	None	Minor limitation	Some limitation	Extremely limited		
Lung Function	Normal FEV ₁ between exacerbations	Normal FEV ₁ between exacerbations	Normal FEV ₁ between exacerbations	Normal FEV ₁ between exacerbations	Normal FEV ₁ between exacerbations	Normal FEV ₁ between exacerbations	Normal FEV ₁ between exacerbations
Impairment	N/A	>80%	>80%	>80%	60-80%	<60%	<60%
	>85%	>80%	>80%	>80%	75-80%	<75%	<75%
Risk	0-1/year (see notes)	≤2 exacerbations in 6 months requiring oral systemic corticosteroids, or ≥4 wheezing episodes/1 year lasting >1 day AND risk factors for persistent asthma	≤2 exacerbations in 6 months requiring oral systemic corticosteroids, or ≥4 wheezing episodes/1 year lasting >1 day AND risk factors for persistent asthma	Relative annual risk may be related to FEV ₁			
Recommended Step for Initiating Therapy (See "Stepwise Approach for Managing Asthma" for treatment steps.)	Step 1 (for both age groups)	Step 2 (for both age groups)	Step 2 (for both age groups)	Step 3 and consider short course of oral systemic corticosteroids	Step 3: medium-dose ICS option and consider short course of oral systemic corticosteroids	Step 3: medium-dose ICS option and consider short course of oral systemic corticosteroids	Step 3: medium-dose ICS option and consider short course of oral systemic corticosteroids
The stepwise approach is meant to assist, not replace, the clinical decisionmaking required to meet individual patient needs.	In 2-5 weeks, depending on severity, evaluate level of asthma control that is achieved. <ul style="list-style-type: none"> • Children 0-4 years old: If no clear benefit is observed in 4-6 weeks, stop treatment and consider alternative diagnoses or adjusting therapy. • Children 5-11 years old: Adjust therapy accordingly. 						

Key: FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; ICS, inhaled corticosteroids; ICU, intensive care unit; N/A, not applicable

Notes:

- Level of severity is determined by both impairment and risk. Assess impairment domain by caregiver's recall of previous 2-4 weeks. Assign severity to the most severe category in which any feature occurs.
- Frequency and severity of exacerbations may fluctuate over time for patients in any severity category. At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma severity. In general, more frequent and severe exacerbations (e.g., requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate greater underlying disease severity. For treatment purposes, patients with ≥2 exacerbations described above may be considered the same as patients who have persistent asthma, even in the absence of impairment levels consistent with persistent asthma.

TABLE 16-6

Assessing Asthma Control and Adjusting Therapy in Children

Components of Control		Assessing Asthma Control and Adjusting Therapy in Children			
		Well Controlled	Not Well Controlled	Very Poorly Controlled	
Impairment	Symptoms	Ages 0-4 ≤2 days/week but not more than once on each day	Ages 0-4 >2 days/week or multiple times on ≤2 days/week	Ages 5-11 Throughout the day	Ages 5-11
	Nighttime awakenings	≤1x/month	>1x/month	≥2x/month	≥2x/week
	Interference with normal activity	None	Some limitation	Extremely limited	
Risk	Short-acting beta ₂ -agonist use for symptom control (not prevention of EIB)	≤2 days/week	>2 days/week	Several times per day	
	Lung function	N/A	N/A	N/A	<60% <75%
Recommended Action for Treatment	Exacerbations requiring oral systemic corticosteroids	>80%	60-80%	N/A	≥2x/year
	Reduction in lung growth	>80%	75-80%	>3x/year	↑
	Treatment-related adverse effects	0-1x/year	2-3x/year	N/A	N/A
Treatment-related adverse effects		Medication side effects can vary in intensity from none to very troublesome and worrisome. The level of intensity does not correlate to specific levels of control but should be considered in the overall assessment of risk.			
Recommended Action for Treatment		<ul style="list-style-type: none"> Maintain current step. Regular followup every 1-6 months. Consider step down if well controlled for at least 3 months. 	<ul style="list-style-type: none"> Step up 1 step 	<ul style="list-style-type: none"> Step up at least 1 step 	<ul style="list-style-type: none"> Consider short course of oral systemic corticosteroids. Step up 1-2 steps
<p>(See "Stepwise Approach for Managing Asthma" for treatment steps.)</p> <p>The stepwise approach is meant to assist, not replace, clinical decisionmaking required to meet individual patient needs.</p>		<ul style="list-style-type: none"> Before step up: Review adherence to medication, inhaler technique, and environmental control. If alternative treatment was used, discontinue it and use preferred treatment for that step. Reevaluate the level of asthma control in 2-6 weeks to achieve control; every 1-6 months to maintain control. Children 0-4 years old: If no clear benefit is observed in 4-6 weeks, consider alternative diagnosis or adjusting therapy. Children 5-11 years old: Adjust therapy accordingly. For side effects, consider alternative treatment options. 			

Key: EIB, exercise-induced bronchospasm, FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; ICU, intensive care unit; N/A, not applicable

Notes:

- The level of control is based on the most severe impairment or risk category. Assess impairment domain by patient's or caregiver's recall of previous 2-4 weeks. Symptom assessment for longer periods should reflect a global assessment, such as whether the patient's asthma is better or worse since the last visit.
- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma control. In general, more frequent and intense exacerbations (e.g., requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate poorer disease control.

National Heart Lung and Blood Institute. (2007). Guidelines for the diagnosis and management of asthma. Author: Washington, DC. Retrieved January 8, 2008, from <http://www.nhlbi.nih.gov/guidelines/asthma/asthsumm.pdf>

T A B L E 16-7

Stepwise Approach for Managing Asthma Long Term in Children, 0-4 Years of Age and 5-11 Years of Age

		Step up if needed (first check inhaler technique, adherence, environmental control, and comorbid conditions) Assess control							
		Step down if possible (and asthma is well controlled at least 3 months)							
		Step 1	Step 2	Step 3	Step 4	Step 5	Step 6		
Children 0-4 Years of Age	Preferred	Intermittent Asthma SABA PRN	Consult with asthma specialist if step 3 care or higher is required. Consider consultation at step 2. Low-dose ICS	Medium-dose ICS + LABA or Montelukast	High-dose ICS + LABA or Montelukast	High-dose ICS + LABA or Montelukast	High-dose ICS + LABA or Montelukast + Oral corticosteroids ICS	Notes <ul style="list-style-type: none"> The stepwise approach is meant to assist, not replace, the clinical decisionmaking required to meet individual patient needs. If an alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up. If clear benefit is not observed within 4-6 weeks, and patient's/family's medication technique and adherence are satisfactory, consider adjusting therapy or an alternative diagnosis. Studies on children 0-4 years of age are limited. Step 2 preferred therapy is based on Evidence A. All other recommendations are based on expert opinion and extrapolation from studies in older children. Clinicians who administer immunotherapy should be prepared and equipped to identify and treat anaphylaxis that may occur. Key: Alphabetical listing is used when more than one treatment option is listed within either preferred or alternative therapy. ICS, inhaled corticosteroid; LABA, inhaled long-acting beta₂-agonist; LTRA, leukotriene receptor antagonist; oral corticosteroids, oral systemic corticosteroids; SABA, inhaled short-acting beta₂-agonist	
	Alternative		Cromolyn or Montelukast						
Children 5-11 Years of Age	Quick-Relief Medication	<ul style="list-style-type: none"> SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms. With viral respiratory symptoms: SABA q 4-6 hours up to 24 hours (longer with physician consult). Consider short course of oral systemic corticosteroids if exacerbation is severe or patient has history of previous severe exacerbations. Caution: Frequent use of SABA may indicate the need to step up treatment. See text for recommendations on initiating daily long-term-control therapy.							
	Preferred	Intermittent Asthma SABA PRN	Consult with asthma specialist if step 4 care or higher is required. Consider consultation at step 3. Low-dose ICS	Medium-dose ICS + LABA + LABA, LTRA, or Theophylline	High-dose ICS + LABA	High-dose ICS + LABA	High-dose ICS + LABA + Oral corticosteroids	Notes <ul style="list-style-type: none"> The stepwise approach is meant to assist, not replace, the clinical decisionmaking required to meet individual patient needs. If an alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up. Theophylline is a less desirable alternative due to the need to monitor serum concentration levels. Steps 1 and 2 medications are based on Evidence A. Step 3 ICS and ICS plus adjunctive therapy are based on Evidence B for efficacy of each treatment and extrapolation from comparator trials in older children and adults—comparator trials are not available for this age group; steps 4-6 are based on expert opinion and extrapolation from studies in older children and adults. Immunotherapy for steps 2-4 is based on Evidence B for house-dust mites, animal danders, and pollens; evidence is weak or lacking for molds and cockroaches. Evidence is strongest for immunotherapy with single allergens. The role of allergy in asthma is greater in children than adults. Clinicians who administer immunotherapy should be prepared and equipped to identify and treat anaphylaxis that may occur. Key: Alphabetical listing is used when more than one treatment option is listed within either preferred or alternative therapy. ICS, inhaled corticosteroid; LABA, inhaled long-acting beta₂-agonist; LTRA, leukotriene receptor antagonist; SABA, inhaled short-acting beta₂-agonist	
Alternative		Cromolyn, LTRA, Nedocromil, or Theophylline	OR Medium-dose ICS	High-dose ICS + LABA + Theophylline	High-dose ICS + LABA + Theophylline	High-dose ICS + LABA + Theophylline + Oral corticosteroids			
		Each Step: Patient Education, Environmental Control, and Management of Comorbidities Steps 2-4: Consider subcutaneous allergen immunotherapy for patients who have persistent, allergic asthma.							
Quick-Relief Medication	<ul style="list-style-type: none"> SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms: up to 3 treatments at 20-minute intervals as needed. Short course of oral systemic corticosteroids may be needed. Caution: Increasing use of SABA or use >2 days a week for symptom relief (not prevention of EIB) generally indicates inadequate control and the need to step up treatment.

*ACQ values of 0.76-1.4 are indeterminate regarding well-controlled asthma.
Key: EIB, exercise-induced bronchospasm; ICU, intensive care unit

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decisionmaking required to meet individual patient needs.
 - The level of control is based on the most severe impairment or risk category. Assess impairment domain by patient's recall of previous 2-4 weeks and by spirometry/or peak flow measures. Symptom assessment for longer periods should reflect a global assessment, such as inquiring whether the patient's asthma is better or worse since the last visit.
 - At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma control. In general, more frequent and intense exacerbations (e.g., requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate poorer disease control. For treatment purposes, patients who had ≥2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have not-well-controlled asthma, even in the absence of impairment levels consistent with not-well-controlled asthma.
- ATAQ = Asthma Therapy Assessment Questionnaire®
ACQ = Asthma Control Questionnaire®
ACT = Asthma Control Test™
Minimal Important Difference: 1.0 for the ATAQ; 0.5 for the ACQ; not determined for the ACT.

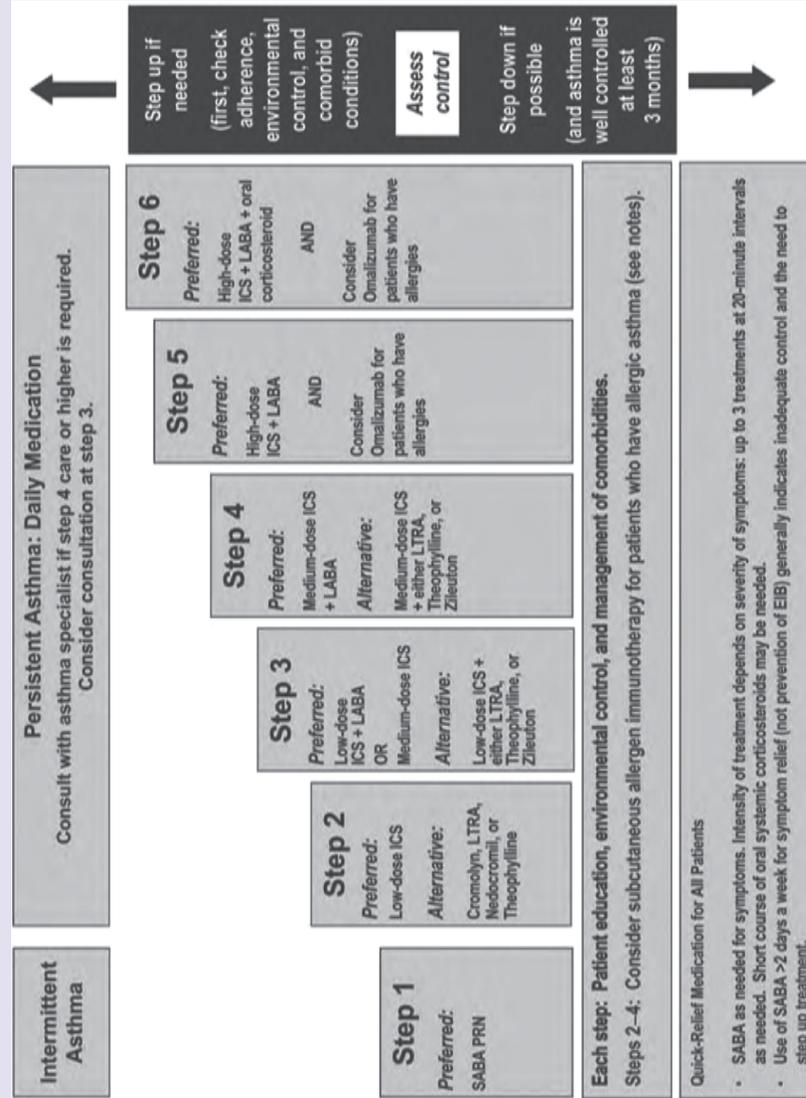

Before step up in therapy:

- Review adherence to medication, inhaler technique, environmental control, and comorbid conditions.
- If an alternative treatment option was used in a step, discontinue and use the preferred treatment for that step.

National Heart Lung and Blood Institute. (2007). Guidelines for the diagnosis and management of asthma. Author: Washington, DC. Retrieved January 8, 2008, from <http://www.nhlbi.nih.gov/guidelines/asthma/asthsumm.pdf>

TABLE 16-10

Stepwise Approach for Managing Asthma in Youths ≥ 12 Years of Age and Adults

Key: Alphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy. ICS, inhaled corticosteroid; LABA, long-acting inhaled beta₂-agonist; LTRA, leukotriene receptor antagonist; SABA, inhaled short-acting beta₂-agonist

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decisionmaking required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- Zileuton is a less desirable alternative due to limited studies as adjunctive therapy and the need to monitor liver function. Theophylline requires monitoring of serum concentration levels.
- In step 6, before oral corticosteroids are introduced, a trial of high-dose ICS + LABA + either LTRA, theophylline, or zileuton may be considered, although this approach has not been studied in clinical trials.
- Step 1, 2, and 3 preferred therapies are based on Evidence A; step 3 alternative therapy is based on Evidence A for LTRA, Evidence B for theophylline, and Evidence D for zileuton. Step 4 preferred therapy is based on Evidence B, and alternative therapy is based on Evidence B for LTRA and theophylline and Evidence D zileuton. Step 5 preferred therapy is based on Evidence B. Step 6 preferred therapy is based on (EPR—2 1997) and Evidence B for omalizumab.
- Immunotherapy for steps 2–4 is based on Evidence B for house-dust mites, animal danders, and pollens; evidence is weak or lacking for molds and cockroaches. Evidence is strongest for immunotherapy with single allergens. The role of allergy in asthma is greater in children than in adults.
- Clinicians who administer immunotherapy or omalizumab should be prepared and equipped to identify and treat anaphylaxis that may occur.

National Heart Lung and Blood Institute. (2007). Guidelines for the diagnosis and management of asthma. Author: Washington, DC. Retrieved January 8, 2008, from <http://www.nhlbi.nih.gov/guidelines/asthma/asthsumm.pdf>

the child should be taught to recognize changes in breathing and to communicate them to a responsible adult. Even the ability to recognize the responsible adult in given a situation should be practiced with a preschool child. Responsibility to recognize changes in breathing patterns, to communicate these changes, and to initiate additional therapies should increase as the child matures.

Fine and gross motor abilities of children and adolescents also play a role in these assessment and self-care management strategies. For example, spirometry and peak flow measurements require fine and gross motor skills. Both require the individual to follow verbal instructions

closely, hold the mouthpiece without air leakage, then fully inhale and exhale. Incorrect technique in these assessments can lead to misguided prescriptions or management plans. Children younger than 7 years old generally lack the motor skills needed to perform these measures. Therefore, assessment of pulmonary function in these children must rely on other measures, such as parent or child recall of symptom history, auscultation of lung fields, assessment of respiratory effort, or pulse oximetry.

The essential components of a parent and patient education program are outlined in Community Care 16–3. Asthma self-management programs have been developed

COMMUNITY CARE 16–3

Components of an Asthma Education Program

Topic	Content
Definition of asthma Signs and symptoms	Emphasize chronic nature of asthma, prognosis, and goals of therapy. Discuss main symptoms of an acute episode, variability of symptoms, ways to recognize mild/prodromal symptoms.
Pathophysiology	Identify symptoms that need immediate treatment. Describe the characteristic changes that occur in the airways (inflammation, bronchospasm, mucus) and the role of medications.
Asthma triggers and avoidance of triggers Management of asthma	Help family/patient identify possible aggravating factors that may exacerbate asthma. Offer suggestions for home environment modification (see Community Care 16–1). Establish an asthma action plan: <ul style="list-style-type: none"> • Monitoring of symptoms (frequency, response to medication, or environmental triggers) • Need for preventive care and routine monitoring • Environmental controls (reduce or eliminate environmental exposures) • Medications (dose, frequency, method of delivery, actions, side effects) for each zone (green, yellow, red); encourage daily medications even when well • Importance of early treatment of asthma exacerbations
Written guidelines	Use an asthma action plan for all children: <ul style="list-style-type: none"> • Plan should be posted at home. • Plan should be shared with child care and school personnel.
Correct use of inhalation devices Use of peak expiratory flow meter	Demonstrate correct use of MDIs, nebulizer treatments, spacing devices, and care of these devices. Instruct in peak flow monitoring as indicated for <ul style="list-style-type: none"> • Children with at least moderate persistent asthma • Children older than 5 years of age Teach use of peak flow meter: <ul style="list-style-type: none"> • Instruct to keep record of readings to identify “personal best” (determined by recording peak flow twice daily for 2 weeks). • Instruct when to initiate or change treatment based on peak flow readings (yellow zone, 50%–80% of personal best; red zone, <50% of personal best).
Fears and misconceptions/feelings about asthma	Respond to patient and family concerns regarding medications. Clear up any misconceptions (asthma not caused by psychological factors, deaths usually related to undertreatment of asthma, children should maintain active lives). Acknowledge negative feelings of having asthma. Refer to appropriate self-management programs/community resources.
Communication with child’s school, daycare, camp, and so forth	Review importance of notifying school of child’s condition, need for medication (especially rescue medications like albuterol) in school, and ability to participate in sports and physical education.

for various settings to promote awareness, knowledge, and treatment adherence. Several of these programs and educational brochures are available through the American Lung Association (Open Airways) or the Asthma and Allergy Foundation of America (Wee Wheezers, Power Breathing) (see [thePoint](#) for organizations) and are presented in the National Heart, Lung and Blood Institute (2007) document. Educational programs that focus on self-management skills help shift the often crisis-oriented nature of asthma care to one of proactive intervention and prevention.

Gear any education and materials to the child's cognitive, affective, and developmental levels. Ensure that the information given to parents and families is also provided to school teachers, the school nurse, coaches, camp counselors, and other community personnel to ensure awareness of asthma, ensure continuity of treatment, and facilitate problem solving if the child has an acute episode. The importance of regular follow-up with a *consistent* healthcare provider cannot be overemphasized. Progress must be closely monitored in relation to history of acute exacerbations, responses to therapy, and adherence to treatment.

ANSWER: The nurse has an obligation to provide ongoing education to the family about the disease and about the medical system. If Claudia made a good decision about when to access care in a hospital, then that should be made clear to Claudia. One of the greatest problems in the management of childhood chronic disease is the lack of continuity of care. Claudia takes her children to the health department for immunizations, to the pediatrician for problems, and now she and Jose have had their first visit to the hospital emergency department. The nurse can ensure the family leaves with a record of the visit so that the pediatrician can fully understand this exacerbation.

Control of Environmental Factors and Comorbid Conditions

Assessment of the environmental factors and comorbid conditions that affect asthma severity can be completed in several ways. A verbal history provided by the child and parent can determine recent exposures, and a history of the symptoms associated with increasing asthma severity. An assessment of the home may reveal the presence of previously unknown or unsuspected allergens (see Tradition or Science 16–3). Advise the family on ways to reduce exposure to environmental allergens within the home and community that may exacerbate asthma (see Community Care 16–1 earlier in this chapter).

Skin or in vitro testing may also be used to assess sensitivity to allergens. Allergen immunotherapy may be considered for children with persistent asthma when there is clear evidence that the asthma symptoms are related to exposure to specific allergens to which the child is sensitive.

A history and treatment of comorbid symptoms may improve overall asthma control. Conditions that may adversely affect asthma control include allergic bronchopulmonary aspergillosis, gastroesophageal reflux, obesity,

TRADITION OR SCIENCE 16–3

Should pets be removed from the home to prevent allergic sensitization in children?

MORE INQUIRY NEEDED

Numerous studies have demonstrated that pet allergies are clearly associated with wheezing and bronchial hyperresponsiveness in adults. Thus, asthma has been thought to be worsened by exposure to pets. However, recent studies indicate that living with a pet early in life reduces the incidence of asthma and may have a possible protective effect. These longitudinal studies demonstrated that children exposed to pets in the home as newborns and during the first year of life had a lower incidence of asthma at ages 12 to 13 than children not exposed to pets. Pet allergen exposure itself does not appear to be the protective factor; rather, endotoxin exposure from presence of the pet in the home is hypothesized to provide the protective influence. Endotoxin, a component of gram-negative bacterial cell walls, is found throughout nature. High levels of allergen exposure are also thought to induce immunologic tolerance. Clearly, more research is needed to better understand the relationship between pet exposure and asthma sensitivity. In the meantime, prospective parents need not remove pets from the home before a child's arrival (Bacharier & Strunk, 2003).

obstructive sleep apnea, rhinitis, sinusitis, stress, and depression. Advise children with these conditions to seek or maintain care provided by a medical specialist to ensure that recognition and treatment of these conditions is maintained.

Medications

A stepwise approach is used to select the medication and delivery devices to meet the child's needs and presenting symptoms (see Tables 16–7 to 16–10). After a diagnosis has been made and therapy has been initiated, the child's level of asthma control is monitored daily, and therapy is adjusted accordingly. The goal of therapy is to identify the minimum amount of medication required to help the child maintain asthma control.

Medications have two primary roles in the treatment of asthma. The first role of medication use is to provide long-term control by preventing symptoms. The second role of medications is to treat acute symptoms and exacerbations.

Corticosteroids are considered to be the most effective method to achieve long-term control of asthma. These anti-inflammatory agents reduce airway hyperresponsiveness, inhibit inflammatory cell migration and activation, and block late-phase reaction to allergens (National Heart, Lung and Blood Institute, 2007). Inhaled corticosteroids are the most consistently effective at all steps of care for persistent asthma. Oral corticosteroids may be used to gain prompt control of asthma and are required for severe persistent asthma (see Tables 16–7 and 16–10).

Other medications used to gain long-term control include cromolyn sodium and nedocromil. These anti-inflammatory agents inhibit activation and release of mediators from mast cells, thus maintaining airway stability. Immunomodulators (omalizumab) is a monoclonal antibody given intramuscularly to prevent binding of IgE to the high-affinity receptors on basophils and mast cells (National Heart, Lung and Blood Institute, 2007). This is used as adjunctive therapy for children 12 years and older who have demonstrated sensitivity to specific allergens and who require a step up in care to manage their persistent asthma. Leukotriene modifiers are used for children requiring step 2 care for mild persistent asthma. These products interfere with the pathway of leukotriene mediators that are released from mast cells, eosinophils, and basophils (National Heart, Lung and Blood Institute, 2007). Long-acting beta₂ agonists such as salmeterol and formoterol are bronchodilators that open the airways by relaxing smooth muscle contraction and reducing bronchospasm, which thereby enhances mucociliary clearance and decreases vascular permeability. Methylxanthine is a sustained-release theophylline that has some mild anti-inflammatory effects and can be used as adjunctive therapy with inhaled corticosteroids for children older than 5 years. For a more detailed description of these medications and their recommended use, dose, adverse effects, and care concerns, please refer to the National Heart, Lung and Blood Institute (2007) asthma guidelines.

Medications are also used to provide quick relief for acute symptoms and exacerbations. These acute symptoms may be brought on by environmental exposures (as described earlier) or perhaps by exercise-induced bronchospasm that was not effectively managed by the medications previously described to step up or down care for long-term asthma control. Quick-relief medications include anticholinergics given via an MDI or nebulizer solution. These agents inhibit muscarinic cholinergic receptors and reduce the intrinsic vagal tone of the airways (National Heart, Lung and Blood Institute, 2007). Short-acting beta₂ agonists (SABAs) such as albuterol, levalbuterol, and pirbuterol are rapid-acting bronchodilators that open the airways by relaxing smooth muscle contraction, enhancing mucociliary clearance, and reducing bronchospasm. Systemic corticosteroids may be used in addition to SABAs for moderate and severe exacerbations to speed recovery and to prevent recurrence of the exacerbation (National Heart, Lung and Blood Institute, 2007) (see the National Heart, Lung and Blood Institute [2007] asthma guidelines for further information on medications to treat acute symptoms of asthma).

Determine the medications the child is using and whether any complimentary and alternative medications or treatments (chiropractic medicine, acupuncture) are be used.

Alert! There is insufficient evidence to support recommending the use of complimentary and alternative medications for treatment of allergy. Families who use herbal treatments for asthma should be cautioned about the interactions that some of the ingredients may have with their prescribed asthma medications.

Ask to view any records the child has been keeping of his or her symptoms and/or peak flow monitoring. Advise children with moderate or severe persistent asthma to keep daily peak flow monitoring records. These tools will aid the child and family to recognize adequate and inadequate asthma control. Watch the child using their peak flow meter and inhaler. Although the steps in this process seem easy, incorrect use of the inhaler means less medication is getting to the airways. Provide instruction materials and sample peak flow charts to the family (see [thePoint](#) for Procedures: Use and Care of Peak Flow Meters and Spacers). Each healthcare encounter should include an assessment of asthma severity, measures to maintain control and the child's responsiveness to the therapies initiated.

Management and Treatment of Exacerbations

QUESTION: Based on the following information and Jose's condition, what do you anticipate the nurse in the emergency department will do next?

An acute or subacute episode of asthma is identified as progressive and worsening shortness of breath, cough, wheezing, and/or chest tightness. These symptoms indicate decreases in expiratory airflow and require immediate intervention. Children whose asthma has been well controlled using inhaled corticosteroids are less likely to have an exacerbation; however, all children are at risk for exacerbations. Respiratory infections, exercise-induced bronchospasm, extreme changes in weather, exposure to a known (or unknown) allergen, and stress can precipitate a worsening of asthma symptoms. Severe exacerbations can be life threatening. Act quickly to assess the degree of severity and to determine the measures already taken to relieve the child's symptoms. Use the child's written asthma plan to help the family determine how to adjust the medications. School nurses should have copies of this written plan at the child's school site. Remove or withdraw the child from allergens in the environment that may be contributing to the exacerbation. If the child does not have a written asthma plan, or if the child continues to deteriorate despite the increased use of inhaled corticosteroids and SABAs, then management in an urgent or emergency care or hospital setting is warranted.

When the child presents in the healthcare setting with an acute exacerbation, assess and carefully monitor alertness, heart rate, respiratory rate, breath sounds, pulse oximetry, and PEFr (if the child is able); and perform a full pulmonary assessment, including visual inspection of chest (accessory muscles), auscultation of breath sounds, and other respiratory assessments. Typically, supplemental oxygen is ordered to correct hypoxemia. Administer repetitive or continuous SABA treatments to reverse airflow obstruction rapidly. Oral systemic corticosteroids may be ordered to decrease airway inflammation if the child does not respond promptly to the SABA treatments. Usually, the child will prefer a high Fowler' position or sitting up and leaning slightly forward. Continuously monitor the child in acute distress, including

comprehensive reassessments of the child's response to therapy after the first hour. For acute exacerbation that responds poorly to initial interventions, or when ongoing observation and stabilization of the child is needed, hospitalization may be indicated. If the child is becoming less alert or drowsy, this may indicate impending respiratory failure. Endotracheal intubation and assisted ventilation must be considered if steady clinical deterioration occurs despite continued intensive therapy.

ANSWER: Jose's history, presentation of physical symptoms, and oxygen saturation will affect the decision regarding whether Jose will receive inhaled SABA by nebulizer or MDI, up to three doses during the first hour, and oral corticosteroids if needed. If Jose is responding to the nebulized medication and his respiratory distress is resolving, inhaled SABA will be continued every 60 minutes. This treatment will continue for 1 to 3 hours. If he continues in respiratory distress, despite his initial treatments, oxygen will be administered. Hospitalization may be warranted for ongoing administration of oxygen, nebulized SABAs, oral or intravenous corticosteroids and intravenous therapy.

Community Care

The National Heart, Lung and Blood Institute (2007) asthma guidelines represent the best evidence to date regarding the assessment, monitoring, and management of asthma. The primary emphasis of these standards of care is to encourage early diagnosis and ongoing assessment by the child's medical home providers, and to provide teaching and preventive measures that will ensure the child's overall health and well-being. Patient education should occur at all points of care with the child and family. Surveillance of environmental triggers must also occur in all settings (home, school, daycare, and so forth) in which the child is likely to spend time. Review the National Heart, Lung and Blood Institute (2007) standards thoroughly and utilize the information and products provided by this agency and others to help children and their families effectively manage the child's chronic condition.

Bronchopulmonary Dysplasia (BPD)

BPD is a chronic lung disease of children that begins in infancy. BPD was first described as the radiographic and clinical syndrome seen in infants who had been treated with mechanical ventilation and high levels of inspired oxygen, and who survived respiratory distress syndrome. Although timing of diagnosis varies, the clinical diagnosis is generally made at approximately 1 month of age in infants who required mechanical ventilation for at least 1 week; have symptoms of persistent respiratory distress; are dependent on supplemental oxygen; and have chest radiographs that show hyperinflation, atelectasis, increased density, and fibrotic areas (American Thoracic Society, 2003).

Because the diagnostic criteria for BPD are not precise and universally distinct, the incidence of this disease is difficult to ascertain. Some retrospective studies of neo-

nates suggest that BPD occurs in 35% of premature births, with the incidence being inversely related to birth weight (Smith et al., 2005). This condition is seen predominantly in infants born prematurely (more than 10 weeks before their due date), infants less than 1,000 g at birth, and in infants with multiple pulmonary disorders who require ventilator support with high positive airway pressures and oxygen during the first 2 weeks of life.

Early deaths from BPD are generally attributed to untreated respiratory failure, with later deaths being associated with infection, pulmonary hypertension, and cor pulmonale, or an acute severe cyanotic episode that does not respond to rapid institution of CPR. The effects of BPD may last several months to years. Although infants with BPD have a prolonged and complicated neonatal course, the long-term pulmonary prognosis for survivors of BPD is relatively good.

Pathophysiology

The pathophysiology of BPD is complex and of multi-etiological and multisystem origins. It starts with an acute insult to the neonate's lungs, such as respiratory distress syndrome, pneumonia, or meconium aspiration, that requires positive pressure ventilation and high concentrations of oxygen over an extended time. These therapies result in tissue and cellular injury to the immature lung. The epithelium of the conducting airways develops lesions from injury thought to be related to hyperoxia and positive pressure. Excessive pulmonary fluid, collection of cellular debris in the alveoli, and recurrent bacterial and viral infections are additional factors contributing to the alveolar tissue damage. Infants with BPD often exhibit a "state of chronic undernutrition" that affects the lung's ability to resist injury and repair damaged tissue (American Thoracic Society, 2003; Huysman et al., 2003).

The most important underlying pathologic process in BPD is the profound alteration of lung compliance, which is reduced as a result of a combination of factors. These factors include fibrosis of the airways and marked hyperplasia of the bronchial epithelium, which occur secondary to alveolar damage; and increased fluid in the lung, as a result of disruption of the alveolar-capillary membrane. Damage to the alveolar supporting structures results in overdistension and leads to air trapping, fibrosis, airway edema, and bronchoconstriction, increasing airway resistance and decreasing compliance. Increased airway resistance increases the work of breathing, resulting in tachypnea and wheezing.

Pulmonary gas exchange is impaired by several factors. Hypoxia occurs secondary to ventilation-perfusion mismatch in the areas of alveolar collapse. Increased pulmonary vascular resistance causes intrapulmonic shunting, thus also contributing to hypoxia. Hypercarbia is common and is also caused by ventilation-perfusion mismatch, as well as by hypoventilation.

Large airway pathology (i.e., in the trachea and bronchi) was not originally described as a component of BPD but has since been recognized to be a frequent finding as the disease progresses. Both tracheomalacia and bronchomalacia are commonly found in this population and

are postulated to be the cause of acute, severe cyanotic episodes in the older infant with BPD.

Growth failure in infants with BPD is almost universal and results from increased caloric needs, caused by the increased work of breathing, and high resting oxygen consumption. Growth failure and lung disease may also be complicated by gastroesophageal reflux with frequent emesis, poor oral feeding skills, and recurrent respiratory infections (Huysman et al., 2003).

Cor pulmonale (hypertrophy or failure of the right ventricle caused by disorders of the lungs, pulmonary vessels, or chest wall), pulmonary hypertension, systemic hypertension, and left ventricular hypertrophy are complications of BPD that result from the fibrosis and chronic hypoxia. The pulmonary vasculature of these infants develops increased reactivity to hypoxia, resulting in pulmonary hypertension and left ventricular hypertrophy with congestive heart failure.

The effect of therapies such as high-frequency oscillatory ventilation and surfactant replacement on the overall incidence of BPD remains to be fully demonstrated. High-frequency oscillatory ventilation delivers gas at extremely high frequencies (>200 “breaths”/minute) and considerably lower pressures than those used for standard mechanical ventilation, thus reducing barotrauma to the alveoli. Studies have shown that surfactant therapy reduces the severity of respiratory distress syndrome and decreases the amount of time on mechanical ventilation.

Assessment

The clinical manifestations of BPD are a direct reflection of the pathophysiology of this disorder. Tachypnea, dyspnea, and wheezing are intermittently or chronically present secondary to airway obstruction and increased airway resistance. Increased work of breathing, as evidenced by intercostal or substernal retractions and use of accessory muscles, is common in the infant with BPD. Infants who have been intubated for long periods may develop subglottic stenosis, which results in inspiratory stridor. Furthermore, hypoxemia and hypercapnia are chronic states that contribute to the problem. The child might turn cyanotic when crying or after a few moments without supplemental oxygen. Infants with moderate to severe BPD are frequently described as irritable and difficult to comfort. This behavior may result from hypoxia or underlying neurologic dysfunction. They may develop irregular sleep patterns as a result of frequent medical treatments, medications, and therapies. Inguinal hernias are often present, which may be a result of the continuous increase in abdominal pressure caused by high airway resistance and use of accessory respiratory muscles. These infants also have extraordinarily large insensible fluid losses because of tachypnea and excessive perspiration related to hypercarbia.

The incidence of neurologic abnormalities and developmental delay in infants with bronchopulmonary dysplasia varies, but these problems are known to occur in children with BPD. Infants who are born prematurely likely experience some degree of developmental delay with or without neurologic insult. Even if there is no evident damage to the neurologic system during hospitalization in the neonatal intensive care unit, children with BPD may show signs of

problems when they are school age. These problems can range from vision and hearing loss to speech delays, learning disabilities, and poor attention span. Developmental delays result from long-term ventilatory support, poor nutritional status, inadequate sensory stimulation, neurologic sequelae, and decreased energy and respiratory reserves.

Nursing assessment requires close observation and awareness of BPD signs and symptoms. Take a thorough history, including the child’s baseline symptoms (retractions, respiratory effort), requirements (oxygen needs), and nutritional intake. Next, complete a physical examination focusing on respiratory, cardiac, nutritional, and developmental status. An interdisciplinary team may assist in a comprehensive evaluation. Report any abnormal findings to the team and implement appropriate interventions and referrals.

Interdisciplinary Interventions

Just as the pathophysiology of BPD is multifactorial, its treatment is multifaceted. Medical management of BPD centers on preventing and minimizing hypoxia and hypercarbia, treating bronchoconstriction and airway hyperreactivity and inflammation, treating pulmonary edema, and promoting repair of chronic lung injury.

These desired ends are achieved in varying degrees by medical therapies such as supplemental oxygen, diuretics, bronchodilators, anti-inflammatory agents, and various modes of assisted mechanical ventilation. Pulmonary hypertension responds at least in part to oxygen, a potent pulmonary vasodilator. Low-flow supplemental oxygen is administered, at times on a long-term basis, in an attempt to prevent chronic hypoxia and subsequent complications. Tracheostomy is considered for those who require assisted ventilation for more than 3 months as a neonate or who have chronic hypercarbia and increased work of breathing.

Management of Hypoxia

The primary and most important aspect of therapy in infants with BPD is managing hypoxia. Maintaining adequate tissue oxygenation is imperative to prevent severe morbidity and potential death. Supplemental oxygen therapy is prescribed to promote growth and neurodevelopment, and to prevent or control pulmonary hypertension. Administering and monitoring oxygen therapy is a major nursing responsibility in the care of an infant with BPD. Pulse oximetry or transcutaneous oxygen monitors are used to continuously or intermittently display oxygen saturation. Oxygen saturation levels (SaO₂) of 92% to 95%, depending on severity of illness, are necessary to facilitate an improved rate of weight gain and to control pulmonary hypertension. The nurse must respond to the infant’s changing oxygen needs, titrating oxygen flow to keep saturations within the prescribed parameters. Feedings, periods of increased activity, and periods of sleep are occasions when desaturations are most likely.

Tailor the mode of oxygen delivery to the specific needs of the infant. Most infants with mild to moderate BPD can tolerate a nasal oxygen cannula. Children with tracheostomies may use a tracheostomy mist collar (Fig. 16–18). Humidification is necessary for liter flow equal to or greater than 1 L/minute to prevent airway irritation

FIGURE 16–18. Humidified oxygen is provided to the child using a mist delivery device.

and mucous plugging. Watch infants for increased oxygen demand, especially during acute illnesses, fever, stress, and periods of increased activity. Reassessment should include child’s color, presence and degree of respiratory distress (report any retractions, nasal flaring, or use of accessory respiratory muscles), breath sounds, vital signs, and level of consciousness.

Other nursing interventions for the infant with BPD include administering multiple oral and inhaled pharmacologic agents, monitoring their effectiveness, and identifying possible adverse effects (Table 16–11).

Respiratory Care

Because excessive airway secretions present difficult problems for the infant or child with BPD, diligent airway clearance is needed to prevent mucous plugging and airway obstruction. Cough is often ineffective in these children because of generalized debilitation and tracheomalacia. Nasopharyngeal or tracheal suctioning is needed frequently to maintain patent airways, especially during illnesses or respiratory tract infections. Chest physiotherapy may also help improve secretion clearance and lessen atelectasis. Always collaborate with respiratory therapists and parents to schedule chest physiotherapy to occur 30 minutes before feedings and before rest periods if possible. Suctioning should immediately follow chest physiotherapy and be done at other times as needed.

Positioning and comforting interventions are of extreme importance in caring for the infant with BPD. Ill or premature infants who are chronically “air hungry” are extremely irritable and may be difficult to console. With the collaboration of physical and occupational therapists, develop individualized plans for the handling and activity level of these infants that accommodate their developmental level and ability to tolerate stimulation. Frequent and prolonged rest periods are necessary because of increased energy demand and sleep deprivation. Watch for signs of overstimulation in the neurologically immature child such as cyanosis, avoidance of eye contact, vomiting, diaphoresis, and falling asleep.

TABLE 16–11

BPD Medications and Side Effects

Type of Medication	Action	Possible Side Effects
Bronchodilators		
Aminophylline Terbutaline Albuterol (inhaled)	Bronchodilators open the airways of the lungs. They work by relaxing the muscles around the airways. These medicines can be used alone or in groups.	Increased heart rate Shakiness or tremors Hyperactivity
Diuretics		
Furosemide (Lasix) Spironolactone (Aldactone) Chlorothiazide (Diuril)	Diuretics cause an increased amount of water and salt to be excreted in the urine. They also decrease the amount of fluid in the lungs.	Imbalances in potassium (hypokalemia/hyperkalemia) and calcium (hypocalcemia) Muscle cramps and irregular heart rhythm are signs that serum electrolytes must be closely monitored
Anti-inflammatory Drugs (Corticosteroids)		
Prednisolone (oral liquid) Budesonide (Pulmicort) (inhaled)	Anti-inflammatory drugs are used in children whose wheezing is not controlled with bronchodilators. These medicines do not reverse or stop existing wheezing. They are used on a long-term basis to prevent wheezing and respiratory distress. They work well only if taken continuously.	Short-term use causes little or no side effects. Longer term effects include impaired growth and decreased ability to fight infections.

Nutritional Support

Because growth failure is common in the infant with BPD, providing nutritional support is a crucial, although difficult, aspect of caring for these children. Management of feedings in infants and young children with BPD has direct implications for long-term outcome, because an adequate caloric intake is necessary for growth of healthy lung tissue and resolution of the disease. Yet, these infants suffer from a myriad of conditions that impair their ability to feed: gastroesophageal reflux, often with aspiration; emesis; chronic fatigue; behavioral oral aversion; and swallowing dysfunction caused by poor oral-motor development. For the healthy infant, feeding is generally viewed as a pleasant and positive experience; however, for the child with BPD, it is often perceived as a battle. It can seem that the more that nurses and parents are concerned and anxious about nutrition and place pressure on the infant or child to eat, the less the child eats. Feeding with the infant or child with BPD can be a frustrating and challenging experience, and coordinated interdisciplinary effort is the key to successfully approaching these problems.

Begin with an nutritional assessment that includes documentation of anthropometric (precise measurement of the body includes weight, height, and head circumference) and biochemical data, dietary intake, and clinical status. Strategies in nutritional support then focus on optimizing the caloric intake to meet individual needs. Concentrating formula to provide more calories per ounce; medication to control gastroesophageal reflux; and small, frequent feedings all are appropriate for mild to moderate growth failure.

Infants with severe growth failure, or for whom the previously listed strategies are unsuccessful, should be consid-

ered for surgical placement of a gastrostomy tube or percutaneous endoscopic gastrostomy tube. This procedure may or may not be performed in conjunction with a Nissen fundoplication, depending on the severity of gastroesophageal reflux. Because parents sometimes view the need for a gastrostomy tube as a sign of their failure to feed their infant orally, the entire healthcare team must provide support and stress the benefits of this mode of therapy. Calorie-dense formulas can be administered with minimal risk of aspiration, in a continuous infusion if necessary, to promote optimal growth. Feeding specialists and caregivers can provide therapy to develop and refine suck and swallow coordination skills concurrently, so that as the infant's growth, strength, and ability to orally feed improve; tube feedings can be slowly weaned and the frequency and amount of oral feedings can be increased (Nursing Interventions 16–2). This strategy temporarily relaxes the intense focus on eating and can transform parental anxiety into energy devoted to interventions such as positive oral stimulation and nonnutritive sucking during tube feedings.

Family Education and Support

Other nursing and social service interventions should focus on providing education and support. Teach parents about all aspects of BPD, especially topics related to home care. If the child is to receive oxygen, arrangements must be made for administering the oxygen (Community Care 16–4). Medication administration, feeding and nutrition, developmental interventions, chest physiotherapy, and suctioning are among the most important topics of education for the parents and family of a child with BPD. Family members are taught CPR. Teach them the

NURSING INTERVENTIONS 16–2

How to Improve Feeding Capabilities in an Infant With BPD

- Have baby in a calm, alert state before beginning to feed.
- Position the baby in the caregiver's lap with the baby's neck in a neutral position, hips and knees at 90 degrees of flexion, both upper extremities with elbows flexed at 90 degrees, and swaddled across the chest. *Note:* If the baby becomes excessively hot or sweaty with swaddling of the entire body, then fold a thin pillowcase or light towel in a long rectangle and swaddle only around the arms and partial trunk to prevent excessive scapular retraction, arching, and flailing of the upper extremities.
- Carefully monitor physiologic parameters, especially respiratory rate. Feedings may need to be limited or postponed if the infant remains tachypneic.
- Choose a nipple that allows moderate resistance to flow without excessive energy expenditure. Standard-shaped nipples are preferred.
- Present the nipple slowly and calmly, with minimal intraoral stimulation.
- Emphasize normal total body posture during feeding. Head and neck posture can alter oral-motor patterns during sucking. Ideally, marked neck extension should be reduced to aid oral-motor control. The goal of improving head and neck positioning may need to be approached slowly, to minimize stress to the infant.
- Allow baby to set the nipping pace, with rests as needed.
- Stop nipping if baby begins to sweat or cries inconsolably for 1 minute or longer; if respiratory rate or heart rate increases excessively, as determined by the physician; or if feeding takes longer than 20 minutes.

COMMUNITY CARE 16-4

Methods of Home Oxygen Delivery and the Child With BPD

Method	Advantages	Disadvantages	Special Considerations
Compressed gas in tank	Usually the least expensive system Can be used with any flow rate; continuously or intermittently (with proper flow meter)	Large tanks take much storage space Under very high pressure; if valve were broken or jarred loose, tank would behave like a high-powered rocket Heavy, cumbersome	Tanks vary in size from very large to portable (with a cart). Store all tanks with a stable base and secured against falling over. When traveling, the system should be secured in the vehicle to prevent rolling or other movement.
Liquid oxygen	Twice as much oxygen can be stored in the same amount of space as tanks Very light and portable; the most convenient system May be more cost-effective than tanks if high flow is required	Usually the most expensive system Evaporates when not being used continuously Not practical with low flow rates	Portable system is filled from a larger reservoir. When traveling, the system should be secured in the vehicle to prevent rolling or other movement.
Oxygen concentrator	Machine separates oxygen from nitrogen in the room air; never needs to be “refilled” Practical for rural areas or areas not routinely serviced by oxygen companies	Runs by electricity; backup system needed for power outages Noisy Increases electric bills Difficult to transport in a two-story home or outside the home	Must have grounded electrical outlet. When traveling, the system should be secured in the vehicle to prevent rolling or other movement. A portable system of compressed gas should be dispersed for emergency use and transport to clinic for illnesses.

All oxygen systems should be kept away from any open flame, combustible materials, or sources of sparks.

symptoms that indicate the child’s respiratory condition is worsening and when to seek medical attention.

Community Care

The emotional effect on parents and family of having a child with BPD is profound. The development of a chronic condition with life-threatening implications in a premature infant, followed by complex home care, is a situation so laden with stress and anxiety that it is often described by families as an “emotional roller coaster” from which they have no opportunity to escape. The family must deal with grief and sorrow over the loss of the expected healthy child, financial demands, and social isolation.

Social isolation is a common psychosocial issue for these families. Caring for a frequently hospitalized infant with a chronic illness can absorb virtually all the parents’ time and energy. They must balance time with the ill child against time with their other children and for them-

selves. Family sacrifices often have to be made. Parents and older siblings may be required to adjust work, school, and recreational schedules. Social interactions are often drastically reduced because of lack of time, energy, transportation, and financial resources. In addition, clear-cut social guidelines for approaching families with chronically ill children are limited. At a time when support is most important, individuals in the family’s social network may feel awkward and tend to withdraw. Assessing social support and interactions is crucial when planning care for a family with a child who has BPD.

Parent support groups facilitated by nursing or social service professionals are often successful in addressing parental anxiety and promoting positive coping. Sibling reactions and coping, financial stress, profound chronic fatigue, and uncertainty about their child’s physical and intellectual future all are topics many parents find comforting to discuss with others who have had similar experiences and concerns. Some families, too, are referred by

social services for private counseling to address and facilitate stress management.

Cystic Fibrosis (CF)

Once considered a fatal childhood disease, CF is a chronic, multisystem condition. Ongoing advances in understanding the pathophysiology of CF, particularly its genetic and molecular mechanisms, has greatly improved diagnosis and treatment, and thus improved survival rates, life expectancy, and quality of life for children and adolescents with CF. The median age of survival for individuals with CF has increased to 37 years in 2004, up from 32 years in 2003 (Cystic Fibrosis Foundation, 2007). Intensive research has also resulted in better screening tests to detect carriers through genetic testing.

CF is a highly complex disease and requires a holistic approach to care by a trained, interdisciplinary team, including physicians, advance practice nurses, nurses, dietitians, social workers, psychologists, and respiratory care therapists. Coordination and communication with the child, family, and other healthcare providers are essential. Specialist care in a dedicated CF center has been associated with improved survival and quality of life in children. As with any chronic condition, the primary objectives of CF care for children should focus on (1) ensuring optimal care, including treatments, routine monitoring, and general pediatric preventive care; (2) facilitating access to pertinent healthcare resources and support; (3) assisting the family in coordinating care among specialists and primary care providers, and in accessing medications, dietary supplements, and durable medical equipment; and (4) supporting quality of life and independence.

Although CF is rare overall, it is more common among white northern Europeans. The overall prevalence of CF in the U.S. population is estimated to be 1 in 3,700 live births (Green et al., 2005). Based on reports from the Centers for Disease Control (2004), the prevalence is 1 in 2,500 to 3,500 births among non-Hispanic whites, 1 in 4,000 to 10,000 births among Hispanics, and 1 in 15,000 to 20,000 births among non-Hispanic blacks.

Pathophysiology

CF is an autosomal recessive genetic condition. In such conditions, the risk of disease transmission is 25% if both parents carry the gene, and the chance that the child will be a carrier of the disease is 50% (see Fig. 3–3). Prenatal screening is common in women from populations that have an elevated prevalence of CF, or in women with known or suspected family histories. Prenatal testing is also done when obstructed fetal bowel is detected by ultrasound, because CF is associated with meconium ileus.

The gene responsible for CF is located on chromosome 7. CF results from mutations in the cystic fibrosis transmembrane regulator (CFTR), a protein that regulates chloride and sodium transport in secretory epithelial cells of the body's exocrine glands. The alteration in the CFTR protein results in abnormal ion concentration across the apical membranes of these cells: They do not release chloride, resulting in an improper salt balance. This imbalance causes the mucus secretions of the

pulmonary, gastrointestinal, and reproductive systems to become thick and sticky, and to block ducts in those organs. The sweat glands are also affected by blocked or abnormal transport and produce sweat with elevated sodium and chloride concentrations (Fig. 16–19).

The most CF common mutation, DF508, occurs in more than 90% of individuals with CF in the United States (Rowe, Miller, & Sorscher, 2005). More than 1,000 other gene mutations of CFTR genes have been described. A small number of these mutations occur with reasonable frequency, but most are rare. Thus, the clinical manifestations (the phenotypic expressions) of CF vary widely. For example, 99% of those who are homozygous for the DF508 allele have pancreatic insufficiency, whereas only 36% of people with CF with other mutations are pancreatic insufficient (Rowe, Miller, & Sorscher, 2005).

Clinical consequences of CF are progressive pulmonary damage (e.g., airway obstruction, inflammation, infection, scarring), pancreatic dysfunction, liver disease that may lead to cirrhosis, gut motility problems, and elevated sweat electrolyte levels. Approximately 80% to 85% of children with CF are pancreatic insufficient, resulting in malabsorption of important nutrients, fats, and proteins. Approximately 98% of males are sterile, because of blockage of the vas deferens by thick secretions, or from abnormal development (atresia of the vas deferens) that prevents passage of sperm. Females can become pregnant, but the thick cervical mucus acts as a natural barrier to sperm. Although the true biologic fertility in CF remains unknown, females with normal lung function appear to experience relatively few problems with pregnancy; those with decreased lung function and chronic infection tend to have poorer pregnancy outcomes (Edenborough, 2001).

The thickened, sticky mucus of a child with CF is ineffective in removing bacteria from the body, and in fact constitutes an ideal medium for bacterial growth. Thus, the child with CF is especially prone to pulmonary infection. Bacterial lung infections are responsible for most morbidity and mortality among children with CF, and these infections are often caused by multiple pathogens. The most common cultured bacteria are *Pseudomonas aeruginosa*, *S. aureus*, *Burkholderia cepacia*, and *H. influenzae*. Children with CF often remain colonized with organisms such as *P. aeruginosa*, which is never eradicated from the lungs.

Alert! *Pseudomonas (Burkholderia) cepacia* cause extremely virulent infections and have been associated with rapid deterioration of pulmonary function. *B. cepacia* has been associated with death in approximately 2% of children with mild or moderate forms of CF. To prevent spreading, children with *B. cepacia* should not have contact with CF patients.

Children with CF often experience acute pulmonary exacerbations, many of which are caused by respiratory viruses. Infections such as RSV may result in severe pulmonary complications, particularly in infants. Exacerbations cause fatigue, decreased appetite, weight loss, increased sputum production, increased cough, hemoptysis, decreased spirometry values, and poor response to outpatient therapeutic measures such as oral antibiotics and increased pulmonary treatments at home. Treating

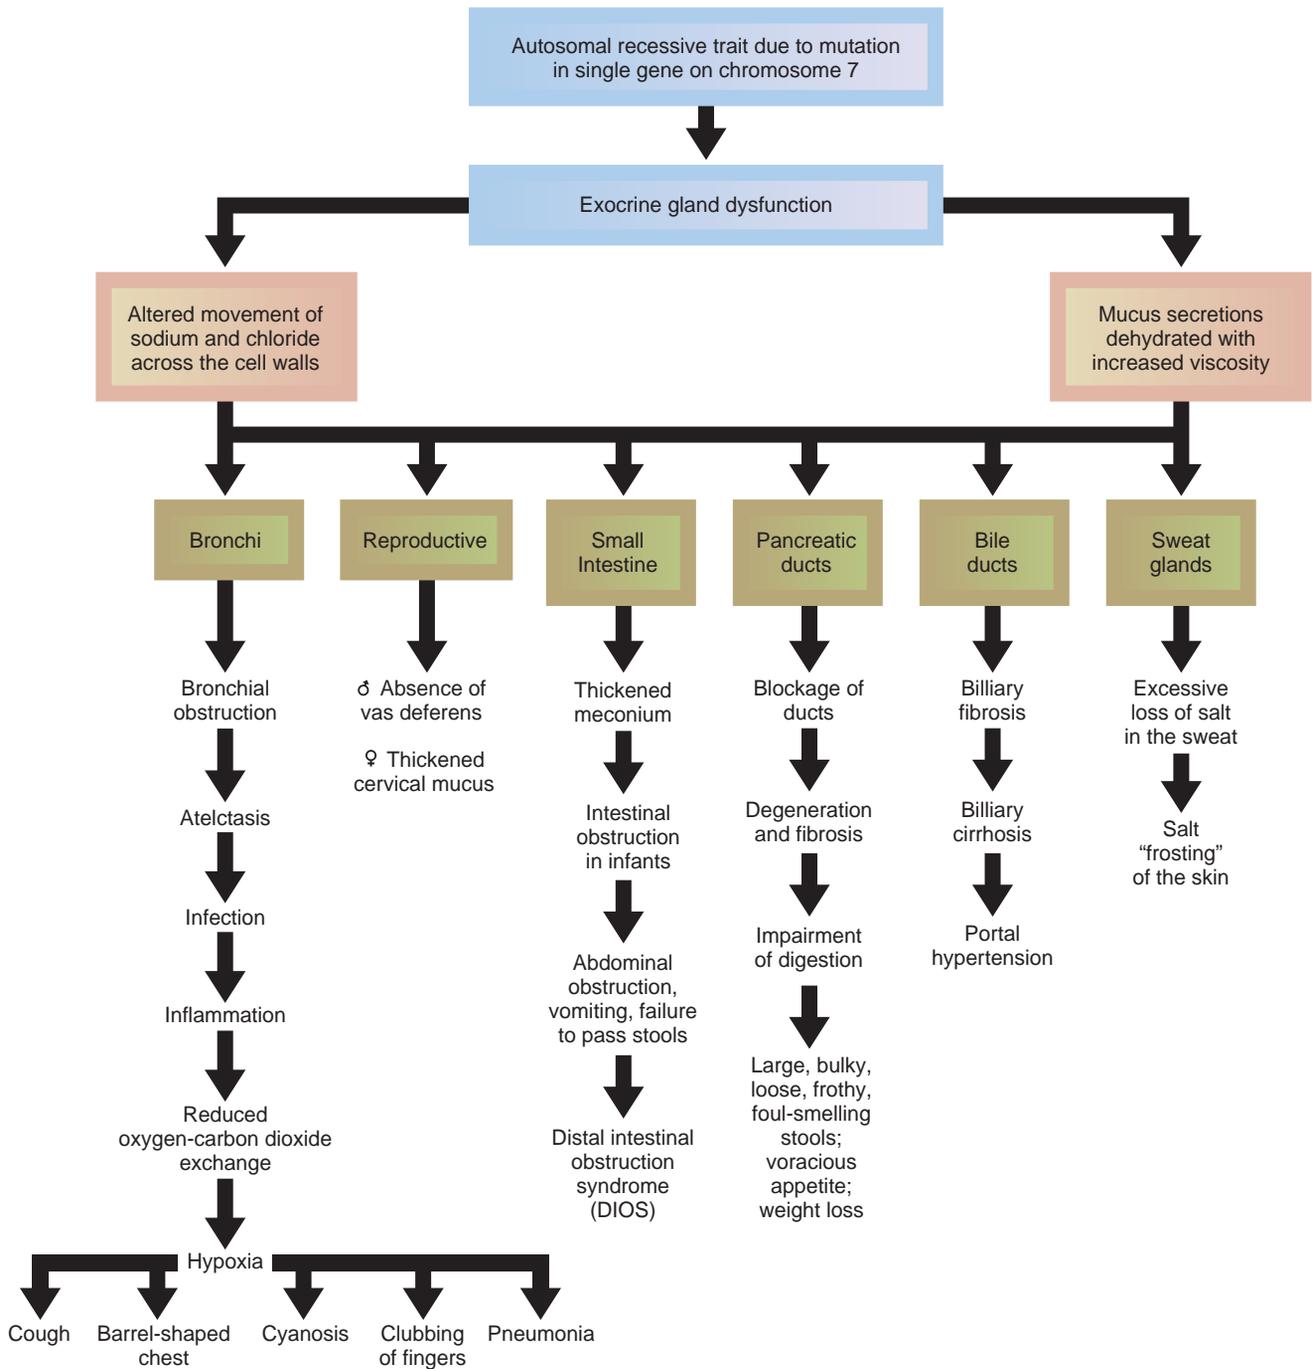

FIGURE 16–19. Manifestations of cystic fibrosis.

pulmonary exacerbations requires careful monitoring, aggressive therapies, and often hospitalization.

Adolescents’ cognitive development is normal, but secondary sexual development may be delayed, causing teens to look younger than their peers. During the adolescent years, infertility must not be assumed for either gender; teens should receive appropriate referrals for informed family planning and life decisions.

Assessment

CF is often diagnosed early in life, although children with less severe CF may not be diagnosed until later childhood. The clinical presentation of CF can be extremely

varied, although the most common symptoms are very salty tasting skin; persistent cough; excessive appetite but poor weight gain; and foul-smelling, greasy, bulky stools. As people live longer with CF, other symptoms and complications may manifest themselves (Chart 16–2).

Before diagnosis, newborns often present with meconium ileus and bowel obstruction, and perforation requiring surgical intervention. Young infants may be irritable and present with failure to thrive despite good appetite. Children with CF may appear physically small for their age in both linear growth and weight.

When assessing a child known to have CF, include an intensive history (by system) of current and past symptoms, changes in activity tolerance, exercise, sleep and

CHART 16-2 COMPLICATIONS OF CYSTIC FIBROSIS

Complications	Causes
Pulmonary	
Minor hemoptysis	Common after 10 years of age. Blood streaking is from mucosal irritation in the airway.
Major hemoptysis	Occurs more frequently with age; in less than 10% of adults. Bleeding caused from high systemic pressure of bronchial circulation when infection erodes a blood vessel.
Pneumothorax	Incidence increases with age (approximately 16% to 20% of patients older than 16 years experience this complication). Rupture of subpleural blebs through visceral pleura. High rate of recurrence.
Nasal polyps	Occurs in 10% to 25% of CF patients. Most common in older children and adolescents; etiology is unknown.
Chronic sinusitis	Occurs in more than 90% of CF patients. Etiology is thought to be from abnormal occlusion of the ducts that prevents mucus drainage; maxillary and ethmoid sinuses are most commonly involved.
Cor pulmonale	Occurs in advanced disease. Right ventricular hypertrophy, chronic hypoxemia and pulmonary hypertension, and right-sided heart failure are noted.
Pulmonary hypertrophic osteoarthropathy	Occurs in approximately 4% of older patients; etiology is unclear.
Gastrointestinal	
CF diabetes	Occurs in 8% to 15% of patients, with onset during adolescence. Etiology is unknown. It is postulated that insulin deficiency is secondary to fibrosis of the pancreas, which destroys the islet's architecture; usually nonketotic.
Distal intestinal obstruction syndrome equivalent (formally called <i>meconium ileus equivalent</i>)	Incidence is 10% to 20% of adult CF patients. Usually occurs during adolescence or later. May be partial or complete obstruction; etiology is multifaceted. Intestinal mucoproteins may be more viscous. Enteroglucagon release results from increased undigested fats that slow transit time. A fecal mass forms at the ileocecal region and extends distally.
Cholelithiasis	Occurs in up to 12% of patients and is rarely symptomatic prior to the teenage years. Stones are usually cholesterol. Etiology results from alterations in bile lipid composition.*
Liver disease	Occurs in about 4% of patients, peaking in adolescence and decreasing after 20 years of age.
Multilobar cirrhosis	Results from thickened secretions in bile ductules, causing plugging, ductular proliferation, inflammation, and cirrhosis.
Gastroesophageal reflux	Occurrence of symptoms varies. There is a transient, inappropriate relaxation of the lower esophageal sphincter. Contributing factors include positioning, cough, and increased intra-abdominal pressures versus thoracic pressure gradient.
Pancreatitis	Acute pancreatitis occurs in approximately 10% of patients. It can occur with pancreatic sufficiency. It is an inflammatory response. The exact causative mechanism is unclear.
Fibrosing colonopathy	Occurs in a small percentage of patients. Risk factors include age younger than 12 years. There is a strong association with oral pancreatic high-dose enzyme intake for more than 6 months.

Sources: Brennan et al. (2006) and Kerem et al. (2005).

rest disturbances, and sleep position. Although you should carefully assess all systems, the primary focus should be on the respiratory system.

The respiratory assessment may reveal a “barrel-shaped” chest with increased anteroposterior diameter, caused by hyperaeration and increased work of breathing. Another physical finding characteristic of hypoxia and common in young children with severe CF is mild to severe clubbing of the nail beds, caused by chronic hypoxia. Assess oxygenation by inspecting the color of the mucous membranes, nail beds, and skin. Use pulse oximetry to monitor oxygen saturation. Assess breath sounds for equal aeration of all lung fields and for presence or absence of rales, crackles, and wheezing, particularly in the upper lobes and the right middle lobe. Assess breathing for rate, depth, effort, and use of accessory muscles. Obtain a history on sputum characteristics, including color changes, volume, viscosity, and presence or absence of blood. Also elicit history of headaches and pain, changes in breathing during activities of a typical day, and cough pattern. The characteristic cough of CF may increase during pulmonary exacerbations, can be paroxysmal, and frequently ends with posttussive emesis. The comprehensive pulmonary assessment in CF includes a comparison of the current chest radiograph with baseline films and spirometry values with prior results.

On physical examination, note the child’s overall size, general condition, muscle tone, and muscle mass. Some children with CF may have a protuberant abdomen. Assess the skin for bruising; old surgical scars; and indicators of adequate, excessive, or inadequate fluid balance. Assess the oral mucous membranes, especially of infants, for oral lesions, which may result from CF medications (pancreatic oral enzymes) or from thrush, a fungal superinfection that may be caused by long-term use of oral antibiotics. Thrush may also manifest as candidal vaginitis in the female adolescent or monilial diaper rash in the infant. Examine the rectal area of infants for perirectal irritation from unabsorbed supplemental pancreatic enzymes. Ask questions to elicit a history of a prolapsed rectum. Other history and symptoms that require assessment are irritability and any associated behaviors; emesis; stool pattern (frequency and characteristics); and reports of abdominal pain, discomfort, “heartburn,” or any combination of symptoms that may indicate gastroesophageal reflux.

The sweat test is the definitive test for CF. An elevated sweat sodium chloride level greater than 60 mEq/L is a positive diagnostic result that should be confirmed by a second test at a CF center (Cystic Fibrosis Foundation, 2007). The sweat sample is usually obtained by stimulating a small patch of sweat glands on the inner aspect of the forearm. An adequate quantity of sweat, at least 50 mg and preferably 100 mg, must be collected to ensure reliable results. Two positive sweat test results and the presence of clinical symptoms or a family history confirm the diagnosis. False-negative skin tests are associated with technical problems (failure to dry skin before collecting sweat; errors in weighing, dilution, elution, or computation) or physiologic factors (inadequate volume secondary to low sweat rate, edema) (Beauchamp & 2005). Siblings are usually tested when a diagnosis is confirmed.

Interdisciplinary Interventions

The care and treatment of CF is often complex and thus requires a multidisciplinary approach. Specialized CF centers that meet specific criteria and are accredited by the Cystic Fibrosis Foundation deliver quality care and maintain strict standards of practice. Although most CF centers are directed by pediatric pulmonologists, other pediatric specialists such as gastroenterologists, infectious diseases specialists, geneticists, and endocrinologists also are involved. Additional team members include nurses, advance practice nurses (pediatric nurse practitioner or clinical nurse specialist), registered dietitian, respiratory care practitioner, medical social worker, physical therapist, child life specialist, and genetic counselor. As the life expectancy for CF increases, and more patients survive into adulthood, pediatric healthcare teams must foster a “wellness” focus and incorporate planning for adult CF care. Planning for a productive life is the norm.

The family is central to chronic disease management teams. The child should be an active member in the CF care team. Working together, the child, parents, family, and the interdisciplinary team develop individualized management plans to treat the complex needs of the child and family (see [thePoint](#) for Care Paths: An Interdisciplinary Plan of Care for the Child With Cystic Fibrosis). Although each member of the CF care team has specialized knowledge and a clearly defined role, overlap in role functions may occur, depending on the needs of the individual family. The goal of the team is to “normalize” the lives of the family, maintain existing pulmonary function, and prevent further pulmonary damage so the child can benefit as new treatment options become available.

WORLDVIEW: CF is a condition that primarily affects people of white European genetic background. The CF care team must be sensitive to cultural issues for individuals and families from varying backgrounds. Families may experience a sense of isolation within their cultural environment. Lifestyle practices within certain cultures may affect the care of an infant or child. The CF team members must work to understand these cultural differences and support choices that will support the child’s healthcare maintenance needs. Further research is needed to examine the effects of cultural differences and practices among families on chronic disease management.

Because of the chronic pulmonary infections, activities and lifestyles for children with CF may be altered. For example, *B. cepacia* is extremely communicable among the CF population, so room isolation, limited social interactions with others with CF, and infection control measures are required during hospitalization and community events for children colonized or infected with this organism. For example the Cystic Fibrosis Foundation has a policy that prohibits the participation of anyone with CF and *B. cepacia* from participating at CF Foundation-sponsored events. Because of the highly communicable nature of *B. cepacia*, the CF Foundation believes this policy enables people with CF who are not infected with *B. cepacia* to more safely participate in its events (Cystic Fibrosis Foundation, 2008).

Medical Management

Medical management of CF is multifaceted. Successful chronic disease management requires complete assessments and routine monitoring of treatments. A comprehensive annual review, generally conducted at CF centers by the multidisciplinary team, should include assessments such as a full clinical examination and respiratory, nutritional, and psychosocial assessments, as well as a critical review of current therapies and treatments. Clinical diagnostic tests during the annual review may include complete blood count including iron status, blood chemistries, microbial cultures, bone density examinations (to evaluate for osteoporosis secondary to poor nutritional intake), and auditory assessments. In addition to the annual reviews, documenting overall health maintenance (immunizations, annual flu vaccine, and adherence history) is important.

For some children with early symptoms of pulmonary exacerbations, treatment may be managed in the home setting with oral antibiotics, aggressive pulmonary therapy, and close follow-up. Hospitalization is required for children who have declining pulmonary status, infection, or both. Such stays are often called “tune-ups.” During the “tune-up” period, aggressive pulmonary and nutritional therapies are instituted, along with intravenous antibiotics and an exercise program, and response to these therapies is evaluated. Frequency of aerosol treatments and airway clearance therapies is increased. A daily program to increase or prevent loss of endurance during hospitalization is part of the plan of care. The gastrointestinal therapies include nutritional assessment and evaluation of blood chemistries for nutritional deficits, including measurement of hematocrit, hemoglobin, albumin, prealbumin, and vitamins A and E levels (see Nutritional Support).

Today, with a shift toward ambulatory services, many individuals with CF initiate their “tune-ups” in the hospital and complete them at home. During the hospital phase, antibiotics are administered as appropriate, based on findings from sputum cultures. The shift to home care depends

on factors such as severity of illness, venous access, ability and resources of the family, and payer source.

The daily medications required to maintain the baseline health include a long list of pharmaceutical agents (Table 16–12). Long-term use of oral antibiotics for chronic bacterial suppression has raised concern that antimicrobial-resistant infections will develop among children and youth with CF (Kerem et al., 2005). Susceptibility testing may be required for some pathogens to determine the effectiveness of unusual antibiotics.

Monitoring all therapies (with laboratory tests, pulmonary function tests, bone density studies, and radiographic studies) and coordinating the team consults are both part of the medical management of CF. Identifying new symptoms that may indicate complications is an ongoing process. Managing CF by intervening promptly when new symptoms occur contributes to improved outcomes.

Nutritional Support

Key components of the nutritional assessment in CF care are to determine baseline nutritional requirements and need for pancreatic enzyme replacement or vitamin therapy and to monitor for changing nutritional needs if comorbidities (e.g., diabetes) develop. Nutritional assessments are conducted at each encounter and hospitalization. Plot physical growth (e.g., height, body mass index) on the growth chart to monitor progress and response to therapeutic interventions. The dietitian assesses physical growth, conducts a nutritional assessment at each admission, identifies dietary requirements and goals, and initiates an overall plan to meet the child’s high-caloric nutritional needs. Serum laboratory results such as albumin, prealbumin, glucose, electrolytes, and complete blood count are assessed. Levels of vitamins A and E are assessed annually, and skin-fold measurements are obtained as indicated. Guidelines for administering pancreatic enzymes are provided in Nursing Interventions 16–3. Effectiveness of replacement enzymes is monitored through fecal fat studies.

TABLE 16–12

Pharmaceutical Agents Used in the Care of the Child With Cystic Fibrosis

Category	Purpose
Aerosols Bronchodilators	Open up airways
Inhaled antibiotics	Antimicrobial, for lung treatment
Mucolytic enzyme	Thins mucus
Pancreatic enzymes	Increase food/nutrient absorption
Vitamins/minerals (A, D, E, K)	Fat-soluble vitamin supplement in water-miscible form; supplement overall diet
H ₂ blocker	Alters gastrointestinal acidic environment; gastroesophageal reflux therapy
Prokinetic agents	Enhances gastrointestinal motility; gastroesophageal reflux therapy
Oral and intravenous antibiotics	Antimicrobial for <i>S. aureus</i> Antimicrobial for <i>H. influenzae</i> Antimicrobial for <i>P. aeruginosa</i>

NURSING INTERVENTIONS 16–3

Administering Pancreatic Enzymes

Recommended dose of lipase: 1,000 to 3,000 lipase units/kg/meal.

- Encourage three meals and two to three snacks per day.
- Discourage eating throughout the entire day.
- Administer enzymes before or with meals (and with vitamins), with snacks, with milk and oral or bolused nutritional supplements, and before nocturnal feeds begin (and occasionally after completion, as prescribed). Usually, half the standard pancreatic lipase dose is given with snacks.
- Open capsules and mix contents with a small amount of applesauce, rice, carrots, or ice cream, or other nonalkaline food. Do not crush microcapsules.
- Avoid allowing microcapsules to sit in alkaline food, which disrupts the enteric coating.
- Assess the oral mucosa and perirectal area for irritation from contact with unswallowed or unabsorbed enzymes.
- Monitor stool pattern and characteristics.
- Be alert to complaints such as bloating, flatus, abdominal pain, loose and frequent stools with steatorrhea, poor growth, or some combination of these symptoms.
- Instruct parent and patient not to adjust the dose.
- Instruct parent and child to check the expiration dates and store enzymes in a cool place.

Infants are usually given an elemental formula to optimize absorption. Elemental formulas are composed of simple and easily absorbed forms of carbohydrates (glucose polymers or monosaccharides), proteins (amino acids or casein hydrolysates), and fat as medium-chain triglycerides. Elemental formulas are relatively expensive, and costs may vary across individual pharmacies. Special state-funded programs may provide assistance. Infants may thrive adequately on breast milk or standard infant formula without gastrointestinal complications, as long as enzymes are adjusted appropriately. The older child is managed with a high-calorie, high-protein diet, including snacks and nutritional oral supplements to boost calories and nutrition. Pancreatic enzymes are administered at each feeding, meal, and snack to optimize nutrient absorption.

If weight gain and progress toward nutritional goals are not demonstrated, alternate feeding routes are considered. Gastrostomy tubes, (such as percutaneous endoscopic gastrostomy tubes), low-profile (“button”) gastrostomies, or jejunostomy tubes (J-tubes) are possible options (see Chapter 18). Nocturnal drip feedings through the gastrostomy tube are recommended to supplement oral intake.

Respiratory Support

A respiratory care practitioner works under the supervision of the physician, as do all team members. The respiratory care practitioner instructs the families on the most effective airway clearance technique (ACT), which is individualized to the patient. The gold standard for airway clearance consists of postural drainage and percussion done after aerosolized treatments, depending on respiratory and general status (e.g., during pulmonary exacerbations, treatments may need to be increased to four times per day).

Nursing Support

The nurse’s primary role is provide direct care. In the hospital setting, this role is central, because the nurse is the person most consistently at the bedside. Coordinating care and monitoring the overall response to therapies (e.g., breathing treatments, self-care participation, activity level, elimination pattern, and appetite) provide essential information to determine progression toward clinical outcomes. The nurse also initiates and maintains intravenous lines for antibiotic therapy and other intravenous medications as needed. Measuring accurate height and weight on admission is essential, along with daily weight measurement to monitor nutritional progress. Additionally, the nurse provides emotional support for the child and parent during frequent and long hospitalizations.

The CF team nurse, usually an advanced practice nurse, assists in coordinating overall care, ensuring that the team functions smoothly, that roles within the team are understood, and that clinical care is properly coordinated. Important functions include assessing for the need for team and family conferences and education regarding treatment, medicines, options for venous access, and alternate routes for nutritional supplementation; assessing for home intravenous antibiotic therapy and discharge readiness; providing follow-up telephone calls to the caregivers and to the schools, when indicated; and ensuring continuity of care by providing care at office or clinic visits. This arrangement puts the nurse in a unique position to follow up and provide interventions from an ambulatory and an inpatient perspective. The nurse, in some centers, may be able to perform school visits and assist with school reintegration, if indicated. Early identification and preparation for procedures, including preparation for changes in level of care, are also central to the CF team nurse’s role. Additionally, the CF team nurse educates the team and coordinates their involvement when a new diagnosis is made.

Social Services

The medical social worker helps caregivers and children to cope with and integrate CF into their lives. The families are helped to obtain linkage with the appropriate state and federal programs for medical care, such as Children’s Medical Services (Title V), state Medicaid, Aid to Families with Dependent Children, and Supplemental Security Income for the Aged, Blind and Disabled. The social worker also is a source of emotional support and provides appropriate referrals as needed. The social worker acknowledges that each family is unique, with individual

needs and stresses. Many social workers facilitate support groups and provide parent-to-parent networking.

Physical Therapy

The physical therapist evaluates the muscles used for breathing and posture and assesses the child's ability to carry out daily activities. The physical therapist also prescribes individualized exercise programs and monitors endurance. The roles of the physical therapist and respiratory care practitioner may overlap in certain regions of the country. The child with CF is assessed on a regular basis and is provided a home exercise program.

Child Life Services

The child life specialist's focus of practice is on therapeutic play along with recreational and diversional activities. This professional helps the child cope with hospitalization, medical visits, and procedures through play, and can contribute to motivational and behavioral programs to encourage children to do their treatments, drink their nutritional supplements, cooperate with therapy, and take medicines. Some child life departments may offer school programs or assist with arrangements for home-bound teachers.

Education regarding self-care and ways to integrate CF care into daily schedules is necessary to help the family foster independence and age-appropriate skills of daily living. All too often, the healthcare team may be so focused on the disease process that lags occur in educating families to integrate developmentally appropriate strategies as a part of the child's care. Each developmental stage merits review with the family and the patient, when age appropriate, to facilitate strategies that will allow this specialized care to be provided daily (Developmental Considerations 16–1). Parents must understand concepts such as offering the toddler a choice of juice to take with medicines; thus, there is no unacceptable choice and the toddler maintains the “control” for mastery of that stage.

Parents, caregivers, and patients must also be kept informed regarding changes in condition and updates on expanding and newer therapies. They must be educated when new therapies are introduced for maintenance care, such as oxygen, enteral home nutrition programs, home intravenous antibiotic administration, home maintenance of venous access devices, administration of aerosolized antibiotics, or the use of newly prescribed medications.

Community Care

CF presents challenges, obstacles, and opportunities that can shape the child's future. For parents, childrearing roles and responsibilities can be complicated by the increased demands and restrictions imposed by CF (e.g., constant need for daily treatments), numerous contacts with healthcare services, altered plans for family outings and vacations, fatigue, depression, and, possibly, financial constraints.

Children living with CF must incorporate a variety of treatments into their daily life, and these treatment demands and restrictions can often result in psychological stress and burdens for children and their families. Psycho-

logical functioning of the child and family depends on multiple factors, such as family income, family structure, parental education levels, social support, and coping styles. Thus, nurses caring for these children and families must carefully assess for developmental and psychosocial risks.

The general approach for children with CF is to “normalize” their daily living activities (e.g., home, school, recreational) within the child's specific limitations. Typical childhood events such as a common cold can create substantial problems for the child with CF. Thus, parents need to use strict respiratory infection prevention strategies such as handwashing, isolating the child from people with respiratory or other infections, and isolating the child from others with CF. Provide anticipatory guidance for parents and children as they seek to maintain normalcy in their daily home lives.

For the parents of an infant or child newly diagnosed with CF, the process of adjustment may be compared with the grief process. Parents often have difficulty regaining stability for 6 months to 1 year after diagnosis. Patients and their families may generally function adequately, but need additional support during times of crisis. Some examples are the first hospitalization after diagnosis, the death of another child at the CF center, the transition to adult care, addition of new home therapies such as oxygen or intravenous antibiotics, or the first day of school.

Work closely with school personnel to develop an educational plan that will promote learning and to reduce CF-associated risks. Encourage parents to provide school personnel with information (available through local CF centers) about CF and about their child's specific needs. Parent-teacher conferences at the beginning of each school year are an effective way to provide information and establish communication to reduce the sense of difference the child may feel at school. Encourage school attendance, so that the child can socialize and diversify his or her strengths to prepare for future goals. Social isolation because of sporadic school attendance can lead to other psychosocial issues, such as depression.

During adolescence, planning for the future and choosing a career are central tasks. Children must choose careers that will fulfill their ability to work despite changing conditions. Career and vocational counselors can assist in this planning process. Transitional care during the adolescent years, necessary to guarantee lifetime continuity of care, requires close cooperation between the patient's pediatric and adult CF centers. Transition to adult care usually occurs around age 16 to 18 years, but the timing should be determined by the adolescent's social maturity and health status.

The CF team members work in concert with each other, the families, and the children to support a common goal. Because of the complexities and variations of CF, many of the team's functions overlap or may be carried out differently across different centers. Supporting a family through the decision-making process of the end-of-life stage is generally a process shared by all team members, but may be the primary responsibility of the clinical social worker. It is also critical for the CF team members to acknowledge the support systems of the family and to consult other professionals, such as pastoral care services or psychologists.

See [thePoint](#) for a summary of Key Concepts.

DEVELOPMENTAL CONSIDERATIONS 16–1

Self-Care Strategies for the Child With Cystic Fibrosis

Developmental Stage	Strategies
Infancy	<p>Discuss normal developmental behaviors with parents.</p> <p>Respond to crying promptly (0–3 months).</p> <p>Respond to cues as indicated (>3 months).</p> <p>Establish regular routines.</p> <p>Incorporate special care into routines.</p> <p>Provide reinforcement about PD&P and comfort related to “sensorimotor stimulation.”</p> <p>Monitor all developmental progress.</p> <p>Provide recommendations for home schedule/time management.</p> <p>Provide healthcare teaching:</p> <ul style="list-style-type: none"> • Disease management • Discuss normal acquisition of developmental skills, especially for first-time, new parent
Early childhood	<p>Discuss normal developmental behaviors with parents.</p> <p>Institute measures to promote age-appropriate behaviors.</p> <p>Assess and monitor feeding behaviors.</p> <p>Support choices for beginning of “daycare”/out-of-home care.</p> <p>Provide information regarding age-appropriate behavioral management.</p> <p>Provide information for self-care skills:</p> <ul style="list-style-type: none"> • Incorporate distraction techniques for resistant behaviors. • Use games to gain cooperation. <p>Allow child simple choices that are all acceptable.</p> <p>Encourage sharing of care between primary caregivers at home.</p> <p>Assist with integrating therapy schedules into family rituals.</p> <p>Teach coughing secretions “up” and in tissue.</p> <p>Provide information to identify basic symptoms that indicate need for healthcare team/doctor visit.</p> <p>Support exercise as part of ADLs:</p> <ul style="list-style-type: none"> • Provide opportunities for therapeutic play. • Offer medications in a medicine cup. • Allow child to help gather supplies. • Encourage “blowing” activities, such as bubbles, horns, pinwheels. <p>Provide information on disease management.</p> <p>Provide information for self-care skills:</p> <ul style="list-style-type: none"> • Assistance with pill swallowing. • Begin PEP therapy (~4 years).
Middle childhood	<p>Institute measures to promote age-appropriate behaviors.</p> <p>Assess understanding of</p> <ul style="list-style-type: none"> • Medications • Nutrition/snacks • Respiratory treatments <p>Provide information for self-care skills:</p> <ul style="list-style-type: none"> • Assist with pill swallowing. • Allow choices with food/snack selection. <p>Give responsibilities for simple tasks regarding therapies:</p> <ul style="list-style-type: none"> • Set up nebulizer. • Prepare medications. • Clean nebulizer.

(Continued)

Developmental Stage	Strategies
Adolescence	<p>Remind child to initiate ACT time. Have child answer health team's questions. Include child in decision making. Incorporate exercise as part of ADLs: group or solo sports. Encourage use of wind instruments (horns). Coach during PEP/ACT therapy by caregiver. Discuss school performance/attendance and ways to ensure self-care at school. Provide information on disease management. Institute measures to promote age-appropriate behaviors. Discuss/assess/monitor normal developmental concerns/issues. Provide information to facilitate increased self-care skills:</p> <ul style="list-style-type: none"> • Self-administer medications, aerosol treatments, snack/meals, ACT. • Take inventory of medications. • Arrange for refills for medications. • Schedule clinic appointments. • Set up nocturnal/daily oxygen and check flow rate. <p>Assess and monitor:</p> <ul style="list-style-type: none"> • Understanding of disease process • Medication • Problem-solving skills • Current self-care behaviors <p>Provide information on disease management. Encourage and facilitate with individual and caregiver:</p> <ul style="list-style-type: none"> • Monitoring of self-care by caregiver from afar • Decision for when parental presence is desired at clinic • Involvement in decision making • Negotiation of schedule with special events <p>Support exercise as part of ADLs:</p> <ul style="list-style-type: none"> • Aerobic and anaerobic • Upper body strengthening • Stretching • Energy conservation techniques <p>Provide information on education and career planning. Facilitate discussion of peer relationships/dating. Discuss transitioning plans and process. Initiate referrals to support choices:</p> <ul style="list-style-type: none"> • Genetic counseling • Sexuality issues <p>Provide information on insurance and healthcare systems.</p>

ACT, airway clearance techniques; ADLs, activities of daily living; PD&P, postural drainage and percussion; PEP, positive expiratory pressure.

The Child With Altered Fluid and Electrolyte Status

Case History

Do you remember Cory Whitworth, the 5-year-old boy from Chapters 6 and 11? In Chapter 11 Cory was diagnosed with a perforated appendix. Upon admission to the emergency department the nurse begins a health history. His mother reports that he has refused to eat for the past couple of days and has had a fever off and on, but was still drinking some fluids. He has been drinking mostly apple juice. She has not taken his temperature with a thermometer, but gauged the fever by touch. When asked about his urine output, his mother explained that Cory takes himself to the bathroom. Cory just looked at the nurse when asked how many times he went “pee-pee” yesterday. They do not have a scale at home; Cory was last weighed at the physician’s office 2 months ago.

Cory is in pain. He alternates between crying and rocking. His knees are drawn up and

he is holding his abdomen. He is pale and his eyes are somewhat sunken. His lips are dry and cracked and his oral mucous membranes are dry. His vital signs are temperature, 101.8 °F (38.8°C); heart rate, 108 beats per minute; and respiratory rate, 34 breaths per minute.

Cory will have emergency surgery because of a ruptured appendix. After surgery he will not be able to take any oral fluids or food. He may have his stomach decompressed with a nasogastric (NG) tube. (NG tube use is not routine, but may be placed. It is important that the child and family are taught about this preoperatively.) His will rely on intravenous (IV) solution to maintain his fluid and electrolyte balance.

Consider the following objectives and apply them to Cory from initial assessment through surgical treatment of his perforated appendix.

CHAPTER OBJECTIVES

1. Discuss the physiologic principles that regulate fluid and electrolyte balance.
2. Compare total water distribution, intracellular fluid, and extracellular fluid in infants, children, and adults.
3. Review assessment parameters for a child at risk for fluid or electrolyte imbalance.
4. Identify laboratory tests used to assess fluid and electrolyte balance.
5. Calculate maintenance fluid therapy requirements and identify nursing care priorities for a child receiving intravenous fluid therapy.
6. Discuss nursing care measures for the child receiving parenteral nutrition.
7. Describe the assessment and treatment of hypertonic and hypotonic dehydration.
8. Explain the principles of acid–base balance.
9. Discuss the causes and treatment of specific electrolyte imbalances.

See [thePoint](#) for a list Key Terms.

Water is critical to human survival. Not only is it the primary fluid within the body, it also provides a medium in which body solutes (electrolytes) are dissolved and metabolic reactions occur. Fluid and electrolyte balances can be altered as a result of a disease, injury, or therapeutic intervention that hinders the body's normal physiologic mechanisms that regulate fluid intake and output.

PRINCIPLES OF FLUID AND ELECTROLYTE BALANCE

QUESTION: Has thirst been an adequate regulatory mechanism to keep Cory well hydrated prior to intervention by the healthcare team?

Distribution of Fluids and Electrolytes

In the human body, water is distributed in two main compartments: **intracellular fluid (ICF)**, fluid located within the cells; and **extracellular fluid (ECF)**, fluid located outside the cells. ECF is further divided into **intravascular fluid** (fluid within the vascular system, also called *plasma*) and **extravascular fluid** (fluid outside the blood vessels). Extravascular fluid is either **interstitial fluid** (located in the spaces between the tissue cells, such as lymph and pulmonary interstitial spaces) or **transcellular fluid** (located in spaces that are separated from plasma and interstitial fluid by cellular barriers, such as cerebrospinal fluid, synovial fluid). The cell membrane provides a barrier between the ECF and ICF; fluid moves through this barrier by osmosis. Fluid movement between the two ECF compartments occurs through filtration.

Electrolyte concentrations are not uniform; they differ between the ECF and the ICF. Fluid and electrolytes continuously move from one compartment to another. This movement is influenced and controlled by regulatory mechanisms: hydrostatic, osmotic, and oncotic pressure; passive and active transport; diffusion; and osmosis (see [thePoint](#) for Supplemental Information: Physical Factors That Affect Fluid Balance). To illustrate the concept of movement and transportation between compartments, consider this example. Sodium is the principal cation in ECF; potassium is the principal cation in ICF. To maintain an equilibrium between sodium and potassium concentrations, water moves from ICF to ECF through passive transport mechanisms. Maintaining this equilibrium is a continuous, ongoing process.

Regulatory Mechanisms

Several physiologic mechanisms regulate fluid and electrolyte homeostasis in the body.

The Kidneys

The kidneys regulate fluid balance through their ability to concentrate and dilute urine. Antidiuretic hormone, a hormone produced by the hypothalamus and stored in the pituitary gland, stimulates renal reabsorption of water. When serum sodium levels are high, antidiuretic hormone is secreted and increases the permeability of the kidneys' distal tubules and collecting ducts to water, enabling the kidneys to retain more water.

The angiotensin–renin system, along with aldosterone, also assists the kidneys in regulating fluid and electrolyte homeostasis. When the kidneys detect reduced blood flow, they produce renin, which in turn stimulates production of angiotensin within the blood vessels. The angiotensin stimulates release of aldosterone, a hormone that stimulates sodium reabsorption. As a result, sodium and water reabsorption is increased in the renal tubules. This mechanism produces (1) increased blood flow to the kidney, (2) increased intravascular volume, and (3) increased blood pressure.

The Gastrointestinal Tract

The gastrointestinal tract affects the electrolyte levels of gastrointestinal secretions. Water and sodium are reabsorbed, and potassium is excreted. Normally, fluid is replaced through oral fluid intake. Because of the large absorptive surface area of the gastrointestinal tract, changes in fluid and electrolyte balances can occur rapidly. Imbalances must be treated quickly and appropriately to prevent decompensation in the child's health status.

Thermoregulatory Mechanism

Insensible water loss refers to invisible, continuous, and passive water loss from the skin and lungs resulting from heat expenditure. This process is one method that the body uses to regulate temperature. No electrolytes are lost or excreted in insensible water loss.

The integumentary system, as a thermoregulatory mechanism, affects fluid and electrolyte balances. Losses of fluid, sodium, potassium, and chloride occur in sweat. In contrast to insensible water loss, this process is intermittent and is more dependent on environmental temperature.

Thirst Mechanism

Most regulatory mechanisms involve the excretion of fluid and electrolytes. The exception is thirst, the impetus to ingest water. The thirst center is located in the hypothalamus; thirst is stimulated by a decrease in the intravascular volume, an increase in the osmolality of ECF, or both. As a major regulatory mechanism, thirst is unreliable. The infant and young child can experience thirst but have a limited ability to take action to meet this need. They depend on others to provide oral fluids and to appropriately regulate the type and amount of fluid intake.

ANSWER: Thirst has not been an adequate regulatory mechanism, as evidenced by the fact that Cory is moderately dehydrated. Despite the fact that he is old enough to communicate his thirst or even go get a cup of water, the combination of fever, abdominal pain, and anorexia he experienced was enough to allow him to become dehydrated.

DEVELOPMENTAL AND BIOLOGIC VARIANCES

Infants and children are more susceptible than adults to fluid and electrolyte imbalances (Fig. 17–1). In an infant, for example, a high basal metabolic rate makes the normal turnover rate of water and electrolytes two to three faster than in an adult. Approximately 50% of ECF in the infant is exchanged each day. This fact makes an infant more susceptible to substantial physical changes from fluid deficit.

The amount of total body water and the proportional sizes of the ICF and ECF compartments change from infancy to adolescence (Fig. 17–2). Infants and young children have a high proportion of total body water, stemming from a high proportion of ECF and low total body fat. Total body fat increases dramatically during the first year of life, with a concurrent decrease in the amount of total body water. During the first year of life, total body water decreases to about 60% of body weight. This proportion remains fairly constant until adolescence, when characteristic sex differences occur. Normally, males have greater muscle mass and less body fat than females. Therefore, the sexually mature male has about 60% total body water; the female, about 55%.

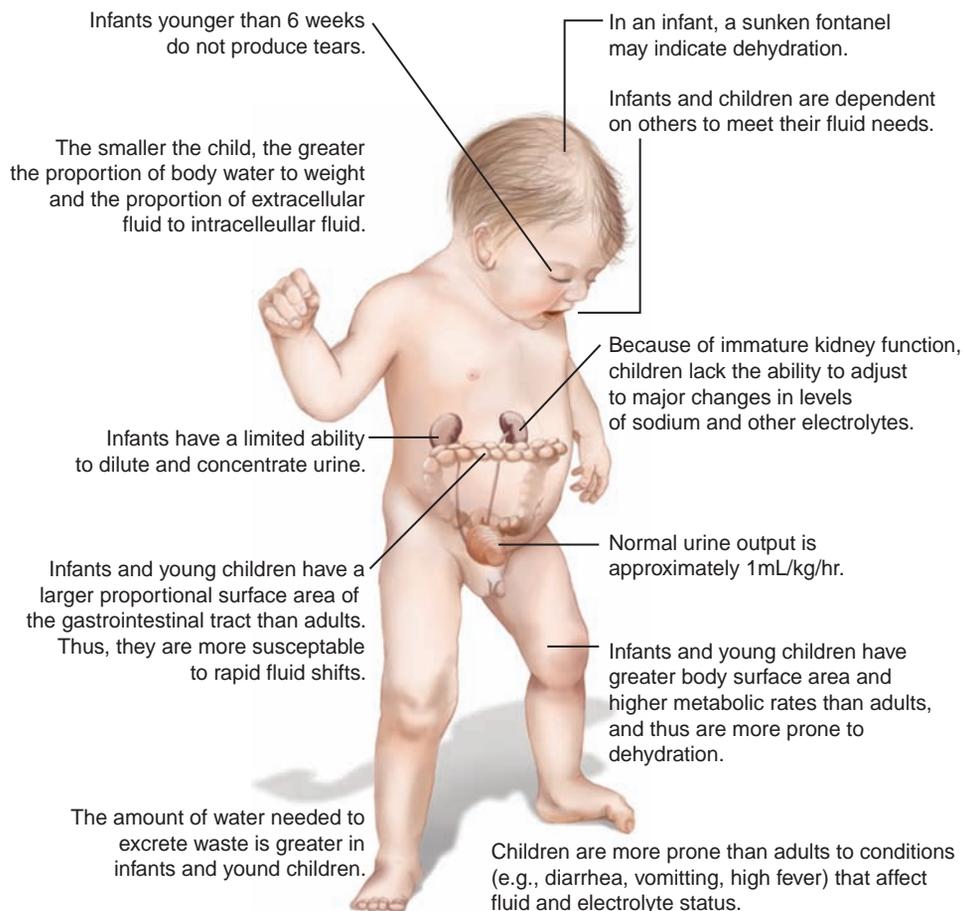

FIGURE 17–1. Developmental and biologic variances: fluid and electrolyte status.

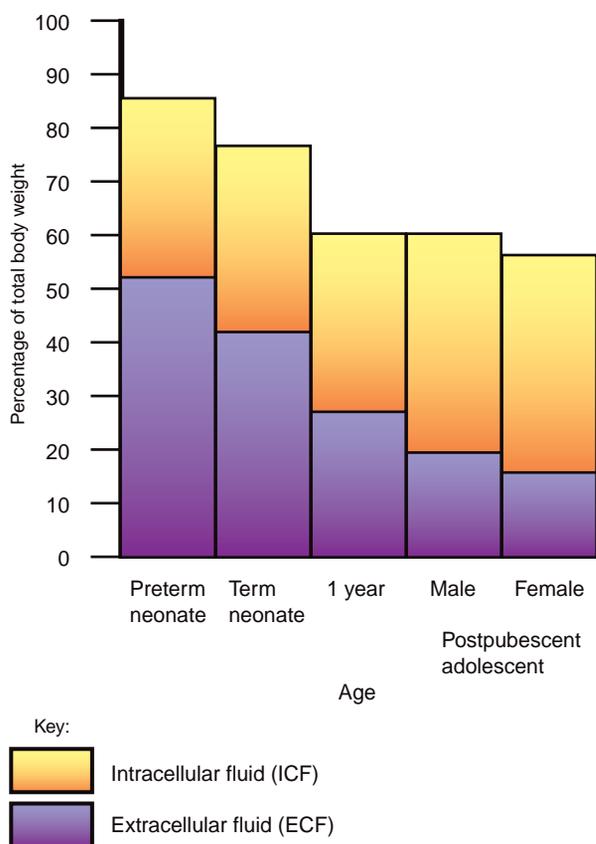

FIGURE 17-2. Total body water distribution by age. Note the changes in intracellular and extracellular fluid volume.

ASSESSMENT OF THE CHILD WITH ALTERED FLUID AND ELECTROLYTE STATUS

Disease, age, environment, and activity level all affect fluid and electrolyte status. Imbalances in fluids and electrolytes are reflected in many body systems. Thus, assessment of a child with a known or suspected fluid or electrolyte imbalance requires a multisystem evaluation.

Focused Health History

QUESTION: Study Focused Health History 17-1. Which of the items identified apply to Cory? Discuss those areas where gaps in the health history the parent and child are able to provide would be frustrating to healthcare workers.

Health history pertinent to fluid and electrolyte status includes current and previous illnesses, health habits, and fluid intake and output (Focused Health History 17-1).

Intake and output affect fluid and electrolyte balance profoundly. In the health history, include questions about the amount as well as the type of fluids ingested. Also

investigate fluid intake carefully to uncover possible causes of imbalance. For instance, feeding an infant formula prepared with too much water, either as a cost-saving measure or through error, may lead to water intoxication. Conversely, feeding formula prepared with too little water (which results in a formula with high osmolality that pulls water into the gut) can lead to dehydration and electrolyte imbalance. An older child or an adolescent with an eating disorder (i.e., anorexia or bulimia) may also have insufficient fluid intake and thus be at risk for severe, possibly life-threatening electrolyte imbalances.

Major routes of fluid output are urine, stool, and vomiting. To assess voiding patterns, ask the parent how many wet diapers the infant or young child has each day, and ask an older child how often he or she voids.

KidKare ■ When asking a child about output patterns, clarify the type of output using terms that the child and family use for urine and stool.

Ask about potential exposure to poisons or toxins, which can interfere with cellular function and metabolism, leading to fluid and electrolyte imbalances.

ANSWER: Children in early childhood are notoriously poor historians and this is frustrating for healthcare workers. They have the skills to take food and drink, and go to the bathroom by themselves, but not to report those activities accurately. Aspects of the Focused Health History with regard to current history that can be applied to Cory include no appetite, but some drinking for 3 + days; presence of fever, but no specific temperatures; undetermined weight loss; and undetermined number of voidings the previous day. It is to be expected that the health history from this age group is lacking specifics, and nurses should not belabor the fact and make the parents feel inadequate.

Focused Physical Assessment

QUESTION: Organize the assessment information from the case study in a system-specific manner. What assessment information do you still need to obtain?

Physical assessment for a child with altered fluid and electrolyte status includes a general survey and a system-specific examination that focuses on level of hydration (Focused Physical Assessment 17-1). The general survey evaluates the child's appearance and level of distress. It always includes weighing the child and comparing the result with previous recent weights, if available. Any substantial fluid loss or gain will be reflected in weight changes.

FOCUSED HEALTH HISTORY 17–1

The Child With Altered Fluid and Electrolyte Status*

Current history	<p>When symptoms started and duration and nature of symptoms, precipitating factors, and home management of current illness</p> <p>Recent contact with someone who is sick; their symptoms (and diagnosis, if known)</p> <p>Recent weight change</p> <p>Fever, diaphoresis</p> <p>Change in level of consciousness or behavior (e.g., lethargy, irritability, weakness), headaches</p> <p>Number of voidings during past 24 hours; time of last void/wet diaper, urine amount, color, odor</p> <p>Stool appearance, consistency, amount</p> <p>Anorexia, nausea, vomiting, or abdominal pain</p> <p>Tingling around mouth, in fingertips or hands (reported with hypocalcemia)</p> <p>Relation of symptoms to food ingestion</p> <p>Presence of sore throat or oral lesions that interfere with intake</p> <p>Exposure to high environmental temperatures</p> <p>All medications (e.g., diuretics, digitalis, potassium supplements), home remedies (e.g., teas, herbs), vitamins, or food supplements the child is currently receiving</p> <p>Known or possible ingestion of or exposure to poisons</p>
Past medical history	<p>Prenatal/Neonatal History</p> <p>Presence of congenital defects, especially those involving the gastrointestinal or genitourinary systems</p> <p>Previous Health Challenges</p> <p>Recurrent, chronic, or episodic illness, hospitalization or surgery and child's response</p>
Nutritional assessment	<p>Time the child last ate; type of food or fluid and amount ingested</p> <p>Is the child retaining food and fluid?</p> <p>Describe typical intake of food and fluid type, how prepared, frequency and quantity; for infants or toddlers include whether intake is by bottle, breast, or cup; if breast-fed, note any change in mother's diet; if a commercial formula is used, note formulation (e.g., ready-to-feed, powder) and how formula is prepared (dilution amounts)</p>
Family medical history	<p>Change in the child's appetite or oral intake; is the child complaining of thirst?</p> <p>History of same illness in other family members (describe symptoms and any treatments)</p>
Social and environmental history	<p>Psychosocial: Financial status, issues regarding obtaining adequate food supply, sanitation for food storage and preparation</p> <p>Child care issues: Who cares for child and where (e.g., child care center, home)</p> <p>Cultural: Practices that may overheat infants (e.g., wrapping in blankets even in hot temperatures), administration of home remedies that may cause fluid or electrolyte imbalance</p>
Growth and development	<p>Daily routines and habits: Sleeping, feeding, toileting</p>

*This history is focused on altered fluid and electrolyte status. See Chapter 8 for a comprehensive format.

Fluid deficit may compromise peripheral perfusion and cause insufficient blood flow to the brain, as reflected in changes in vital signs and level of consciousness. The child may report dizziness when standing up after laying down. Electrolyte imbalance may also cause altered vital signs and level of consciousness, as well as more system-specific findings (e.g., impaired muscle function). Specific

vital sign changes point to the type and degree of imbalance. For example, temperature elevation typically occurs in hypernatremia (sodium excess), because hypernatremia causes excessive fluid loss, making less water available for heat loss through sweating. Note the child's temperature. Fever, which increases metabolic rate, increases the rate of fluid loss.

FOCUSED PHYSICAL ASSESSMENT 17-1

Altered Fluid and Electrolyte Status

Assessment Parameter	Alterations/Clinical Significance
General appearance	Level of distress associated with degree of alteration Weight change over time: If the child is not following growth trajectory as plotted on growth charts, weight loss or failure to gain weight may indicate malnutrition; rapid weight loss may indicate fluid volume deficit; rapid weight gain may indicate fluid volume excess
Integumentary system	Pale, ashen, mottled, or cyanotic skin, nail beds, or mucous membranes; diaphoresis; delayed capillary refill (>3 seconds); decreased skin temperature may indicate poor perfusion associated with fluid volume deficit Increased skin temperature may be seen with hypernatremia; also may indicate fever, which increases insensible water loss Dry skin and mucous membranes, poor turgor, tenting, sunken eyeballs, absence of tears associated with fluid deficit Doughlike feel to skin seen with hypernatremic dehydration Edema can be seen with fluid volume excess Excoriated anal and diaper area from diarrheal stools
Thorax and lungs	Change in respiratory rate and quality: <ul style="list-style-type: none"> • Slow and shallow seen with hypochloremia • Deep and rapid seen with moderate and severe dehydration • Tachypnea increases insensible water loss Moist breath sounds (crackles) and cough associated with fluid volume excess
Cardiovascular system	Change in pulse rate or quality: <ul style="list-style-type: none"> • Rapid, weak, thready with fluid deficit • Bounding pulse, neck vein distention with fluid volume excess Gallop rhythm with fluid volume excess Dysrhythmias associated with electrolyte imbalance (hyper- and hypokalemia) Elevated blood pressure may be seen with fluid volume excess Decreased blood pressure seen with fluid volume deficit
Abdomen	Abdominal distention (hypokalemia, in neonate associated with hypocalcemia) Hepatomegaly with fluid volume excess Abnormal peristaltic waves seen with pyloric stenosis, which can result in hypochloremic alkalosis
Neurologic system	Change in level of consciousness: Unresponsiveness, irritability, lethargy, confusion associated with fluid volume deficit and electrolyte imbalance (sodium, calcium, magnesium, phosphate) Weak, high-pitched cry associated with hypernatremia Sunken or bulging fontanel in infant may indicate fluid deficit or excess Change in muscle tone: Hyperreflexia (hypomagnesemia), weakness or flaccidity (hyper- and hypokalemia, hypercalcemia, hypermagnesemia); tetany or positive Chvostek’s sign (i.e., facial twitching as the facial nerve is tapped) (hypocalcemia)

Alert! Because a child’s young, healthy blood vessels normally compensate well in response to decreased fluid volume, decreased blood pressure is an ominous, late sign of fluid volume deficit.

Skin turgor is an indication of fluid status. To evaluate skin turgor, gently lift the child’s abdominal skin between the thumb and forefinger, then release. Skin that does not return to its original shape but stays raised or “tenting” indicates poor turgor.

Electrolytes play a vital role in cellular metabolism and neuromuscular function. Electrolyte imbalances may produce neurologic symptoms, muscle cramps, increased or decreased muscle tone, and hypoactive or hyperactive reflexes.

ANSWER: Organize Cory’s assessment data as follows:

- Integumentary system: Pale, dry lips and oral mucous membranes; sunken eyeballs
- Thorax and lungs: Increased respiratory rate
- Cardiovascular: Increased heart rate
- Neurologic: Irritable

Also obtain vital signs, including heart and respiratory rates, blood pressure, and temperature, and obtain a weight. Checking and noting skin turgor and capillary refill can be quickly accomplished. Monitor for changes in pulse rate or quality and other vital signs and neurologic changes.

Diagnostic Criteria for Evaluating Fluid and Electrolyte Status

Diagnostic tests assist in evaluating fluid and electrolyte balance in the body (Tests and Procedures 17–1). Nursing responsibilities related to diagnostic studies include obtaining specimens, accurately labeling and sending specimens to the laboratory, and following up on results. Follow-up involves evaluating results and notifying the physician or advanced practice nurse of values outside normal age-appropriate ranges.

TREATMENT MODALITIES

QUESTION: How do you anticipate Cory's fluid deficit will be managed? What does the nurse need to prepare?

Alterations in fluid and electrolyte balance are managed by correcting the specific imbalance (e.g., giving fluid when the child is dehydrated) and treating the underlying cause (e.g., controlling diarrhea). Whenever possible, fluid and electrolyte imbalances are treated with oral fluid ingestion. When oral fluids cannot be given, IV fluids or enteral or parenteral nutrition (PN) must be administered to meet the child's fluid, electrolyte, and nutrition needs. Enteral feeding may be possible when oral is not, and is physiologically superior and preferred over parenteral feeding.

Intravenous Therapy

IV therapy is used in clinical situations that require administration of fluids (and sometimes medications) to a child who cannot maintain a normal fluid balance by oral ingestion. The route, volume, and type of fluid administration are key factors in managing the child receiving IV therapy.

Route of Administration

IV fluids can be given by peripheral vein, central vein, or intraosseous access. The route of fluid administration depends on the child's clinical situation, the type of fluids and medications administered, and the duration of IV fluid therapy. In addition, the potential for **infiltration** (inadvertent escape of nonvesicant fluids or medications from the IV tubing or vein into subcutaneous tissues) or **extravasation** (inadvertent escape of vesicant fluids or medications, typically chemotherapeutic agents, from the IV tubing or vein into subcutaneous tissues) must be minimized, because some agents can cause tissue damage.

Peripheral Venous Access

Peripheral IV lines are used for short-term administration of fluids and medications that are isotonic and not irritants or **vesicants** (agents that produce tissue blistering). Potential sites of peripheral IV catheter placement

include the scalp (in infants), dorsum of the hand, arm (including the antecubital fossa), foot, and leg. Factors considered in determining placement site include the child's age and condition, comfort, safety, measures required to position or secure the IV line, and condition of the vein (see [thePoint](#) for Procedures: Intravascular Therapy: Peripheral). In infants, for instance, the scalp veins generally are easier to cannulate than extremity veins, so they are sometimes used. Many parents find a scalp IV line in their infant quite distressing. Discuss the scalp placement procedure, including the rationale, with the parents before placing the IV line and offer to save for them any hair that is shaved from the infant.

Preferably position the child upright for IV starts. Children in early childhood who were held upright by a parent during IV starts demonstrated lower distress, and parents were more satisfied than when the IV was started with the child in a supine position (Sparks, Setlik, & Luhman, 2007). When placing IV lines in extremities, access the most distal sites first. Do not use the antecubital fossa until other sites have been exhausted. A catheter in the antecubital region, or any joint, is easily disturbed by joint flexion, and the immobilization required may cause joint stiffness and pain. Allow an older child a choice of catheter placement sites, as appropriate. If the arm is used, use the nondominant one when possible; in an ambulatory child, avoid using the feet or legs, if possible.

KidKare ■ If it is necessary to secure an IV line with an arm board, tell the child that the arm board is there to help him or her remember not to move that arm too much.

When a peripheral IV line is needed for intermittent administration of medication but is not required for continuous IV fluid administration, an IV lock may be used (see [thePoint](#) for Procedure: Heparin Lock/Flush). Catheter gauge, the child's diagnosis, the medication administered, the flush solution used, and the length of time between flushes are all variables that affect longevity of the IV site. Whether to use heparin or saline solution to flush the IV lock is controversial (Tradition or Science 17–1). Follow facility-specific protocols for maintaining IV locks, which are based on patient population and standards of practice in the community.

Central Venous Access

Central venous catheters (CVCs) are catheters that are inserted into the superior or inferior vena cava (Fig. 17–3). The umbilical vein may be used in an infant during the first few days after birth. CVCs are used in situations that require long-term venous access. They are particularly good for administering fluids with high dextrose concentrations (>10%) and hyperosmolar solutions (>600 mOsm/L) (Infusion Nurses Society, 2006), blood and blood components, medications that are irritating to peripheral vessels, and chemotherapy agents; and for obtaining blood samples. Generally, CVCs are classified

Tests and Procedures 17–1 Evaluating Altered Fluid and Electrolyte Status

Diagnostic Test or Procedure	Purpose	Findings/Indications	Healthcare Provider Considerations
Blood chemistry/ electrolyte analysis (Na ⁺ , K ⁺ , Ca ²⁺ , Cl ⁻ , Mg ²⁺ , PO ₄ ⁻ , albumin, blood urea nitrogen [BUN], creatinine)	Analyzes various chemical components of blood	Few disorders produce a single abnormality; several components are usually analyzed to detect a pattern of abnormal results that may point to a disorder. Na ⁺ , K ⁺ , and Cl ⁻ help maintain osmotic pressure and acid–base balance. <ul style="list-style-type: none"> • Hyponatremia associated with severe diarrhea, vomiting, edema • Hypernatremia associated with dehydration • Hypokalemia associated with diarrhea, severe vomiting • Hyperkalemia associated with renal disease, massive cell damage, acidosis • Hypoproteinemia results in decreased Ca²⁺ levels • Hypoalbuminemia often results in edema • Increased BUN leads to kidney disease, shock, dehydration • Decreased BUN leads to negative nitrogen balance and overhydration 	Obtain specimens correctly. Get free flow of blood because when hemolyzed, cells break, releasing potassium, resulting in elevated K ⁺ levels and an inaccurate analysis of actual serum K ⁺ values. Do not draw blood from same extremity in which an IV line is infusing. Provide psychological and physical support when specimen is obtained; use topical anesthetic when possible. Evaluate results based on patterns of findings, including child’s symptoms.
Blood hemoglobin (Hgb) and hematocrit (Hct)	Measures Hgb, the main component of erythrocytes, which is the vehicle for transporting oxygen and carbon dioxide, and Hct—the concentration of erythrocytes in plasma. Hgb is important buffer in blood; helps maintain acid–base balance.	Increased Hgb and Hct lead to ECF volume decrease (decrease in blood loss) and hyperosmolar fluid imbalance Decreased Hgb and Hct lead to ECF volume excess and hypo-osmolar fluid imbalance	Support child when obtaining specimen. Put blood in correct tube and label specimen accurately. Ensure that results are obtained in a timely manner.
Arterial blood gases	Assesses acid–base status	Based on uncompensated values: <ul style="list-style-type: none"> • Low pH: Acidosis • High pH: Alkalosis • Elevated PCO₂: Respiratory acidosis • Decreased PCO₂: Respiratory alkalosis • Decreased HCO₃⁻ plus base excess: Metabolic acidosis • Increased HCO₃⁻ plus base excess: Metabolic alkalosis 	Use local anesthetic; specimen collection is painful. Maintain pressure over puncture site with two fingers for minimum of 2 minutes, longer if child has bleeding problems. Expel air bubbles in syringe. Place sample on ice if not immediately analyzed.
Urine specific gravity	Measures kidney’s ability to dilute and concentrate urine	Normal values: neonate, 1.001 to 1.020; older than 1 month, 1.001 to 1.030 Low specific gravity may indicate fluid excess or kidney disease. High specific gravity may indicate fluid deficit, the presence of glucose, large	Evaluate findings in relation to age (infants do not concentrate urine well, so usually have low readings) and confounding factors (e.g., if a child with diabetes is spilling

(Continued)

Tests and Procedures 17–1 Evaluating Altered Fluid and Electrolyte Status (Continued)

Diagnostic Test or Procedure	Purpose	Findings/Indications	Healthcare Provider Considerations
		amounts of protein or radiographic contrast media elevate results.	glucose in urine, the specific gravity does not accurately reflect hydration status).
Urine osmolality	More exact measure of urine concentration than specific gravity	Normal value: 50 to 1,400 mOsm/kg H ₂ O, depending on fluid intake Normal value after 12-hour fluid restriction: >850 mOsm/kg H ₂ O	Evaluate findings in relation to age and confounding factors.
Urine pH	Measures acidity/alkalinity of urine; reflects ability of renal tubules to maintain normal hydrogen ion concentration in plasma and ECF	Varies widely with kidney function, average pH = 6 Acidic urine (pH <7): High-protein diet or acidosis (e.g., diarrhea, dehydration, respiratory disease, uncontrolled diabetes) Alkaline urine (pH >7): Vegetarian diets and those high in citrus fruits and dairy products; diseases associated with hyperventilation, urinary tract infection, or chronic renal failure	Obtain freshly voided specimen for most accurate results; otherwise, refrigerate specimen.
Stool analysis	Evaluates stool for consistency, color, odor, absence or presence of blood, mucus, food residue, tissue fragments, bacteria, and parasites	Diet influences color; normal brown color is the result of the breakdown of bile; if passage is rapid (e.g., diarrhea), stool may be yellow or green (normal findings in breast-fed infant). Consistency may indicate amount of water loss. Characteristics may help diagnose disease—for example, diarrhea with mucus and blood (typhus, cholera, amebiasis), diarrhea with mucus and pus (ulcerative colitis, shigellosis, salmonellosis).	Obtain fresh stools to provide the most accurate results; warm stools are best for ova and parasite detection. Avoid testing stool contaminated with urine or toilet bowl water.

as nontunneled, tunneled, implanted ports, or peripherally inserted central catheters (PICCs).

Nontunneled Catheters

Nontunneled catheters are generally used for short-term central access in the acute care setting. They are placed percutaneously, usually into the femoral, subclavian, or jugular vein, using local anesthesia and sedation or general anesthesia. Because of the insertion method (direct puncture into a large vein, not tunneled under the skin), nontunneled catheters carry a greater risk than tunneled catheters of becoming dislodged or infected.

Tunneled Catheters

Broviac, Hickman, and Groshong are some brand names of catheters that are *tunneled* beneath the skin for several inches (the tunnel may be shorter in infants and young children) from the skin exit site to the vein insertion point

(Fig. 17–4) (see [thePoint](#) for Procedure: Intravascular Therapy: Tunneled Catheter). These catheters have a Dacron cuff situated under the skin 1 to 2 in proximal to the exit site, which secures the catheter and reduces the risk of infection by blocking the migration of pathogens from the skin along the catheter tunnel to the central circulation. General anesthesia is required to place tunneled catheters in children. Broviac and Hickman catheters, when not used for infusion, require a heparin flush after each use or at least once daily. Check facility and manufacturer's recommendations. A Groshong catheter requires a saline flush. Participation in contact sports may be limited for a child with a tunneled catheter.

Implantable Ports

Implantable ports (e.g., Port-A-Cath, Infuse-A-Port) are surgically placed under the skin of the arm or chest, and sutured to the muscle wall with the child under general

TRADITION OR SCIENCE 17-1

What flush solution should be used to lock peripheral IV catheters in children?

MORE INQUIRY NEEDED

Saline flush has been demonstrated to be sufficient to maintain patency in IV lines that are larger than 24 gauge (Hanrahan, Kleiber, & Fagan, 1994; Randolph, Cook, Gonzales et al., 1998; Shah, Ng, & Sinha, 2005). When smaller than 24-gauge catheters were used, some studies found heparin more effective in maintaining patency of the line (Danek & Noris, 1992; Kleiber, Hanrahan, Fagan et al. 1993; Mudge, Forcier, & Slattery, 1998; Schultz, Drew, & Hewitt, 2002; Treas & Latinis-Bridges, 1992); others found no difference between heparin and saline (Hanrahan, Kleiber, & Berends, 2000; Heilskov et al., 1998; Kotter, 1996; Paisley et al., 1997). Goldberg et al. (1999) found that saline prolonged catheter longevity for 24-gauge catheters. In studying 22- and 24-gauge catheters (the vast majority were 24 gauge), Mok et al. (2007) found no differences in catheter longevity and incidence of IV complications between saline, 1 U heparin/mL, and 10 U heparin/mL. They suggest that catheter longevity may be the result of using a positive-pressure flush technique and not the type of solution. Definitive recommendations for type of flush solution for 24-gauge catheters therefore cannot be made at this time.

Use preservative-free saline and heparin for neonates, because neonates are not able to metabolize preservatives well. This inability may result in the accumulation of toxic amounts, a condition called *gray baby syndrome* or *gasping syndrome* that presents as metabolic acidosis, lethargy, and hypotension. The most common preservative is benzyl alcohol, an antibacterial agent that is used in many medications.

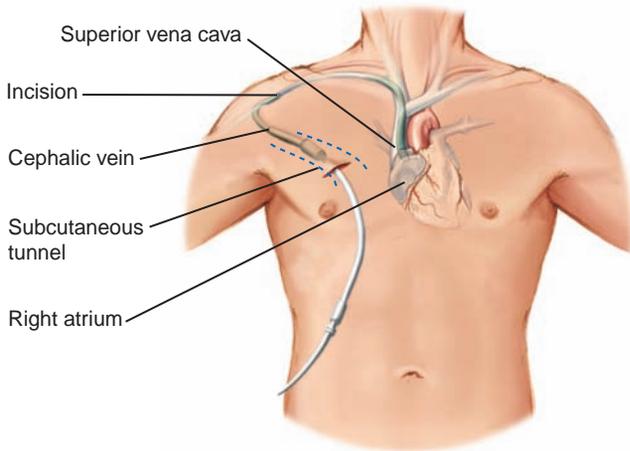

FIGURE 17-3. Position of a tunneled central venous catheter in the superior vena cava. Note that the skin insertion site is a distance from the vein entry site, with the catheter being tunneled under the skin for this distance.

FIGURE 17-4. Although a tunneled CVC can be hidden under clothing, it often has a negative effect on body image.

anesthesia. No part of the port is external. Implantable ports have a self-sealing silicon septum (which can be palpated under the skin) enclosed in a metallic or plastic chamber. This chamber provides a reservoir that connects to a large central vein by means of a Silastic catheter. The port is accessed with deflected-tip (Huber-type), noncoring needles to prevent leakage (see [thePoint](#) for Procedure: Intravascular Therapy: Totally Implantable Device [TID]). Patients generally report that accessing the port with a needle is less traumatic than venipuncture, although some children still react negatively to the needle stick associated with port access. To make port access more tolerable, topical anesthetic can be used. To insert the needle, palpate the skin over the port to identify the septum. Needles can be left in place for a maximum of 7 days (Fig. 17-5). The port should be flushed with heparin to maintain patency. Because an implanted port is placed under the skin, it is less visible than other catheters

FIGURE 17-5. Implanted ports are accessed with special noncoring needles, and a semipermeable dressing is used when the port is accessed for continuous infusions.

and may affect body image less negatively, although body image may still be altered. When the site has healed after placement, the child usually has few restrictions on activity, although contact sports usually are discouraged.

Peripherally Inserted Central Catheters

A PICC line (Fig. 17–6) is inserted peripherally by means of a percutaneous puncture. It is generally inserted above the antecubital fossa into the basilic or cephalic vein and is threaded into the superior vena cava (see [thePoint](#) for Procedure: Intravascular Therapy: Peripherally Inserted Central Catheter [PICC]). In infants, other sites may be used. A PICC line is a good choice for the child who requires antibiotic therapy for a period of weeks up to a year. Insertion is usually performed under local anesthesia combined with sedation. However, in infants, local anesthesia often causes the vessels to constrict; thus, IV sedation and analgesia may be given before PICC insertion. Although complications are fewer with sutures versus tape (Graf, Newman, & McPherson, 2006), a PICC line is often not sutured in place. Use extreme caution during dressing changes not to displace the catheter.

Complications of CVC Use

Pneumothorax, hemothorax, malposition, arrhythmias, and perforation of the central vessel are possible complications directly related to percutaneous CVC placement and presence. Malposition and catheter embolism are possible complications of PICC placement and presence.

Because of the CVC's central access and long-term use, infection is a particular concern when these catheters are used. Children are at increased risk for catheter-related infection and skin irritation (which can lead to infection) because they tend to play with the dressing or tubing, which can introduce contamination from soiled hands, vomit, or stool. Several factors are associated with an increased incidence of catheter-related bloodstream infections in children, including PN infusions, neutropenia, frequent manipulation and use of the catheter (de Jonge, Polderman, & Gemke, 2005), weight less than

8 kg, dwell time longer than 12 days (Garcia-Teresa et al., 2007), and multiple CVCs (Kline, 2005).

Thrombus formation is another risk associated with CVCs. Factors that may increase the risk of thrombosis include small vessel size compared with the catheter size, a relatively short catheter, and a long dwell time. PN may also increase risk of thrombosis (de Jonge et al., 2005).

CVC Site and Line Care

Meticulously follow facility protocols for CVC insertion site and line care. These protocols should detail how often to clean the site, the proper cleansing technique, how often to flush the catheter, appropriate flushing solution, how often to change tubing, and how to properly maintain a dressing. Dressings on CVCs are either transparent semipermeable membranes (e.g., Tegaderm), changed weekly; or gauze and tape, changed every 2 days (Centers for Disease Control, 2002). Implanted ports need a dressing only when accessed.

When a small-gauge CVC is in place, as is common in infants, administering blood may clot the catheter. Follow the manufacturer's recommendations for appropriate use. When CVCs do not have infusions running, most must be flushed with heparin to maintain patency; follow facility protocol and manufacturer recommendations. If a tunneled catheter is ruptured or fractured, it can often be repaired.

Intraosseous Access

The intraosseous route provides temporary vascular access in children age 6 years and younger in emergency situations until venous access can be obtained. A large-bore needle is placed into the bone marrow cavity, optimally in the proximal tibia (Fig. 17–7). Fluids, blood, and most medications (cytotoxic drugs should be avoided) are rapidly absorbed into the systemic circulation from this site. The marrow space can be rapidly accessed, even in hypotensive children or when CPR is in progress. After initial fluid resuscitation, vascular access may be more readily achieved. Bone marrow obtained when the

FIGURE 17–6. A PICC line in place. Use caution not to displace the catheter; note the securement device to assist with this.

FIGURE 17–7. Intraosseous needle being inserted for emergency vascular access.

intraosseous needle is inserted can be used to assess hemoglobin, electrolyte levels, blood chemistry values, and blood gases.

Volume of Fluid Administered

Calculation of fluid and electrolyte requirements takes into consideration the child's maintenance needs, volume needed to replace ongoing abnormal losses, and volume needed to correct existing fluid deficits. The child's clinical condition is also a determining factor. For example, a child with impaired renal or cardiac function may be given less fluid to prevent fluid overload, whereas a child with major burns likely will require increased fluid intake.

Maintenance fluid therapy provides fluid and electrolytes in amounts equal to normal ongoing losses. Normal metabolism produces solutes, which must be excreted in urine, and heat, which is dissipated by insensible water loss. Therefore, fluid needs are related to metabolic rate. Weight is widely used to calculate maintenance fluid requirements. IV fluids are calculated per hour, so a quick method for estimating hourly fluid requirements is also used; note that these two methods arrive at similar, but not precisely the same, calculations (Developmental Considerations 17-1).

Abnormal losses are those that occur either in excessive amounts or by abnormal routes. Abnormal ongoing losses are calculated by measuring losses in vomitus, gastrointestinal suction, diarrhea, and excessive urine output, and considering any conditions that increase insensible water loss, such as increased ambient temperature, use of radiant warmers, fever, hyperventilation, burns, or excessive sweating. Abnormal losses are corrected on an ongoing basis to prevent further fluid and electrolyte deficits.

Correcting fluid deficits replenishes fluids lost before initiation of treatment. This amount is calculated based on measured weight loss or on an estimated percentage of fluid lost, based on clinical signs of dehydration.

Type of Fluid Administered

Both glucose and electrolytes should be included in maintenance IV solutions administered to children. In short-term IV therapy, 5% dextrose solutions help minimize protein catabolism, ketosis, and negative nitrogen balance, although they do not provide total caloric needs. A 10% dextrose solution is usually administered to neonates.

Glucose is metabolized rapidly, which decreases the osmolality of the solution. Decreased osmolality allows the "free water" to move rapidly to a more hypertonic space, often the brain in young children, causing cerebral edema. Electrolytes in solutions help prevent fluid from shifting out of the vascular space. A hypotonic solution (e.g., D₅ 0.2 NS) is usually given, because children need more free water than adults as a result of their higher daily fluid turnover. The optimum concentration of these components depends primarily on the child's serum electrolyte values and on the underlying disease process as well.

Two basic types of IV fluid preparations are used: crystalloid and colloid (see [thePoint](#) for Supplemental

Information: Table: Crystalloids Versus Colloids). The type used for volume replacement depends on the nature of the loss as well as on ongoing maintenance needs. Crystalloids are solutions that equilibrate rapidly between the vascular and interstitial spaces.

In the plasma, colloids help maintain plasma oncotic (osmotic) pressure. Albumin is the most abundant plasma protein. Because large plasma proteins like albumin are unable to cross the capillary membrane easily, these colloids remain in the vascular space and exert osmotic force to pull fluid into the circulatory space. This dynamic serves to maintain intravascular volume.

Interdisciplinary Interventions

Prepare the child and the family to ease their anxiety and fear. Clearly describe the IV equipment, supplies, and the procedure itself to the child and family.

KidKare ■ Allow an older child to make choices about the therapy whenever it is medically safe to do so. Permit the child to choose the extremity to be used or the timing of catheter placement to give the child some sense of control over his or her environment.

Before initiating IV fluid therapy, review the documented order to double-check that the appropriate solution and rate of infusion have been ordered. Address any questions or concerns about the documented order to the prescriber before initiating therapy.

Usually, the nurse is responsible for placing peripheral IV catheters. PICC lines are inserted by trained practitioners. Other central catheters require surgical placement. Before placement of any type of catheter, question family members and the child, if appropriate, about any specific concerns that they may have.

caREminder

When documenting catheter placement, include the exact location of the catheter, the gauge or size of the catheter, the date that the catheter is placed, number of attempts, and the name of the person who performed the placement.

After the catheter is placed, ensure a safe environment for the child during IV therapy. Secure the catheter, taking care not to obscure the insertion site (Fig. 17-8). In some cases, the child's extremity also may have to be secured to prevent the catheter from becoming dislodged.

Monitor the IV infusion carefully to ensure that the child receives the correct volume of fluid at the correct rate of infusion. Infusion pumps are usually used for IV therapy in infants and young children. Verify that the pump has free-flow protection, is set correctly, and is delivering the infusion at the rate ordered. If an infusion pump is not used or if it malfunctions, the IV fluid can be delivered through microdrip tubing that delivers fluid at a slow rate.

DEVELOPMENTAL CONSIDERATIONS 17-1

Maintenance Fluid and Electrolyte Requirements

Body Weight	Daily Maintenance Formula	Hourly Maintenance Formula
Maintenance Fluid Calculations		
Up to 10 kg	100 mL/kg/24 hours	4 mL/kg/hour
11 to 20 kg	1,000 mL + 50 mL/kg/24 hours for each kilogram more than 10 kg and less than 20 kg	40 mL/hour + 2 mL/kg/hour × (weight - 10 kg)
>20 kg	1,500 mL + 20 mL/kg for each kg more than 20 kg (<i>maximum total fluids are normally 2,400 mL/24 hours</i>)	60 mL/hour + 1 mL/kg/hour × (weight - 20 kg) (<i>maximum rate of fluids per hour is 100 mL</i>)
Maintenance Electrolytes		
Sodium	2 to 3 mEq/kg/24 hours	
Potassium	1 to 2 mEq/kg/24 hours	
Example: A 22-Kg Child		
100% maintenance	<p>Daily Maintenance Formula</p> $10 \text{ kg} \times 100 \text{ mL} = 1,000 \text{ mL}$ $10 \text{ kg} \times 50 \text{ mL} = 500 \text{ mL}$ $2 \text{ kg} \times 20 \text{ mL} = 40 \text{ mL}$ Total = 1,540 mL/24 hours, or 64 mL/hour Sodium = 44 - 66 mEq/24 hours Potassium = 22 - 44 mEq/24 hours	<p>Hourly Maintenance Formula</p> $60 \text{ mL} + (1 \text{ mL} \times 2 = 2)$ or 62 mL/hour
Two-thirds maintenance (e.g., for child needing fluid restricted)	$2/3 = 66\%$ $1,540 \times 0.66 = 1,016 \text{ mL/24 hours, or } 42 \text{ mL/hour}$	

Observe the child and site of IV infusion for signs of complications every hour. Potential complications include infection, infiltration of fluid into the surrounding tissue, phlebitis, and thrombophlebitis (Nursing Interventions 17-1) (see [thePoint](#) for Procedures: PICC, TID, and Tunneled Catheters for troubleshooting these catheters). Air embolus is a concern, particularly with CVCs. Signs of air emboli include respiratory distress, cyanosis, tachypnea,

and hypotension. To prevent air embolus, secure all tubing connections and use air-eliminating filters on tubing and IV pumps that set off an alarm when air in tubing is detected. When air is detected, clamp IV catheter or tubing to prevent further air entry. Place the child in the left lateral Trendelenburg position to try to prevent air from entering the left side of the heart and circulating through the system. Promptly aspirate air from the catheter with a

FIGURE 17-8. Peripheral IV catheter in place. An IV House over the IV site secures the device and protects it from bumping or pulling.

NURSING INTERVENTIONS 17–1

Preventing and Treating Complications of Peripheral Intravenous Therapy

Complication/Signs	Nursing Interventions
<p><i>Infection: Introduction of pathologic organisms locally or systemically</i></p> <p>Redness at the catheter insertion site</p> <p>Exudate from the catheter insertion site</p> <p>Fever</p> <p>Elevated white blood cell count</p>	<p>Perform hand hygiene before and after contact with child. Maintain sterility of supplies and site for IV insertion, and dressing and tubing change.</p> <p>Minimize manipulation of, or trauma to, the insertion site. Change IV solution per protocol, usually within 24 hours. Change tubing per protocol, usually within 24 to 72 hours.</p>
<p><i>Catheter occlusion: Blockage of catheter usually by clotted blood or precipitates such as incompatible solutions, parenteral nutrition (PN), medications</i></p> <p>Fluid will not infuse or unable to flush</p> <p>Frequent infusion occlusion or high-pressure pump alarms</p>	<p>Maintain fluid infusion rate. If catheter appears occluded, gently flush line (avoid exerting too much force, which may push the clot into the vascular system or rupture the vein or the catheter); use normal saline initially to flush. If unable to establish patency, remove IV.</p>
<p>Infiltration (extravasation): Fluid leaks into subcutaneous tissues</p> <p>Fluid leakage around the catheter site</p> <p>Swelling when compared with the opposite extremity</p> <p>Site cool to the touch</p> <p>Decreased rate of infusion</p> <p>Tenderness, pain</p>	<p>Ensure that site, especially distal to catheter insertion, is easy to assess.</p> <p>Monitor the area distal to catheter insertion site and dependent area for signs of complications at least every hour.</p> <p>If complications occur, discontinue IV. Use a standard scale to document the degree of infiltration (Infusion Nurses Society, 2006). Apply warm or cold compresses, depending on the infiltrated fluid or medication: cold for hypertonic fluids and medications, heat for vinca alkaloids and epipodophyllotoxins, either heat or cold for isotonic or hypotonic fluids and medications, depending on child preference (Hadaway, 2007).</p> <p>Notify prescriber if medications have extravasated. As ordered, administer drugs (e.g., hyaluronidase) to neutralize or help diffuse extravasated vesicants (medications that cause tissue damage on extravasation).</p> <p>Usually, no neutralizing drugs are given when fluid or non-vesicant medications have infiltrated. A saline washout procedure to remove extravasated solution may be used (Clifton-Koeppel, 2006).</p>
<p><i>Phlebitis: Injury to the vein without clot</i></p> <p>Red streak along the vein</p> <p>Warmth along the vein, tenderness</p> <p>Possible edema</p>	<p>Dilute antibiotics in adequate amount of fluid; infuse over longest period recommended to provide better hemodilution of drug.</p> <p>Change insertion site routinely per facility protocol. Use a standard scale to document the degree of phlebitis (Infusion Nurses Society, 2006).</p> <p>Apply moist heat to site for 20 minutes several times a day. Consider a PICC if medications are irritants.</p>
<p><i>Thrombophlebitis: Injury to the vein with a clot</i></p> <p>Tenderness</p> <p>Edema</p> <p>Area warm to touch</p>	<p>Discontinue IV. Elevate the extremity.</p> <p>Monitor for signs and symptoms; notify prescriber if any develop.</p>

CLINICAL JUDGMENT 17-1

Child With Phlebitis

Tran is a 3-year-old who has a peripheral IV for antibiotic therapy. His current IV has been in place 2 days. Shortly after the nurse started this antibiotic dose, Tran started crying and picking at the IV site in his left hand.

Questions

1. What assessment data regarding the IV site should the nurse collect?
2. Are any of the IV site assessment findings abnormal? If so, which ones?
3. Should the IV be taken out?
4. After discontinuing the IV in the left hand, what should be done to care for the site?
5. What is the usual course of symptom resolution with phlebitis?

Answers

1. Color of the site (redness), streaking, pallor (there is a faint red line proximal to the IV site); temperature of the surrounding skin (left wrist is warmer

- than right); presence of edema (left hand and wrist appear slightly more swollen than right); palpate the site (unremarkable, no fibrosis or hardened line felt)
2. Yes; a faint red line proximal to site, site warmer than opposite limb with slight edema. Tran is also complaining of pain at the site.
3. Yes
4. Apply warm or cold compresses, depending on what seems to soothe Tran. Let Tran assume position of comfort. Elevation has not been shown to help fluid reabsorption or pain (Yucha, Hastings-Tolsma, & Szeverenyi, 1994). Monitor site for symptom resolution. Teach these interventions to the parents and child (if old enough).
5. Swelling, redness, and pain will decrease during the next 1 to 3 days.

syringe. If symptoms occur, notify the prescriber immediately; this may be a medical emergency. Support cardiorespiratory function; administer oxygen as ordered.

Vascular overload or electrolyte imbalance may also occur. Teach the older child, the parents, and other caregivers to observe for and report any signs of complications, particularly infiltration (Clinical Judgment 17-1).

Playing with or pulling at the catheter or tubing increases the risk of breaking the IV line, which can result in complications such as exsanguination and air embolism. Regardless of the type of venous access device used, it must be protected as developmentally appropriate (Developmental Considerations 17-2). If the child attends school or day-care, provide guidelines for catheter care for parents to give to teachers and care providers (see Community Care 17-1).

Nursing responsibilities also include assessing the child's overall status and monitoring intake and output. This measure includes both IV and oral intake as well as all output. Record daily weights to assess the adequacy of fluid volume management.

Alert! During IV fluid therapy, monitor for and promptly report signs of fluid volume overload, such as increased respiratory rate, respiratory distress, and crackles on lung auscultation. If signs of fluid volume overload occur, support the child's respiratory effort, elevate the head of the bed, and check the infusion setup for errors (e.g., inaccurate programming of the pump infusion rate).

Parenteral Nutrition (PN)

Children have enormous metabolic needs and require high amounts of energy and protein to support their

continued growth. The basic purpose of IV nutritional support is to restore or maintain optimum nutritional status. IV nutrition also provides fluid to aid in the excretion of wastes and to replace insensible fluid losses. However, the parenteral method of delivering fluids, electrolytes, and calories into the central venous system bypasses the gastrointestinal tract, the central thirst mechanism, and the hunger regulatory mechanism. Therefore, the gut should therefore be used possible to provide nutrition (see Chapter 18). Enteral (oral or tube) feedings, even in small amounts of 5 to 10 mL/hour, are beneficial in helping maintain gut structure, integrity, and function. Use of the gut maintains the intestinal villi (which atrophy if not stimulated) and enzyme activity, and prevents breaks in the mucosal wall, through which bacteria can enter the system and cause sepsis. Using the gut also helps avoid the hypermetabolic state that occurs after major stress or critical illness.

PN provides complete nutrition for children who cannot consume sufficient nutrients through the gastrointestinal tract to meet and sustain metabolic requirements. PN solutions provide protein, carbohydrates, electrolytes, vitamins, minerals, trace elements, and fats.

Good candidates for PN include children with short-gut syndrome, cancer, or increased metabolic needs because of injury. Contraindications to using PN include an anticipated course of less than 5 days, the immediate postoperative period after surgery, risk that exceeds the perceived benefit, and situations in which aggressive nutritional support is not desired. A child rarely receives PN exclusively for prolonged periods, with no oral intake. Partial therapy, in which enteral intake is

DEVELOPMENTAL CONSIDERATIONS 17-2

Safety Implications for Venous Access Devices

General Precautions	When Connected to Infusion	When Heparin or Normal Saline Locked
<p>Maintain meticulous hand hygiene practices. When involving the child in self-care activities related to the venous access device, make sure they have completed hand hygiene.</p> <p><i>Never</i> use scissors near venous access devices. For central venous access devices, keep extra clamp with child.</p> <p>For a tunneled catheter, after transparent dressing is applied, coil and tape catheter on top of, or to the side of, the dressing.</p>	<p>Use IV extension tubing to</p> <ul style="list-style-type: none"> • Enable mobility related to developmental level • Keep infusion out of reach of child from crib, playpen, and so forth 	<p>Peripheral IV: Verify joint/extremity mobility and that no pressure areas are present. Ensure that the catheter is secured with tape and that the slide clamp is in the closed position.</p> <p>Tunneled catheter: Keep clamped on designated clamp area.</p> <p>Accessed port: Keep noncoring needle extension clamped.</p> <p>PICC: Keep clamp on extension tubing (if present).</p>
<p>Only use Luer-Lock connections.</p>	<p>Tape connections for added security.</p>	<p>Secure any dangling catheter or extension tubing to avoid pulling and possible dislodgment.</p>
<p>For infants and young children: Dressing in a “onesie” or close-fitting clothing helps protect from exploring hands. Tunnel IV tubing under clothing and away from infant.</p>	<p>For infants learning to walk or ambulatory young children: Tape IV tubing over shoulder and to the back to prevent repeated stepping on IV tubing and subsequent pulling at the exit site.</p>	<p>Secure tubing.</p>

Home Care

Perform hand hygiene after toileting/changing diapers, before manipulating catheter or line, and frequently.

Place bottles of alcohol-based hand rub throughout home.

Assess typical activities for developmental level and provide anticipatory counseling related to safety with venous access—for example, child has a PICC and typically takes Tae Kwon Do classes so alternate activity may need to be substituted; infant should be mastering crawling so tubing extension may be needed, monitor child to avoid entanglement in tubing

Child should wear medical alert bracelet.

When leaving home, carry emergency kit in diaper bag or backpack along with alcohol-based hand rub, a backup smooth-edged clamp, tape, equipment to access device, card with information about type of device and its location, and contact information for child’s healthcare provider.

Turn infusion pump control panel away from child; keep pump out of reach of child.

Make sure that caregiver can hear pump alarms when not in same room (increase alarm volume, use an intercom).

COMMUNITY CARE 17-1

Information to Give Teachers and Care Providers About Central Venous Access Devices

[Child's name] has a tube (catheter) in place that is used to deliver medicine into his/her bloodstream. The device should not be noticeable under most clothing. It should not interfere with most normal activities; however, this child should avoid contact sports. The catheter/tubing should be secured close to the child's body to prevent it from dangling and possibly pulling or becoming dislodged. A clear bandage over the site helps to secure the catheter. If the dressing is loose, have the school nurse or the child reinforce it with tape and notify the parent or caregiver. The child should be carrying emergency supplies to help take care of problems, such as cleaning supplies, syringes, and a clamp if the tubing does not have one on it.

Tailor information to the type of access device the child has:

Implantable device (port): This device is under the skin and usually requires no additional care. If a needle is in place, with tubing attached, and any bleeding occurs from the tubing, use the clamp to compress the tubing and stop the bleeding.

Tunneled catheter (e.g., Broviac): The catheter is placed in the child's chest and is well secured, but avoid manipulating the catheter and do not let children pull at it or play with it. The catheter has a cap on the end. In the unlikely event that the cap comes off or the catheter is severed and blood comes out of the catheter, use the clamp to compress the catheter.

PICC: The catheter is well secured and covered with a clear bandage, but avoid manipulating the catheter and dressing, and do not let children pull at them or play with them. The catheter has a cap on the end. In the unlikely event that the cap comes off or the catheter breaks, pinch the tube firmly between your fingers, fold it over on itself, and tape securely (it may be recommended not to use a clamp).

No problems are anticipated, but please contact parents if any of these problems, or other problems, occur or if you have any questions.

Ensure that parent contact information is on school and health records.

supplemented with PN, provides the benefit of gut stimulation while still providing adequate calories, nutrition, and fluids.

PN can be provided by peripheral or central venous access. Peripheral delivery of IV nutrition should be restricted to a maximum of 10% dextrose and 5% protein, and peripheral administration should not continue for longer than 7 to 10 days (Infusion Nurses Society, 2006). If the final concentrations of the PN solutions exceed 10% dextrose and 5% protein, pH less than 5 or more than 9, and osmolality more than 600 mOsm/L, the solution should be administered through a CVC (Infusion Nurses Society, 2006). Concentrations higher than this frequently produce a chemical phlebitis. Peripheral PN should be limited to short-term support when the benefit exceeds the risk. In younger children, the large amounts of protein and calories needed for growth necessitate prohibitively high fluid volumes for peripheral delivery. Even with calorie supplementation with fat emulsions, the full caloric needs of smaller children usually cannot be met by peripheral PN. For these children, PN infusion through a CVC is usually required.

Daily caloric requirements are calculated along with disease-specific needs when administering PN. Caloric intake must be more than the child's maintenance

requirements (which are based on body weight) to allow for growth and any necessary healing. Caloric requirements are increased in many clinical situations, including burns, sepsis, major surgery or injury, cardiac dysfunction, and chronic illness.

To balance nutrition during prolonged therapy and to prevent fatty acid deficiency, IV fat solutions (lipids) are required. The younger the child, the more quickly fatty acid deficiency can occur. If preterm infants do not receive essential fatty acids, 40% demonstrate deficiency by the third day of life, and 81% have essential fatty acids deficiency by day 7 (Farrell et al., 1988).

Fat emulsions have a low osmolality; therefore, they may help decrease the incidence of phlebitis when administered peripherally with solutions that have high dextrose concentrations. Administration of fat emulsions has been associated with detrimental effects, however, such as decreased pulmonary diffusion and peripheral oxygenation, bilirubin displacement from albumin, alteration in leukocyte function, hyperphospholipidemia, hypercholesterolemia, and changes in prostaglandin metabolism (American Society for Parenteral and Enteral Nutrition, 2002). Serum triglyceride levels also must be monitored periodically in the child receiving IV fat emulsions.

Complications of Parenteral Nutrition

Possible complications of PN include all of those commonly seen in any form of IV therapy (see Nursing Interventions 17–1). Sepsis and metabolic complications such as hyperglycemia and hypoglycemia, acidosis, calcium and phosphorus abnormalities, and trace metal deficiencies may occur. Electrolyte and mineral levels, blood urea nitrogen (BUN), creatinine, liver enzymes, bilirubin, total protein, albumin, and a complete blood cell count are some of the values that should be monitored on a routine basis during prolonged therapy.

Liver dysfunction may also occur. Etiologies of this complication include sepsis, prematurity, hepatotoxicity, deficiency of the infusate, and lack of enterally stimulated bile flow (Carter & Karpen, 2007). Other complications can occur if the PN solution is infused too rapidly. These events can include respiratory distress, nausea, and electrolyte imbalances.

Interdisciplinary Interventions

Care responsibilities for a child receiving PN include those for any child receiving IV therapy: site, catheter, and tubing care; and close monitoring for signs of complications from the catheter (infiltration, occlusion, infection, phlebitis) and from the IV infusion (fluid and electrolyte imbalances, metabolic complications). Vigilantly maintain clean technique for catheter site and tubing care. Lipids provide an excellent medium for bacterial growth; thus, maintain sterile technique when preparing and administering these solutions.

Monitor the child's rate of growth by recording daily weights and evaluating growth on a standardized growth chart. Keep careful intake and output records.

caREminder

During continuous infusion, maintain a fairly constant PN infusion rate to avoid glucose overload. Never abruptly increase or decrease the infusion rate in an attempt to “even out” the infusion, unless otherwise ordered.

Monitor laboratory values according to facility protocol; note and investigate abnormal results. Monitor serum glucose level by serum laboratory values or by bedside capillary blood glucose methods because the child receiving PN is adapting to a high glucose solution. Report values out of normal range values.

Promote developmentally appropriate tasks that might be limited by restrictions imposed by long-term PN infusions (TIP 17–1). Depending on the child's needs, parents, the nurse, a child life specialist, and a physical or occupational therapist may all be involved in promoting the child's physical and emotional development.

Consider the child and family's psychological needs in both hospital and home care situations. Lack of, or restrictions on, oral intake can be very frustrating for the child and family. Many social situations have eating as a focal point; to many parents, being able to feed their child is a central facet of being a “good,” nurturing par-

ent. Use principles of therapeutic communication when dealing with the child and family.

Children receiving PN who have other medical needs may associate oral intake (stimulation) with uncomfortable procedures such as suctioning, nasogastric or orogastric tube insertion, or endotracheal intubation and may therefore develop an aversion to oral feeding. This possibility underscores the importance of providing positive oral experiences, such as sucking on a pacifier for younger children or hard candy, if allowed, for older children. Take a proactive approach to prevent adverse psychosocial and developmental effects of prolonged restriction of oral intake during PN therapy. The child should receive a program of oral stimulation, coordinated by the occupational therapist, as well as positive tactile and social stimulation during PN infusion. The *oral stimulation program* promotes dealing with textures, tastes, and movement of food in the mouth and decreases aversive responses to the introduction of food, and may involve gum massage and oral-motor exercises to promote muscle strengthening for specific muscle groups with increased or decreased tone.

Other challenges associated with resuming oral intake are also best addressed by anticipating them. The child receiving PN may not be hungry and may not want to eat. Parenteral nutritional support should be decreased as oral intake is increased. Monitor intake, but do not focus on how much is eaten, and do not force the child to eat. Promote mealtimes as pleasant social situations. Ill children often have little control over situations; one situation in which they often can exert control is refusing to eat when allowed oral intake. Not focusing on the issue, offering as many choices as possible (e.g., type of food, where to eat, when to eat), and emphasizing control in other areas (which games to play, when to have rest periods) may help defuse the situation.

The dietitian should be involved in ensuring that PN infusions are nutritionally complete and, along with the occupational therapist, should facilitate the transition to oral intake. If the child is experiencing discomfort related to an underlying disease process, provide adequate pain relief to facilitate positive interactions during mealtime.

Home PN Therapy

Teamwork is essential to ensure that PN therapy is successful at home. Child, parent, and caregiver education is a major component of discharge planning. Address social, financial, and medical issues considering parent and caregiver limitations. If the child requires a continuing program of oral-motor stimulation, an occupational or speech therapist may teach parents what to do.

Begin parent, caregiver, and child education in the hospital as soon as the need is identified. Coordination between the hospital, the home care agency, and all caregivers is a priority when planning for discharge. Financial support is a major concern for many families. Social services personnel, the case manager, and others involved in discharge planning should help the family assess their financial and social support resources and provide assistance before deciding to discharge the child on PN. Care

TIP 17–1 A Teaching Intervention Plan for the Family With a Child Requiring Home PN

Nursing diagnoses and outcomes

- Risk for injury related to effects of ongoing PN infusion

Outcomes

- Child will suffer no injury associated with PN infusion
- Deficient knowledge: Management of PN therapy

Outcome

- Parents, caregivers, and the child, if old enough, will be knowledgeable about and appropriately manage home PN

Teach the child/family

Safety Issues Regarding Child Health

- How to assess fluid balance
- Assessment for signs of electrolyte imbalance and infection

Safety Issues Regarding Child Development

- Use techniques to promote achievement of age-appropriate developmental milestones (e.g., place infant who is learning to crawl, or toddler learning to walk, on the floor with enough tubing to be mobile; monitor to prevent child chewing on, pulling on, or getting entangled in tubing; closely monitor a child in early childhood who is using scissors so the catheter or tubing is not inadvertently cut; involve children in middle childhood and adolescents in their own care to promote independence; use portable infusion pumps for mobility).
- Stabilize infusion pumps and poles so they will not fall on child.
- Have plastic cover over pump controls so the child cannot change the infusion settings; turn pump face away from child so the lighted numbers are not tempting to play with (check pump settings frequently).
- Use developmentally appropriate methods to secure venous access device (see Developmental Considerations 17–2).
- Often, home PN is cyclically delivered, usually during sleep time; encourage gross motor activity during infusion-free periods; if awake during infusion, limit activities to circumscribed areas and

arrange quiet activities (e.g., doing homework at the kitchen table, watching television in the family room).

- Promote mealtimes as pleasant social events; encourage the entire family to eat together.

Basic Emergency Measures

- General problem-solving techniques
- How to clamp the catheter if it breaks or becomes disconnected
- What to do if the infusion infuses too rapidly (slow infusion rate, monitor child, test blood glucose level, notify healthcare provider)
- Keep a list of emergency phone numbers posted by every phone in the house.
- Notify local electric and utility companies of the child's medical situation in case of a power outage.
- Pumps need to be plugged into a three-pronged outlet for grounding; an adaptor can be obtained from a hardware store if needed.

Safety Issues for Night PN Infusion

- Adapt sleeping arrangements so the parents can hear and respond to pump alarms.
- Keep the path to the child's room clear to avoid parental injury from tripping over obstacles.

Management of PN Therapy

- Review and observe return demonstration on central line site and catheter care.
- Properly store supplies (clean, dry place away from high-traffic areas [the kitchen counter is not a good place for storage]) and parenteral solutions (keep in small cardboard box in top shelf of refrigerator to avoid anything spilling on them).
- Take a small bag of supplies (syringe, heparin, tape, clamp, extra cap) when going away from home.
- Know procedure for initiating and maintaining the PN infusion (visual inspection of solution, expiration date, clean technique, managing infusion device).

Contact Healthcare Provider if:

- Child develops signs of fluid or electrolyte imbalance or infection
- Catheter problems occur

needs of the child with a chronic condition and home care needs are discussed in Chapter 12.

Children discharged on home PN therapy, and their parents, have multiple teaching needs (see TIP 17–1).

Reinforce the importance of ongoing care to evaluate the effectiveness of therapy; assess the family's knowledge and ability to provide home PN safely during these visits.

ANSWER: The nurse would anticipate that Cory will receive fluids and medications via a peripheral IV for a few days. To Wendy Whitworth, this sounds like a very long time, but in the realm of venous access, it is not a long time. Cory is already in pain, distressed, and dehydrated. He may be unable to cooperate for this procedure and, as a result of his degree of dehydration, it may not be easy to start an IV on him. In the interest of atraumatic care, the emergency department nurse should coordinate with the surgery department to determine how quickly Cory might move to a presurgical area, and the surgical nurse or perhaps the anesthesiologist might place the peripheral IV. Immediate appropriate actions would include assessing potential IV sites, applying topical anesthetic cream, verifying fluid orders, and preparing the IV bag and tubing.

NURSING PLAN OF CARE FOR THE CHILD WITH ALTERED FLUID AND ELECTROLYTE STATUS

QUESTION: Which nursing diagnoses listed in Nursing Plan of Care 17-1 are applicable to Cory?

Nursing diagnoses and care generally appropriate for the child with altered fluid and electrolyte status are identified in Nursing Plan of Care 17-1. Because fluid and electrolyte imbalances produce widely varying effects, additional diagnoses not listed may be appropriate for children with specific alterations.

ANSWER: The nursing diagnoses most pertinent to Cory are as follows:

- Risk for imbalanced fluid volume related to NPO status, presence of an NG tube, inadequate fluid resuscitation or overhydration, equipment malfunction, child/parent changing infusion rate
- Imbalanced nutrition: Less than body requirements related to effects of disease process or condition (inability to ingest sufficient nutrients, inability to absorb nutrients via gastrointestinal tract)

ALTERATIONS IN FLUID AND ELECTROLYTE BALANCE

Normally, thirst mechanisms, the kidneys, and the respiratory system work together to maintain fluid and electrolyte balance. When this balance is upset, the resulting alterations can be life threatening.

FLUID IMBALANCES

The body maintains a delicate fluid balance. Excessive fluid losses or inadequate intake may result in dehydration; excess fluid volume may result in edema.

Dehydration

QUESTION: Based on his history, which type of dehydration do you think Cory has?

Dehydration occurs when fluid loss exceeds fluid intake. The primary cause can be an overall increase in fluids lost or a decreased intake. Dehydration can also result when fluid shifts occur and the fluid accumulates in a space outside ICF and ECF spaces, such as the abdominal cavity (a phenomenon sometimes called *third spacing*). Because fluid moves from the intravascular space, this shift results in intravascular fluid deficit and dehydration. The body maintains equal osmolality between ICF and ECF compartments. Osmolality changes in one compartment lead to compensatory water shifts as the body attempts to restore equal osmolality among compartments.

In adults, the greatest proportion of water is stored in the intracellular space. Therefore, to be lost from the vascular volume, water must shift out of the intracellular space into the extracellular space. Children have a greater proportion of body water in the extracellular space (see Fig. 17-2), which makes it easier for water to be lost from the intravascular space. This is one of the reasons why children are more prone to dehydration than adults.

Gastrointestinal output, in the form of diarrhea and emesis, is the most common cause of dehydration in children. Worldwide, diarrheal disease is a leading cause of morbidity and mortality in children, causing approximately 2 million deaths yearly (Freedman, 2007). In the United States, gastroenteritis and dehydration account for about 220,000 hospitalizations yearly (Zolotor et al., 2007). Fever, increased respiratory rate, diuretics, hemorrhage, burns, and adrenal insufficiency can also lead to dehydration.

Untreated, dehydration can negatively affect circulatory blood volume. Initially, reduced blood volume results in a reduction of blood flow to the skin, muscles, and viscera, and later to the kidneys. As plasma blood volume becomes more depleted, circulation is further compromised, resulting in reversible (and eventually irreversible) shock and death.

Classification of Dehydration

Classification of dehydration is made based on the child's serum sodium level: 130 to 150 mEq/L in isotonic dehydration, less than 130 mEq/L in hyponatremic (hypotonic) dehydration, and more than 150 mEq/L in hypernatremic (hypertonic) dehydration.

Isotonic Dehydration

Isotonic dehydration occurs when sodium and water are lost in proportional amounts. The net result is a reduction in the circulating blood volume. The major fluid loss is from the ECF compartment, which in children is proportionally larger than the ICF compartment.

NURSING PLAN OF CARE 17–1 THE CHILD WITH ALTERED FLUID AND ELECTROLYTE BALANCE

Nursing Diagnosis: Risk for imbalanced fluid volume related to inadequate fluid resuscitation or overhydration, equipment malfunction, child/parent changing infusion rate

Interventions/Rationale

- Calculate fluid requirements for the child, and evaluate whether they coincide with the order for fluid infusion and with the child's diagnosis.
Fluid needs are calculated based on the child's weight and condition (e.g., may be decreased in children with neurologic, cardiac, or renal problems, or increased in the presence of high metabolic needs or certain conditions, such as sickle cell disease).
- Use infusion device with free-flow protection to monitor flow rate; use volume control chambers per facility policy.
Infusion devices provide more accurate fluid delivery than by gravity alone; free-flow protection helps avoid inadvertent fluid administration. Volume control chambers limit the amount of fluid available for infusion at one time.
- Keep infusion device positioned so that the child cannot change the rate or stop/start infusion.
Reduces the chance that child will alter the ordered infusion rate.
- Assess the child, IV site, and infusion system every hour for complications; discontinue the IV as indicated and assess need for restarting the line.
IV administration is an artificial method of delivering fluids that bypasses the body's regulatory systems, thus making it easy to under-/overhydrate a child. Frequent assessments facilitate prompt detection and treatment of complications.
- Monitor vital signs, maintain accurate intake and output, weigh daily at the same time on the same scale in the same clothes; assess for edema (e.g., bulging fontanel, periorbital, dependent) or fluid deficit (e.g., sunken fontanel, poor skin turgor, dry mucous membranes, tachycardia).
Changes in these parameters may reflect alteration in fluid balance.
- Explain to child/parents importance of keeping infusion constant; caution them not to regulate the IV (unless appropriate, as in care-by-parent units, teaching for home IV therapy).

Expected Outcomes

- Child will maintain normal fluid balance evidenced by normal heart rate, blood pressure, urine output for age and weight; the infant will have a normal fontanel (not sunken or bulging); eyes will not be sunken and periorbital edema will not occur.

Nursing Diagnosis: Ineffective tissue perfusion (specify type: renal, cerebral, cardiopulmonary, gastrointestinal, peripheral) related to effects of fluid deficit, electrolyte imbalance

Interventions/Rationale

- Monitor for signs of ineffective tissue perfusion:
 - Renal: urine output less than 1 mL/kg/hour, high specific gravity (≥ 1.030)
 - Cerebral: irritable, altered behavior, decreased level of consciousness, sluggish pupillary response
 - Cardiopulmonary: capillary refill time more than 2 seconds, weak or thready pulses
 - Gastrointestinal: decreased bowel sounds, nausea or vomiting, abdominal distention
 - Peripheral: cool, clammy, pale, mottled, or cyanotic skin
Symptoms vary based on the system affected. Early detection facilitates prompt intervention and reduction of negative sequelae.
- Notify physician or advanced practice nurse immediately if signs of ineffective tissue perfusion are noted.
Immediate notification facilitates initiation of treatment. Prolonged ineffective tissue perfusion leads to anaerobic metabolism, lactic acidosis, organ ischemia, and, ultimately, multiorgan system failure.

Expected Outcomes

- Child will regain and maintain adequate tissue perfusion.

Nursing Diagnosis: Imbalanced nutrition: Less than body requirements related to effects of disease process or condition (inability to ingest sufficient nutrients, inability to absorb nutrients via gastrointestinal tract)

Interventions/Rationale

- Assess for factors contributing to current imbalance (presence of illness or condition; child's intake of food and fluids; how food and formula are prepared; alteration in parent child interactions, neglect, abuse).
Allows identification of cause of problems, so interventions can be targeted appropriately.
- Observe child's relationship to food. Attempt to distinguish between physical and psychological causes for inadequate intake.
Ill children often have little control over situations. One situation in which they often can exert control is refusing to eat when allowed oral intake. Interventions will vary based on cause of inadequate intake.

- Calculate child's caloric needs; obtain nutrition consult as indicated. Measure weight daily, measure height and head circumference (in children younger than 3 years) weekly or as indicated. Periodically plot measurements on growth chart. Record oral intake accurately, monitor intake and output, and note unusual losses (e.g., vomiting, diarrhea, increased metabolic needs).

Regardless of the specific situation, the child needs enough protein for tissue repair; calories for energy (both carbohydrate and fat sources); and enough electrolytes, vitamins, minerals, and trace elements for normal body functioning. Children experience growth spurts, which require an increase in required nutrients. Ongoing monitoring of intake, output, and growth parameters gives an indication of whether intake is adequate to meet needs.

Expected Outcomes

- Child will take in (oral, enteral, IV) sufficient fluid and nutrients based on age and medical needs.
- Child will gain weight at a rate appropriate for his or her age, and will maintain growth on own trajectory.

Nursing Diagnosis: Deficient diversional activity related to restriction/limitation of movement, weakness from disease process

Interventions/Rationale

- Take the child for walks, to the playroom, or sit in the hallway, where there is activity. Have developmentally appropriate toys, games, books in crib/at the bedside. Encourage activities that do not require use of the extremity in which an IV is present.

Activities provide a distraction, take the child's mind off imposed limitations, and may improve coping. A lack of stimulation may result in boredom, irritability, or depression.

- Teach the child/parents how to move the IV pole, unplug the infusion pump (if battery operated) for walks, and plug it back in.

Gives the child/parent control in a situation and knowledge to safely manipulate equipment.

- Set up study schedule and encourage keeping up with lessons from school if appropriate.

If the child will be unable to attend school, keeping up with assignments may provide distraction and a feeling of accomplishment, and may reduce anxiety related to missing schoolwork.

- Encourage peer visitation if not contraindicated.

Peers can help occupy the child's time and provide a distraction. Peers are very important to adolescents,

and interactions help them meet developmental milestones.

Expected Outcomes

- Child will be able to perform activities normal and appropriate for his or her developmental level.
- Child will verbalize no complaints of boredom, nor display apathy from lack of stimulation.

Nursing Diagnosis: Deficient knowledge: Recognition and management of fluid and electrolyte imbalance and complications of therapy

Interventions/Rationale

- Discuss with the child/parents why various tests and procedures are indicated, and why IV infusion is necessary. Show equipment to the child. Explain that a catheter is like a plastic noodle in their arm and that the needle is not left in.

Understanding the rationale for interventions helps the child and parents cope with and adhere to the treatment regimen. Children fear needles; reassurance that a needle is not present may decrease anxiety.

- Teach reasons for covering the infusion site and limiting movement (e.g., to avoid touching/picking at site; immobilize the area to reduce catheter dislodgment, limit movement to avoid pulling on infusion tubing).

The child/parents need information and teaching to deal appropriately with IV equipment, to cope with limitations of movement, and to help prevent complications.

- Explain to parents that an infant still needs to be held; teach them methods to pick up and hold their infant with an IV.

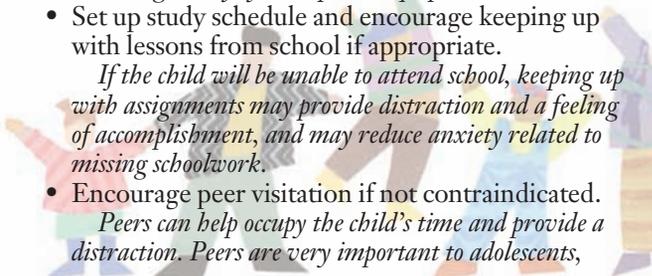

Helps parents to overcome their fear of handling their child and to better meet the child's needs.

- Tell them to call the nurse if the IV is not infusing (e.g., not dripping; alarm is sounding; or if the site is painful, red, swollen, cool or warm to the touch).

Facilitates prompt recognition and treatment of adverse events.

Expected Outcomes

- Child and parents will demonstrate understanding of the tests and procedures performed.
- Parents will provide care to their child, including providing appropriate nutritional intake.
- Child, if old enough, and parents will recognize early symptoms of fluid and electrolyte imbalance and implement appropriate interventions.

Hyponatremic Dehydration

Hyponatremic dehydration, also commonly called *hypotonic dehydration*, can result from either water retention or sodium loss. Defects in renal water excretion are almost always the cause of water retention, resulting in hyponatremia. Hypotonic dehydration can occur when sodium is lost with water but the net loss of fluid is replaced, either orally or intravenously, by hypotonic solutions. This imbalance may occur if formula is diluted with water beyond manufacturer recommendations or if fluid is replaced with electrolyte-free water. Because sodium is more abundant in the extracellular space, fluid in the intracellular space is normally hypotonic in relation to fluid in the extracellular space. In hypotonic dehydration, the ICF becomes relatively more concentrated, because the sodium in the extracellular compartment is diluted. Because water follows sodium, water shifts from the ECF to the ICF compartment.

Hypernatremic Dehydration

Hypernatremic dehydration is marked by elevated sodium levels in the ECF compartment. Thus, water shifts from the ICF to the ECF compartment in an effort to restore equal osmolality. This shift decreases intracellular volume substantially, but clinical signs of fluid loss are not as apparent as in other types of dehydration, even in the presence of similar fluid loss, because the shift of fluid into the extracellular space helps to maintain vascular volume.

ANSWER: Cory's dehydration is a result of inadequate oral intake in the presence of increased metabolic need from his fever. The history is not compatible with

hyponatremic dehydration. He most likely has isotonic dehydration. When his sodium level returns, it can be confirmed.

Assessment

QUESTION: You have already identified the manifestations of dehydration that Cory exhibits. What is another factor that may affect your assessment?

Dehydration is classified as mild, moderate, or severe. Clinical manifestations depend on the type of dehydration, its cause, and the severity of fluid loss (Table 17-1). Infants and young children are more susceptible to dehydration and may have more severe manifestations.

Obtain a thorough history of the child's recent intake and output (see Focused Health History 17-1) and ask about potential exposures to ill persons, poisons, and hot environments. Assess peripheral perfusion, as reflected in changes in vital signs and level of consciousness. Weigh the child and compare the result with previous recent weights, if available. Rapid weight loss is a sign of fluid loss. Assess for other signs of fluid deficit, such as dry mucous membranes, sunken eyeballs, lack of tears when crying (in children 6 weeks and older), sunken fontanel in infants, and poor skin turgor.

Signs and symptoms of isotonic dehydration may be similar to those of hypovolemic shock. The risk of hypotonic dehydration is increased in infants with immature renal function and in those whose oral intake after diarrhea consists of hypotonic or electrolyte-free solutions. The most common solutions erroneously used in

TABLE 17-1

Clinical Signs of Dehydration

Sign	Severity		
	Mild	Moderate	Severe
Loss of body weight	5%	5% to 9%	>10%
Level of consciousness	Alert to restless, irritable	Restless to lethargic	Lethargic to comatose
Blood pressure	Normal	Normal; may be low when upright	Low
Heart rate	Normal	Increased	Increased
Pulse	Normal	Faint, thready	Impalpable
Mucous membranes	May be dry	Dry	Dry, parched
Eyeballs, fontanel	Normal	May be normal or sunken	Sunken
Skin turgor	May be normal	Poor	Poor; tenting
Skin temperature	Normal	Cool	Cool, mottled, cyanotic
Urine output	May be low (normal is 1 mL/kg/hour)	Low, concentrated, oliguric	Low, anuric

these situations are water or sugar water. Assess for the presence of clinical signs, including poor skin turgor and signs of vascular collapse (e.g., increased heart and respiratory rates, decreased blood pressure, delayed capillary refill). Neurologic manifestations may occur as brain cells swell.

Clinical manifestations of hypertonic dehydration include a doughlike feel to the skin, lethargy, irritability, and seizures. Neurologic signs are related to the decreased intracellular volume of brain cells.

ANSWER: Cory is in acute pain. He is tachycardic and tachypneic, but this can also be a result of pain. Obtaining Cory's blood pressure may or may not be helpful. Although a decreased blood pressure is a late sign of dehydration, Cory's level of pain may be increasing a somewhat low blood pressure so that it appears normal for his age.

Diagnostic Tests

Serum sodium is evaluated to identify the type of dehydration. Serum BUN and creatinine, and urine specific gravity and osmolality, which are increased in the presence of fluid volume deficit, may also be evaluated. Research indicates that urine specific gravity may not identify dehydration in gastroenteritis (Steiner, Nager, & Wang, 2007).

Interdisciplinary Interventions

QUESTION: Why is oral fluid intake not appropriate for Cory?

Dehydration that causes clinical manifestations calls for prompt fluid replacement. The priority intervention is to restore and maintain intravascular volume. After volume is restored, any remaining fluid and electrolyte deficit can be corrected by administering an appropriate solution at an appropriate rate. This solution is given in addition to any normal maintenance fluids that the child needs.

Mild to moderate dehydration can be corrected with oral fluid intake. Severe dehydration may require IV fluid replacement therapy (see [thePoint](#) for Care Path: An Interdisciplinary Plan of Care for the Child With Severe Isotonic Dehydration). Indications for IV therapy to correct a fluid deficit include shock and impaired circulation, severe dehydration, uncontrollable vomiting (more than three times per hour), or inability to ingest oral fluids, as in lethargy, coma, or abdominal distention (ileus) (Alam & Ashraf, 2003).

Isotonic solutions—never hypotonic solutions—should be used for initial rehydration therapy. Hypotonic fluid shifts out of the extracellular space and thus does not help restore vascular volume.

Alert! Using isotonic fluids is critical in children with hypernatremia, because hypotonic solutions cause water to move into brain cells, causing cerebral edema, seizures, and profound neurologic sequelae. The rate of fluid replacement should also be more gradual, over 48 hours rather than 24 hours, in the case of hypertonic dehydration. When the sodium level decreases too quickly, similar fluid shifts occur in the brain.

IV fluids should contain sodium when the serum sodium level is below normal limits. Common solutions include lactated Ringer's, normal saline (NS), $1/2$ NS, and $1/4$ NS (see Tradition or Science 17–2). If the child is hemodynamically unstable, 20-mL/kg boluses of isotonic solutions should be given until vital signs indicate stability.

caREminder

To avoid serious cardiac sequelae associated with hyperkalemia, potassium should not be added to IV fluids until the child has voided, demonstrating adequate renal function.

Therapy, whether oral or IV, should continue until

- Vital signs are stable
- Weight has stabilized
- Adequate urine volume is present
- Serum electrolytes are within normal limits
- Acidosis, if present, has been corrected

Nursing responsibilities when caring for a child with dehydration include initial assessment and ongoing monitoring. Investigate the underlying cause of the

TRADITION OR SCIENCE 17–2

What fluid is most appropriate as maintenance fluid?

MORE INQUIRY NEEDED

Historically, isotonic solutions were recommended to restore volume followed by hypotonic fluids for maintenance (Holliday, Ray, & Friedman, 2007). Isotonic solutions (e.g., normal saline) for maintenance fluid has recently been advocated (Choong et al., 2006; Moritz & Ayus, 2007; Neville et al., 2006). Because administration of hypotonic fluids does not always explain the development of hyponatremia (Beck, 2007) and inappropriate fluid management occurs (Friedman & Ray, 2007), further research is indicated to determine the appropriate recommendation. Dextrose also must be considered, because in children with gastroenteritis and dehydration, larger amounts of IV dextrose administration were associated with fewer return visits requiring admission (Levy & Bachur, 2007). Clinical judgment considering the child's situation is required to prescribe the correct fluid.

CLINICAL JUDGMENT 17-2

A Dehydrated Infant

Ten-day-old Dan is brought to the clinic by his mother. She states that he is sleeping a lot, feeding poorly, and is very fussy when he is awake. The nurse's physical assessment findings include heart rate, 160 beats per minute; respiratory rate, 60 breaths per minute; capillary refill, 2 seconds; skin and mucous membranes, dry; abdominal skin remains raised for 2 seconds after being pinched; fontanel, sunken; weight, 3.5 kg.

Questions

1. What questions should the nurse ask the mother?
2. What signs and symptoms indicate dehydration?
3. What is the problem? How severe is it?
4. What interventions should be implemented?
5. What follow-up is appropriate?

Answers

1. How many wet diapers has the baby had in the past 24 hours? (three) How much stool? (no change in stooling patterns, about three per 24 hours) Any fever? (no) Is the baby breast- or bottle-fed? If bottle-fed, what type and how is formula prepared? For any feeding method, how often does the baby eat? How much? (Dan is breast-fed three to four times in 24 hours, 10 minutes each side is attempted; he latches intermittently during feeding; mother complains of sore, cracked, bleeding nipples) What did the baby weigh at birth? (3.8 kg)
2. Three wet diapers during the past 24 hours (normal is six to eight); increased heart rate, respiratory rate, delayed capillary refill, dry skin and mucous membranes, poor skin turgor, sunken fontanel, and behavior changes; only three to four feedings per 24 hours (normally, should nurse 10 to 12 times in 24 hours)
3. Dehydration secondary to poor feeding. Dan has lost 0.3 kg since birth. He is moderately dehydrated.
 $3.5 \div 3.8 = 0.92 = 92\%$ of birth weight = 8% weight (fluid) loss

- Dan's poor latch during breast-feeding is the major contributing factor to mother's sore, dry, cracked nipples. Candidiasis of the breast can also lead to nipple cracking, redness, and discomfort, but this possibility was ruled out.
4. The dehydration must be addressed while supporting continued breast-feeding, if possible. Assist mother to comfortable breast-feeding position, then in latching Dan to breast. Observe for deep latch, suck, and swallow. Teach mother to evaluate appropriate latch (Dan is fish-mouthed, she can see and hear Dan swallow, she does not have breast pain after initial latch). Review breast-feeding techniques with mother. Instruct mother to breast-feed every 2 to 3 hours around the clock; supplement with formula as needed. Teach mother how to manually express milk. Manual expression can assist in achieving good latch if breasts are engorged, give reassurance that mother has plenty of milk for the baby, and expressed milk can be used as a nipple and areolar lubricant and protectant. The antibodies in breast milk can assist in healing any cracks, prevent infection, and soothe any sensitivity. Also educate mother on use of lanolin on nipples as a soothing and protective agent. Instruct parents to call healthcare provider if Dan does not have six to eight wet diapers in 24 hours, if lethargy increases, or if he does not eat well (if he breast-feeds poorly and then refuses supplemental formula).
 5. Return to clinic tomorrow to ensure Dan has sufficient intake, as evidenced by weight gain, voiding six to eight times in 24 hours, normal vital signs and capillary refill, good skin turgor, moist mucous membranes, and decreased fussiness and sleepiness. Observe feeding technique; refer to lactation consultant if problems with breast-feeding continue.

dehydration (Clinical Judgment 17-2). Assess cardiac output by measuring blood pressure with the child in both the upright and supine positions. Lower blood pressure in the upright position may indicate a decrease in ECF volume. The nurse can expect the child to exhibit tachycardia as a compensatory measure to maintain cardiac output in the presence of decreased vascular volume. Assess temperature; increased body temperatures can lead

to increased respiratory rate and a resulting increase in metabolic needs. This process can increase insensible fluid loss through skin and lungs. Administer antipyretics as ordered. Weigh daily and monitor trends.

ANSWER: Cory is NPO for surgery. His fluids will have to be administered intravenously.

Community Care

Oral fluid replacement therapy is commonly provided in the home care setting. Commercial oral solutions (e.g., World Health Organization oral rehydration salts, Rehydralyte, Pedialyte, Infalyte) contain water, electrolytes, bicarbonate or citrate, and glucose. Glucose is necessary to facilitate transport of sodium and water across the bowel wall.

WORLDVIEW: Oral rehydration therapy is commonly used, particularly in developing countries, to treat diarrheal dehydration. Oral rehydration therapy is simpler to implement than IV rehydration and effectively treats dehydration (Hartling et al., 2006). In developed countries, IV therapy is still commonly used to treat dehydration, probably because it is readily available, and established care patterns are difficult to change.

Oral rehydration should be given frequently and in small amounts (TIP 17–2). When educating parents, provide detailed, specific information about the type of fluids to give, how much to give, and how long to continue rehydration therapy.

Edema

Fluid movement between the vascular and interstitial compartment is regulated by hydrostatic pressure and osmotic pressure (see [thePoint](#) for Supplemental Information: Physical Factors That Affect Fluid Balance). Edema—abnormal accumulation of fluid in the interstitial tissues—results from an imbalance in the physiologic forces that regulate fluid movement. This imbalance either causes excess fluid to enter the interstitial fluid compartment or causes excess fluid to remain in this compartment. *Filtration* (movement of fluid across a semipermeable membrane) occurs across capillary beds and also influences the movement of fluid into the interstitium. Hypoproteinemia (low serum protein level), for instance, decreases oncotic pressure in the capillaries. Thus, because of osmotic pressure, fluid shifts out of the vascular bed and into the interstitial space, resulting in edema. In another example, increased fluid in the blood vessels causes vascular congestion. As a result, fluid leaks from the vessels, across the capillary membrane, and into the interstitial space, causing edema. Edema can be local or generalized throughout the body. Severe edema in all body tissues is known as *anasarca*.

Various conditions, such as renal dysfunction (which influences sodium reabsorption and retention), liver disease (which often causes hypoproteinemia), cerebral edema, and steroid administration, influence the formation of edema. Managing each of these conditions is more difficult in a child with coexisting cardiovascular disease, because the compensatory mechanisms by which the body might respond (sympathetic nervous system activa-

tion, activation of the renin–angiotensin–aldosterone system, and ventricular hypertrophy) may already be activated to manage the cardiovascular disease.

Assessment

Excess fluid in the ECF compartment can be detected through a rapid gain in body weight. Parents may be the first to note the child's unusual weight gain by observing that his or her clothes suddenly do not fit. Weigh the child.

caREminder

One kilogram of body weight equals the weight of 1 L of water; thus, the amount of fluid gain or loss can be calculated from weight gain or loss.

Assess for edema, which in a child usually occurs first in dependent areas (the sacrum, ankles, and feet) or in the periorbital area. Assess for other physical signs of edema, which include a bounding pulse and hepatomegaly (enlarged liver). In the presence of respiratory distress, crackles can be heard on auscultation of the lungs. Distended neck veins may be visible in an older child assessed in a spine or semi-Fowler position.

Nursing Diagnoses and Outcomes

In addition to those presented in Nursing Plan of Care 17–1, the following nursing diagnoses and outcomes may apply to the child with edema:

Excess fluid volume related to effects of disease process or treatment, inability to excrete fluid, or osmolality imbalance

Outcomes: Child will not experience respiratory distress, as evidenced by normal respiratory rate, absence of retractions or nasal flaring, and no cyanosis of nail beds and mucous membranes.

Child will maintain baseline weight, without rapid gain from fluid excess, and will demonstrate slow, long-term weight gain along his or her growth curve.

Risk for impaired skin integrity related to friable skin

Outcomes: Child's skin will remain intact, without any evidence of breakdown.

Interventions will be implemented to prevent tissue breakdown at pressure sites and dependent areas.

Impaired physical mobility related to restriction of normal range of motion

Outcomes: Child will maintain maximum range of motion while edema is present.

Child will remain as independent as possible within the limits set by the edema.

Disturbed body image related to perception of the edema

Outcomes: Child will verbalize acceptance of his or her physical appearance.

TIP 17-2 A Teaching Intervention Plan for Home Management of the Dehydrated Child

Nursing diagnoses and outcomes

Deficient fluid volume related to effects of increased fluid losses or needs or of decreased intake

Outcomes

- Child will maintain vascular volume, as evidenced by normal heart rate and blood pressure.
- Child's urine output will be at least 1 mL/kg/hour.
- Deficient knowledge: Management of dehydration

Outcome

- Child's parents will verbalize understanding of how to treat episodes of vomiting and diarrhea and state methods to manage fluid loss at home.

Teach the child/family

Detection, prevention, and management of dehydration

- Signs of dehydration (decreased urine output, dry mucous membranes, lack of tears, sunken eyeballs or fontanel, change in level of consciousness)
- *Not* to use boiled skim milk or other concentrated solutions, because they contain too much salt
- *Not* to use home remedies (uncarbonated soda, Jell-O, fruit juice, tea), because they usually have low sodium concentrations, which can cause hyponatremia, and have inappropriately high osmolality from excessive carbohydrates, which can exacerbate diarrhea
- Proper methods of preparing infant formula; not to overdilute formula to make more
- The importance of good handwashing technique, particularly in the presence of infectious diseases
- Components of
 - Oral rehydration therapy (ORT) to replace existing losses
 - Maintenance therapy to replace continuing losses after ORT is completed; ways to combine with adequate dietary intake

Amount of Oral Rehydrating Solution to Give

- ORT: 75 mL/kg over 4 hours
- Offer a teaspoonful every 1 to 2 minutes. If vomiting occurs, wait 5 to 10 minutes then give a teaspoonful every 2 to 3 minutes. Continue to repeat unless emesis consistently occurs in an amount that exceeds the intake.
- If the child wants more solution and exhibits no signs of overhydration, give more.
- Increase the amount of solution given if diarrhea or symptoms of dehydration continue.
- Decrease the amount of solution if the child appears well hydrated or periorbital edema develops.
- Continue breast-feeding throughout ORT and illness.
- For nonbreast-feeding or older children, oral feedings should be resumed as soon as possible after initial rehydration.
- Stop giving ORT when hydration is normal.
- Maintenance therapy: Give the child as much fluid as he or she wants. A after each diarrheal stool or emesis, give
 - Younger than age 2 years: 50 to 100 mL fluid
 - Age 2 to 10 years: 100 to 200 mL fluid
 - Older children: As much fluid as they want

Contact Healthcare Provider if:

- The amount or frequency of vomiting or diarrhea is increasing
- Diarrhea or vomiting does not improve after 24 hours of treatment
- Child appears worse (decreased level of consciousness, decreasing urine output, dizziness when upright, increased fever, seizures)
- Child's fluid status does not improve (no urine output within 8 hours, tongue and cheeks do not become moist, no tears with crying)
- Child refuses to eat or is unable to ingest more solution than is vomited

Data from World Health Organization (2005).

Child will continue to have social interactions with peers, consistent with his or her age and developmental milestones.

Deficient knowledge: Care of the child with edema

Outcomes: Child and parents will demonstrate an understanding of causes of edema and of the need for any tests and procedures.

The parents will provide care to their child, including appropriate nutrition and measures to prevent sequelae of edema such as skin breakdown.

The child will provide self-care, as appropriate.

Interdisciplinary Interventions

Interventions for the child with edema focus on determining and treating the underlying cause. Diuretics may be administered to promote renal excretion of water and sodium, and to help remove excess fluid. Diuretics are indicated in children with pulmonary edema, increased cerebral edema, generalized edema, hypertension, or renal dysfunction. If a potassium-wasting diuretic is administered, carefully monitor serum potassium levels.

Nursing care of the child with severe edema requires strict and accurate monitoring of intake and output. Note discrepancies between intake and output and discuss them with the healthcare team. Weigh the child each day, at the same time of day, on the same scale, and with the child wearing the same amount of clothing.

caREminder

Compare daily weight with previous measurements and note trends. If a substantial weight gain occurs, assess the child for other signs of fluid retention, such as rales or periorbital or dependent edema.

Protect edematous tissue, which is easily injured. Regularly change the position of a child with limited mobility. Use low-pressure mattresses and other devices that help reduce the pressure on dependent areas when needed. Elevating areas of localized edema promotes increased venous and lymphatic drainage of interstitial fluid. Keep the child's skin clean and dry and inspect all pressure areas for signs of breakdown at least daily.

Ensuring appropriate nutritional intake can be a challenge in the child who must receive a minimal amount of fluids but has high caloric needs. Record daily calorie counts. A dietitian can help devise meal plans that provide all necessary nutrients and are appealing to the child.

Community Care

The nurse, child life specialist, social worker, and parent can help the child deal with any distortions of his or her normal body image. Body image can be a major issue to the child or adolescent with severe edema. Include on-site school personnel and the child's regular teacher in the plan of care. They may be able to provide routine, normalizing experiences for the child.

Teach parents and siblings, as appropriate, about disease management, administration of medications and side effects, skin care, positioning, and promoting appropriate nutritional intake.

ACID–BASE IMBALANCES

Regulation and maintenance of acid–base balance in body fluids is essential to the action of hormones, enzymes, and all basic physiologic functions. Normal acid–base balance is maintained through the interaction of a complex system of buffers, respiratory compensation, and the metabolic component of kidney function. When an alteration occurs, the body mobilizes these physiologic mechanisms to restore normal acid–base balance.

A buffer is a weak acid. It can facilitate a change in the pH of the blood when a stronger acid or a base is added. The body's most effective buffer is the bicarbonate–

carbonic acid system. Other effective buffers include proteins, hemoglobin, and phosphates.

In normal metabolism, all cells produce carbonic acid (H_2CO_3) and metabolic acids. Carbonic acid is excreted by the lungs in the form of carbon dioxide. Metabolic acids are excreted through the kidneys. The effectiveness of the bicarbonate and carbonic acid buffering systems can be measured in the arterial blood gas values of pH, carbon dioxide, and bicarbonate (HCO_3^- ; see Tests and Procedures 16–2 for more information on these values).

Alterations in acid–base homeostasis are classified as either metabolic or respiratory, based on their cause. The imbalance is termed *respiratory* when it is primarily caused by a change in the partial pressure of carbon dioxide in arterial blood (PaCO_2); imbalances resulting from all other primary changes are classified as *metabolic*. An abnormally low pH is called *acidosis*, or *acidemia*. An abnormally high pH is termed *alkalosis*, or *alkalemia*. Severe acidosis (pH <7.0) and severe alkalosis (pH >7.55 with a HCO_3^- level >28 mEq/L) are life threatening if not corrected.

Respiratory compensation can be affected within minutes by any change in respiratory pattern. Any clinical condition that affects the respiratory system can also affect respiratory compensation. If a child's respiratory rate is too slow or too shallow, carbon dioxide will increase, serum pH can decrease, and acidosis may occur. If a child's respiratory rate is too rapid, carbon dioxide will decrease, serum pH may increase, and alkalosis can occur.

The renal system regulates the excretion of hydrogen ions and HCO_3^- . This compensatory mechanism is a slow, long-term response that can take days to restore acid–base balance. Urine pH can be valuable in determining whether the renal compensatory mechanism is functioning. In metabolic acidosis, urine pH less than 6.0 indicates that the renal system is reabsorbing HCO_3^- and excreting hydrogen ions, and thus compensation is occurring. Renal compensatory mechanisms to correct acidosis help protect the cells but do not change the underlying cause of the disorder.

Acid–base disorders are common in children. The causes are varied and cover a wide range of clinical conditions and exogenous pathologic processes (see Table 17–2). Arterial blood gas and serum electrolyte values are used to diagnose the imbalance's origin (metabolic or respiratory) and devise a plan of care.

Interdisciplinary Interventions

The goal of treatment for a child with an acid–base disorder is to correct the primary cause, for example by administering insulin and fluid to a child with diabetic ketoacidosis. Most children who are acidotic and who have adequate circulation, renal function, and pulmonary function can be managed by treating the underlying cause of the acid–base imbalance. Many do not require alkali therapy such as with sodium bicarbonate.

TABLE 17-2

Acid–Base Imbalances

	Respiratory Acidosis	Respiratory Alkalosis	Metabolic Acidosis	Metabolic Alkalosis
Imbalance	Carbonic acid excess; CO ₂ is retained and pH decreases	Carbonic acid deficit; not enough CO ₂ is retained, and pH increases	Bicarbonate deficit	Bicarbonate excess
Causes	<p>Events that depress the respiratory drive or interfere with ventilation:</p> <ul style="list-style-type: none"> • Pulmonary diseases (e.g., pneumonia, asthma) • Central nervous system disorders that affect the neuromuscular system (e.g., muscular dystrophy, Guillain-Barré syndrome, tumors, botulism) • Ingestion of substances (e.g., opiates, barbiturates, alcohol) 	<p>Events that can cause hyperventilation:</p> <ul style="list-style-type: none"> • Hypoxia • Sepsis • Fever • Anxiety • Ingestions • Pulmonary disease (e.g., pneumonia, chronic lung disease) • Mechanical overventilation 	<p>Loss of base from ECF via renal or intestinal loss or gain of acid by ECF:</p> <ul style="list-style-type: none"> • Hypovolemia • Diabetes • Congenital heart disease • Sepsis • Cold stress • Inborn errors of metabolism 	<p>Hydrogen ion loss or HCO₃ retention:</p> <ul style="list-style-type: none"> • Vomiting or NG suctioning • Administration of sodium bicarbonate • Massive blood transfusion • Milk–alkali syndrome (chronic ingestion of milk and antacids containing calcium carbonate)
Signs to assess for	<p>Respiratory distress</p> <p>Central nervous system depression: disorientation, coma</p> <p>Hypoxia: restlessness, irritability, tachycardia, arrhythmias</p> <p>Muscle weakness</p>	<p>Dizziness</p> <p>Numbness and paresthesias of fingers and toes</p> <p>Tetany</p> <p>Convulsions</p> <p>Unconsciousness</p>	<p>Deep, rapid breathing (Kussmaul respirations)</p> <p>Shortness of breath on exertion</p> <p>Weakness</p> <p>Drowsiness, stupor</p> <p>When pH is <7.2, cardiac contractility is reduced; thus blood pressure decreases, dysrhythmias occur, cardiovascular collapse typically follows</p>	<p>May be asymptomatic or show signs similar to those of dehydration</p> <p>Tachycardia</p> <p>Hypoventilation</p> <p>Muscle hypertonicity or tetany (alkalosis decreases blood levels of ionized calcium), progressing to convulsions</p> <p>Confusion, irritability, coma</p>
Treatment	<p>Correct underlying problem.</p> <p>Administer oxygen; low flow only if carbon dioxide narcosis is present.</p> <p>Improve ventilation, increase aeration (position to facilitate ventilation, antibiotics for respiratory infections, chest physical therapy).</p> <p>Administer sodium bicarbonate.</p>	<p>Correct underlying problem.</p> <p>Do not overventilate; have child focus on slowing breathing, breathe into paper bag.</p>	<p>Correct underlying problem.</p> <p>Administer sodium bicarbonate.</p> <p>Provide low-protein, high-calorie diet</p> <p>Position to facilitate ventilation.</p>	<p>Correct underlying problem.</p> <p>Administer fluid containing sodium and potassium.</p> <p>Avoid antacids.</p>

Alert! It is imperative to correct any low blood pressure along with the acidosis. Together, they present a life-threatening situation. Complete collapse of the cardiovascular and respiratory systems may be imminent.

Nursing responsibilities include monitoring the child's status and adequacy of ventilation, including vital signs (heart rate and rhythm, respiration, blood pressure, and temperature). Maintain a clear airway and ensure adequate ventilation.

caREminder

Observe the child's work of breathing and auscultate the lungs. Assess for actual air movement along with respiratory effort. Assist the child with positioning for maximum ventilation and minimum effort by elevating the head of the bed and not letting the child slouch, which interferes with diaphragmatic excursion. Administer oxygen and perform suctioning, if necessary. Provide manual ventilation if the child's respiratory effort does not appear to be adequate.

If a child requires mechanical ventilation, the nurse and respiratory therapist must collaborate to evaluate ventilator settings frequently. One iatrogenic cause of respiratory alkalosis is overventilation. Frequently monitor the appropriateness of ventilator parameters, the adequacy of ventilation, and the child's response to any changes made. Compare vital signs with those obtained previously and observe for trends that indicate that the child's status is improving or deteriorating. A normal temperature should be the goal, because body temperature alterations (hypothermia and hyperthermia) increase metabolic demands and cause further deterioration of acid–base balance. Warm a child with hypothermia with blankets and an external warming source, if necessary. Provide a child with hyperthermia with a light or no bed-cover, and lower the room temperature, if possible. Antipyretics, such as acetaminophen and ibuprofen, may be ordered to decrease fever and thus decrease metabolic demands.

Monitor the child continuously for changes in level of consciousness. Closely monitor laboratory values, interpret the findings in light of the child's condition, and change the treatment regimen accordingly. Report significant changes or findings that do not fall within normal parameters for the child's age to the medical team.

Monitor intake and output. Parents and other family members who stay with the child can aid you in obtaining this information. The method of fluid administration depends on the child's physical condition, level of consciousness, and age. The physician or advance practice nurse will order IV therapy, if indicated.

Community Care

Reinforce safety issues (keeping poisons out of reach; providing appropriate, balanced intake) with children and parents. Teach the family how to manage conditions, such as vomiting and diarrhea, that cause dehydration and can lead to metabolic alkalosis or metabolic acidosis. In children with chronic conditions such as diabetes, maintain blood glucose within acceptable ranges and adhere to treatment regimen. Help the child to manage anxiety that may lead to respiratory alkalosis.

ELECTROLYTE IMBALANCES

The body maintains a delicate balance of electrolytes, all of which contribute to homeostasis and healthy functioning. Electrolyte imbalance has many causes. More than one electrolyte imbalance may occur simultaneously.

Assessing all electrolytes and addressing each imbalance is important to provide complete, comprehensive treatment (NIC 17–1).

QUESTION: After surgery, Cory returns with an NG tube placed to decompress his stomach and remove gastric secretions. What are the two electrolytes that are affected by removing gastric secretions?

Sodium Imbalance

Sodium (Na) is the principal cation in ECF. Therefore, it exerts the greatest proportion of ECF osmolarity. Sodium influences distribution of body water and helps maintain acid–base balance and neuromuscular function.

Hyponatremia

Hyponatremia is defined as a serum sodium level less than 130 mEq/L. Clinical symptoms are more severe with a level less than 120 mEq/L.

A variety of situations can cause hyponatremia that result in either a net sodium loss or net water excess. Net sodium loss can result from increased gastrointestinal output such as diarrhea, vomiting, NG suction (a major cause of hyponatremia in children), diuretic therapy, excessive diaphoresis, and kidney disease. Net water excess can be caused by dilutional hyponatremia or sodium deprivation that results from increased water intake with decreased sodium intake, administration of hypotonic IV solutions, administration of excessively diluted formulas, or syndrome of inappropriate antidiuretic hormone secretion (see Chapter 26).

Important factors in the development of symptoms include the rate at which the sodium level declines and the duration of the low level. Severe hyponatremia that occurs rapidly over a few hours is called *water intoxication*. Neurologic consequences result from a too-rapid change in sodium balance, which causes massive fluid shifts into the cerebral space. The cranium of a child with a closed fontanel is a fixed space. Normal cerebral contents (brain, cerebrospinal fluid, blood) occupy part of that space. Shifting of excess fluid into the cerebral compartment causes cerebral edema, which can produce seizures, coma, respiratory arrest, and brain damage (see NIC 17–1).

Interdisciplinary Interventions

Treatment of hyponatremia depends on the cause. The goal is to raise the serum sodium level in a slow and controlled manner and then maintain within normal limits.

caREminder

Hyponatremia can be prevented in the child receiving IV fluids by not infusing hypotonic solutions unless their use is indicated by a documented elevated serum sodium level.

NIC 17–1 Nursing Interventions Classification: Electrolyte Monitoring

Definition: Management of the patient with urinary drainage equipment

Activities:

Monitor the serum level of electrolytes
 Monitor serum albumin and total protein levels, as indicated
 Monitor for associated acid–base imbalances
 Identify possible causes of electrolyte imbalances
 Recognize and report presence of electrolyte imbalances
 Monitor for fluid loss and associated loss of electrolytes, as appropriate
 Monitor for Chvostek’s and/or Trousseau’s sign
 Monitor for neurologic manifestation of electrolyte imbalance (e.g., altered sensorium and weakness)
 Monitor adequacy of ventilation
 Monitor serum and urine osmolality levels
 Monitor ECG tracings for changes related to abnormal potassium, calcium, and magnesium levels
 Note changes in peripheral sensation, such as numbness and tremors
 Note muscle strength
 Monitor for nausea, vomiting, and diarrhea
 Identify treatments that can alter electrolyte status, such as gastrointestinal suctioning, diuretics, antihypertensives, and calcium channel blockers
 Monitor for underlying medical disease that can lead to electrolyte imbalance
 Monitor for signs and symptoms of hypokalemia: muscular weakness, cardiac irregularities (PVC), prolonged QT interval, flattened or depressed T wave, depressed ST segment, presence of U wave, fatigue, paresthesia, decreased reflexes, anorexia, constipation, decreased gastrointestinal motility, dizziness, confusion, increased sensitivity to digitalis, and depressed respirations
 Monitor for signs/symptoms of hyperkalemia: irritability, restlessness, anxiety, nausea, vomiting, abdominal cramps, weakness, flaccid paralysis, circumoral numbness and tingling, tachycardia progressing to bradycardia, ventricular tachycardia/fibrillation, tall and peaked T waves, flattened P wave, broad and slurred QRS complex, and heart block progressing to asystole
 Monitor for signs/symptoms of hyponatremia: disorientation, muscle twitching, nausea and vomiting, abdominal cramps, headaches, personality changes, seizures, lethargy, fatigue, withdrawal, and coma
 Monitor for signs and symptoms of hypernatremia: extreme thirst; fever; dry, sticky mucous membranes; tachycardia, hypotension, lethargy, confusion, altered mentation; and seizures

Monitor for signs and symptoms of hypocalcemia: irritability, muscle tetany, Chvostek’s sign (facial muscle spasm), Trousseau’s sign (carpal spasm), peripheral numbness and tingling, muscle cramps, decreased cardiac output, prolonged ST segment and QT interval, bleeding, and fractures

Monitor for signs and symptoms of hypercalcemia: deep bone pain, excessive thirst, anorexia, lethargy, weakened muscles, shortened QT segment, wide T wave, widened QRS complex, and prolonged PR interval

Monitor for signs and symptoms of hypomagnesemia: respiratory muscle depression, mental apathy, Chvostek’s sign (facial muscle spasm), Trousseau’s sign (carpal spasm), confusion, facial tics, spasticity, and cardiac dysrhythmias

Monitor for signs and symptoms of hypermagnesemia: muscle weakness, inability to swallow, hyporeflexia, hypotension, bradycardia, central nervous system depression, respiratory depression, lethargy, coma, and depression

Monitor for signs and symptoms of hypophosphatemia: bleeding tendencies, muscular weakness, paresthesia, hemolytic anemia, depressed white cell function, nausea, vomiting, anorexia, and bone demineralization

Monitor for signs and symptoms of hyperphosphatemia: tachycardia, nausea, diarrhea, abdominal cramps, muscle weakness, flaccid paralysis, and increased reflexes

Monitor for signs and symptoms of hypochloremia: hyperirritability, tetany, muscular excitability, slow respirations, and hypotension

Monitor for signs and symptoms of hyperchloremia: weakness; lethargy; deep, rapid breathing; and coma
 Administer prescribed supplemental electrolytes, as appropriate

Provide diet appropriate for patient’s electrolyte imbalance (e.g., potassium-rich foods or low-sodium diet)

Teach patient ways to prevent or minimize electrolyte imbalance

Instruct patient and/or family on specific dietary modifications, as appropriate

Consult physician, if signs and symptoms of fluid and/or electrolyte imbalance persist or worsen

From Bulechek, G. M., Butcher, H. K., & Dochterman, J. M. (2008). *Nursing interventions classification (NIC)* (5th ed.). St. Louis, MO: Mosby. Reprinted with permission.

When a net loss of sodium and body water is present, oral or IV sodium and fluid replacement may be ordered. Nursing assessments and interventions are similar to those for preventing or treating hypovolemic shock in children with hyponatremic dehydration. When a net water excess is present, treatment is directed toward reducing the ECF and ICF excess. Measures may involve restricting water intake or diuretic therapy. Nursing care is similar to that for the child with fluid overload and edema.

The nurse is responsible for implementing treatment, monitoring the child's response, and providing child and family teaching. Monitor and document the child's intake, output, and fluid balance.

Community Care

If hyponatremia is caused by excessive oral fluid intake, either directly or through diluted formula, assessing the family's socioeconomic status is important. Parents experiencing financial hardship may dilute formula to make it last longer. They may not understand that prolonged feeding with overdiluted formula can harm their child. Provide education on formula preparation and delivery. Dietitians and social service case workers can also provide valuable assistance and resources to families in need.

Hypernatremia

Hypernatremia is a serum sodium level exceeding 150 mEq/L. The most severe clinical manifestations of hypernatremia occur when the serum sodium level exceeds 160 mEq/L.

Hypernatremia results from insufficient fluid intake or excessive fluid loss, or from excessive salt intake or insufficient sodium excretion. This may be caused by an altered thirst mechanism or an inability to respond to thirst (as may occur in infants and disabled or comatose children), increased insensible water loss, increased gastrointestinal output, excessive solute intake (e.g., from incorrectly diluted formulas, boiled skim milk), renal immaturity (e.g., in premature infants), or such disorders as diabetes insipidus or renal medullary impairment.

Children with hypernatremia are almost always dehydrated (Finberg et al., 1993). Cellular dehydration results when water shifts out of the ICF, pulled by the now hyperosmolar ECF. Children with hypernatremia often do not have circulatory disturbances, because of the relative increase in vascular volume that occurs as fluid is pulled from the ICF into the ECF. Neurologic manifestations result when cerebral vessels shrink and tear as cellular dehydration occurs. The outcome is often a cerebral hemorrhage. Assess for neurologic signs in children with hypernatremia that may include lethargy, with irritability on stimulation, and a high-pitched cry. Irritability may be a worrisome clinical sign, possibly indicating a cerebrovascular injury.

Interdisciplinary Interventions

The primary goals in treating hypernatremia are to bring the serum sodium level down to normal and to restore

adequate hydration gradually, allowing the child's body to adjust to these changes. A too-rapid change in sodium level can disrupt the cell membranes in the cerebral vessels, possibly causing cerebral hemorrhage. If fluid is replaced too rapidly, water quickly crosses into brain cells (sodium levels decrease more slowly because of the blood-brain barrier), causing swelling of the brain cells and increased intracranial pressure (see Chapter 21). To reduce the risk of increased intracranial pressure, replacement of fluid deficit in hypernatremia is done over at least 48 hours. Fluid boluses of 20 mg/kg or more may be administered to a child in shock, however (see Chapter 31).

After fluid replacement therapy is initiated, the focus shifts to determining and treating the underlying cause of hypernatremia. Obtain a complete history to help evaluate the onset of clinical symptoms including the child's normal weight and a dietary history, including the amount and types of intake and output. Record the child's daily weight and compare it with previous weights to monitor fluid balance. Monitor laboratory data and report any clinically meaningful findings to the physician or advanced practice nurse. Other nursing responsibilities may include administering prescribed IV fluids with the appropriate sodium content. If the child has altered level of consciousness, position the child upright or on his or her side to enable adequate ventilation and to decrease the risk of aspiration.

A nutrition consultation can help provide the optimum electrolyte concentration and the maximum calories for the prescribed volume of fluid intake, whether administered orally or intravenously.

Community Care

Teach children and parents to maintain adequate fluid intake, particularly when children have excessive losses, as when sick (e.g., vomiting, diarrhea, fever) or in high environmental temperatures. Also educate parents to avoid excessive solute administration (e.g., dilute formula properly; do not give boiled skim milk).

Potassium Imbalance

The primary intracellular ion, potassium (K^+), plays a major role in neuromuscular excitability. The ratio of intracellular potassium to extracellular potassium is a major determinant of cell membrane resting potential. Potassium also participates in cell metabolism through its action in protein and glycogen synthesis. Potassium is absorbed from the intestines and excreted in urine, feces, and sweat.

Blood pH affects serum potassium levels. When acidosis occurs, hydrogen ions (H^+) increase in number and are distributed equally in body compartments. To maintain electroneutrality, as H^+ moves into the cell, K^+ moves out of the cell. The result is an elevated serum potassium level with a concomitant decrease in serum pH. With alkalosis, this shift is reversed, and changes in potassium levels are less pronounced.

caREminder

If acidosis persists, total body potassium may be depleted even though the serum potassium level is elevated, because potassium is moving out of the ICF, where it is most abundant.

Hypokalemia

Hypokalemia, defined as a serum potassium level less than 3.5 mEq/L, may be caused by inadequate potassium intake and excessive renal potassium loss, as often occurs in a child receiving diuretic therapy (many diuretics promote increased potassium excretion in the distal tubule of the kidney). In diabetes, hyperglycemia typically produces an osmotic diuresis and high urine output, resulting in potassium loss. Because the hyperglycemic child is acidotic, serum potassium levels may not decrease to reflect the total body deficit of potassium until the acidosis starts to resolve. Gastrointestinal potassium losses occur through vomiting and diarrhea. Integumentary loss of potassium occurring in sweat and burns may also occur.

Clinical manifestations of hypokalemia include general muscle dysfunction and dysrhythmias (see NIC 17–1).

Interdisciplinary Interventions

When the potassium level falls below normal values, oral or IV potassium replacement is needed to restore and maintain adequate intracellular potassium concentrations. The route and rate of potassium replacement depends on the child's serum potassium concentration and renal function. Moderate to severe hypokalemia may be treated with potassium supplements, administered either orally or IV.

Alert! Before administering a potassium supplement, ensure that the child is producing urine, which demonstrates renal function. Because potassium is excreted through the kidneys, if renal function is inadequate, potassium readily accumulates. This can lead to ventricular dysrhythmias and cardiac arrest.

Mild hypokalemia can often be resolved with dietary modifications. A dietitian can help the child and family increase potassium content in their diet based on the child's preferences and the family's resources and finances. For instance, salt substitutes that contain potassium can provide a low-cost potassium source. Involve social services to help low-income or at-risk families identify and use community resources.

Nursing responsibilities include ongoing assessment. Because potassium influences cell membrane excitability, muscle weakness or dysfunction is often apparent. Observe the child's activity level to evaluate generalized weakness and determine whether it is progressive. If the child is receiving a potassium-wasting diuretic or has other risk factors for hypokalemia, ask whether he or she is tired ("Can you do the things you normally do?"), or ask the parents about the child's activity level. Instruct the child to tell the parent or caregiver if he or she feels tired or otherwise "different."

Also assess respiratory effort, cardiac function, and the presence or absence of bowel sounds. Report signs of compromise to the healthcare team. Position the child with the head of the bed elevated to optimize respiratory effort and provide manual ventilation as needed. Withhold feedings when bowel sounds are absent.

Assess the child receiving digoxin therapy for signs of digoxin toxicity, because hypokalemia potentiates digoxin.

Community Care

Teach the child and parents how to administer prescribed medications and monitor for their side effects, and how to avoid potentially dangerous drug interactions. For example, if the child is taking a potassium-wasting diuretic and a potassium supplement, the family needs to remind the healthcare provider of this regimen when changing medication (hyperkalemia can occur if the diuretic is discontinued but not the potassium supplement). Discuss with the family the benefit of obtaining all prescriptions from one pharmacy, or at least informing the pharmacist of other medications or food supplements that the child is receiving. Often the pharmacist monitors for potential drug interactions and alerts the prescriber and family if any are noted.

If the family's financial status or access to medications is an issue, they can request that the prescriber order a commercial salt substitute (KCl) rather than a more costly pharmaceutical preparation.

Hyperkalemia

A serum potassium level more than 5.0 mEq/L can result from various conditions. Dehydration or renal disease can impair renal excretion of potassium. Because potassium is the primary intracellular ion, damage to cells or the cell membrane (as occurs in crush injuries and burns, for instance) releases potassium from the cells into the ECF. This process may also occur with transfusion of stored blood, when old, damaged red blood cells release their intracellular potassium.

Clinical manifestations of hyperkalemia vary with the severity of the imbalance (see NIC 17–1). The most serious manifestations are cardiovascular changes. Severe hyperkalemia is a life-threatening emergency that requires immediate treatment.

Alert! Severe dysrhythmias and cardiac arrest may result when potassium levels rise above 6.0 mEq/L.

Interdisciplinary Interventions

Treatment of hyperkalemia must be initiated promptly to prevent serious physiologic effects. Several measures can lower a dangerously high potassium level (Nursing Interventions 17–2). During treatment, assess for rebound hypokalemia that may result.

Continuously monitor electrocardiogram (ECG) waveforms for dysrhythmias. Assess vital signs, including heart rate, heart rhythm, and blood pressure, and intervene to

NURSING INTERVENTIONS 17–2

Management of Hyperkalemia*

Medical Treatment Option	Nursing Intervention
<p>Create Chemical Antagonism to the Membrane Effects of Potassium</p> <p>Administer calcium gluconate 10% IV to temporarily stabilize the cell membrane.</p>	<p>Ensure that IV is not infiltrated; monitor IV closely before and during infusion, because calcium extravasation causes severe tissue necrosis.</p> <p>Administer calcium slowly, as ordered.</p> <p>Monitor ECG during infusion; report ECG changes, bradycardia immediately.</p> <p>If child is receiving digoxin, administer calcium slowly while monitoring for signs of digoxin toxicity, because hypercalcemia potentiates digoxin toxicity.</p> <p>Monitor effectiveness of therapy (decrease in signs of hyperkalemia) and for return of negative effects resulting from hyperkalemia, because effects of calcium are effective within minutes but are short-lived.</p>
<p>Expand the ECT Volume</p> <p>Decrease, by dilution, the extracellular potassium concentration.</p>	<p>Administer IV fluid as ordered.</p> <p>Monitor for change in signs of hyperkalemia that indicate effectiveness of therapy.</p> <p>Monitor for signs of fluid overload.</p> <p>Calculate fluid balance and intake and output.</p>
<p>Increase Cellular Uptake of Potassium</p> <p>Administer insulin IV, which facilitates cellular potassium uptake; glucose is usually administered with insulin to prevent hypoglycemia.</p> <p>In the presence of metabolic acidosis, administer sodium bicarbonate to normalize pH and reverse the shifting of potassium out of the cell that occurs with acidosis.</p>	<p>Administer insulin and glucose as ordered.</p> <p>Monitor for signs of hypoglycemia.</p> <p>Monitor for changes in potassium levels; effects usually occur in 30 minutes and last several hours.</p> <p>Administer sodium bicarbonate as ordered.</p> <p>Monitor for return of hyperkalemia because effects may only last 1 to 2 hours.</p>
<p>Remove Potassium From the Body</p> <p>Administer potassium-wasting diuretics (e.g., furosemide) to increase renal excretion of potassium.</p> <p>Administer a cation exchange resin (e.g., Kayexalate) that exchanges 1 mEq potassium for 1 mEq sodium; it is usually administered in a suspension with sorbitol.</p>	<p>Administer diuretic as ordered.</p> <p>Monitor urine output.</p> <p>Monitor for signs of dehydration.</p> <p>Evaluate effectiveness of therapy based on clinical changes.</p> <p>Administer via NG tube or by enema as ordered.</p> <p>Maximize effect of enema by having the child retain it for 2 to 3 hours.</p> <p>Monitor for signs of dehydration because sorbitol creates an osmotic load that pulls water into the gut.</p> <p>Monitor for change in potassium levels, which show a maximal decrease in 3 to 4 hours (other treatment options are usually used as interim measures to decrease the cardiotoxic effects of excess potassium, while waiting for removal techniques to have an effect).</p> <p>Monitor serum sodium and potassium levels.</p> <p>Monitor for fluid overload and hypernatremia resulting from sodium-exchanging properties of resin.</p> <p>Prepare child for dialysis as appropriate.</p> <p>Implement interventions and monitoring as specific to type of dialysis.</p>
<p>Institute peritoneal dialysis or hemodialysis.</p>	

*Treatment choice is based on symptoms (e.g., dysrhythmias) rather than serum level.

support optimal cardiorespiratory function, as needed. Have emergency equipment readily accessible.

Monitor serum potassium levels. Collect blood specimens carefully, because a hemolyzed blood sample can result in falsely elevated potassium levels.

caREminder

To avoid blood cell hemolysis, warm an extremity if blood is being obtained by skin puncture. Do not excessively squeeze or milk an extremity to obtain blood. Use blood that flows easily from a skin puncture or vein, and do not use excessive pressure to force blood from the syringe into the specimen collecting device.

Monitor potassium intake by calculating intake of potassium from IV fluids, medications, and foods. Many foods contain potassium. Foods low in potassium include pears, apples, pineapple, rice, green beans, and salads without tomatoes.

Ensure adequate fluid intake to help increase output of potassium in urine. Potassium is excreted through the kidneys; therefore, monitor renal function through urine output volume and related laboratory values such as BUN and creatinine levels.

Monitor for hyperkalemia in a child receiving multiple blood transfusions or a child with renal dysfunction who requires blood administration. To help prevent this complication, the freshest blood available should be transfused.

Community Care

For the child with hyperkalemia resulting from a chronic medical condition, teach the family how to manage the child's condition at home. Include other members of the healthcare team, such as social service case workers and the dietitian, in designing the teaching plan for the family.

Instruct the child and family to avoid foods high in potassium and assist them to make dietary modifications that fit in with the family's lifestyle and dietary habits. Teach parents to keep potassium-containing salt substitutes away from children and to avoid their use in a child with renal problems.

Calcium Imbalance

Calcium is vital to cardiac, muscle, and nerve function, and helps maintain normal cell membrane permeability. It also plays a role in the secretion of certain hormones (e.g., parathyroid hormone, calcitriol, calcitonin) and the activation of some enzymes (e.g., insulin and glucagon). Circulating calcium concentrations are maintained by interactions of vitamin D metabolism, calcitonin, and parathyroid hormone. Parathyroid hormone helps regulate calcium concentration by stimulating reabsorption of calcium from bone and glomerular filtrate.

The largest calcium stores in the body are in the bones and teeth. This calcium is not readily available for use by

the body. A small amount of body calcium is found in the plasma as protein-bound calcium, bound to diffusible molecules such as phosphate and citrate, or as ionized calcium. The level of ionized calcium, the physiologically active form of calcium, is about half that of total calcium.

Serum calcium levels are affected by serum protein concentration, pH, and phosphorus. Because calcium binds to protein, hyperproteinemia may result in hypocalcemia. pH affects the physiologic availability of calcium. Acidosis causes hypercalcemia by decreasing calcium binding to serum proteins and increases the amount of calcium released from bone; alkalosis causes the opposite effect. Calcium and phosphorus normally have an inverse relation; when the level of one rises, the level of the other falls.

Hypocalcemia

Defined as a total calcium concentration less than 8.8 mEq/L, hypocalcemia can result from inadequate dietary intake, vitamin D deficiency, hyperalbuminemia, renal disease, or diuretic therapy. Transfusion of blood containing citrate as an anticoagulant, particularly large or rapid infusions, may cause hypocalcemia because the citrate binds with calcium and decreases the amount of available ionized calcium. In a newborn, ingestion of cow's milk, which is high in phosphate, may lead to hypocalcemia, because newborns have a relatively high rate of tubular phosphate absorption and a physiologically low glomerular filtration rate. Correcting acidosis may lead to hypocalcemia because, in an acidotic state, the calcium that moves out of the bones may be lost through urine output. Restoring normal pH causes calcium to reenter the bones, resulting in hypocalcemia.

Hypocalcemia causes increased cell membrane permeability. Thus, clinical manifestations are characterized by increased neuromuscular excitability, particularly affecting the neuromuscular and cardiovascular systems (see NIC 17–1); assess for these signs. The child may complain of numbness or tingling of the nose, ears, fingers, and toes. Laryngospasm may produce high-pitched inspiratory noises and may result in apnea. Severe hypocalcemia can cause seizures and cardiac arrest.

Interdisciplinary Interventions

Asymptomatic hypocalcemia can be treated with dietary modifications, involving increased intake of foods rich in calcium, such as dairy products, bony fish (e.g., sardines), and green leafy vegetables (see Table 20–1). Calcium supplements and vitamin D may be administered. Treatment of symptomatic hypocalcemia typically includes IV administration of calcium.

Alert! Before administering IV calcium, ensure that the IV is correctly placed with no signs of complications. Infiltration of calcium causes severe tissue necrosis. Administer IV calcium slowly, monitor the site closely, and monitor the ECG during infusion for QRS changes and bradycardia.

Maintain seizure precautions for a child with hypocalcemia. Ensure that emergency equipment to provide manual ventilation is readily available.

Community Care

Teach children and families which food sources are rich in calcium and encourage adequate intake of calcium and vitamin D. Ten to 15 minutes of sun exposure, without sunscreen, two to three times a week to the face, arms, or hands may also help satisfy vitamin D requirements. Instruct parents not to give cow's milk to young infants.

Hypercalcemia

Hypercalcemia is defined as a total calcium level exceeding 10.8 mEq/L. Causes include increased resorption of calcium from bone resulting from a malignancy (see Chapter 22), immobility, hyperparathyroidism, or hyperthyroidism; increased gastrointestinal absorption of calcium from excessive oral intake of calcium or vitamin D; and decreased excretion of calcium resulting from renal failure or diuretic therapy. Acidotic states also cause an increase in physiologically available calcium.

Hypercalcemia decreases cell membrane permeability, with a resultant decrease in neuromuscular excitability. High calcium levels may be asymptomatic, an incidental finding when other laboratory values are obtained. Hypercalcemia may also have a nonspecific presentation such as bone pain, fatigue, or polyuria and polydipsia (Finberg et al., 1993). Assess for ECG changes that may be present (see NIC 17-1). Assess deep tendon reflexes, which are usually hypoactive, with diminished muscle tone and strength. Renal calculi and renal failure, caused by the increased excretion of calcium in urine, or pathologic fractures may occur. Decreased motility in the gastrointestinal tract may cause abdominal pain, anorexia, nausea, and vomiting.

Interdisciplinary Interventions

Hypercalcemia is often an indication of an underlying disease that requires treatment. Severe hypercalcemia is treated with aggressive hydration with normal saline. Generous fluid administration helps maintain vascular volume in the presence of dehydration and promotes calcium excretion, which occurs through the kidneys. After ensuring adequate hydration, diuretics are often administered to further promote diuresis. Administration of phosphate binds the calcium and can rapidly lower serum calcium levels. Medications that decrease the absorption of calcium, such as calcitonin, glucocorticoids, and IV bisphosphonates (which inhibit bone resorption of calcium) may also be administered (Kerudo et al., 2005).

Nursing responsibilities include monitoring serum calcium levels and reporting any abnormal findings to the healthcare prescriber. Also assess neuromuscular and cardiac status (including ECG waveforms), maintain fluid balance, and provide parent teaching.

Monitoring fluid balance in hypercalcemia is important for several reasons. The child may be dehydrated on initial presentation or during the course of therapy, or administration of large fluid volumes may overload the vascular system. Moreover, two goals of treatment are to

promote urinary calcium excretion and prevent renal damage from the deposits of calcium salts. Thus, monitor intake and output, and evaluate fluid balance as often as indicated by the child's overall status (e.g., every hour, every 12 hours, or every 24 hours). Evaluate other indicators of fluid balance (e.g., blood pressure, presence of edema or signs of dehydration, rales when auscultating breath sounds) and implement interventions as indicated. If the child's blood pressure is low or unstable, diuretics should be used with caution.

Encourage mobilization to prevent the development of hypercalcemia caused by excessive resorption of calcium from the bones. If the child must be immobilized, ensure adequate fluid intake to prevent renal damage and handle the child gently when moving to avoid fractures.

Community Care

Education is an important component of family care, particularly when the primary cause of the hypercalcemia is a chronic condition. Teach the child and family signs and symptoms of calcium imbalance and instruct them to notify their healthcare provider if they occur. If medications are used to manage hypercalcemia, teach the child and family about administration, side effects, and potential interactions with other medications or food.

Include teaching about food sources of calcium and the degree to which these sources must be limited. A dietitian should be involved to help the family adapt dietary restrictions to their lifestyle. Because excessive intake of vitamin D can cause hypercalcemia, instruct parents to keep vitamin supplements out of children's reach and tell them about the hazards of excessive vitamin supplementation.

Magnesium Imbalance

Magnesium imbalance is less common than imbalances of other electrolytes, but it can be life threatening if severe. A neuromuscular depressant, magnesium is necessary for forming soft tissue and bone, and for maintaining normal cellular function and muscle and nerve activity. It is the second most abundant intracellular ion and is found in small amounts in the ECF. Normal plasma values in children are 1.5 to 2.3 mEq/L (Finberg et al., 1993).

Magnesium affects cell functions through its interactions with calcium. Calcium often opposes the actions of magnesium. Magnesium is excreted primarily in urine and in small amounts through the gastrointestinal tract. Absorption occurs primarily in the upper gastrointestinal tract. Food sources of magnesium include green vegetables, whole grains, legumes, nuts, meat, and dairy products.

Besides restoring magnesium balance, treatment also focuses on correcting the primary cause of the imbalance. Because magnesium imbalances are relatively rare compared with other electrolyte imbalances, they may be overlooked. Assess the child for conditions that may lead

to imbalance, as well as for electrolyte imbalances associated with hypomagnesemia (e.g., hypokalemia, hypocalcemia, hypochloremic alkalosis) and hypermagnesemia (e.g., elevated BUN and creatinine levels). Assess the child's vital signs to detect hypotension, cardiac dysrhythmias, and respiratory impairment. Also assess muscle tone and monitor serum electrolyte values.

Hypomagnesemia

Defined as a serum magnesium level less than 1.5 mEq/L, hypomagnesemia can be caused by inadequate intake (e.g., malnutrition, prolonged IV therapy without supplement), impaired absorption (e.g., in the presence of excessive calcium intake, diarrhea, vomiting, hypoparathyroidism, or bowel resection), or increased excretion (e.g., use of thiazide diuretics, aldosterone excess). Administration of citrated blood, which binds free magnesium, may also cause hypomagnesemia. Severe hypomagnesemia interferes with the release of parathyroid hormone; thus, hypomagnesemia and hypocalcemia often coexist. Parathyroid hormone stimulates absorption of magnesium in the intestines and release of calcium from bones. Hormones (e.g., calcitonin, aldosterone) that inhibit intestinal absorption of magnesium also stimulate calcium resorption into the bones.

caREminder

Hypocalcemia that does not respond to treatment may indicate a concomitant hypomagnesemia that also requires treatment.

Assess for signs and symptoms of hypomagnesemia, which can be similar to those of hypocalcemia. Manifestations of increased neuromuscular irritability (hyperactive reflexes, tetany, seizures) and impaired cardiac function (hypotension, tachycardia, ECG changes, and dysrhythmias) are of most concern.

Interdisciplinary Interventions

Mild hypomagnesemia can be corrected by increasing the child's intake of magnesium-rich foods. This diet may be supplemented by magnesium-based antacids (e.g., milk of magnesia). Moderate to severe hypomagnesemia may require IV administration of magnesium supplements. Assess renal function (which is necessary for excretion of excess magnesium) before administering these supplements to prevent iatrogenic hypermagnesemia.

IV administration of magnesium requires close monitoring. Infiltration of magnesium into the tissues can lead to necrosis and sloughing of the surrounding area. Optimally, magnesium is administered into a central vein and is infused slowly to decrease discomfort caused by vasodilation (feeling hot, flushing). Rebound hypermagnesemia may result from magnesium infusion. Assess deep tendon reflexes during infusion to detect hyporeflexia, a relatively early sign of hypermagnesemia.

Nursing care also addresses symptom management. For instance, a child with muscle spasms needs reduced

environmental stimuli (e.g., low noise level, dim lighting). Handle the child gently to avoid causing additional discomfort from neuromuscular excitability.

Hypermagnesemia

Hypermagnesemia, a serum magnesium level exceeding 2.3 mEq/L, can be caused by impaired excretion (e.g., decreased renal function) or excessive intake (e.g., magnesium-containing antacids, IV supplementation, treatment of maternal eclampsia with magnesium, which crosses the placenta and can cause elevated magnesium levels in neonates). Signs and symptoms of hypermagnesemia reflect altered neuromuscular function (e.g., hyporeflexia, lethargy, respiratory depression) and cardiac function (e.g., flushing from vasodilation, bradycardia, hypotension, dysrhythmias). Assess for the presence of these manifestations.

Interdisciplinary Interventions

If hypermagnesemia is detected, promptly discontinue all medications and IV fluids containing magnesium, as ordered. Severe hypermagnesemia, or hypermagnesemia in the presence of renal failure, is treated with IV administration of calcium (usually calcium gluconate in children), which blocks the neuromuscular effects of magnesium. (See the section on hypocalcemia for discussion of hazards associated with IV calcium infusion.) Thiazide diuretics may be given to remove excess magnesium, and IV fluids may be given to increase urine output. Children with severe hypermagnesemia may require dialysis.

Nursing care focuses on carefully monitoring fluid balance. Fluid excess may occur because of impaired myocardial contractility arising from the effects of magnesium, because of impaired renal function, or as a result of both. Signs of fluid overload include fluid intake greater than output, increased respiratory rate, and rales.

Phosphorus Imbalance

Although it is relatively rare, phosphorus imbalance can be life threatening when severe. Phosphorus is crucial to the integrity of cells and cell membranes and plays an important role in producing energy for normal metabolic activity and growth. Most phosphorus, like calcium, is found in the bones. A small percentage is found in ECF. Children have higher serum phosphorus levels than adults because of their rapid skeletal growth. Normal serum phosphorus levels vary depending on age (see Appendix 6). Renal excretion, intestinal absorption, and bone mineralization all affect serum phosphorus level. Parathyroid hormone inhibits tubular reabsorption of phosphorus and increases its excretion in urine (Finberg et al., 1993). The excretion and retention of phosphorus is closely related to glomerular filtration and general kidney function. When renal function is impaired, the kidney retains phosphorus, and serum levels become elevated.

Increased serum phosphorus levels can lead to decreased levels of serum calcium. Usually phosphorus

and calcium vary inversely because parathyroid hormone, while inhibiting absorption of phosphate, promotes calcium uptake. In a child with malabsorption or malnutrition, levels of both electrolytes are low.

As with all electrolyte imbalances, in phosphorus imbalance, identifying and treating the underlying cause of the imbalance is the ultimate goal. Phosphorus levels are monitored along with associated electrolytes such as calcium and magnesium, as well as serum pH. Indicators of renal function, such as BUN and creatinine, are also monitored.

Hypophosphatemia

Hypophosphatemia may result from inadequate intake and impaired absorption. Inadequate phosphorus intake is particularly prevalent in preterm infants, who have high phosphorus needs because of rapid growth. Hypophosphatemia caused by “refeeding syndrome” may occur after carbohydrate administration in severely malnourished children. In this syndrome, phosphate shifts intracellularly, leaving the ECF and entering the cell when glucose enters the cell. Intracellular shifting of phosphate also occurs with alkalosis and after administration of corticosteroids or insulin. Antacids containing aluminum or magnesium hydroxide bind phosphate and can decrease serum phosphate levels. Hypophosphatemia also may result from increased urinary excretion of phosphorus stemming from decreased tubular reabsorption, administration of thiazide diuretics, ECF volume expansion, or hyperparathyroidism.

Because of phosphate’s role in energy production for cellular metabolism, mild hypophosphatemia may manifest as weakness and tissue hypoxia. As the deficit becomes more severe, signs and symptoms similar to those of encephalopathy (irritability, confusion, seizures, coma, paresthesia) and other manifestations may appear (see NIC 19–3). Assess for these signs and symptoms.

Interdisciplinary Interventions

Ensuring adequate phosphorus intake is the primary preventive measure in hypophosphatemia. This measure is especially important in preterm infants receiving PN or breast milk, which does not adequately meet their phosphorus needs during rapid growth. Breast milk fortifier should be given as ordered. The healthcare prescriber and dietitian should collaborate in writing orders for PN to ensure a balance of essential nutrients.

Treatment of mild hypophosphatemia typically involves increasing dietary phosphorus intake to restore serum phosphorus levels. Phosphorus supplements can be given orally, in the form of phosphate salts, or intravenously. The route of administration is chosen according to the cause and severity of deficit. During IV phosphorus administration, carefully monitor renal function to avoid hyperphosphatemia. Levels of other electrolytes are also monitored to detect any imbalances that may be associated with hypophosphatemia or its treatment.

Teach the child and family about treatment measures, ways to increase intake of foods high in phosphorus, and

the need to avoid phosphate-binding antacids and diuretics.

Hyperphosphatemia

Phosphorus excess is generally not of major concern unless renal excretion of phosphorus is impaired. Hyperphosphatemia most commonly results from decreased glomerular filtration of phosphorus, such as occurs in chronic renal disease. It can also be caused by excessive phosphorus intake, either orally, intravenously, or from administration of phosphate-containing enemas. Hyperphosphatemia also may develop in children receiving treatment for malignancies, especially lymphoma or leukemia, who have rapid cytolysis of cells with resultant release of intracellular phosphorus.

Because of the inverse relationship between phosphorus and calcium, hypocalcemia usually develops concurrently with hyperphosphatemia. Thus, signs and symptoms of hyperphosphatemia mimic those of hypocalcemia. Assess for these signs and symptoms, which include hyperreflexia, tetany, tachycardia, nausea, abdominal cramps, and diarrhea.

Interdisciplinary Interventions

Treatment of hyperphosphatemia aims to increase phosphorus excretion and decrease phosphorus intake. Excretion is promoted by maintaining high urine output through the administration of oral and IV fluids. Dietary intake of high-phosphate foods (see Table 20–1) is reduced. Calcium carbonate and calcium acetate can be used as oral phosphate binders. Aluminum-containing antacids bind phosphorus, preventing gut absorption, and thus may be ordered. However, phosphate binders that contain aluminum have a limited role in therapy (only when serum phosphate is more than 7 mg/dL), because they cause heavy metals to accumulate in the brain and bones, causing osteomalacia and encephalopathy (Schucker & Ward, 2005). Sevelamer and lanthanum are calcium-free phosphate binders used in adults; preliminary data suggest that sevelamer can be safely used for children (Querfeld, 2005). Hypocalcemia should be treated concurrently. A child with severe hyperphosphatemia may need dialysis.

Monitor for electrolyte imbalances associated with hyperphosphatemia (e.g., hypocalcemia, hypomagnesemia) and assess urine output as an indicator of renal function. Institute seizure precautions to prevent injury caused by tetany. Teach the child and family about the treatment regimen and instruct them to avoid phosphate-containing foods.

ANSWER: NG suction causes both sodium and potassium loss. Cory’s sodium and potassium levels will be monitored and he will receive IV fluid replacement with sodium and possibly with potassium supplement as well.

See [thePoint](#) for a summary of Key Concepts.

The Child With Altered Gastrointestinal Status

Case History

Recall Cory Whitworth featured in Chapters 6, 11, and the previous chapter? Review the case study in the previous chapter for more information about the history and assessment of Cory's fluids and electrolytes. Cory is a 5-year-old kindergartner who, at his last appointment, was above the 97th percentile for his height but below the 25th percentile for his weight. His history reveals that he is a poor and picky eater. During the previous several days Cory has complained of a stomachache; has been refusing to eat, but is drinking a little. His fever has come and gone periodically. Early this morning he seemed better, but about an hour ago he began crying and guarding his abdomen.

The nurse in the emergency department begins examining Cory. His appearance is of a pale, thin boy in acute pain. He is crying

and holding his stomach area. His vital signs are as follows: temperature, 101.8 °F; heart rate, 108 beats per minute; and respiratory rate, 34 breaths per minute. His abdomen is flat and firm with hypoactive bowel sounds in all four quadrants. Cory allowed the nurse to listen to his abdomen with the stethoscope, but when the nurse attempts a deeper palpation he begins to thrash and fight. The nurse obtains a blood sample for lab work and inserts a peripheral intravenous (IV) line. Cory then goes to the imaging department for an ultrasound, which is equivocal, followed by a computed tomographic (CT) scan with contrast. The diagnosis of ruptured appendix is confirmed and Cory undergoes an appendectomy. After surgery, Cory is admitted to a pediatric surgical unit.

CHAPTER OBJECTIVES

1. Discuss components of the history and physical assessment that are important to consider when evaluating a child with an alteration in gastrointestinal status.
2. Identify specific tests and laboratory results that assist the healthcare team to identify alterations in gastrointestinal status.
3. Discuss diet modifications and alternative feeding methods used to treat alterations in gastrointestinal status.
4. Review the important pathophysiologic principles that help to differentiate gastrointestinal disorders.
5. Describe the interdisciplinary interventions commonly used for disorders of the gastrointestinal system.

See [thePoint](#) for a list of Key Terms.

The gastrointestinal (GI) system is a complex organ system that extends from the mouth to the anus and includes the esophagus, stomach, small and large intestines, liver, and pancreas. The primary functions of the GI system are ingestion, digestion, absorption of nutrients, and excretion of solid waste. Proper function of the GI system is essential for normal growth and for maintaining fluid and electrolyte balances. This system also plays an important role in metabolic functions, such as protein synthesis and glucose homeostasis, and in immunologic function.

Alterations in GI status may be congenital or acquired, acute or chronic, and may vary in severity from minor to life threatening. The nurse may encounter the child with altered GI status in both acute care and community settings.

DEVELOPMENTAL AND BIOLOGIC VARIANCES

Developmental and biologic variances in the GI system are most pronounced during infancy, especially in the preterm infant. The GI tract begins to develop during the fourth week of gestation. By the end of the second trimester, the organs of the GI tract are formed and have many of the structures that enable elementary physiologic function. During the third trimester, these structures become more developed and differentiated in their functions. Some functions, particularly those related to ingestion, digestion, and absorption of nutrients, are not fully developed at birth, a circumstance that accounts for the special feeding requirements of infants (Fig. 18–1).

Ingestion of Nutrients

Food intake, along with calorie and nutrient requirements, varies from infancy to childhood to adolescence. During periods of rapid growth, such as infancy and adolescence, calorie and nutrient requirements are increased, which in turn leads to an increase in food intake. During periods of slower growth, food intake may decrease. This

variation may help to explain the behavior of the toddler or preschooler who has become a “picky eater.”

Digestion and Absorption of Nutrients

The mechanisms for digesting and absorbing major nutrients are not fully mature in the premature and term infant. As the child ages, these mechanisms mature. Normally, the initial breakdown (hydrolysis) of *carbohydrates* depends on both salivary and pancreatic amylase. However, in the infant, carbohydrate hydrolysis is limited by the fact that although salivary amylase is present by 34 weeks' gestation, secretion of pancreatic amylase does not begin until age 4 to 6 months. Because of this delay, young infants are relatively intolerant of starches and may experience diarrhea if starchy food sources, such as cereals, are offered too early.

Lactose is the primary source of carbohydrate in breast milk and most infant formulas. Lactose is hydrolyzed in the intestinal villi by the enzyme lactase. Lactase levels are highest during early infancy and begin to decline after 4 years of life, depending on ethnicity. In some individuals, lactase levels may decline to the point where lactose intolerance occurs. Therefore, school-aged children may not tolerate lactose well.

WORLDVIEW: Lactase deficiency and lactose malabsorption occur in 50% to 80% of Hispanic people, in 60% to 80% of black and Ashkenazi Jewish people, and in almost 100% of Asian and American Indian people. Approximately 20% of Hispanic, Asian, and black children younger than 5 years of age experience lactase deficiency and lactose malabsorption in contrast with white children, whose symptoms usually do not present until after this age (Heyman, 2006).

Digestion and absorption of *protein* is relatively efficient in the preterm and newborn infant. The infant's highly permeable intestine enables uptake of protective immunoglobulin proteins from human milk. This same permeability allows cow's milk protein and other potential allergens to pass through the intestinal barrier into the bloodstream, making infants more susceptible to food protein allergies and GI infections.

Digestion and absorption of *fat* during infancy is limited by low concentrations of bile acids and low levels of pancreatic lipase, one of the enzymes responsible for breaking down ingested fats. The breast-fed infant absorbs fat more efficiently than the formula-fed infant, as a result of unique characteristics of the lipase in breast milk.

Elimination

Normal patterns of GI elimination vary throughout the life cycle. The number and consistency of stools, as well as the ability to control elimination, change from infancy to early childhood. Stool frequency in the infant may be highly variable. During the first 3 days of life, the infant has meconium stools that are dark green-black, thick, and sticky. The newborn may have three to seven stools per

Abnormal distention can cause respiratory distress in young children because the accessory muscles of respiration are less developed and they are more dependent on the diaphragm as the primary muscle of respiration.

Coordinated suck and swallow ability develops by 34 weeks' gestation.

Stomach capacity increases from 10–20 mL in early infancy to up to 3 L by late adolescence.

Levels of pancreatic lipase are low in early infancy and increased thereafter.

Infants and young children may have a palpable liver edge 1–2 cm below the right costal margin.

Lactase levels are low in the preterm neonate, peak in infancy, and gradually decline after early childhood.

The small intestine is only 200 to 250 cm long at birth; it lengthens to 350–600 cm by adulthood.

Pancreatic amylase secretion does not begin until age 4 months

Coordinated oral pharyngeal movements necessary to swallow solids develop after age two months.

The infant's intestine is highly permeable, allowing uptake of protective immunoglobulin from human milk.

Stool frequency is highest in infancy and decreases to adult frequency by age 4 years.

Defecation is involuntary, under reflex control, in infancy. Voluntary control is achieved by age 18 months–4 years, depending on physiologic and cultured variables.

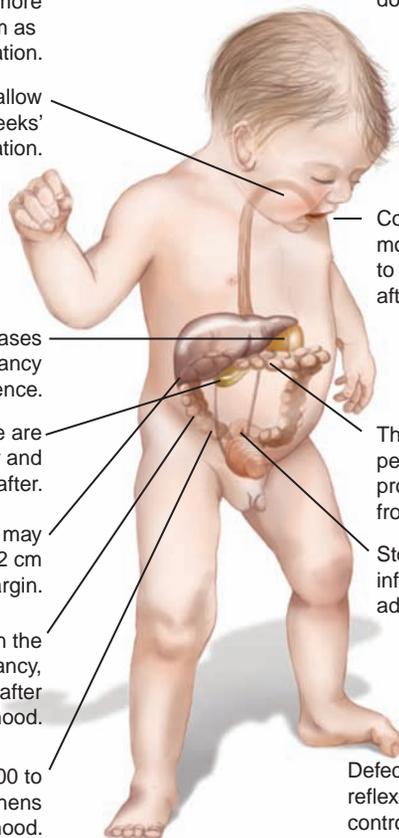

FIGURE 18–1. Developmental and biologic variances: gastrointestinal system.

day, depending on the type and amount of feeding given. After about a month, the breast-fed infant may go up to a week without any stool, without any signs of discomfort or abdominal distention, because of the low residue of breast milk. The color and consistency of stool also vary. A breast-fed infant's stools may have a yellow, "seedy" appearance and a somewhat runny consistency; a formula-fed infant's stools may have a yellow or brownish color and a more pasty consistency. As solid foods are introduced, stool color may be affected by the particular foods the child eats. By age 4 years, stool frequency decreases to the adult level of one or two stools per day. Stool consistency is also comparable with the adult's.

ASSESSMENT OF THE CHILD WITH ALTERED GASTROINTESTINAL STATUS

Assessment of the child with altered GI status relies on a careful health history, physical assessment, and diagnostic tests.

Focused Health History

QUESTION: Review Cory's case and identify critical information provided that correlates with the areas identified in Focused Health History 18–1. What are other critical pieces of information the nurse should gather?

The focused health history is an important part of the overall assessment of the child with altered GI status (Focused Health History 18–1). Many GI conditions have relatively few observable physical findings, which makes the history of symptoms and factors that affect their onset and duration an important tool. Conversely, symptoms that initially appear to be of GI origin may indicate a pathologic process in another system. For example, pneumonia or urinary tract infections may present as abdominal pain.

Ask about feeding habits—for example, what the child eats, when, how often, and how foods are prepared. Also inquire about changes in appetite and fluid intake (increased, decreased, type of intake), and bowel habits

FOCUSED HEALTH HISTORY 18–1

The Child With Altered Gastrointestinal Status*

Current history	<p>Recent weight loss or gain Nausea, retching, regurgitation Abdominal pain or distention, when pain occurs in relation to vomiting Bulges in abdominal or inguinal area with crying or straining Diarrhea Constipation Blood in vomitus or stool Color and characteristics of vomitus and stool Related systemic problems: fever, fatigue, urinary tract symptoms (change in color, frequency, pain), respiratory symptoms (cough, wheezing, asthma), skin lesions, rashes, pruritus, changes in hair or nails Presence of pain/discomfort/irritability Changes in sleep patterns</p>
Past medical history	<p>Prenatal/Neonatal History</p> <ul style="list-style-type: none"> • History of maternal prenatal infections • Birth weight, length, gestational age • Failure to pass meconium <p>Previous Health Challenges</p> <ul style="list-style-type: none"> • History of GI illness, recurrent respiratory or urinary tract infection, congenital heart disease • Problems with growth, weight gain • Feeding difficulties • Formula, milk, and food allergies • Experiences with pain
Nutritional assessment	<p>Status of immunization with hepatitis B vaccine Usual diet and intake; recent change in diet, food intake</p> <ul style="list-style-type: none"> • Feeding method (breast, bottle, cup, tube fed) • Method of formula preparation <p>Systemic medications child has recently taken or is currently taking; how the medication is taken (e.g., on empty stomach; with food or fluid, with what and how much; taken in conjunction with other medications; if tablets, swallowed or crushed); any changes noted in GI tract function secondary to medication; complementary or alternative healthcare practices</p>
Family medical history Social history	<p>Use of vitamin, mineral supplements Family history of GI conditions Disturbed/abnormal parent–child interaction Recent changes, stressors in family, lifestyle Exposure to affected individuals (hepatitis, diarrhea) in home, daycare, school History of recent travel History of recent trauma (e.g., falling off bicycle or skateboard, car accident) or emergency room visits Presence or exposure to pets or animals Recent exposure to food prepared outside home School absences</p>
Growth and development	<p>Developmental milestones, especially feeding milestones</p>

*This history focuses on the GI system; see Chapter 8 for a comprehensive format.

(frequency, appearance, use of aids such as laxatives or enemas). Ask whether symptoms are related to meals, specific food intake, lifestyle, activity, or sleep patterns. Obtain information on the absence or presence of pain, including onset, type and characteristics of pain, location, duration, and any measures that relieve or exacerbate pain (see Chapter 10 for more information about pain).

When obtaining the history, pay careful attention to the timing and characteristics of the symptoms. Include the child in the interview as much as possible and encourage description of symptoms in familiar terms. Clarify the parent's or child's reports to avoid underrepresentation or overrepresentation of symptoms. For example, if the parent reports that the child had "a lot of diarrhea last night," ask the parent to estimate how many episodes of diarrhea the child has had during the previous 24 hours and at what times the episodes occurred. Question the parent regarding the volume of the stool output, using a familiar measure such as a tablespoon, a cup, or number of saturated diapers to estimate the amount. Finally, define the characteristics of the stool, including color, consistency, presence of blood or mucus, greasiness, and presence of foul smell.

ANSWER: Cory has had a stomachache, intermittent fever, and refused to eat. In addition, the nurse should ask about Cory's most recent healthy weight and if he is on any medication. Try to determine Cory's output the previous day with regard to urine, stool, and vomiting. Ask Cory directly about his abdominal pain: "Where does it hurt most?" "Does anything make it hurt less?" "Does anything you do make it hurt more?"

Focused Physical Assessment

QUESTION: Based on the information you have about Cory's physical assessment, what additional information do you anticipate finding in your physical assessment?

Physical assessment of the GI system must occur in the context of an overall comprehensive physical examination. Manifestations of altered GI function are varied and may be subtle. Children with conditions that alter intake, digestion, or absorption of nutrients may exhibit signs of growth failure or malnutrition. These children may have altered skin integrity or abnormal findings on neurologic or musculoskeletal examination. Children with conditions that result in excessive loss of fluid and electrolytes from the GI tract may present with the physical findings of acute dehydration. The child with gastroesophageal reflux disease (GERD) may present with the physical findings of pneumonia secondary to aspiration of refluxed stomach contents.

Throughout the physical assessment, keep in mind the potential relationships between the GI system and altered physical findings in other systems (Focused Physical Assessment 18–1).

Because GI tract function may be reflected in growth and nutritional status, accurately measuring and recording growth parameters are critical aspects of GI assessment. Measuring weight daily is essential to evaluate the child's progress toward the goals for growth, development, and nutrition with GI dysfunction (see Chapter 8 for information on obtaining anthropometric measurements).

The abdominal examination is a major part of GI system assessment; this evaluation may present unique challenges in children. (For further discussion of techniques for physical examination, see Chapter 8.)

caREminder

The usual order of physical assessment techniques is altered during assessment of the abdomen. To obtain an accurate assessment of bowel sounds, auscultation must precede percussion and palpation.

An infant may become distressed during the examination, crying and tensing the abdominal wall. This behavior may interfere with the nurse's ability to appreciate changes in assessment parameters. Place the infant in a parent's lap during the examination to help soothe the infant and facilitate the examination. Provide comfort measures, such as a pacifier.

The older child may become frightened or ticklish during the examination. Demonstrate parts of the examination on a doll or stuffed animal to help put the child at ease and enhance cooperation. Allow the child to handle examination tools. Distract the child with toys or conversation about favorite activities. Drape the adolescent to avoid unnecessary exposure and acknowledge their privacy concerns.

During *inspection*, observe the color, shape, and contour of the abdomen. Note any signs of distention or asymmetry. Peristalsis may be visible in the thin, malnourished infant or in the infant with obstruction caused by pyloric stenosis. Note the presence of any hernias. A prominent venous pattern may be seen in children with cirrhosis of the liver.

Inspect GI tract secretions, such as vomitus and stool, if available. Mucus and blood may suggest infectious and inflammatory conditions. Changes in stool color, consistency, or odor can point to GI tract dysfunction (Table 18–1).

Auscultate all four abdominal quadrants to assess bowel sounds, which represent peristaltic movement of contents throughout the intestinal tract. Normal bowel sounds have a metallic, tinkling quality and may be heard every 10 to 30 seconds. The absence of bowel sounds indicates intestinal **ileus** or functional intestinal obstruction. Increased, or hyperactive, bowel sounds may be heard in acute gastroenteritis. High-pitched, hyperactive bowel sounds may indicate partial intestinal obstruction.

FOCUSED PHYSICAL ASSESSMENT 18–1

The Gastrointestinal System

Assessment Parameter	Alterations/Possible Clinical Significance
General appearance	<p>Change deviating from growth trajectory in weight and height; head circumference for children less than 3 years of age: Potential over- or undernutrition, acute or chronic condition</p> <p>Unwell, listless: Acute or chronic illness, anemia</p> <p>Poor state of hygiene: Neglect, abuse</p> <p>Obese, cachectic: Possible over- or undernutrition</p> <p>Alterations in speech: Cleft palate, altered motor development, undernutrition, congenital syndromes, cerebral palsy</p> <p>Flat affect: Possible profound nutritional deficit</p>
Integumentary system (skin, hair, nails)	<p>Color: Jaundice may indicate liver dysfunction or pancreatitis; pallor is a sign of blood loss or iron deficiency</p> <p>Integrity: Lesions, rashes may be seen with malnutrition, diarrhea, poor hygiene, neglect, or chronic conditions</p> <p>Impaired wound healing, skin lesion can be a result of zinc deficiency, malnutrition, steroid side effects</p> <p>Turgor: Tenting is present in dehydration; edema may indicate fluid volume excess or protein deficiency or hypoalbuminemia</p> <p>Hair: Color changes, depigmentation; dry, coarse texture; sparse distribution; hair that is easily plucked may be signs of vitamin or protein deficits or general malnutrition</p> <p>Nails: Clubbing can be present in cystic fibrosis, liver disease; splitting is seen with nutritional deficiencies</p>
Eyes	<p>Periorbital edema can be present with fluid volume excess or protein deficiency/hypoalbuminemia</p> <p>Jaundiced sclera often indicates elevated bilirubin levels, liver dysfunction</p>
Ears/hearing	Structural deformities may be associated with oral, facial defects or syndromes and cleft palate
Face, nose, and oral cavity	<p>Perioral, oral lesions may be present in malnutrition, Crohn's disease, ulcerative colitis, celiac disease, immunodeficiency or suppression</p> <p>Enamel hypoplasia associated with celiac disease, cheilosis; glossitis/vitamin B₆ deficiency, vitamin B₁₂ deficiency</p> <p>Fetor may indicate Progressive lower bowel obstruction</p>
Thorax and lungs	<p>Increased respiratory rate associated with abdominal distention, ascites resulting from compression of the diaphragm</p> <p>Breath sounds (wheeze, rhonchi) may be associated with GERD, primary aspiration resulting from oral–motor dysfunction</p>
Abdomen	<p>Inspection:</p> <ul style="list-style-type: none"> • Shape, contour; presence of distention may indicate partial or total bowel obstruction, malnutrition, retained flatus, ascites; irregular contour may indicate pyloric stenosis • Color, discoloration; erythema associated with necrotizing enterocolitis, trauma • Visible peristaltic waves seen in pyloric stenosis • Visible mass may suggest hernia, hydrocele • Prominent venous pattern associated with collateral circulation resulting from presence of implanted venous access device, portal hypertension, superior vena cava syndrome • Note presence and location of appliances, such as gastrostomy tube, colostomy, implanted venous access device • Note presence and location of prior surgical incisions and the corresponding surgical procedure <p>Auscultation:</p> <ul style="list-style-type: none"> • Absent bowel sounds indicate postoperative ileus or ileus from other etiologies • High-pitched, hyperactive high-pitched bowel sounds associated with obstruction • Vascular bruits, rushes suggest vascular abnormality <p>Percussion</p> <ul style="list-style-type: none"> • Tympanic sound of higher pitch associated with presence of excessive gas; dull sound associated with masses, fluid or solid organ elicits a dull pitch • Enlarged liver span may suggest biliary atresia, cholestasis, heart failure <p>Palpation</p> <ul style="list-style-type: none"> • Pain, tenderness associated with appendicitis, inflammatory bowel disease, functional abdominal pain, inflammatory process • Rigidity associated with peritonitis, obstruction

(Continued)

FOCUSED PHYSICAL ASSESSMENT 18–1

The Gastrointestinal System (Continued)

Assessment Parameter	Alterations/Possible Clinical Significance
	<p>Abdominal girth (circumference); compare with baseline to determine whether the abdomen distention is trending upward or decreasing in response to therapy or disease progression</p> <p>Inguinal region: Bulging, more prominent with crying, straining or laughing and possibly mild tenderness suggests the presence of hernia; bulging with acute irritability, refusal to eat, followed by bilious or feculent vomiting indicates incarcerated hernia</p>
External genitalia and breasts (includes anus)	<p>Anus, rectum, vagina: Presence of urine or stool in an unusual place associated with anorectal malformations</p> <p>Fissure associated with constipation</p> <p>Lesions, excoriation, inflammation associated with infection, diarrhea</p> <p>Rectal prolapse associated with cystic fibrosis, malnutrition</p> <p>Skin tags associated with Crohn's disease</p> <p>Rectovaginal fistula suggests congenital structural defects</p>

caREminder

Listen for a full 5 minutes in all four abdominal quadrants to establish the absence of bowel sounds.

Use abdominal percussion to distinguish between solid organs or masses versus the presence of fluid or gas in the abdominal cavity. Percuss the abdomen in all four quadrants. Tympanic, drumlike sounds are heard

over air-filled organs, particularly the stomach and intestines. When the abdomen is distended, increased tympanic sounds may be heard if gas has accumulated because of an ileus or obstruction. In some cases, an infant may have increased tympanic sounds because he or she has swallowed air while feeding or crying. Flat, dull sounds on abdominal percussion may indicate an accumulation of fluid, a solid mass, or an organ such as the liver.

TABLE 18–1

Abnormal Findings: Emesis and Stool

Parameter	Finding/Potential Pathology
<i>Emesis</i>	
Hematemesis	<p>Emesis containing blood</p> <p>Bright-red blood indicates acute upper GI bleeding</p> <p>Brown, “coffee ground” blood indicates ongoing or chronic process</p>
Bilious vomiting	<p>Emesis containing bile</p> <p>Green or yellow, indicates GI obstruction</p>
Feculent vomiting	<p>Emesis containing stool</p> <p>Brown, foul smelling, indicates GI obstruction</p>
<i>Stool</i>	
Hematochezia	<p>Bright-red or maroon blood per rectum</p> <p>Usually associated with bleeding from lower GI tract or anal fissures</p>
Melena	<p>Dark, tarry stool</p> <p>Usually associated with bleeding passed from upper GI tract versus bright red from lower GI tract</p>
Currant jelly stool	<p>Stool with red blood and mucus</p> <p>Associated with intussusception</p>
Steatorrhea	<p>Fatty stools</p> <p>Possibly pale, bulky, malodorous, float in toilet or have an oily ring in the diaper</p> <p>Associated with fat malabsorption, pancreatic insufficiency, such as with cystic fibrosis</p>
Acholic stool	<p>Clay-colored stool</p> <p>Occurring with biliary atresia, biliary tract obstruction or bile deficiencies</p>

Measure liver size, or span, by percussing along the right midclavicular line. The normal liver span of the child varies according to age. It averages 2.6 cm at 6 months, 3 cm at 12 months, 3.5 cm at 24 months, 4.4 cm at 4 years, 5 cm at 6 years, 5.4 cm at 8 years, and 5.8 cm at 10 years.

Palpate the abdomen to assess for enlargement of solid organs and to detect the presence of masses. Also assess the character of the abdomen (soft or hard) and the presence of tenderness or pain. To promote relaxation of the abdominal muscles, have the child lie supine and flex the knees before palpating. Preschool and school-aged children in particular may be ticklish, which makes palpation difficult.

KidKare ■ To reduce ticklishness during palpation, ask the child to place his or her hand on top of your hand, and palpate or press down with you. Coach the child to breathe normally throughout the examination.

If a child is crying, you can best feel the difference between a firm and soft abdomen when palpating during the inspiratory phase of the respiratory cycle. Palpate in an area distant from the identified area of pain when abdominal pain is reported. In the case of the preverbal child or the child who has difficulty verbally identifying the exact location of the pain, observe for changes in facial expression or body posture or changes in the pitch of crying during palpation of the abdomen to assess for the location of pain.

Alert! If you identify a mass in the area of the kidneys, do not repalpate it. If the mass is a tumor, repeated palpation can cause it to release cells that are potentially metastatic.

In infants and young children, the edge of the liver is normally palpable 1 to 2 cm below the right costal margin in the midclavicular line. The liver edge should not be palpable in the adolescent. Enlargement of the liver, known as *hepatomegaly*, is present when the liver is palpable more than 3 cm below the right costal margin. Report any enlargement to the advanced practice nurse or physician.

Measuring abdominal girth is a fairly accurate way to monitor progressive abdominal distention in children. Use a paper tape measure, to avoid the stretching that may occur with a cloth tape measure and to promote infection control. If the tape measure is not long enough, tape two together to provide sufficient length. Measure the abdomen over the umbilicus, pulling the tape measure taut but not tight (Fig. 18–2). Obtain the measurement on expiration. When ostomies, tubes, or other devices prevent measuring over the umbilicus, obtain the measurement over the same area each time to enable comparison. When taking serial measurements, mark two small lines with a marker or ballpoint pen on each side margin of the tape measure and on the right and left sides

FIGURE 18–2. Measure abdominal girth over the umbilicus whenever possible.

of the abdomen, to indicate where to place the tape measure. If you are doing serial readings and movement causes the child discomfort, leave the tape measure in place under the child, making sure that it is smooth and not twisted.

ANSWER: You may have anticipated dry mucous membranes related to decreased fluid intake. You may have also anticipated that Cory identifies the right lower quadrant of his abdomen is more painful and that rebound tenderness of the abdomen is present.

Diagnostic Criteria

QUESTION: Which tests can assist in the diagnosis of appendicitis/ruptured appendix (refer to Tests and Procedures 18–1)?

A wide variety of diagnostic tests and procedures is used to evaluate alterations in GI structure and function. Laboratory studies analyze blood, GI secretions, urine, and stool. Radiographic and non-radiographic imaging techniques visualize both the structure and the function of GI organs. Endoscopic examination enables direct visualization of the inner lumen of the GI tract. Tissue samples from biopsies determine alterations in GI organs at the cellular level. State-of-the-art technology is providing newer methods to evaluate segments of the GI tract (see Tests and Procedures 18–1) that have been historically difficult to access—for example, the videocapsule endoscopy (M2A capsule) can be used to visualize the small intestine between the ligament of Treitz and distal ileum.

The nurse must be familiar with both the purpose of and the procedures for the various diagnostic tests and studies used to evaluate alterations in GI status. This familiarity is important to ensure that both the patient and family are appropriately prepared and

Tests and Procedures 18–1 Evaluating Altered Gastrointestinal Status

Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
<i>Imaging (Radiographic and Non-Radiographic)</i>			
Plain film abdominal radiograph; also can be ordered as KUB (kidney, ureter, and bladder)	Initial radiographic; evaluation of structures of the organs within the abdomen	Obstruction, air and fluid levels, structural changes, and calcifications	Infants and younger children may require assistance with positioning and immobilization.
Barium swallow	Radiographic evaluation of esophagus	Structural abnormalities, strictures, foreign bodies, ulcerations, varices, and motility disorders	Child must be NPO before examination
Upper gastrointestinal series with small bowel follow-through	Radiographic evaluation of esophagus, stomach, and small intestine with contrast medium	Structural abnormalities, strictures, obstruction, ulcers, inflammatory bowel disease, and motility disorders	Child must be NPO before examination (infants, 3–4 hours; older children, after midnight for morning test). Children who are unable or unwilling to drink contrast medium used in examination may require nasogastric administration. Younger children may require immobilization during examination. Fluids are given after the test to facilitate passage of barium. Stool may be whitish or clay-colored from barium.
Barium enema	Radiographic evaluation of colon with contrast medium	Structural and functional changes; polyps	Contraindicated in patients with fulminant ulcerative colitis or suspected perforation. Test performed before upper GI studies to prevent contamination from previous contrast. Infants do not require bowel preparation. Bowel preparation for older children may include clear liquid diet, cathartics, or enema. Stool may be whitish or clay-colored from barium.
Gastric emptying study	Evaluates rate at which stomach empties after ingestion of radionuclide-labeled solid or liquid meal	Motility disorders of stomach	Child must be NPO before test. Prepare child and parents about the need to ingest radionuclide-labeled meal in radiology, with images taken every 15 minutes for up to 3 hours.
Abdominal ultrasound	Visualization of size, structure of liver, gallbladder, biliary tract Differentiation of solid organs, cysts, and fluid collections	Strictures, cysts, abscesses, tumor, gallstones, and appendicitis Solid organs appearing as echogenic structures (consist of tissues with multiple acoustic interfaces); cysts and fluid collections echo free (echolucent or anechoic) because they lack internal reflectors	Prepare child and family by advising them that test will take 20 to 30 minutes. Lubricant gel, which feels wet and cold, will be used on skin over abdomen. Younger children may require assistance with positioning and immobilization.

Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
CT, with or without contrast	Radiographic study that shows relationships among anatomic structures; reveals the shapes of the organs, tissue densities, outlines; shows structural alterations	Tumors, presence of intra-abdominal or hepatic abscess or cyst, and obstruction of biliary ducts	Child may be required to take oral or IV contrast material before the test. If unable to take contrast by mouth, may require nasogastric administration. Child must lie still for 30 to 90 minutes during test. Often requires sedation in young children who are unable to cooperate.
Endoscopic retrograde cholangio-pancreatography	Combines endoscopy with imaging and contrast medium to identify pancreatic and biliary duct disorders; used for both diagnostic and interventional therapy; interventions include stricture dilation, stent placement, cyst drainage, and stone extraction	Structural disorders, such as duct stenosis; choledochal cyst; obstructions caused by bile duct stones	Same as preparation for upper GI endoscopy. IV access for administration of contrast medium; obtain signed consent.
Magnetic resonance cholangiopancreatography (MRCP)	Noninvasive imaging study of the biliary and pancreatic ducts	Structural disorders indicating such alterations as inflammation, cysts, congenital abnormalities	Contraindications are similar to those for magnetic resonance imaging: Presence of cardiac pacemaker, ocular or cochlear implants, possibly nerve stimulating devices.
Liver biliary scan (hepatoiminodiacetic acid [HIDA] scan)	Radionuclide scan to visualize flow in the biliary ductal system, both uptake and excretion	Biliary atresia, biliary tract obstruction after liver transplant	Child is NPO before test. IV access required to administer contrast medium.
Cholangiogram, intra-operative study	A radiograph study to evaluate the biliary tract. The iodine is excreted in the bile from the liver. Intra-operative cholangiogram: A needle or catheter is inserted into the gallbladder, where diluted contrast is injected to observe the extent of the biliary obstruction.	Presence and location of stones and other causes of obstruction, such as strictures; biliary atresia	Document patient allergies before procedure (contrast medium used is usually iodine based). Patients with history of iodine or seafood allergy or history of previous reaction to iodine-based contrast medium must be identified.
<i>Endoscopic Examination</i>			
Esophageal manometry	A long, flexible catheter with pressure transducers is passed into the esophagus orally or transnasally; intraluminal pressures of the lower esophageal sphincter and esophageal body are measured.	Motility disorders of the esophagus. Used in the workup of patients with dysphagia and dysmotility.	The child must be NPO before the procedure. Sedation is required for catheter placement.

(Continued)

Tests and Procedures 18–1 Evaluating Altered Gastrointestinal Status (Continued)

Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
Upper gastrointestinal endoscopy	<p>Uses a fiberoptic endoscope to directly visualize the lumen and mucosal lining of the esophagus, stomach, and upper portion of the small intestine.</p> <p>Biopsies are acquired to substantiate diagnoses. Used therapeutically to sclerose esophageal or gastric varices, evaluate hiatal hernia, remove a foreign body, dilate esophageal stricture, place a percutaneous endoscopic gastrostomy tube or a gastrostomy–jejunostomy tube.</p>	Tissue abnormality from biopsy, upper GI bleeding, ulcers, gastritis, esophagitis, and hiatal hernias identified and evaluated	The child must be NPO before the procedure. Sedation or general anesthesia will be used depending on child's clinical risk and purpose of procedure. IV required. Monitor vital signs and oxygen saturation are monitored during the procedure and afterward until the child is fully awake. Monitor for signs of pulmonary aspiration, perforation, or bleeding.
Endoscopy, wireless capsule	<p>Noninvasive evaluation of the entire small bowel through an ingestible capsule that contains a camera. Two images are captured per second and are transmitted from the capsule via digital radio-frequency to a receiver that is worn on the body in a vest-type carrier. The data are then downloaded and analyzed using a special program.</p>	Evaluation of disorders of the small bowel, such as in Crohn's disease or a history of bleeding without an identified source. Contrast radiographic studies are done prior to the wireless capsule to rule impeding the forward movement of the capsule.	<p>The child is NPO 8 hours prior to the procedure and longer as indicated. Clear liquids may be taken several hours after the initiation of the study. A light meal may be eaten 2 hours or more into the study, which is completed in 8 hours. Parents need to notify physician for complaints of chest pain, dysphagia, nausea, vomiting, or fever. Parents are instructed to check frequently for presence of pulsing light on the receiver device and to return to outpatient setting if pulsing stops before 6 hours. Patient returns to the outpatient setting after 8 hours when study is completed. Parents need to monitor the child's stool for passing of capsule after procedure is completed. Currently approved as an outpatient study.</p> <p>Use is limited to about age 6 years or ability to swallow the capsule, although there are reports of endoscopic placement. Limitations include inability to obtain biopsies, battery life if progression is slow because of decreased motility, and age. Adaptations are underway for use with younger children. A dissolvable capsule design without the video that</p>

Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
			can be administered prior to the video capsule to screen for potential impediment is also underway.
Lower gastrointestinal endoscopy (colonoscopy)	<p>Uses a fiberoptic endoscope to directly visualize the lumen and mucosal lining of the colon and terminal ileum.</p> <p>Used therapeutically to remove polyps.</p> <p>Biopsies may be done in conjunction with colonoscopy.</p> <p>Flexible sigmoidoscopy is an examination of the last few inches of the large colon.</p>	<p>Diagnosis and evaluation of inflammatory bowel disease, gastrointestinal or rectal bleeding, and diarrhea</p>	<p>Bowel preparation usually required preprocedure, determined by physician. Infants may require only clear liquids 12 to 24 hours before the procedure. Older children's preparation may include cathartics by mouth, or nasogastric tube or enemas. Sedation is used in pediatrics.</p> <p>Requires an IV. Pulse oximetry monitoring. Monitor the child during and after procedure for abdominal pain, bleeding, and any change in vital signs.</p>
Anorectal manometry	<p>Flexible catheters with attached pressure transducers are inserted into the colon and record the response of the internal sphincter's ability to relax and contract with distention of balloons recorded on the manometry equipment.</p>	<p>Diagnosis and treatment of chronic constipation, fecal incontinence, and dysmotility disorders.</p> <p>May be used in the diagnosis of Hirschsprung disease.</p>	<p>Requires bowel preparation per prescriber. Child is sedated for placement of the catheters.</p> <p>Requires an IV. Monitor child for signs of rectal bleeding, abdominal distention, or perforation after procedure. During the study, the child remains in the area of the testing and is confined to the bed.</p> <p>Family is prepared to bring activities for distraction because the duration of the test may be 4 to 6 hours.</p>
pH study	<p>Traditionally, a pH probe is passed transnasally into the distal esophagus. The probe is attached to an external monitor that measures and records the intraesophageal pH.</p> <p>Alternatively, an intraluminal esophageal wireless pH capsule (BRAVO Capsule) is placed endoscopically. Recordings are transmitted to a pager-sized device worn by the patient or placed in a backpack.</p>	<p>Used to evaluate for gastroesophageal reflux. Reflux of acid stomach contents will result in pH readings less than 4.</p>	<p>The traditional pH study is usually 18 to 24 hours. The wireless pH study is usually a 48-hour study. The child must be NPO before the probe placement and must be off acid antagonists during the examination. pH probe placement must be maintained throughout the test. A log is kept to record sleep/wake periods, start and stop of feedings, position changes, and occurrence of any reflux symptoms (cough, choking, emesis, apnea, bradycardia, or cyanosis). Family members may participate in record keeping and should have instruction.</p> <p>With the pH wireless capsule, the child is instructed to take small bites of food and chew well for comfort and to avoid dislodging the capsule. The recording</p>

(Continued)

Tests and Procedures 18–1 Evaluating Altered Gastrointestinal Status (Continued)

Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
			device must remain within 3 ft of the patient when showering and with a maximum range of 9 ft for receiving data. Caution must be taken not to drop or damage the wireless receiver.
<i>Biopsy</i>			
Liver biopsy	Percutaneous needle aspiration of liver used for microscopic examination of tissue cells and structure	Used to diagnose and/or evaluate the extent of liver disease, evaluate graft function after liver transplant	Child must be NPO for biopsy. Blood prothrombin time, activated partial thromboplastin time, and platelet count are done before the procedure. Notify the physician regarding any abnormal levels. The procedure is most often done with moderate sedation. Establish IV access for administration of the necessary medications. Monitor vital signs and oxygen saturation during the procedure and for 6 to 8 hours afterward. The child must remain positioned on the right side for 2 to 4 hours after the procedure. A pressure dressing is placed over the biopsy site. Observe the child for signs of bleeding, peritonitis, or pneumothorax after the procedure. Check hematocrit level 4 to 6 hours after the procedure.
Esophagus, stomach, intestinal biopsy	To diagnose mucosal abnormalities and evaluate response to therapy; done in conjunction with endoscopic procedure	Abnormal findings from biopsy are histologic changes, which can be caused by GERD or gastritis; infectious processes such as <i>Helicobacter pylori</i> infection. Intestinal biopsy for diagnosing celiac disease, villous atrophy from infection or malnutrition. Used to confirm diagnosis in inflammatory bowel disease. Indicated to evaluate the response to therapy when symptoms persist and child does not exhibit anticipated progress toward goal.	Same as for endoscopic procedures

Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
<i>Stool</i>			
Occult blood (guaiac test)	To detect fecal occult blood from a GI source. A small amount of stool is applied to guaiac paper; then two drops of developing solution are placed on the reverse side. Paper will turn blue in the presence of blood.	Gastritis, inflammatory bowel disease, peptic ulcer disease, malabsorption, chronic unexplained anemia. Menstrual blood, anal fissures, and perianal skin breakdown may cause false-positive results.	Family education about collection of specimen if home testing is desired. Use standard precautions.
Stool pH	Bedside screening test for malabsorption of sugar, using pH paper. Small amount of fresh liquid stool is applied to pH paper, and resulting color is compared with pH color chart.	A pH value less than 6 indicates malabsorption.	Use standard precautions.
Reducing substances	Screens for intestinal malabsorption of sugars. A Clinitest tablet is placed in five drops of fresh liquid stool mixed with 10 drops of water. Resulting color is compared with Clinitest color chart.	A reading more than 0.5% indicates malabsorption of sugars.	Use standard precautions.
Fecal fat	A 72-hour stool collection to evaluate the ability of the GI tract to digest and absorb fat from dietary intake	Elevated levels of fat in the stool are found in patients with malabsorption syndromes, short bowel syndrome, biliary tract obstruction, and pancreatic insufficiency with cystic fibrosis.	All stool for a 72-hour period is collected in one heavy plastic screw-cap container. Specimen must stay refrigerated during collection period. A concurrent diet record may be requested. Provide instructions regarding collection procedure if home testing is desired.
Stool for white cells (methylene blue stain)	Rapid, nonspecific screening test to detect the presence of polymorphonuclear leukocytes in the stool	Leukocytes may be present in diarrhea caused by invasive bacteria such as <i>Salmonella</i> or <i>Shigella</i> species and in ulcerative or antibiotic-associated colitis. Barium in the specimen may interfere with test results.	Collection of fresh stool specimen in clean, plastic container with a lid. Specimen sent immediately to the lab.
Ova and parasite	To identify the presence of specific parasites in the GI tract	Presence of parasites or their eggs indicates infestation.	Special specimen container with preservative necessary. Fresh stool specimen is placed in designated container. Test may be repeated on 3 consecutive days.

(Continued)

Tests and Procedures 18-1 Evaluating Altered Gastrointestinal Status (Continued)

Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
Bacterial culture	To identify presence of bacterial organisms that cause intestinal infections, commonly in children with fever and diarrhea. Other bacterial tests may be ordered that are organism specific (e.g., <i>Clostridium difficile</i> , cryptosporidium).	Presence of abnormal bacteria indicates infection. Infection with organism specific to the ordered study	Specimen should be obtained before antibiotic therapy is started. Specimen should not be mixed with urine and should be transported directly to the lab.
Rotazyme (enzyme immunoassay)	To identify presence of rotavirus	Infection with rotavirus, a common cause of vomiting and diarrhea in infants and toddlers during the winter months	Stool should be collected in sterile specimen container. Specimen should be refrigerated if immediate transport to lab is not available.
Alpha 1-antitrypsin	To identify protein loss in the stool	Protein-losing enteropathies and diarrheal disease	Fresh stool specimen sent to lab in clean container.
<i>Other</i>			
Hydrogen breath test	Uses gas-liquid chromatography to measure amount of hydrogen exhaled after ingestion of a carbohydrate solution; usually lactose based	Used to diagnose carbohydrate malabsorption and bacterial overgrowth of the intestine. Elevated levels of hydrogen may be found in the breath of patients with lactase deficiency, mucosal damage, delayed intestinal transit, or colonic flora in the small intestine.	Child must be NPO before the procedure. Expired air is collected before ingesting a carbohydrate drink and at 30-minute intervals for 3 hours afterward. Family to bring child's usual bottle or cup from home to facilitate intake of drink, and a favorite toy or activity to provide distraction during waiting time.
Gastric pH	To assess pH of gastric secretions. Gastric secretions are aspirated from a nasogastric or gastrostomy tube. Secretions are placed on pH paper, and resulting color is compared with color chart.	Low pH may indicate gastritis. Usual goal in treating gastritis is a gastric pH level more than 4. For checking newly inserted nasogastric tubes, gastric placement indicators are an aspirate of pH less than 5 along with aspirate characteristics Aspirate characteristics that indicate gastric origin: Grassy green color; clear, colorless, or off-white to tan mucus with sediment; brown mucus. Aspirate characteristics that indicate inadvertent respiratory placement: Watery,	pH may be altered by medications such as proton pump inhibitors, H ₂ -receptor antagonists.

Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
		<p>straw-colored fluid, possibly with streaks of bright-red blood; mucus-containing fluid that resembles secretions obtained with tracheal suction.</p> <p>Aspirate characteristics that indicate intestinal placement: Light to dark golden yellow or brownish green color (from bile staining).</p> <p>If pH is more than 6, suspect inadvertent respiratory placement, especially if aspirate characteristics support this possibility.</p>	
Alanine aminotransferase (ALT), aspartate aminotransferase (AST)	To assess the degree of hepatocellular damage in liver disease and graft function in liver transplantation. Also used to monitor liver function in children receiving hepatotoxic medications and parenteral nutrition.	<p>ALT is the enzyme that most specifically indicates hepatocellular injury.</p> <p>AST is the enzyme that is present in heart, muscle, and liver; levels increase with hepatocellular injury.</p>	<p>For all blood tests, explanation of procedure and support of child during specimen collection.</p> <p>Blood sample collection, sending to lab in correct container.</p> <p>Assessment for best choice of local topical anesthetic agent and administer prior to venipuncture for serum studies. Use standard precautions.</p>
Gamma glutamyl transferase (GGT), alkaline phosphatase (ALP)	To assess liver function	<p>GGT elevation indicates cholestasis, obstructive liver disease.</p> <p>ALP indicates cholestasis disorders or extrahepatic obstruction. ALP may also be elevated in children with rickets secondary to impaired intake or absorption of calcium and phosphorus.</p>	
Ammonia	To monitor patients with severe liver failure	<p>Normal level indicates liver is functioning and is able to excrete ammonia.</p> <p>Elevated in patients with hepatic encephalopathy.</p>	
Bilirubin (total, direct [conjugated], indirect [unconjugated])	To evaluate liver function and determine cause of various forms of jaundice	<p>Levels are elevated in many forms of liver disease.</p> <p>Unconjugated bilirubin reflects altered function outside the liver, whereas conjugated bilirubin</p>	<p>Normal neonatal hyperbilirubinemia has elevated unconjugated bilirubin.</p>

(Continued)

Tests and Procedures 18–1 Evaluating Altered Gastrointestinal Status (Continued)

Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
		reflects altered function within the liver. Total bilirubin is the sum of the two values.	
Hepatitis antigens, antibodies	To detect causative agents of hepatitis infection	Specific antibodies and antigens help to determine whether infection is active, chronic, or resolved.	
Total protein, albumin	To monitor nutritional status and liver function	Levels may be elevated with dehydration. Levels are decreased in patients with malnutrition, liver disease, and protein-losing enteropathies. Albumin takes a long time to become depleted in the body, so a low level reflects a long-term chronic problem.	Low levels may manifest by peripheral edema or ascites.
Vitamins A, D, E, and K	To identify deficiencies and evaluate response to replacement therapy	Absorption of fat-soluble vitamins A, D, E, and K may be impaired in children with malabsorption syndromes or liver disease.	Vitamin A important in maintaining skin and mucous membranes; plays a role with night vision. Vitamin D promotes intestinal absorption of calcium, phosphate; depleted in peripheral neuropathy, rickets, osteoporosis. Vitamin E acts as an antioxidant; depleted in peripheral neuropathy. Vitamin K, synthesized by gut flora; necessary for blood clotting factors; depleted in coagulopathies, hemorrhagic manifestations such as bruising and bone mineralization.
Zinc	To determine zinc levels	Zinc is normally excreted through the GI tract. Children with excess losses through the GI tract from diarrhea or prolonged nasogastric drainage may be at risk for deficiencies.	Zinc is an important element in protein synthesis and wound healing.

supported before, during, and after each diagnostic procedure. Preparing the child and family includes providing developmentally appropriate explanations of the test's purpose, steps, and duration, as well as anticipatory guidance about sensations the child may experience

during the test. Sedation is commonly used for many endoscopic procedures and requires vigilant monitoring of the child (see Chapter 10). Consult with a child life specialist, when available, to aid in preparing the child.

Obtain and handle diagnostic specimens carefully. Many agents that cause GI illness, such as viral and bacterial stool pathogens, are highly infectious. Maintain meticulous attention to standard precautions.

ANSWER: Although both ultrasound and CT scanning can provide images of the appendix, CT scanning with contrast will provide much more information. After the contrast has progressed through the bowel to the cecum, it will very quickly highlight images of the ruptured appendix. The contrast will then be absorbed and begin to collect in the bladder. If the child's kidneys are functioning normally, this will be verified by the CT scan as well.

TREATMENT MODALITIES

The disease and child's clinical condition determine the treatment needed. Treatment may include therapeutic endoscopy, surgical intervention, or nutritional therapy with targeted infant formulas, modified oral diets, or enteral or parenteral nutritional support.

Therapeutic Endoscopy

Therapeutic endoscopy involves the use of endoscopic techniques to treat specific GI alterations. It may be used for dilation of strictures (most commonly in the esophagus), foreign body removal, sclerotherapy (use of an agent that leads to thrombosis and obliteration of the vein) to treat esophageal and gastric varices and dilated blood vessels, and excision of polyps. Gastrostomy tubes, such as a percutaneous endoscopic gastrostomy (PEG) tube, transpyloric tubes, or gastrostomy-jejunostomy (G-J) tubes, used to deliver enteral nutrition, may be placed by endoscopy.

Surgical Intervention

Surgical intervention is used to repair alterations in GI tract structures, remove diseased structures, or, in the case of liver transplantation, replace nonfunctional structures. Surgical intervention may also be used to place medical devices, such as gastrostomy tubes and central venous catheters, used for therapeutic interventions. Surgical interventions specific to the GI disorders described in this chapter, along with the associated nursing care issues, are discussed in the section covering that disorder.

General care of the child undergoing surgery is discussed in Chapter 11.

Controlling pain and promoting deep breathing are particularly important for the child after abdominal surgery. Pain may prevent full diaphragmatic excursion and proper lung expansion, increasing the risk of atelectasis. Encourage the use of an incentive spirometer to promote lung excursion.

Peristalsis takes longer to return after abdominal surgery than after surgery in other systems. This delay

TRADITION OR SCIENCE 18–1

Are bowel sounds adequate for assessing the return of GI motility after abdominal surgery?

MORE INQUIRY NEEDED

Listening to bowel sounds has long been the traditional way to determine when GI motility resumes after abdominal surgery, but the usefulness of this practice has not been rigorously tested. A recent study conducted on adults who had undergone abdominal surgery found that auscultation of bowel sounds was not a reliable postoperative clinical indicator of return of GI motility. The study findings indicate that the return of flatus and first postoperative bowel movement are more appropriate for this purpose. More inquiry is needed to provide evidence that these findings can be applied to the pediatric population (Madsen et al., 2005).

depends in part on the extent of bowel manipulation during surgery. Monitor for the return of bowel sounds by auscultating the child's abdomen periodically (see Tradition or Science 18–1). Assist with early ambulation to facilitate peristalsis and keep the child NPO until peristalsis returns.

Excess losses of fluid from the GI tract, such as with suction, vomiting, diarrhea, hypoproteinemia, and malnutrition, may cause fluid and electrolyte imbalance. Monitor the child's fluid and electrolyte status, and administer appropriate replacement therapy as ordered.

Ostomy

An **ostomy**, or *stoma*, is a surgically created opening between the GI tract and the outside of the body (Fig. 18–3). Ostomies can be created at various sites in the GI

FIGURE 18–3. An ostomy with a healthy, pink, moist stoma.

tract and may be temporary or permanent, depending on the child's clinical condition. An *esophagostomy* communicates between the esophagus and an external site on the neck. A *gastrostomy* provides an opening between the stomach and the abdominal wall. Ostomies may be created at various sites in the small intestine (e.g., jejunostomy, ileostomy) or in the large intestine (e.g., colostomy).

A certified wound, ostomy, continence nurse (CWOCN)—a registered nurse with specialized training and certification in the management of ostomies and skin care—is an essential resource and support person for the child with an ostomy and the child's family. The CWOCN collaborates with the surgeon in ostomy site selection whenever possible and provides information regarding product selection, pouching techniques, and patient and family education.

Interdisciplinary management of the child with an ostomy includes both interventions involving direct care and those that promote self-care or care by parents. Developmental issues are varied. The parents of an infant with an ostomy may need instructions about clothing options that protect the pouch system from the infant's exploring hands. School-aged children and their parents, along with school personnel, may need help in dealing with an ostomy in the school setting. The adolescent may have concerns regarding body image and sexuality that need to be discussed. Referral to community support groups may provide children and their families with additional resources to assist with adjustment issues.

Nutritional Therapy

Modified infant formulas, specific oral diets, enteral and parenteral nutrition (PN), and specialized feeding techniques are all used in treating the child with altered GI status. Nutritional therapy is an interdisciplinary effort and requires the participation of many healthcare team members. The nurse plays an important role not only in delivering the various nutritional therapies, but also in assessing the child's response to therapy and in teaching the child and family about the therapeutic regimen.

QUESTION: Will Cory require special nutritional therapy?

Infant Formulas

Infant formulas are available in a wide range of formulations designed to meet a variety of nutritional needs. *Breast milk* is the gold standard for infant feeding. The composition of breast milk is ideally suited to the term infant's nutritional needs and the digestive and absorptive capabilities of the infant's GI system. When breast milk is fed to a preterm infant, it must be supplemented with a *human milk fortifier*. This product supplements

the caloric, protein, vitamin, and mineral (especially calcium and phosphorus) content of the breast milk to meet the increased requirements of the preterm infant. *Standard cow's milk infant formulas* are designed to meet the nutrient needs of infants up to age 1 year. They are commonly available in powder, liquid concentrate, and ready-to-feed preparations. There is an increase in the number of infant formulas containing the long-chain polyunsaturated fatty acids docosahexaenoic acid and arachidonic acid. These long-chain polyunsaturated fatty acids are components of lipids that make up cell and intracellular membranes. Docosahexaenoic acid is found in high amounts in the retina and brain whereas arachidonic acid is essential for normal growth (Hattner, 2005). For home use, the powdered form is usually the most economic. *Preterm infant formulas* contain increased concentrations of calories, protein, electrolytes, minerals, vitamins, and long-chain polyunsaturated fatty acids to meet the unique physiologic and nutritional needs of the premature infant's immature system. *Soy-based infant formulas* use a soy protein instead of cow's milk protein and are designed for infants with lactase deficiency, galactosemia, or allergy to cow's milk protein, or those whose parents want to feed them a vegan diet. A substantial number of infants with lactose intolerance or true cow's milk allergy also exhibit allergy to soy proteins. For these infants, as well as infants with various disorders of digestion and absorption, *protein casein hydrolysate formulas* may be indicated. These formulas are hypoallergenic; their protein component is broken down, and their fat and carbohydrate components are modified to facilitate digestion and absorption. Pregestimil (Mead Johnson) and Alimentum (Ross) have 55% and 33% fat, respectively, as medium chain triglycerides, which do not require the normal fat digestive pathway. Pregestimil formula is most commonly used in the care of infants with short bowel syndrome and disorders that result in malabsorption of fat, such as biliary atresia or cystic fibrosis. Nutramigen (Mead Johnson), although it has casein hydrolysate, also has a regular fat source and is indicated only for milk and soy protein allergy. Pure amino acid-based formulas, Neocate (SHS) and EleCare (Ross), are chemically defined formulas based on synthetic amino acids. These formulas are appropriate for infants who have cow's milk protein intolerance or multiple food protein allergies and cannot tolerate casein hydrolysate formulas (Hattner, 2005).

Modular components can be added to the various infant formulas to increase the concentration of a specific component within the formulas. Individual fat (e.g., medium chain triglyceride oil), carbohydrate (e.g., Moducal, Polycose), and protein (e.g., Casec) supplements are available that may be used to increase the caloric or nutrient density of the formula.

The caloric and nutrient density of infant formulas may also be altered by varying the amount of water used to mix the formula. Normal caloric density of infant formula is 20 cal/oz. An infant who has increased calorie and nutrient requirements but is fluid restricted or cannot tolerate a large volume of formula may need a concentrated

formula. Formula is concentrated by mixing less than the standard amount of water to formula in the powder or liquid concentrate form. Formulas may be concentrated up to as much as 30 cal/oz in this manner. Formulas may be diluted by mixing them with more water to create various strengths. An example is the use of one-half strength formula advanced to three-quarters strength and then to full strength while the infant is monitored for formula intolerance. Dilution is usually a short-term strategy. Teaching parents and other caregivers about the proper use of infant formulas is an important nursing responsibility in both acute care and ambulatory settings. Topics to cover include appropriate formula selection, proper technique for mixing and storing formula, and assistance with formula procurement (see Chapter 4). Parents may try to save money by diluting formula or attempt to “give better nutrition” by feeding concentrated formula. Teach parents that altering caloric density by adding more or less water should be done only with the guidance of a healthcare provider. Also teach parents never to mix powdered infant formula with oral electrolyte or rehydrating solutions. Doing so can cause electrolyte imbalance.

Modified Oral Diets

Modified oral diets are another form of nutritional therapy used to treat children with GI disorders. The consistency of oral diets may be altered to facilitate ingestion of food for children with oropharyngeal, esophageal, or neuromuscular (e.g., cerebral palsy) impairments that

make ingesting foods difficult. The nutrient composition of a child’s diet may be altered to meet disease-specific requirements (Table 18–2).

Various oral supplements can be used to increase caloric and nutrient intake for a child unable to meet nutritional needs from usual dietary sources. Milk-based oral supplements, such as Carnation’s Instant Breakfast or dried powered milk, may be added to cow’s milk to supplement calories and protein. Clear liquid oral supplements, such as Resource (Novartis) or Carnation Instant Breakfast Juice Drink (Nestle), a juice drink, are supplemented with protein. Lactose-free oral supplements may be used as a supplement or as a sole source of nutrition. These formulas (e.g., PediaSure [Ross], Kindercal [Mead Johnson]) have 1 cal/mL, are isotonic, and are formulated to meet the nutritional requirements of children 1 to 10 years of age when adequate volumes are tolerated. Adult lactose-free oral supplements may be used for older children and are available in a variety of preparations, including fiber-enriched, high-protein, and high-calorie formulas.

Although most oral supplements are available in a variety of flavors, many children may initially complain about their palatability. Collaboration with the child and parent, as well as creativity, is helpful in promoting acceptance of oral supplements.

KidKare ■ Provide opportunities for the child to try different flavors. Altering the temperature and texture of the oral supplement to present them in

TABLE 18–2

Modified Oral Diets

Diet	Description	Indications
Puree, mechanical soft	“Blenderized,” ground, or chopped whole foods	Dysphagia, esophageal stricture
High fiber	Dietary fiber increased in soluble and nonsoluble forms	Constipation, irritable bowel syndrome
Lactose free	Milk, milk products, lactose-containing foods eliminated	Lactose intolerance, primary or secondary
High protein, high calorie	Added portions of food sources of protein, fat provided to increase calorie, protein content of diet	Weight less than ideal for age; increased calorie and protein needs for wound healing; cystic fibrosis
Fat controlled	Limiting of dietary fat	Pancreatitis, gall bladder disease
Protein restricted	Limiting protein intake to decrease nitrogenous waste products in bloodstream	Advanced liver disease, renal dysfunction
Salt restricted	Sodium intake restricted to varying degrees, depending on whether purpose is to reduce sodium, fluid retention, or both	Liver disease, children on corticosteroid therapy, renal dysfunction
Gluten free, gliadin free	Avoids gluten-containing foods; eliminates gliadin to reduce symptoms caused by sensitivity to gliadin from wheat, rye, oats, and barley	Celiac disease, celiac sprue (gluten intolerance)

child-friendly forms may also be helpful. Popsicles can be made by freezing the supplement, or a slushy drink can be made by blending the formula with ice. Some supplements offer flavor packets to avoid taste fatigue.

Formulas and nutritional supplements continue to be modified and expanded as a result of advances in nutrition. Prebiotics (nondigestible substances that stimulate the growth of normal flora) and probiotics (live bacteria that benefit the host) have gained increased attention. The purpose of these substances is to support the environment of the GI tract in restoring and maintaining a healthy immunologic state (Hattner, 2005). Probiotics have been shown to be effective in the reducing the risk of antibiotic-associated diarrhea, decreasing the duration of acute diarrhea, and supporting growth of healthy infants during the first 6 months of life (Kligler, Hanaway, & Cohrssen, 2007). Studies have also examined their use to treat infant colic (Savino et al., 2007) and to establish the safety of administering probiotics to infants. However, more controlled studies are needed to provide evidenced-based recommendations for use with children to identify specific products to treat specific conditions and doses.

Enteral Nutrition

Children with functional GI tracts who are unable to meet their fluid or nutrient requirements by oral feeding may require enteral nutrition (Chart 18–1). Enteral feeding allows fluids and nutrients to be delivered directly into the GI tract by means of an enteral feeding tube. Contraindications to enteral nutrition include complete intestinal obstruction, intractable vomiting, and severe enterocolitis.

Enteral Formulas

Various formulas are used for enteral feeding. Formula selection is dictated by the child's age, clinical condition, and nutrient requirements. Children younger than age 1 may receive breast milk and standard or specialty infant formulas by enteral feeding tube. For older children, a number of enteral feeding formulas are available.

Standard tube feeding formulas are nutritionally complete and designed for use in children with normal digestion and absorption, such as the formulas used as a sole source of nutrition discussed earlier in Modified Oral Diets. *Elemental formulas* are designed for use in children who have impaired digestion and absorption. These formulas are partially predigested, with protein supplied as peptides or amino acids and a large proportion of fat supplied in the form of medium chain triglycerides. Elemental formulas are available in both pediatric and adult formulations (e.g., Pediatric Vivonex, Peptamen Junior [Clinitec]). Older children and adolescents may use formulas designed for adults, such as Ensure or 2 cal HN, depending on the underlying GI condition. Occasionally, an elemental formula

CHART 18–1 INDICATIONS FOR ENTERAL NUTRITION

Gastrointestinal Disorders

- Esophageal atresia, strictures
- Gastroesophageal reflux
- Inflammatory bowel disease
- Liver disease
- Malabsorption, chronic diarrhea
- Motility disorders
- Pancreatitis
- Short bowel syndrome

Increased Metabolic Needs

- Burns
- Sepsis
- Trauma
- Congenital heart disease
- Bronchopulmonary dysplasia
- Cancer
- Cystic fibrosis

Chronic Disease

- Acquired immune deficiency syndrome
- Renal disease

Neurologic Disorders

- Head injury, coma
- Cerebral palsy with oral–motor impairment
- Dysphagia
- Tumor

Prematurity

Psychiatric Disorders

- Anorexia nervosa

may be used as an oral supplement. Flavor packets are available to increase the palatability of these formulas. Some tube feeding formulas are designed for use in specific disease states, such as renal failure or liver failure. Modular components may be added to elemental formulas to supplement their carbohydrate, fat, or protein concentrations.

Enteral Feeding Methods

Enteral feedings are delivered into the stomach or into the small intestine if the child is at risk for pulmonary

aspiration. Feedings may be delivered on a continuous or an intermittent schedule. *Continuous enteral nutrition* feedings are administered slowly over 12 to 24 hours using an enteral pump. Continuous feedings are used when feedings are being delivered into the small intestine. They are also indicated whenever an enterally fed child is assessed to be at high risk for aspiration or has impaired digestion and absorption of nutrients. Nocturnal continuous feedings may also be used to supplement the daily dietary intake in children with some chronic conditions who have increased nutritional needs (e.g., cystic fibrosis, inflammatory bowel disease [IBD]).

Intermittent enteral nutrition is administered by bolus or gravity drip method on an interval schedule. The frequency and volume of the feedings are determined by the patient's age, size, and nutritional goals. A small infant may receive intermittent feedings every 3 to 4 hours, whereas an adolescent may require feedings only every 6 to 8 hours. Intermittent feedings more closely approximate the normal hunger–satiety physiologic cycles of normal meals.

Enteral Feeding Tubes

Various enteral feeding tubes may be used to deliver enteral nutrition. Tube selection depends on the child's age, clinical condition, nutrient requirements, desired feeding route, and the expected duration of therapy. The orogastric feeding tube is most commonly used for premature infants or infants younger than age 4 weeks, who are obligate nose breathers and who might experience respiratory distress, airway obstruction, or both if a feeding tube is passed transnasally.

Nasoenteric feeding tubes (nasogastric [NG] or nasojejunal tubes) are small-bore feeding tubes passed transnasally through the esophagus into the stomach or small intestine (see Nursing Interventions 11–6; see also [thePoint](#) for Procedure: Enteral Tubes: Naso/Orogastric Placement and Management and Nasojejunat Management). NG or nasojejunal tubes are used for short-term enteral nutrition when the length of therapy is expected to be less than 3 months. These tubes may stay in place continuously or may be inserted intermittently, as indicated by the child's feeding regimen (Fig. 18–4).

Nasoenteric tubes for short-term or intermittent use were previously made from polyvinyl chloride (contains di-[2-ethylhexyl] phthalate, a chemical compound that makes plastic products flexible, strong, and moldable). This substance was found to pose risks to the pediatric population. Today nasoenteric tubes are made from polyurethane or silicone. These tubes are less irritating and may stay in place for up to 4 weeks. They come with a wire stylet, which may be inserted into the tube to stiffen it and facilitate placement. When the stylet is used, it is removed before using the tube for feeding. For feeding, select a tube of appropriate length with the smallest available exterior diameter. Polyurethane tubes are often preferred, because their internal diameter is larger than that of comparably sized silicone tubes

FIGURE 18–4. The child with an NG tube. Assess to ensure that the NG tube does not exert pressure on the nares to avoid skin breakdown. Commercially available securement methods are available or tape can be used to secure the tube.

Alert! If you encounter resistance during placement of a nasoenteric feeding tube, do not force the tube. Withdraw the tube and attempt placement again. Use of excessive force may cause perforation. Because of the potential for perforation, never reinsert a stylet while the tube is in the patient.

Gastrostomy tubes and *jejunostomy tubes* are placed to support nutritional needs in a variety of conditions and routes (Fig. 18–5). Many types of tubes are available, from a variety of manufacturers. Follow the manufacturer's instructions for use and ensure that you are familiar with the types used in your institution. Review and know the policies and procedures specific to each device (see [thePoint](#) for Procedures: Enteral Tubes Placement and Management: Gastrostomy, PEG, Skin-Level Devices, and Jejunostomy; see also [thePoint](#) for Supplemental Information: Comparative Chart of Gastrostomy Tubes in Children and Troubleshooting Common Gastrostomy Tube Problems).

Interdisciplinary Interventions

Care of the child receiving enteral nutrition involves the following activities:

- Managing the enteral feeding tube and enteral nutrition delivery system to ensure accurate delivery of fluid and nutrients, and prevent system-related complications
- Monitoring the child's response to enteral nutrition, including metabolic complications

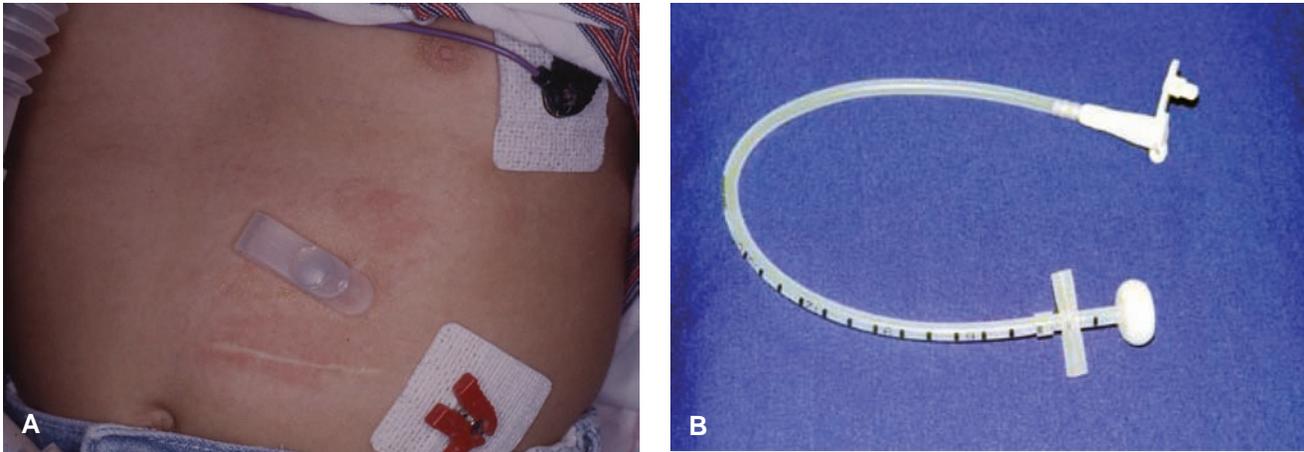

FIGURE 18–5. Gastrostomy tubes. (A) A skin-level gastrostomy access device has a low profile and therefore is not as bulky or obvious as other gastrostomy tubes. (B) A PEG gastrostomy tube has an internal tip that is dome shaped and anchors the tube in the body, which prevents the tube from falling out. The crossbar at skin level prevents internal tube migration.

- Supporting the child’s and family’s educational and developmental needs with regard to the therapy

Care of the child receiving enteral nutrition is an interdisciplinary effort, and interventions are enhanced through collaboration with other members of the health-care team. The dietitian plays a key role in assessing nutritional status, calculating nutrient requirements, selecting formulas, monitoring response to therapy, and educating the patient and family. The occupational therapist may be involved in helping to promote oral feeding skills (see Chapter 17). Collaborate with the advanced practice nurse or CWOCN to teach care of the enteral tube site. The pharmacist is a valuable consultant for drug and nutrient interactions when medications must be administered by enteral feeding tubes.

Before administering a feeding, verify that the feeding tube is placed as is appropriate for the type of tube. To minimize the possibility of aspiration with enteral feedings, elevate the head of the bed to a minimum of ≥ 30 degrees, and preferably to 45 degrees, for all patients receiving enteral nutrition unless a medical contraindication exists (Bankhead, Boullata, Brantley et al., 2009). Administer feeding as ordered (Fig. 18–6). Although flushing enteral feeding tubes with cranberry juice or carbonated cola beverages is frequently cited as the most effective method for maintaining tube patency, research has indicated that water is an equally effective flushing agent (Metheny, Eisenberg, & McSweeney, 1988) (see Tradition or Science 18–2 and [thePoint](#) for Procedures: Enteral Feeding).

Research has suggested that the practice of providing nonnutritive sucking (NNS) experiences is beneficial to infants. NNS incorporates the use of a pacifier to stimulate oral-motor function when alternate feeding routes are indicated. Improved weight gain, decreased heart rate and energy expenditure, decreased restlessness, and increased alert states have all been documented with NNS, as have decreased length of stay and pain control (Pinelli & Symington, 2005). However, an extensive review of well-controlled studies in hospitalized preterm

infants, in which NNS was examined as part of the plan of care, concluded that further research is needed to establish evidence that NNS provides a direct benefit in terms of behavioral outcomes, GI function, or feeding (Pinelli & Symington, 2005). No harmful effects of NNS were reported when a pacifier is used safely.

Assess GI, hydration, and nutritional status. Monitor the child for abdominal distention, nausea, or vomiting. Assess stool output and stooling patterns. When the child’s nutritional status and enteral intake are being stabilized, monitor gastric residuals before each intermittent feeding and every 4 to 6 hours during continuous feedings. If residuals exceed ordered parameters, hold the feeding and notify the physician or advanced practice nurse. Gastric emptying is facilitated by a right-side-down or prone position. However, the child’s position after feeding must be in accordance with the American Academy of Pediatrics’ Back to Sleep recommendations for safety. (Task Force on Sudden Infant Death Syndrome, 2005).

Obtain and document the child’s weight daily. Check height and head circumference (in children younger than age 3 years) weekly. Compare current and previous values to evaluate the child’s growth pattern. Also monitor for signs of dehydration or fluid overload; electrolyte imbalance; and vitamin, mineral, and trace element deficiencies.

Community Care

Most children with feeding tubes are sent home with the tube in place, making parent education and planning for home management a priority in the plan of care. Collaborate with discharge planning personnel to ensure that the child and family have appropriate formula, supplies, and home equipment. Teach the family (and child, as developmentally appropriate) how to care for the enteral feeding tube, to prepare and administer enteral feedings, to monitor for complications, and attend to developmental and safety issues. Ensure that the outpatient follow-up plan is coordinated with the home health agency (TIP 18–1). Collaborate with the parents and school staff

FIGURE 18–6. (A) Enteral devices such as the “button” require that a feeding tube be connected to the device to instill fluids. (B) Before beginning the feeding, gently aspirate a gastrostomy tube for gastric contents or attach the barrel of a syringe to the tubing and gently palpate the child’s abdomen. Note the presence of gastric contents in the syringe. Avoid vigorous aspiration because it might pull gastric mucosa against the tube.

to facilitate transition back to school and the standard classroom (see Chapter 12).

ANSWER: Not necessarily. Cory will not receive any oral feeding immediately after surgery until his intestines are active and functioning. During this recovery period, he will receive fluid, glucose, and electrolytes via

TRADITION OR SCIENCE 18–2

Is the time-honored practice of auscultation after insufflation of air over the epigastric region adequate for verifying NG or orogastric feeding tube position?

EVIDENCE-BASED PRACTICE

Nursing research indicates that testing the pH of aspirates and evaluating the aspirated contents is a more reliable way of verifying enteral feeding tube placement than the commonly used practice of auscultating the abdomen while insufflating air through the feeding tube (Huffman, Jarczyk, O’Brien, et al., 2004; Metheny & Meert, 2004; Westhus, 2004).

his peripheral IV. When he has evidence of return of bowel function, he will start with a soft diet and progress to a regular diet. However, as noted in Chapter 6, Cory’s nutritional status was not optimal before this illness. He may benefit from nutritional supplements, particularly protein. Protein is necessary for wound and tissue healing, and Cory has poor protein stores and often refuses to eat foods that are high in protein.

NURSING PLAN OF CARE FOR THE CHILD WITH ALTERED GASTROINTESTINAL STATUS

QUESTION: Which of the nursing diagnoses in Nursing Plan of Care 18–1 are applicable to Cory?

Analysis of assessment findings will identify nursing diagnoses pertinent to that child and family. Chapter 11 identifies nursing diagnoses commonly applicable to the psychosocial needs of the acutely ill child. Nursing diagnoses pertinent to the child with an alteration in GI status often reflect an alteration in nutrition or fluid and electrolyte status resulting from the GI condition. Nursing diagnoses generally applicable to a child with altered GI status are identified in Nursing Plan of Care 18–1. Nursing diagnoses more specific to each particular GI disorder are identified in the section covering that disorder.

ANSWER: Nursing diagnoses applicable to Cory may include the following:

- Deficient fluid volume related to inadequate intake
- Acute pain related to the effects of GI system dysfunction
- Imbalanced nutrition: Less than body requirements related to effects of alteration in GI tract function

TIP 18-1 Teaching Intervention Plan for the Child With a G-tube, or J-Tube, or G-J Tube

Nursing diagnoses and family outcomes

Deficient knowledge

- Care of enteral feeding tube; safety issues regarding enteral feeding

Outcomes:

- Family and child, if developmentally appropriate, will demonstrate proper care of tube.
- Child will not develop complications associated with the presence of an enteral feeding tube (displacement, blockage, infection).

Imbalanced nutrition:

- Less than body requirements related to effects of child's condition

Outcomes:

- Child will demonstrate appropriate weight, height, and head circumference growth along own growth curve.
- Family and child will demonstrate appropriate feeding techniques.

Teach the child/family

Enteral Feeding Tube Care

Maintaining Placement

- Monitor integrity of system used to secure tube. Resecure as necessary.
- Monitor position of G-tube or G-J tube before each feeding and with site care by pulling back gently on the tube to ensure inner balloon or retention device is snug against abdominal wall (cannot be done with skin-level G-tubes). For tubes with an external segment, compare the graduated centimeter markings with the baseline measurement for tube position verification.
- If the tube becomes dislodged, cover site with clean gauze and tape, and notify the healthcare provider.

Maintaining Patency

- Flush tube with water after each intermittent feeding or every 4 to 6 hours during continuous feedings, per protocol. Monitor total fluid volume of flushes to prevent fluid overload.
- Administer medications in liquid form. If medications must be crushed, consult with pharmacist regarding appropriate solution for dissolving medications. Never crush enteric-coated or time-release medications.

- Administer medications one at a time. Flush before, after, and in between multiple medications.
- Flush every 8 hours if tube is not being used.
- For G-J tubes, verify the port for medication administration (usually the feedings are given through the J-port and the G-port is used for gastric decompression). Maintain scheduled flushing; for example, flush J-tubes every 4 to 6 hours around the clock during the continuous delivery of feedings.

Preventing Infection

- Provide site care every 24 hours or whenever area around tube is moist or crusted with secretions.
- Use sterile saline to clean around newly placed tubes; use half-strength hydrogen peroxide if necessary to remove dried blood or crusted secretions at tube exit sites.
- Use of soap and water are recommended on well-healed tube sites.
- Dry site thoroughly after cleaning and apply external securing device as necessary for specific tubes.
- Avoid covering tube sites with ointments or occlusive dressings unless otherwise instructed. This practice may cause moisture retention at the tube site and may promote granuloma formation.
- Rotate the gastrostomy tube every 24 hours when performing skin care. Turn the tube 360 degrees, which helps to prevent the tube from imbedding in the gastric mucosa. *Do not rotate J- or G-J tubes*, because doing so may cause torque and retraction of the tube into the stomach or kinking of the tube.

Administration of Enteral Feedings

Preparing for Feeding

- Prepare formula, including type, concentration, amount. Use premeasured volume of formula at room temperature.
- Check for gastric residual before starting feeding by gently aspirating from tube with a syringe or positioning the tube below the level of the stomach with only the barrel of the syringe attached.
- Position with head elevated 30 to 45 degrees, either upright in lap, lying on right side, or sitting and supported as indicated.

Administering Feeding

- By enteral pump, connect the tubing to the enteral feeding tube and adjust the rate.
- By syringe, connect the syringe barrel to the tube, pour the formula into the syringe, and let it free flow slowly by gravity. It should take about as long as it would if the child was sucking or drinking the formula.
- If formula does not flow freely, reposition the child slightly and give a brief but gentle push to start the flow with syringe plunger. Do not force, and do not use plunger to infuse entire feeding.

After Feeding

- Flush tube with a small amount of water, unless contraindicated. Leave G-tube open for 5 to 10 minutes after feeding to allow for escape of air.

Preventing Infection

- Change enteral feeding pump bags every 24 hours.
- Limit formula in enteral feeding bags to no more than 4 hours worth or per policy.
- Refrigerate excess formula after opening and use within 24 to 48 hours.

Safety

- Never use parenteral infusion equipment for administration of enteral feedings. Inadvertent administration of enteral formulas through the parenteral route has been reported and has led to fatal complications.
- Keep the tube secured to the body to prevent dangling and accidental dislodgment.
- Elevate the child's head at least 30 degrees during feedings and for 30 to 60 minutes afterward to reduce the risk of aspiration.
- Avoid warming the formula using a microwave oven.

Developmental Considerations

- Provide infant with pacifier during enteral feedings.
- Provide all children with developmentally appropriate social interaction during enteral feedings.
- Use developmentally appropriate safety precautions to ensure integrity and safety of enteral feeding system. For example, cover site with a shirt so an infant cannot pull at tube. Use longer feeding tubing when child is learning to walk. If the child is on nighttime feedings, thread tubing through pajamas and out the bottom of the leg to avoid the child getting tangled up in tubing.
- Normalize the child's routine so that the feeding can be administered during mealtimes with family.

Contact Healthcare Provider if:

- Feedings will not infuse
- The tube looks shorter or the centimeter markings on the external tube segment have changed (the tube may have moved/migrated)
- Child has diarrhea or vomiting with no other signs of illness
- Child has signs of infection, such as increased amounts of yellow or green drainage from the skin exit site; tenderness, swelling, or increased redness around the skin exit site; fever
- Child has vomiting, diarrhea, constipation, increasing abdominal distention, general discomfort, or signs of dehydration (decreased urination, lack of tears, dry mucous membranes) or fluid overload (shortness of breath, edema)
- Child experiences pain with feeding
- The tube has leakage or redness around it
- The tube is accidentally dislodged

ALTERATIONS IN GASTROINTESTINAL STATUS

Alterations in GI status can take many forms. The cause can be difficult to ascertain, as in failure to thrive (FTT) or, more obvious, as with physical malformations. GI status is also affected by inflammatory disorders; disorders that affect GI motility, function, and absorption; and hepatic disorders.

FAILURE TO THRIVE (FTT)

FTT is often used as a diagnosis, yet it is actually a symptom. Continuing debate in the literature illustrates the

lack of consensus in using FTT as a diagnosis as well as in defining it. Some experts propose abandoning the term *FTT* altogether for one that is more accurate, such as *pediatric undernutrition*, *inadequate growth*, or *growth deficiency*.

Although consensus does not exist on the definition of FTT, a working definition for this text can be considered. FTT is the failure to grow at a rate consistent with expected standards for infants and toddlers younger than 3 years of age (Gahagan, 2006). FTT is thought to be a result of interaction between the environment and the child's health, development, and behavior.

Traditionally, discussion has included three types of FTT:

NURSING PLAN OF CARE 18–1: FOR THE CHILD WITH ALTERED GASTROINTESTINAL STATUS

Nursing Diagnosis: Deficient fluid volume related to inadequate intake or excessive losses from GI tract

Interventions/Rationale

- Assess child's hydration status (moistness of mucous membranes, presence of tears when crying, skin turgor).
Assessment provides baseline data to evaluate changes in child's status and facilitates early detection of changes.
- Monitor for factors that might cause deficient fluid volume (e.g., inadequate intake, diarrhea, vomiting, fever).
Early identification of risk factors enables early intervention to minimize the fluid deficit.
- Weigh the child daily.
Change in weight is a good estimate of fluid balance, especially in young children, who have a greater proportion of body water in the extracellular space.
- Record intake and output; weigh diapers.
Measurements provide quantitative evidence that enables evaluation of fluid balance to detect imbalance.
- Monitor for signs of increasing dehydration (e.g., less elastic skin turgor, depressed fontanel, sunken eyes, weight loss, rapid pulse, dry mucous membranes, decreasing urine output) and report to physician or advanced practice nurse.
Early identification of fluid deficit enables early intervention to replace lost fluid.
- Monitor laboratory reports (e.g., electrolytes, pH, hematocrit, serum albumin, urine specific gravity).
Laboratory test results facilitate evaluation of child's status and response to therapy.

Expected Outcomes

- Child will achieve and maintain normal fluid and electrolyte balances.
- Child and parents will identify signs of fluid imbalance and implement interventions to treat it.

Nursing Diagnosis: Acute pain related to the effects of GI system dysfunction, procedures, and treatments

Interventions/Rationale

- Assess and document the onset, location, duration, character, intensity, and aggravating and relieving factors of pain during the initial evaluation. Assess

pain with vital signs or more frequently when clinically indicated. Use a validated scale with which the child and staff are familiar.

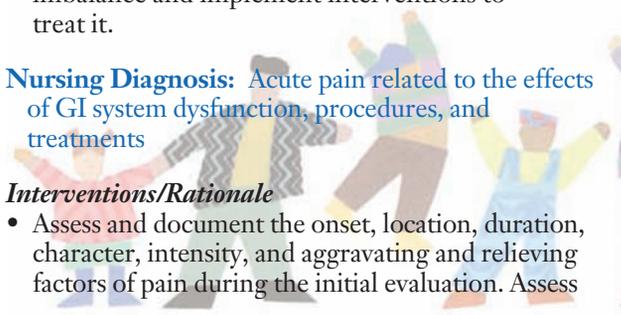

The bowel is sensitive to pressure; increased bowel transit time and a hyperosmotic load cause stretching and spasms in the intestines. When diarrhea or vomiting is present, abdominal cramping and distension are often accompanying symptoms. The initial assessment directs the pain management plan. The child's self-report is the most reliable evidence. To obtain accurate assessments, reliable and valid scales must be used correctly.

- Minimize crying, burp child as necessary.
Crying may increase swallowing of air, which may lead to abdominal distention. Burping helps to expel swallowed air.
- Use biobehavioral methods to cope with pain. Position the child with knees flexed. If age appropriate, teach the child to use slow, controlled breathing.
Positioning with knees flexed minimizes stretching of the peritoneum; relaxation may help reduce anxiety, which can intensify the pain experience, and may provide distraction from the pain.
- Administer ordered medications when indicated (e.g., postoperative narcotics, topical anesthetic for IV insertion). If pharmacologic management is indicated but not ordered, contact the advanced practice nurse or physician to obtain orders.
Appropriate medications may be necessary to ensure effective relief from pain.
- Prepare children and families for procedures and teach them pain relief interventions that they can use (e.g., deep breathing, relaxation, distraction).

Anxiety may exacerbate pain. Knowing what to expect during medical encounters and how to manage discomfort through the procedure may help alleviate anxiety. Knowing how to manage pain may empower the child and family, and also facilitates prompt implementation of comfort interventions. Collaborate with a child life specialist to incorporate multimodal interventions.

Expected Outcomes

- Child will verbalize complaints of discomfort.
- Child will state a decrease in pain level with appropriate interventions.
- Child will remain free of behavioral signs of discomfort.

- Child and family will describe interventions to be implemented if the child experiences pain.

Nursing Diagnosis: Imbalanced nutrition: Less than body requirements related to effects of alteration in GI tract function

Interventions/Rationale

- Assess and document growth parameters; activity; eating behaviors, patterns, and habits; dietary choices, including food likes, dislikes, and intolerances; and knowledge about development, diet, and nutrition, using an interdisciplinary approach.

An interdisciplinary approach with a nurse, physician, dietitian, occupational therapist, and child life specialist augments the assessment process to incorporate developmentally based nutritional goals for the plan of care.

- Include the parents and child in goal development and solicit input about their perceptions of and ability to meet the nutritional goals and plan of care.

Parent and child “buy-in” is essential to the success of the plan of care.

- Encourage parents to bring in the child’s favorite foods or those that are most culturally familiar within prescribed restrictions if appropriate, if they cannot be provided within the organization.

Favored or familiar foods are more likely to be accepted and consumed by the child.

- Consider placing the child on a reward system based on meeting nutritional goals, such as a sticker chart with incremental rewards. Computer or video game time may be effective in rewarding the older child.

A reward system provides positive feedback and an incentive to the child to try to meet the goal or perform the desired behavior.

- Document intake and output, and daily weights.

Measurements provide objective data to evaluate the child’s response to therapeutic nutritional goals.

- Determine and implement behavioral modifications as clinically indicated, including feeding and eating techniques, such as postural or oral control techniques; portion control; environment control, such as eating meals with family and others or creating a TV-free environment during mealtime; offering scheduled nutritional oral supplements and snacks; position to prevent aspiration; avoid odors that may stimulate nausea.

Appropriate environmental controls may make it easier for the child to consume adequate nutrients.

- Explore the parents’ and child’s perception of body image and concerns of health status as it

relates to nutrition. Solicit concerns and questions.

Lack of knowledge or inaccurate perceptions may increase anxiety and result in activities that undermine the treatment plan. Knowing the child and parents’ perceptions enables teaching to address inaccurate beliefs or modification of the treatment plan to accommodate the concerns.

- Discuss and explore feelings about alternative feeding approaches if oral methods continue to place the child at nutritional risk. Emphasize that alternative feeding methods do not indicate failure on anyone’s part, but rather are needed to provide the recommended nutrition as a result of the underlying GI condition.

Implementing an individualized plan of care with nutritional goals optimizes the likelihood of increasing nutritional intake and of implementing an ongoing plan to meet the needs of children at nutritional risk.

Expected Outcomes

- Child and family will identify ways to achieve appropriate nutritional intake.
- Child will demonstrate appropriate nutritional intake.
- Child will maintain growth velocity along own growth curve.

Nursing Diagnosis: Impaired skin integrity related to inadequate nutritional intake
See Nursing Plan of Care 25–1.

Nursing Diagnosis: Deficient knowledge: Child’s GI condition and treatment

Interventions/Rationale

- Assess family’s knowledge of child’s condition and care needs.

Baseline assessment assists in focusing teaching to family’s needs.

- Use developmentally appropriate methods to teach child and family about the condition.

Knowledge facilitates appropriate management of the condition and enhances the transition to successful home management.

- Instruct parents in the proper method of making, storing, and giving formula/meals.

Inappropriately prepared or stored formula/food may cause dehydration (concentrated, hyperosmolar solutions), inadequate weight gain and nutrition (overly dilute formulas do not provide sufficient calories), and disease (bacterial overgrowth may occur).

- Teach parents to manage child’s condition (diet, treatments) and what symptoms to report to healthcare provider.

(Continued)

NURSING PLAN OF CARE 18–1: FOR THE CHILD WITH ALTERED GASTROINTESTINAL STATUS (CONTINUED)

Appropriate management facilitates optimal outcomes. Appropriate intake may reduce fluid and electrolyte imbalances and support weight gain.

- Use facts and examples to teach good hand hygiene technique and sanitation habits; observe return demonstration.

Hand hygiene reduces transmission of microorganisms.

Expected Outcomes

- Child and family will describe the illness and will identify important clinical manifestations and potential complications.
- Child and family will describe the treatment plan for the illness and will demonstrate the ability to administer the necessary medications and treatments.

Nursing Diagnosis: Delayed growth and development related to lack of opportunity or restrictions imposed by condition, parents, or self; inability to participate in developmentally appropriate activities

Interventions/Rationale

- Routinely compare weight and height measurements with previous measurements and age-appropriate norms.

Comparisons can provide evaluation of the child's growth trajectory.

- Assist the family in evaluating the child's regressive response to illness or chronic health condition. Explain the effect of acute illness or a chronic condition on the child.

Children typically regress when ill. A chronic condition may impose restrictions that limit the child's energy or ability to engage in age-appropriate activities. Parents who understand their child's responses are better able to support the child and assist him or her in achieving full potential.

- Provide developmentally appropriate activities, tailored to the child's needs and situation.

Tailored activities facilitate the child's ability to participate and achieve milestones.

Expected Outcomes

- Child will perform developmentally appropriate tasks.
- Parents will identify normal developmental milestones for their child and ways to help their child achieve these milestones.

1. Organic FTT: Associated with an underlying medical condition
2. Nonorganic FTT: Most commonly diagnosed at 5 years or younger, has no associated medical conditions affecting poor growth
3. A combination of both types

The etiology of organic-related FTT is linked to a vast number of diagnoses resulting in poor growth that may span all systems. Table 18–3 provides some selected examples in each system that may affect growth. More descriptive diagnoses for nonmedical FTT are now identified as having developmental or psychological problems, such as sensorimotor disorder, disorder of infancy, family relationship problem, or oral–motor dyspraxia (Gahagan, 2006).

The precise incidence of FTT is not known. However, nonorganic FTT is reported to occur in 5% to 10% of the pediatric population and in 3% to 5% of all admissions to pediatric acute care units. At least 80% of cases occur before 18 months of age, during the time of rapid weight gain and linear growth (Locklin, 2005).

Pathophysiology

Regardless of the etiology, FTT during the first year of life is a serious condition. The brain grows as much during the first year of life as it grows throughout the rest of the child's life (Bauchner, 2007). Maximal post-natal brain growth occurs during the first 6 months of life.

The pathophysiology of organic FTT depends on the causative condition. Nonorganic FTT was recognized during the early 20th century. Historically, the mother's characteristics, such as depression, substance use, social isolation, and maltreatment of mother during childhood, were attributed as the central cause of this condition. These characteristics rendered the mother unable to effectively nurture, parent, or feed her infant or child. "Maternal deprivation syndrome" or "maternal neglect" was a diagnosis given to infants and children whose FTT was thought to have a psychosocial origin. Certain infant behaviors also may contribute to growth failure. Some of these behaviors include being difficult to feed, apathetic, aversive to

TABLE 18-3

Medical Conditions That Contribute to Organic Failure to Thrive

System	Contributing Etiology
GI	GERD, celiac disease, malabsorption syndromes, structural anomalies that effect oral-motor function (e.g., cleft palate), tracheo-esophageal fistula, pyloric stenosis, intractable diarrhea, Hirschsprung disease, inflammatory bowel disease, chronic liver disease (e.g., biliary atresia, hepatitis)
Cardiopulmonary	Congenital heart disease, heart failure, chronic lung disease, asthma, cystic fibrosis
Renal	Chronic kidney diseases, renal tubular acidosis
Metabolic/genetic	Inborn errors of metabolism, congenital syndromes (e.g., Pierre Robin Syndrome), chromosomal conditions (e.g., Cornelia de Lange syndrome)
Neuromuscular	Cerebral palsy, degenerative diseases (e.g., muscular dystrophy, spinal muscular atrophy), conditions that include dysphagia
Endocrine	Hypothyroid, hypoparathyroid, pituitary disorders (e.g., congenital hypopituitary, adrenal disorders, growth hormone deficiency), diabetes mellitus, diabetes insipidus
Infection	Intrauterine infections, human immunodeficiency virus, tuberculosis, parasitic infections
Miscellaneous	Malignancy, lead poisoning

cuddling, passive, inactive, irritable, and not wanting to be touched. Despite these known behavioral descriptions, the etiology of nonorganic FTT remains poorly understood.

Altered maternal-infant interaction is agreed to play a major role, however. The transactional model is used to explain this relationship. The model examines the altered reciprocal interaction between the mother and infant, including environmental influences that affect the relationship over time. For example, the household is a disorganized and chaotic environment, the infant is apathetic and passive, and the mother misinterprets the infant cues and therefore does not meet the infant's needs. Over time, this ineffective interaction alters the mother-infant dyad. The poor fit between the infant and mother results in malnutrition. Many studies conducted on nonorganic FTT have described the characteristics of the mother, infant, and environment after the diagnosis. Greater understanding of how nonorganic FTT develops may be gained by prospectively assessing the mother-infant interaction to help sort out those characteristics of the mother-infant dyad that contribute to nonorganic FTT.

Assessment

A careful history is the cornerstone to direct the plan of care. This history includes the prenatal history with regard to maternal lifestyle, medication use, and illnesses; birth history; postnatal history; and the condition that triggered the current medical encounter. Verify the child's age to ensure that the child's growth parameters are plotted correctly on growth charts. After malnutrition

or inadequate growth is established, a plan is developed to support the nutritional deficit while the workup for the etiology ensues.

Inadequate growth may result from inadequate caloric intake, inability to retain the calories (e.g., malabsorption), and/or increased caloric expenditure (e.g., chronic lung disease). Obtain a careful dietary history to assess whether intake is inadequate because the nourishment provided is inappropriate, or nourishment is appropriate but intake is inadequate. Ask about type of formula, volume consumed per 24 hours, and method of formula preparation. If the child is eating solid foods, a typical recall of the day's intake may be helpful, as will the frequency of meals and snacks. Inquire about the timing and type of food introduced in the diet. Elicit information about the characteristics and number of stools per day and wet diapers or voids. Also ask whether vomiting occurs, its characteristics, and amounts.

WORLDVIEW: Sensitivity to ethnic, cultural, and religious differences may help clarify information, understand the use of home remedies, and avoid misunderstandings about growth problems. For example, duration of breast-feeding and introduction of solid food may be culturally determined. Contemporary cultural norms regarding fear of obesity and the desire to maintain a "healthy" or "organic" diet may also play a role in some situations.

Diagnostic Tests

In general, when nonorganic FTT is suspected, no single study can verify this diagnosis. Studies are guided from

positive findings from a careful history and physical. Basic screening tests may be performed to obtain baseline information. Screening for iron deficiency anemia, tuberculosis, lead poisoning, and chronic urinary tract infection along with review of neonatal screening test results are recommended. Other tests include complete blood count (CBC); electrolytes, including blood urea nitrogen; creatinine; and liver function tests, including total protein and albumin. Prealbumin, a hepatic protein also called *transthyretin*, may be obtained as a baseline nutritional marker, because prealbumin levels are a good measure of visceral protein status. Prealbumin is more sensitive than albumin as an indicator of nutritional recovery, because it has a half-life of 2 days, reflecting more recent changes in nutritional status than albumin's 21-day half-life (Loughrey & Duggan, 2005). Monitoring prealbumin trends and patterns provides information to direct nutritional interventions. Findings from the history and physical examination determine indications for additional specific tests. For example, an infant with a history of frequent regurgitation may need a pH study to rule out GERD.

Nursing Diagnoses and Outcomes

Nursing Plan of Care 18–1 presents a variety of nursing diagnoses that can be applied to the child with altered GI status. Nursing diagnoses applicable to the child with organic FTT are dependent on the causative condition. The following nursing diagnoses and outcomes are specifically applicable to the child with nonorganic FTT:

Impaired parenting related to parental low-self-esteem, depression, or other psychosocial issues; negative perception of the child; poor fit between parent and child temperaments or interactional styles

Outcome: Parent will express acquisition of progress toward positive feelings and demonstrate adequacy in the parenting role.

Ineffective health maintenance related to impaired family dynamics, lack of resources

Outcomes: The family will identify existing medical and community services and accept assistance.

Interdisciplinary Interventions

When FTT is determined to be secondary to a medical diagnosis, the ability to intervene with an effective plan of care is more direct than for FTT from a nonmedical and environmental/developmental/behavioral cause. Ongoing monitoring, with supportive interdisciplinary interventions, is necessary for all children. This discussion focuses primarily on nonorganic FTT.

An interdisciplinary team is most effective in this complex condition. The team consists of a physician, nurse, dietitian, medical social worker, occupational therapist, and child life specialist. Additional expertise,

such as that of a psychologist or psychiatrist, may be indicated.

Providing adequate energy through calories for growth is the cornerstone of therapy. The physician and dietitian develop a plan of care to meet the nutritional goals based on assessment findings. Calorie-dense formulas for infants and high-calorie foods for older children are given, including oral nutritional supplements. Multivitamin supplements with minerals, including iron and zinc, are recommended.

The occupational therapist assesses oral–motor dysfunction; the medical social worker assesses the family system related to stressors, financial issues, support systems, and feelings the parents are experiencing. The nurse provides support, education, and accurate information about feeding and setting limits; and feedback about interactions, reading behavioral cues, and developmentally based parenting skills. Careful measurement of weight, length, and, for children younger than 3 years of age, head circumference is done on admission. Daily monitoring of weight is critical to assess the response to the plan of care and nutritional interventions. When possible, weigh the child before breakfast, at the same time of day on the same scale, without clothing unless the child is older than 36 months.

Observing the primary caregiver and the child's response to her or him is a critical part of determining an individualized plan of care. Observing these interactions during feeding or mealtime can yield valuable information, because caregiver–child relationships are demonstrated through these interactions. Insights into the nature of nonorganic FTT may be revealed. Note concerning behaviors on the part of the caregiver, such as making negative comments about the child, not paying attention to the child, lack of responsiveness or awareness of the child's feeding cues, inability to feel comfortable around the child, or rough handling of the child. Also note positive actions of the caregiver, such as talking to the child, and positioning the child so that the child is comfortable for feeding and can make eye contact. Note concerning behaviors of the child, such as crying, agitation, or rigidity during feeding. Also note positive feeding behaviors of the child, such as appearing relaxed and interacting with caregiver. Nurses often address the more salient behaviors of the caregiver–child interactions, but frequently fail to address the synchrony of behavioral cues between the mother and child (MacPhee & Schneider, 1996).

Community Care

After the child has demonstrated a successful weight-gaining pattern, a follow-up plan is determined. The interdisciplinary approach ensures that all aspects of community programs are accessed. If FTT is found to originate from a medical condition, then the follow-up plan and home care management are focused to meet the needs of the family and child with a new medical diagnosis and possibly a lifelong chronic condition.

Subspecialist care and follow-up care are determined based on diagnosis.

Close follow-up with a monitoring plan for continuity of care when the infant shows developmental/behavioral problems related to FTT (e.g., occupational therapy) may be an option. When FTT is determined to be from neglect or maltreatment, referrals to Child Protective Services may be needed to determine the risk and safety factors if the child is returned home with the same caregiver. Family preservation and maintenance with close monitoring through home health visits and Child Protective Services to support the child's continued positive growth pattern may be the best option. Depending upon the severity of their conditions, some children may be placed out of the home. The appropriate support systems, referrals, and education are directed to optimize transition to home and to normalize the family and child's function as much as possible. Referral to Women, Infants and Children (WIC) to obtain formula and nutrient-rich foods is helpful when financial resources are stressed. Additional programs that provide coordinated interdisciplinary follow-up when the child or family meets criteria for these services are arranged; for example, they may qualify for Medicaid, Children's Medical Services, and parenting classes (see Chapter 2).

MALFORMATIONS OF THE UPPER GASTROINTESTINAL TRACT

Malformations of the upper GI tract that can affect GI function include cleft lip, cleft palate, esophageal atresia (EA), tracheo-esophageal fistula (TEF), and pyloric stenosis.

Cleft Lip and Palate (CLP)

Cleft lip and cleft palate, which often occur together, are the most common congenital craniofacial anomalies. The overall incidence of cleft lip and palate (CLP) malformations varies by ethnic group—1 in 300 in the Asian population and 1 in 2,000 in the African American population. The distribution of cleft types is approximately 46% for combined CLP, 21% for isolated cleft lip, and 33% for isolated cleft palate (Brown et al., 2006).

Multiple causes have been identified for CLP. Familial patterns of inheritance have been established for CLP and, to a lesser extent, for cleft palate alone. Environmental factors have also been identified in the etiology of CLP, such as alcohol and tobacco use (resulting in fetal hypoxia). Drugs such as phenytoin and retinoids (Sadove, van Aalst, & Culp, 2004), dietary factors such as folic acid and vitamin deficiencies, and intrauterine irradiation have all been implicated. Folic acid is recommended as a supplement for women of childbearing age not only to prevent neural tube and abdominal wall defects, but also to help prevent CLP (Merritt, 2005). CLP is also associated

with particular syndromes, and advances in genetics continue to add information to assist in differentiating etiologies.

The child with CLP may have long-term problems with impaired facial growth and dental anomalies. Speech disorders may also occur. Eustachian tube dysfunction is also associated with cleft palate and can increase risk for recurrent otitis media and associated hearing impairment. Mortality is related to the severity of associated syndromes.

Pathophysiology

Cleft lip results from incomplete or failed fusion of embryologic structures, the maxillary and medial nasal elevations, between the fifth and eighth weeks of gestation. The cleft may be unilateral or bilateral and may vary from a small indentation in the lip to a wide, deep fissure that extends to the nostril (Figs. 18-7 and 18-8). Dental anomalies may also be present, with missing, malpositioned, or deformed teeth.

Between the seventh and 12th weeks of gestation, the palate is formed by the migration and fusion of the lateral palatine processes. Cleft palate occurs when the processes fail to migrate and fuse normally. The cleft may involve only the soft palate or may extend into the hard palate. A less obvious type of cleft palate, a submucous cleft, is the most common of the posterior palate clefts. The incidence is estimated to be between 2 and 8 per 10,000 (Sadove et al., 2004).

Children with CLP may have other associated anomalies. Although some may be relatively minor, others, such as cardiac malformations, may be life threatening. More than 300 different syndromes that include cleft defects, particularly cleft palate, have been reported. Cleft palate is most often part of a syndrome, whereas cleft lip is more often isolated (Merritt, 2005). Trisomy 13, Pierre Robin syndrome, and Treacher Collins syndrome are associated with a cleft palate. Because of familial patterns of inheritance and the many associated syndromes, genetic counseling is recommended for families.

Assessment

If a diagnosis of CLP is made in utero by ultrasound early during the pregnancy, the family is referred to the interdisciplinary cleft team before the birth of the child. If not diagnosed in utero, cleft lip and, in most cases, cleft palate is immediately obvious at birth.

Visual inspection and palpation of the palate all the way back to the soft palate should be done as part of every newborn examination. When cleft palate is not noted at birth, nasal regurgitation of fluids may alert the healthcare team to its presence. Submucous clefts are difficult to diagnose, because the entire palate may appear intact. Therefore, the defect may not be identified until the child is older and presents with hypernasal speech. A bifid uvula, a hard palate with a notched posterior, or a translucent area in the midline of the soft palate are anatomic clues leading to diagnosis.

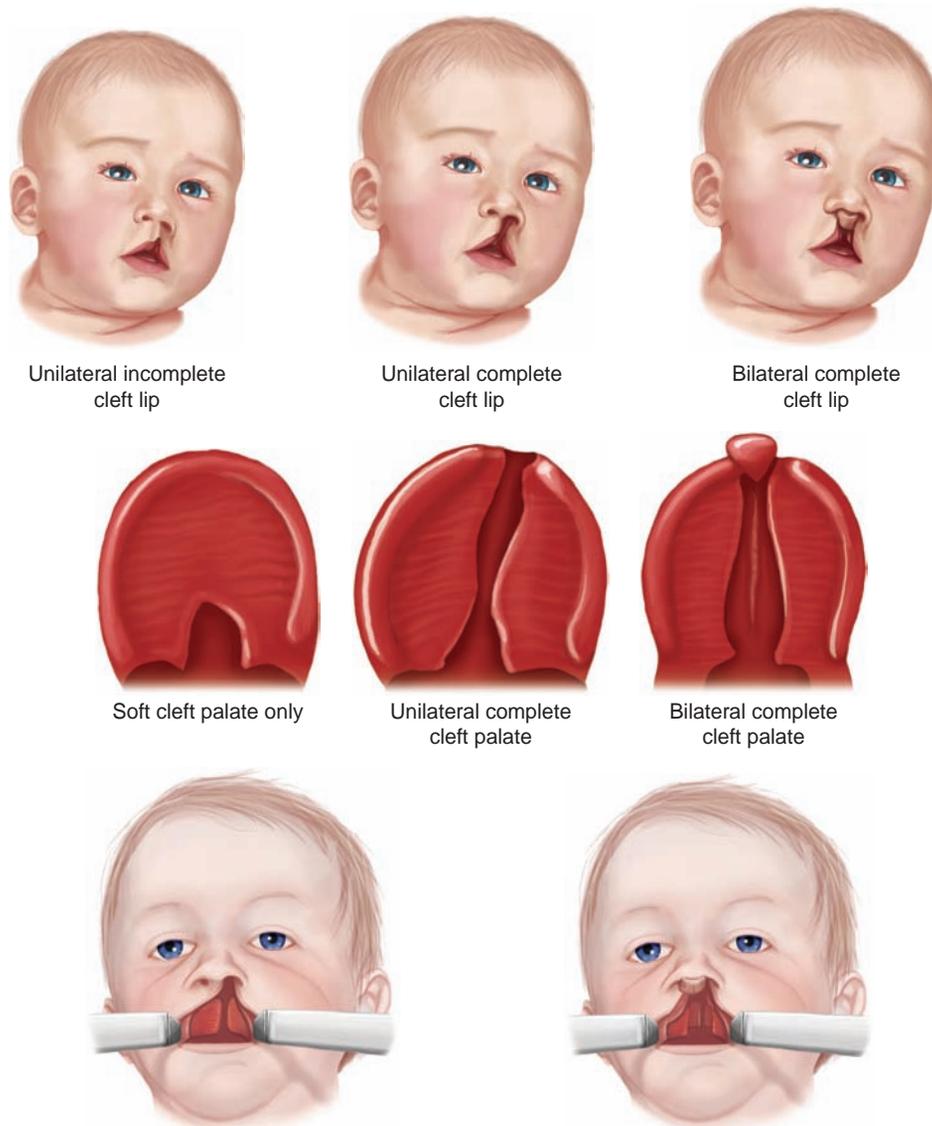

FIGURE 18–7. Variations of cleft lip and palate.

Nursing Diagnoses and Outcomes

In addition to those listed in Nursing Plan of Care 18–1, the following nursing diagnoses and outcomes may apply to the child with CLP:

Impaired parenting related to perception of an infant with a cleft lip, palate, or both

Outcomes: Parents will verbalize acceptance of the child and demonstrate appropriate nurturing behaviors.

Parents will use psychosocial support and services to facilitate their coping and adjustment responses.

Chronic low self-esteem related to perception of facial deformity and speech impediment

Outcomes: Child will demonstrate appropriate behaviors consistent with their developmental level.

Child will demonstrate absence of signs of depression, and will report sleeping well and performing well in school.

Interdisciplinary Interventions

Care of the child with cleft lip or palate involves a large interdisciplinary team, including the pediatrician; nurse; plastic surgeon; oral surgeon; ear, nose, and throat surgeon; audiologist; orthodontist; speech therapist; occupational therapist, social worker; and geneticist. The nurse's role involves providing direct care to the child, along with supporting the parents, educating them about their child's care, and coordinating services.

FIGURE 18–8. (A–C) Child with cleft lip and palate at birth (A), immediately after lip repair (B), and at 3 years of age (C).

Psychological Support

When the diagnosis of cleft lip is made at birth, after the initial stabilization and assessment, the parents need information about their neonate's condition. Because of the obvious and disfiguring nature of the defect, its presence is often very distressing to the family. Provide information about the anomaly and anticipated care needs in simple, direct terms. Providing the same information during more than one encounter is helpful, because parents may easily become overwhelmed trying to process new information while dealing with the crisis of the birth of a child with a visible defect. Early involvement of a member of the CLP team is recommended to provide the family with accurate information about the child's condition and treatment plan.

The family's emotional response to the birth of a child with cleft lip, palate, or both may range from grief to anger to denial (see Chapter 12). Convey an open, nonjudgmental attitude to encourage the parents to express their feelings. Support the family's adjustment to a child's condition by demonstrating an accepting, caring attitude toward the child and family, and by providing the parents with opportunities and support for normal infant–parent interactions.

caREminder

Point out positive qualities in the infant, such as hair and eye color, turning toward the parents' voice, and alertness to surroundings.

A systematic review of psychosocial effects of CLP reported the overall majority of children and adults do not experience major psychosocial problems. Behavioral problems, satisfaction with facial appearance, and particular aspects of social functioning were some of the reported

difficulties. Self-esteem was generally reported as good. The findings acknowledged that limited evidence exists from well-controlled studies, which are needed to clarify discrepancies in the literature (Hunt, Burden, Hepper, et al., 2005).

Feeding

The infant with cleft lip or palate presents special challenges in terms of feeding. Although the infant with cleft lip alone may do well with either breast- or bottle-feeding, the infant with a cleft palate may experience problems if the defect renders the infant unable to generate negative suction pressure in the oropharynx, and milk is regurgitated into the nasal cavity. Breast-feeding may be more successful, because the compliant breast forms a seal on the lip, palate, or both. Consultation with a lactation specialist may be helpful. Bottle-feeding may require modification of the nipple.

Alert! Closely monitor an infant with CLP who is being breast-fed for weight gain and hydration status.

Many feeding methods have been described to facilitate feeding the infant with cleft palate, including use of various nipple designs, cross-cut nipples, and palatal obturators. No single feeding technique is best; any method that enables the infant to complete feeding in a 20- to 30-minute period and supports adequate growth is acceptable.

Use feeding methods that promote sucking, whenever possible, because use of the orofacial muscles is necessary to develop those muscles and to develop feeding and speech skills. Rarely, feeding must be done using a large syringe with rubber tubing at the tip to instill formula in the side of the infant's mouth or by

FIGURE 18–9. The Haberman Feeder is used for children with cleft palate and other orofacial problems that hamper the child’s ability to nurse.

NG tube. If these feeding methods are necessary, involve an occupational therapist, a speech and language therapist, or both to assess, develop, and maintain oral–motor skills. The Pigeon Bottle (Children’s Medical Ventures) may be recommended for an infant with bilateral or a wide unilateral cleft. A compressible-type squeeze bottle is helpful when the infant cannot feed within an appropriate time frame with a standard bottle. Other products used include the Haberman Feeder (Medela) and Mead Johnson Cleft Palate Nurser (Fig. 18–9). Remind parents that patience is the key to the feeding process.

Surgical Interventions

Operative repair of a cleft lip usually takes place at age 2 to 3 months. The goals of the surgery are to close the defect and to achieve a balanced, symmetric appearance. The timing of cleft palate repair is controversial and varies from age 6 months to 2 years. It also depends on the nature of the defect, the presence of other anomalies, and surgeon preference. Earlier repairs are believed to support normal speech development, whereas later repair is thought to support palatal growth with less disruption of the midfacial hypoplasia. The lack of clear evidence favoring one approach over the other has led to a compromise: Most cleft palate repairs are done at age 12 to 24 months, and preferably prior to 18 months of age, after speech patterns have been established. The insertion of bilateral ventilation tubes (in the ears) has become the standard of care. Tube insertion has been correlated with better outcomes by reducing hearing screening failures and by preventing otitis media.

Cleft lip repair usually involves only a 24-hour hospital stay or is done as an outpatient procedure, whereas cleft palate repair typically involves a 2-day hospital stay. Preoperative preparation of the family focuses on providing information regarding the surgical procedure and the

child’s postoperative care needs both in the hospital and at home (TIP 18–2).

Immediate postoperative care focuses on airway management, hemostasis, and pain control. The child is at risk for airway compromise because of laryngeal edema caused by intubation during surgery and incisional edema. After palate repair, the child must learn to breathe through smaller nasal passages. Blood clots may also fall off the incision and obstruct the airway. Use of a high-humidity oxygen tent may be ordered. Observe the child carefully for signs of respiratory distress, bleeding, and excess mucus in the mouth.

Alert! Use a bulb syringe for suctioning. A soft catheter or low suction should be used only in an emergency, avoiding the suture lines. Remember that the roof of the mouth is also the floor of the nose.

Position the child with the head of the bed elevated 30 degrees to prevent secretions from pooling in the oropharynx. If only the palate has been repaired, position the child on his or her abdomen.

Bleeding may occur at the suture line. Apply gentle pressure or ice to the lip incision, as ordered. If the child is bleeding from the palate repair, intervene as needed for respiratory distress and notify the physician.

Pain is not unusual during the first 24 to 48 hours postoperatively. Assess the need for analgesics and evaluate their effectiveness after administration (see Chapter 10). Anticipate the child’s needs and meet them *before* the child becomes distressed. Medicate for pain relief. Also minimize pain and discomfort from other sources (e.g., hunger, wet diaper, need for attention or repositioning) to prevent crying, which results in tension on the suture line.

The child must be prevented from putting his or her hands near the mouth, to avoid disturbing the incision. Therefore, elbow immobilizers are used for the first 10

TIP 18-2 A Teaching Intervention Plan for the Family of the Child With Cleft Lip/Palate

Nursing Diagnoses and outcomes

- Imbalanced nutrition: less than body requirements related to impaired ingestion of nutrients

Outcomes:

- Infant will take in adequate nutrients for normal growth and development.
- Infant will show weight/length increases along growth curve.
- Parents will demonstrate the ability to feed the infant in a manner that facilitates optimal intake of nutrients.
- Risk for infection related to effects of dysfunctional eustachian tubes, aspiration, or surgery

Outcomes:

- Child is free from ear and respiratory infections, incisional infection postoperatively
- Parents verbalize an understanding of the symptoms of infection and appropriate follow-up measures.
- Risk for injury related to potential trauma at operative site post cleft lip/palate repair

Outcomes:

- Operative site will be protected from injury using developmentally appropriate measures. Family will demonstrate an understanding of how to prevent injury to the operative site

Deficient knowledge:

- Cleft lip/palate pathology and treatment, feeding and suctioning techniques, surgical site care

Outcomes:

- Child is free from complications associated with cleft lip/palate.
- Family is able to describe the pathology of cleft lip/palate, short- and long-term potential complications, and treatment plan.
- Family verbalizes the need for corrective surgery and possible later revisions.
- Family demonstrates appropriate feeding, suctioning, and restraint techniques and surgical site care.

Teach the family

Preoperative Care

Feeding

- Children with cleft palates in particular may have trouble generating enough pressure to feed.

- If breast-feeding manually extend nipple and place it in child's mouth. Talk with a lactation consultant.
- If not breast-feeding, use squeezable bottles which may be easier for the child to feed from.
- Place the nipple in the child's mouth; ensure that the nipple is in a normal feeding position, not the cleft. Place your index finger lengthwise over the cleft in lip to help create suction. Encourage sucking by stroking cheek or moving jaw.
- Compress the bottle with infant's sucking cues and allow rest time.
- Feed the child slowly in an upright position. Watch for cues that infant is getting too much formula or not enough (if formula flow is a consistent problem, the feeding system may need to be modified) or needs to rest. Burp frequently but not so often that it frustrates the infant, causing increased distress.
- Hold and feed the infant in a relaxed manner to avoid communicating anxiety to the Infant.
- Position the infant in an infant seat or on right side after feeding.

Oral hygiene

- Offer the infant water after every feeding to clean the mouth of formula.
- If the infant has a removable maxillary prosthesis, remove and clean it every day.

Preventing infection

- Monitor for signs of infection such as fever over 101°F (38.3°C), excessive mucus, coughing, rubbing ears, diarrhea, and irritability.
- Keep child away from persons with upper respiratory tract infections.
- Use good feeding techniques to prevent aspiration; suction oropharynx with bulb syringe as needed.
- Reposition the child every 2 hours.

Preparation for surgery

- Practice feeding technique that will be used postoperatively; check with surgeon to verify. Which technique will be used, some may allow breast-feeding or bottle-feeding with enlarged nipple; others prefer a syringe with feeding tube at the end be used for feeding; it is helpful to teach this technique regardless so the child will be familiar with it, because pain may prevent the child from sucking postoperatively.

TIP 18–2 A Teaching Intervention Plan for the Family of the Child With Cleft Lip/Palate (Continued)

- Use rubber tubing or 8 French feeding tube cut to 1 inch, attach to 30-mL syringe, and pull formula into syringe; fill enough syringes for the feeding to avoid having to stop feeding and frustrating the infant.
- Hold infant upright as for normal feeding; direct tube to side of cheek away from surgical site.
- Drip feeding into mouth by gently pushing on the plunger.
- Burp after every 15 mL.
- Practice this until comfortable; this may help avoid distress postoperatively.
- Apply elbow immobilizers for a few hours each day so the infant becomes used to wearing them.
- Secure immobilizers snugly enough so they do not slip, but not so tight that they impair circulation; your index finger should be able to fit under the immobilizer to make sure they are not too tight, check the child's hands to make sure they are warm and pink.
- Remove the immobilizers every hour, one at a time, so the child can exercise that arm; check the skin under the immobilizer at this time for signs of irritation.

Postoperative Care

Pain management

- Administer analgesic as prescribed, for pain; do not hesitate to medicate for pain because a comfortable child is less likely to cry and put stress on the suture line. Discomfort usually lasts 2 to 4 days after surgery.
- Use biobehavioral measures such as distraction, putting in swing, reading books, or playing music to comfort child.

Positioning

- Position the child upright in infant seat, on side or back; do not put the infant on his or her abdomen after lip repair to avoid rubbing the incision on the sheets and injuring it.

Incision care

- Clean the lip incision three times a day with sterile water or ordered solution and apply thin layer of antibiotic ointment (how often to clean, solution, and ointment will be prescribed by the surgeon)

Feeding

- Use the feeding method practiced preoperatively; avoid touching or putting stress on the suture line. Usually for lip repairs breast- or bottle feeding is permitted, for palate repairs, use syringe with feeding tube at end.
- Avoid putting things into the child's mouth, such as pacifiers, feeding utensils, straws, or cups with a spout.
- Feed only liquids or pureed foods as ordered; do not give foods that need to be chewed or have chunks in them.
- Offer infant water after every feeding to clean mouth of formula.

Immobilizers

- Keep the elbow immobilizers on at all times; to check fit use the same technique as practiced preoperatively; monitor for adequate circulation and skin irritation.
- Remove immobilizers every hour, one at a time, and closely monitor the child so nothing goes near the mouth.
- Offer a variety of developmentally appropriate distractions to keep the child content: holding, cuddling, looking, at books, touching different textured objects, picking up small objects and putting them in a container, puzzles, clay; wagon rides.
- Use the immobilizers until the surgeon says to stop, usually 2 to 6 weeks.

Contact Health care Provider if:

Preoperatively

- Child has signs of infection fever over 101°F (38.3°C), excessive mucus, coughing, rubbing ears, diarrhea, irritability.

Postoperatively

- There is bright red bleeding from mouth or nose.
- Above signs of infection, swelling, increasing redness, or pus around the suture line is present.
- Pain is not controlled with the prescribed medications and child cannot be comforted
- Child refuses to eat.

to 14 days postoperatively. The child's hands are still free, but the elbow immobilizers prevent elbow flexion and touching or injuring the operative site. The elbow immobilizers must be secure enough so they do not slide off, but loose enough so a finger can slide underneath. Perform and document neurovascular checks on a routine basis. Release the immobilizers every hour, one at a time, to allow motor activity that encompasses the child's entire range of motion.

After cleft lip repair, the child will have sutures on the exterior portion of the lip that remain in place for up to a week. Provide wound care by cleaning the suture line regularly with normal saline; use dilute hydrogen peroxide only to remove any crusted drainage. Apply an antibiotic ointment. Clear liquids are usually offered after the child recovers from the anesthesia. The infant's usual breast- or bottle-feedings are commonly resumed within 6 to 24 hours of cleft lip repair. Resumption of oral feeding is usually delayed up to 48 hours after cleft palate repair. Use caution during the first 10 to 14 days postoperatively to avoid injury to the palatal suture line. During bottle-feeding, position the nipple so that it does not touch the palatal suture line. Avoid using straws or cups with spouts. Pureed or soft foods may be carefully fed to the child by spoon or cup. Offer water after feedings to cleanse the oral cavity.

Community Care

After surgical repair, the child with cleft lip or palate faces various ongoing health challenges. The child with cleft palate is at risk for hearing loss because eustachian tube dysfunction may cause recurrent otitis media. Speech impairments may be present because the repair may affect the function of the pharyngeal and palatal muscles, requiring long-term speech therapy. Abnormal dental development and malocclusion require the ongoing involvement of pediatric dentists and orthodontists. Maxillofacial surgery and rhinoplasty may be required later in life if midfacial growth is impaired and the nasal septum is deviated. Alterations in appearance and speech impairment may have a negative effect on the child's self-image. The involvement of social workers or other mental health practitioners is important in dealing with these concerns.

Esophageal Atresia (EA) and Tracheoesophageal Fistula (TEF)

EA is a congenital anomaly that results from failure of the esophagus to develop normally between the fourth and sixth weeks of fetal development. The proximal esophagus ends in a blind pouch instead of communicating normally with the stomach. In most cases, EA is associated with TEF, an abnormal communication between the esophagus and trachea. TEF results from failure of the trachea and esophagus to separate, an event that normally takes place between the sixth and seventh weeks of gestation.

TEF or EA occurs in 2.2 per 10,000 live births; in a recent study, 67.2% of cases were EA with TEF, 21.3% were TEF alone, and 11.5% were EA alone (Forrester & Merz, 2005). The etiology is unknown. In 40% of cases, associated congenital anomalies such as cardiac defects, or anorectal or renal abnormalities are seen (Bruch & Coran, 2006). In approximately 25% of cases, TEF occurs as a part of VACTERL association. Infants affected with VACTERL (Vertebral, Anal, Cardiac, Tracheal, Esophageal, Renal/Radial, Limb anomalies) association have three or more anomalies from a group that includes vertebral defects, anorectal malformations, cardiac anomalies (ventral and atrial septal defects are most common), TEF, EA, renal defects, and limb defects. Infants who have EA or TEF with VACTERL association tend to have higher proximal pouches, more complications, and greater mortality rates than those infants with isolated EA or TEF. GI malformations occur in 15% of infants, with anal atresia being the most common, requiring a diverting colostomy (Berseth & Poenaru, 2005).

Overall survival among children with EA and TEF approaches 90% as a result of improvements in neonatal care and surgical techniques. Prematurity and low birth weight along with congenital anomalies, most commonly cardiac, increase the mortality risk. Children with EA and TEF may experience long-term problems with esophageal dysmotility and GERD. After surgical repair, esophageal stricture at the surgical anastomosis may occur in up to one half of repairs, requiring recurrent esophageal dilation (Mortell & Azizkhan, 2009).

Pathophysiology

The esophagus and trachea normally begin to develop from a common foregut between the third and fourth weeks of gestation. During the sixth to eighth weeks of embryologic development, the mesodermal ridges form and separate the esophagus from the trachea. EA and TEF result when the trachea and esophagus fail to separate normally during this period. Epithelialization and recanalization of the esophagus also occur at this time. Failure of these normal recanalization processes has been hypothesized as a cause of EA.

EA and TEF present in various ways (Fig. 18–10). In 80% of cases, the esophagus ends in a blind pouch, with a fistula communicating between the distal esophagus and the trachea. EA without TEF is the next most common form, occurring in up to 8% of cases. TEF without EA occurs in approximately 4% of cases. This form is also known as the “H” type of TEF. Other configurations of EA and TEF have been classified.

Assessment

Clinical manifestations of EA and TEF may be noted prenatally. A maternal history of polyhydramnios is usually present in one third of cases of EA and in some cases of TEF. Inability to identify the fetal stomach strongly suggests EA.

At birth, the infant demonstrates excessive oral secretions accompanied by coughing, choking, and cyanosis,

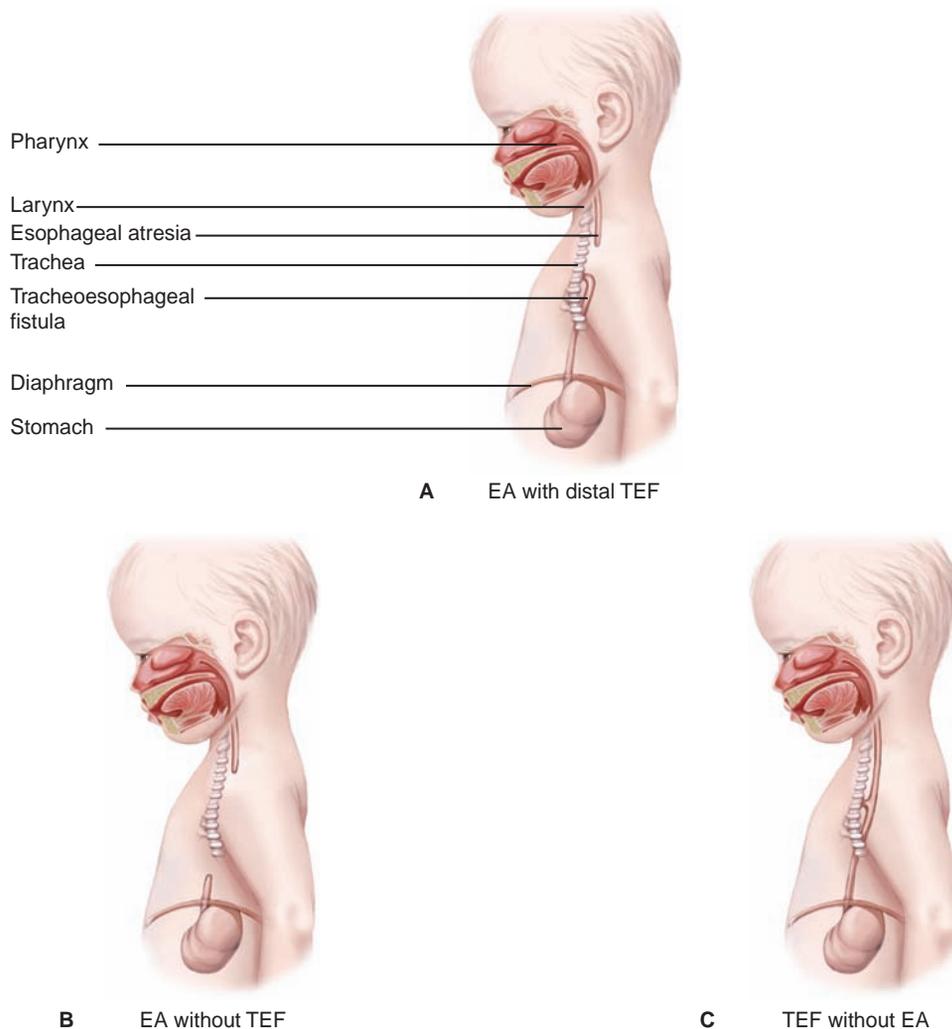

FIGURE 18–10. (A) The esophagus ends in a blind pouch with a fistula between the distal esophagus and trachea. (B) Esophageal atresia without fistula. (C) Tracheo-esophageal fistula without esophageal atresia.

which become worse when feeding is attempted (Clinical Judgment 18–1).

caREminder

Excessive drooling of saliva may be the first symptom of TEF. When fed, the infant sucks well but then chokes and coughs as the feeding enters the lungs.

Be alert for potential problems in the newborn, particularly when a maternal history of polyhydramnios exists. During physical assessment, attend to signs that may indicate a more severe problem. Problems with initiating oral feeds and signs that the infant's response to feeding is ineffective are early signals that indicate a need for further critical assessment. Assess respiratory status and position the infant supine with the head elevated to decrease aspiration risk and to protect the airway. Respiratory distress may ensue from aspiration of pooled secretions in the proximal esophageal pouch or from

secretions passing through a proximal fistula. In the presence of distal TEF, gastric juices can reflux into the respiratory tract, causing a chemical pneumonitis. Overt clinical manifestations of cardiac, musculoskeletal, or other GI anomalies may also be present.

When TEF is present without EA, diagnosis may be difficult, and the defect may not be diagnosed for several months. The infant may choke during some feedings as the formula crosses the fistula and enters the lungs. Other feedings may proceed without symptoms.

Diagnostic Tests

When TEF is suspected, a feeding tube is passed into the esophagus. If EA is present, the tube will pass only a few centimeters before resistance is felt. The diagnosis is confirmed by radiographs, which will show the tube in an air-filled upper esophageal pouch and will also indicate the presence or absence of gas in the stomach. The presence of gas in a distended stomach indicates a

CLINICAL JUDGMENT 18–1

An Infant With Tracheo-esophageal Fistula

Anh is a term newborn female, 2 hours old, with Apgar scores of 9 and 9 with no obvious congenital anomalies. The nurse noted a large amount of mucus, but, because the infant had a rapid descent through the birth canal, attributed the excessive mucus to that. Anh's father is bottle-feeding her first feeding. Anh started sucking and then turned extremely blue. The nurse suctioned Anh with a bulb syringe, getting copious amounts of secretions, and gave free-flow oxygen. Anh responded immediately and regained a pink color. The nurse tried to feed Anh herself to determine whether the cyanotic episode would be repeated. Anh eagerly began sucking, then started coughing, and became extremely cyanotic. Again, Anh responded promptly to suction and oxygen.

Questions

1. Is Anh demonstrating normal newborn behavior?
2. What behaviors are of concern?
3. Are the symptoms that Anh presents classic signs of TEF? What other pathologic process might be considered?
4. What should the nurse do?
5. Anh is 36 hours postoperative TEF repair and has a chest tube in place. What should the nurse evaluate? What are signs of complications?

Answers

1. No.
2. Duskiness with feeding and excessive saliva during the first few hours after birth are not normal. Acrocyanosis is to be expected for the first few

hours after birth; central cyanosis around the mouth and mucous membranes is not normal. A moderate amount of mucus is normal for the first 24 hours, as the infant goes through the transition to extrauterine life.

3. Anh does present with classic TEF, particularly the *immediate* color change with feeding and swallowing of fluid. Cardiac or respiratory pathology manifests as cyanosis that does not respond as well to suctioning and oxygen administration. Such cyanosis is prolonged after feedings, or continuous, and can be exacerbated by other things such as stress.
4. Position Anh upright. Maintain a clear airway with intermittent or continuous suction as necessary. Notify the physician or advanced nurse practitioner. Continue to assess Anh's cardiorespiratory status and maintain a neutral thermal environment during diagnostic testing such as chest radiograph. Provide psychosocial support for Anh's parents. Maintain NPO and IV fluids as ordered.
5. The nurse should evaluate respiratory status, functioning and integrity of chest tube, efficacy of pain management, fluid and electrolyte balance including nutritional support, incision site for integrity and infection, and parental coping. Signs of complications resulting from anastomosis leak include respiratory distress with tachypnea, cyanosis, the presence of saliva in the chest tube tubing, and signs of sepsis caused by the leak (e.g., temperature instability, hypoglycemia, apnea, bradycardia).

distal TEF. The absence of gas in the stomach is associated with EA without TEF. Chest radiographs also screen for the presence of pneumonia, cardiac defects, or vertebral anomalies. Contrast studies, bronchoscopy, or endoscopy may also be used to establish the presence of TEF with or without EA. Contrast medium is used with caution, because the risk of aspiration is high. An echocardiogram is done to evaluate cardiac anatomy and function.

Nursing Diagnoses and Outcomes

In addition to those listed in Nursing Plan of Care 18–1, the following nursing diagnoses and outcomes may be applicable to the child with TEF:

Ineffective airway clearance related to inability to swallow secretions preoperatively

Outcome: Infant will demonstrate a clear, patent airway, without signs of airway compromise.

Risk for aspiration related to secretions or fluids entering the respiratory tract secondary to structural defect

Outcomes: Infant will remain free of signs and symptoms of aspiration of secretions or fluids.

Infant will remain free of infection secondary to aspiration.

Risk for injury related to procedures disrupting integrity of postoperative suture line

Outcomes: Infant will exhibit an intact surgical site without signs of disruption of anastomosis.

Infant will demonstrate secure positioning and appropriate placement of the NG tube.

Impaired swallowing related to presence of esophageal stricture or impaired peristalsis secondary to surgery

Outcomes: Infant will remain free of signs of stricture development, and dilation will be performed as needed.

Child will use methods to enhance effective swallowing, such as eating slowly, chewing foods well, and maintaining an upright position.

Interdisciplinary Interventions

Surgical repair of EA and TEF is delayed until the infant is medically stable. The goal of preoperative care is to prevent and treat any complications that may arise from aspiration or reflux of secretions into the respiratory tract.

caREminder

The surgeon writes specific orders for positioning the infant. Orders usually specify maintaining the infant with EA in an upright position preoperatively to reduce the risk of aspiration. However, some surgeons prefer to have the infant positioned prone to facilitate drainage of the blind pouch by gravity. Clarify the desired position if no specific orders are provided.

Ensure that emergency equipment is readily available at the bedside. A sump catheter can be maintained in the upper esophageal pouch to provide continuous suction of pooled secretions. Respiratory support and broad-spectrum antibiotics are given as needed to treat aspiration pneumonia. In many cases, a gastrostomy may be performed to provide gastric decompression and, eventually, enteral nutrition. Nutritional support with PN is initiated after the infant is stabilized.

The timing of definitive surgical repair of EA and TEF depends on the infant's condition. The infant who is close to term and is without other significant medical problems, such as aspiration pneumonia, may undergo repair within 24 to 72 hours of birth. If cardiac defects are present, they are corrected first. Premature infants with major respiratory distress or associated severe anomalies are maintained with proximal esophageal low suction, gastric decompression, and PN until medically stable enough to undergo definitive repair of EA and TEF.

Typically, surgical repair is done through a thoracotomy. However, thoracoscopic repairs are gaining acceptance as a result of successful outcomes and better cosmetics, along with a promise of fewer musculoskeletal complications, such as scoliosis, as the child's development progresses (van der Zee & Bax, 2007).

During surgery, the TEF is ligated, and then the proximal and distal segments of the esophagus are anastomosed. If primary anastomosis is not possible because

the length of the esophageal segments is inadequate, then the esophagus may be replaced with portions of the stomach (gastric interposition). If the infant's condition does not permit esophageal replacement during the initial surgery, a cervical esophagostomy may be done, with subsequent esophageal replacement at age 6 months to 1 year by gastric or colonic interposition, during which a portion of the stomach or colon is used to replace the esophagus.

During the initial postoperative period, the infant will have a chest tube, gastric decompression, and continued respiratory support. Interventions such as fluid management, pain management, and hemodynamic support are used as clinically indicated. Special care to prevent aspiration is vital. A suction catheter with markings to indicate the distance from the infant's nose to the point just above the anastomosis may be kept at the bedside. This tool can be used to guide consistent depth of insertion for the suction catheter to avoid trauma at the anastomotic site. Effective pain control is important so the infant does not disrupt the anastomosis by crying and moving excessively in response to pain.

Alert! Insert suction catheters less than the distance to the anastomosis. An approximate measurement can be done from the tip of the nose to the earlobe. Secure the NG tube well and use extreme caution to avoid displacement. If displacement occurs, do not reinsert the tube. Introducing catheters around the area of the suture line increases the risk of disrupting the suture line and causing leaks.

Antibiotics are continued and nutritional support with PN is maintained until full enteral feedings are tolerated. Enteral nutrition through an NG or gastrostomy tube may be started as early as the fourth postoperative day. Small-volume drip feedings are usually instituted, because bolus feedings may cause gastroesophageal reflux (GER). Acid suppression therapy is instituted to reduce irritation at the anastomosis. A radiographic study with water-soluble contrast medium is done by postoperative days 5 to 7 to assess the integrity of the esophageal anastomosis. If no leak is seen, the chest tube is removed and oral feedings are begun.

Ongoing assessment for anastomotic leak or stricture is essential. Anastomotic leaks occur in about 12% of cases (Holcomb et al., 2005). The infant typically exhibits respiratory distress, with tachypnea, cyanosis, and signs of sepsis. Continued NPO status and PN support are required, along with antibiotics and respiratory care, until the leak heals. Most leaks heal spontaneously within 1 to 3 weeks.

The infant with an esophageal stricture at the anastomotic site may demonstrate coughing, regurgitation, recurrent aspiration, and FTT. A stricture may not be evident in an infant until after solid foods are introduced. The older child may complain of **dysphagia** (inability to swallow or difficulty swallowing) or may exhibit difficulties swallowing solid foods. Strictures are managed with esophageal dilations.

Tracheomalacia (softening of the tracheal cartilage) occurs in 10% to 20% of children with TEF. These children exhibit bradycardia, cyanosis, and apnea, usually after feedings. They also have a characteristic harsh cough and are at risk for frequent respiratory infections during infancy and early childhood. The diagnosis is made by flexible bronchoscopy. The symptoms of a child with mild distress may improve spontaneously during the first 2 years of life.

GERD commonly occurs after a repair. Medical management may be initially successful, but many children need surgical intervention. All children should adhere to nursing interventions for GERD.

Lifelong esophageal dysmotility is present in a large number of these children. Infants with EA and TEF are at risk for oral feeding dysfunction related to prolonged NPO status, subsequent reliance on NG or gastrostomy feeds, and frequent problems with esophageal function. Early attention to oral–motor stimulation and involvement of an occupational therapist in the infant’s plan of care may help address such dysfunction. As the child advances in age, caution parents to cut table foods into small pieces and to avoid foods that are difficult to chew and swallow, such as hot dogs. Children must be supervised during mealtime and need reminders to chew well, take small bites, and wash down their food with fluids as needed to ease swallowing.

Community Care

Management of the infant with EA and TEF presents challenges across the continuum of care when preparing the child and family for the transition to home and coordinating care with multiple healthcare providers. The child with EA and TEF frequently has other associated medical conditions that can make discharge teaching very complex. The child with EA and TEF as a part of VACTERL association requires follow-up with numerous healthcare providers. The nurse plays a key role in case management of these children by promoting coordination of care and facilitating communication among the various healthcare providers as well as providing ongoing parent support and education.

Pyloric Stenosis

Pyloric stenosis, also called *hypertrophic pyloric stenosis (HPS)*, is the most common cause of gastric outlet obstruction in infants. It is more common in males and occurs in approximately 2 to 4 per 1,000 live births in western populations, but is less common in African and Asian populations (Aspelund and Langer, 2007). The exact cause is not known, but, because of regional differences in incidence, environmental factors are thought to play a role. An association of HPS with orally administered erythromycin for *Bordetella pertussis* treatment or prophylaxis in infants younger than 1 month of age has been reported. For these infants, the risk of developing pertussis outweighs the possible risk of developing HPS.

Education of caregivers is recommended when therapy is needed in this age group (American Academy of Pediatrics, 2006).

Surgical correction of pyloric stenosis is curative. With prompt diagnosis and treatment, the operative mortality for treatment of pyloric stenosis is less than 1%.

Pathophysiology

In pyloric stenosis, hypertrophy and hyperplasia of the circular smooth muscle of the pylorus of the stomach occurs (Fig. 18–11). The lumen of the pylorus narrows and lengthens, and the gastric outlet is progressively obstructed.

Assessment

Typically, manifestations of pyloric stenosis become apparent at age 3 to 5 weeks. The infant usually presents with a history of regurgitation and nonbilious vomiting during or shortly after feeding. Within a week of onset of symptoms, the vomiting may become projectile. The vomitus usually consists of gastric contents but may become “coffee ground” in color if esophagogastritis causes bleeding. Parents may describe the infant as irritable and hungry all the time. Weight loss and FTT may be noted. Because of persistent vomiting, the infant with pyloric stenosis presents with varying degrees of dehydration. As dehydration caused by vomiting progresses, the parents may report lethargy, decreased urine output, and constipation.

On physical examination, the infant may appear fussy and fretful. With severe dehydration, the infant may seem apathetic and even moribund. The upper abdomen is typically distended, and visible peristaltic waves may be seen moving from left to right across the upper abdomen. When the abdomen is palpated, a mass may be felt in the epigastric region. The mass is hard, mobile, nontender, and usually is described as an “olive.” Palpation of the “olive” may be difficult to appreciate in an irritable infant. It is best identified when the infant is calm.

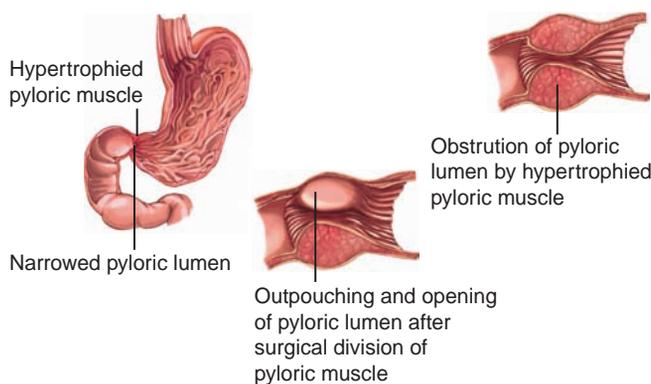

FIGURE 18–11. In pyloric stenosis, the pyloric muscle hypertrophies and obstructs the passage of stomach contents into the intestines. Surgically splitting the muscle relieves the obstruction.

Diagnostic Tests

Diagnosis of pyloric stenosis can usually be made based on health history and physical assessment findings. If the examiner is unable to palpate the olive-sized mass in the epigastrium, an ultrasound study may be used to establish the diagnosis. It is also used to measure the length and diameter of the pyloric muscle, which can determine whether stenosis is present. A barium study will demonstrate the “string sign,” which indicates a narrowed pyloric channel and retained gastric contents.

Blood tests may be performed to determine the extent of dehydration. A hypochloremic metabolic alkalosis and hypokalemia result from depletion of sodium, potassium, and hydrochloric acid.

Interdisciplinary Interventions

After establishing the diagnosis of pyloric stenosis, the initial goal of therapy is to correct any fluid and electrolyte imbalances. IV fluid replacement is initiated to rehydrate the child and to correct electrolyte imbalances. The infant may be made NPO to prevent further fluid losses from vomiting. A NG tube may be inserted if excessive vomiting is present, to empty and decompress the stomach. Carefully monitor IV fluid intake, and quantify and document urine output and losses from emesis. Implement comfort measures for the infant, as well as parent reassurance and support.

The definitive treatment of pyloric stenosis is surgical pyloromyotomy via an open or laparoscopic approach. Laparoscopic approach has been described with favorable outcomes when compared with the open surgical approach (Aspelund & Langer, 2007).

After fluid and electrolyte balance is reestablished, the infant is taken to surgery. A small abdominal incision is made and the pyloric mass is incised longitudinally, splitting the underlying muscle. This procedure allows the gastric mucosa to bulge up between the split, relieving the obstruction.

WORLDVIEW: Medical management, primarily outside of North America, involving IV fluid administration, oral atropine, and fluid and electrolyte therapy have been reported. In one study, oral therapy was continued for several months and the infants were closely monitored with favorable outcomes compared with those undergoing pyloromyotomy. It is thought that atropine decreases muscle spasms and peristalsis, which contribute to the fixed obstruction that leads to the hypertrophied and stenotic pylorus. Although this approach will not replace surgical correction, it may have a role for the treating an infant with contraindications to anesthesia or infants who are a high surgical risk (Aspelund & Langer, 2007).

Postoperatively, the infant receives IV fluids until shortly after recovering from anesthesia, when oral feedings are usually started. Small amounts of an oral electrolyte solution such as Pedialyte or sugar water may be offered for the initial feedings. Traditionally, if this solution is tolerated, the volume and concentration of

feedings are advanced until full feedings are achieved, usually 24 to 48 hours postoperatively. Frequent burping is recommended.

Up to 50% of infants may have some vomiting postoperatively as a result of persistent edema of the pylorus and inefficient gastric emptying (see [thePoint](#) for Care Path: An Interdisciplinary Plan of Care for the Child With Pyloric Stenosis). Decrease in the swelling of the muscles takes place by 3 weeks, and at 6 weeks normal muscle thickness is expected (Alexander, 2006b). Parent education about intermittent postoperative emesis is crucial to minimize parent anxiety.

Community Care

Infants with pyloric stenosis may be discharged at 24 to 48 hours, depending on the postoperative feeding approach and when normal feedings are reestablished. Parents require instruction regarding the infant’s feeding schedule and any necessary wound care for the abdominal incision. Teach them about the signs of complications, such as recurrent vomiting, wound infection, fever, abdominal pain, and signs of dehydration. Reinforce with the parents that some emesis is expected, but that persistent vomiting requires a call to the physician. Explain that the risk for wound infection may be higher if the infant experienced malnutrition preoperatively. Follow-up referral to a community pediatric caregiver is recommended to ensure that the infant is monitored for normal growth and weight gain after surgery.

MALFORMATIONS OF THE LOWER GASTROINTESTINAL TRACT

Malformations of the lower GI tract include intestinal atresia and stenosis, hernias and hydroceles, gastroschisis and omphalocele, congenital diaphragmatic hernia (CDH), Meckel’s diverticulum, malrotation and volvulus, intussusception, Hirschsprung disease, and anorectal malformations.

QUESTION: Most of the malformations discussed in this section are repaired while the child is an infant. How would you compare nursing interventions for infants and school-aged children, such as Cory, who is undergoing GI surgery?

Intestinal Atresia and Stenosis

Intestinal atresia is a congenital defect that results in complete obstruction of the bowel. *Duodenal atresia* (accounting for approximately 50% of all atresias of the small intestine) (Arthur & Schwartz, 2005) is frequently associated with other congenital defects, including trisomy 21, intestinal malrotations, congenital heart defects, and VACTERL association. Vertebral and renal

problems are also common. *Jejunioleal atresia* results in the obstruction of one or multiple segments of the jejunum or ileum. It is not commonly associated with other congenital defects. *Stenosis* of the intestine results in a partial or incomplete obstruction.

The prognosis for duodenal atresia after surgical repair is excellent, with most patients experiencing no long-term sequelae. The prognosis for infants born with jejunioleal atresia is affected by the amount of bowel involved and the birth weight of the infant. Overall survival rates have improved greatly during the past decade, with survival as high as 95% for infants with isolated duodenal atresia (Stellar & Young, 2007).

Pathophysiology

Because of the congenital malformations with which duodenal atresia is commonly associated, it is believed to occur very early during embryologic development, resulting from a failure of the lumen of the intestine to recanalize during the eighth to 10th week of gestation. Jejunioleal atresia is believed to occur at a much later stage of gestation, because of the observation that meconium is commonly present in the bowel distal to the atretic segment. A mesenteric vascular insult, resulting in ischemia of the affected portion of intestine, may be the causative factor in jejunioleal atresia.

Various forms of duodenal and jejunioleal atresia result in intestinal obstruction. Type I atresia occurs when a mucosal membrane or web occludes the inner lumen of the bowel. In type II atresia, the proximal intestine ends in a blind loop and is connected to the collapsed distal intestine by a fibrous cord. Type III atresia results in both the proximal and distal segments of intestine ending in blind loops with no connection. In cases of jejunioleal atresia, a type IV defect may also occur, resulting in multiple atretic segments of bowel, often described as having the appearance of a string of sausages.

Assessment

Polyhydramnios is observed in many cases of both duodenal and jejunioleal atresia. Most infants become symptomatic within the first 24 hours of life. Bilious vomiting and abdominal distention occur in most cases. Infants with duodenal atresia may present with upper abdominal distention but with a scaphoid abdomen because of the lack of distal intestinal air. Failure to pass meconium may be observed, although normal meconium may be present with more distal atresia. Conduct a careful physical assessment, noting abdominal contour, and palpate the abdomen for softness or distension. Monitor for passage of meconium; report progressive gastric distention and vomiting to the physician.

Diagnostic Tests

Intestinal atresia may be diagnosed by prenatal ultrasound. In cases of intestinal atresia, the ultrasound examination demonstrates polyhydramnios during the third

trimester, along with fluid-filled cysts in the abdomen of the fetus.

When intestinal atresia is not diagnosed in utero, initial evaluation of a symptomatic infant includes a flat-plate abdominal radiograph. The infant with duodenal atresia customarily demonstrates a “double-bubble” sign on radiograph both the stomach and duodenum are dilated and filled with gas. The infant with jejunioleal atresia demonstrates distended loops of intestine with multiple air–fluid levels. In some cases of jejunioleal atresia, when obstruction is evident in the distal intestine, a water-soluble contrast enema is the test of choice (Arthur & Schwartz, 2005).

Interdisciplinary Interventions

Prenatal diagnosis enables parents to plan for the infant to be delivered in a facility where further diagnostic workup and intervention can be done soon after birth. The nurse may provide anticipatory guidance to the parents so that they understand the infant’s condition and know what to expect at the time of delivery.

At birth or when clinical symptoms otherwise become evident, the infant requires initial stabilization with IV fluids to ensure that maintenance needs are met and that ongoing losses are replaced. An NG tube is placed to provide gastric decompression and to prevent aspiration of gastric contents. Serum electrolytes and blood cell counts are monitored, and any abnormalities are corrected. The infant’s blood glucose levels are closely monitored. Broad-spectrum IV antibiotics may be administered prophylactically. Respiratory support may be necessary because of the risk for aspiration, the stress that altered GI function places on the newborn, or other anomalies that compromise the infant’s condition.

Surgical correction of duodenal atresia involves resection of the atretic segment of duodenum and duodeno-duodenal or duodenojejunal anastomosis. Resection and primary anastomosis are also commonly done during surgical correction of jejunioleal atresia.

In cases involving extensive resection of bowel, massive dilation of proximal bowel, or colonic atresia, a two-stage procedure is done. A jejunostomy or ileostomy is created initially to drain the proximal bowel, with final anastomosis to the remaining distal intestine done some months later. In all cases, the surgical goal is to preserve as much intestine as possible. Massive resection of the small intestine may leave the infant with short bowel syndrome (described later in this chapter), leading to long-term problems with meeting fluid and nutrient requirements using the GI tract.

In infants with both duodenal and jejunioleal atresia, a gastrostomy tube may be placed at the time of surgery to facilitate gastric decompression during the initial postoperative period and to administer enteral nutrition support if poor tolerance to oral feedings is anticipated. If a large amount of bowel has been resected or a very proximal ostomy exists, a central venous catheter may be inserted to administer PN.

Postoperative care continues with many of the interventions begun during the preoperative period. Respiratory support may continue during the early postoperative period. Continue gastric decompression by NG tube or gastrostomy until intestinal motility normalizes. Monitor progress by measuring and observing gastric aspirates, which should decrease in quantity and change from bilious to a clear, saliva color. Normalization may take from 5 days up to 3 weeks, depending on the location and the extent of the atresia. Monitor the surgical site and provide pain management.

Maintaining the patency of the gastric drainage system and close monitoring of output are essential. PN is initiated to meet the infant's nutritional needs. Administer IV fluids and replacement as indicated by losses. Carefully monitor the infant's fluid and electrolyte status. Expect to continue IV antibiotics for 5 to 7 days postoperatively.

Begin enteral or oral feedings when the intestinal motility normalizes. Formula choice varies, depending on the extent of bowel resected. Infants with limited resection may be given breast milk or cow's milk infant formula, and infants with massive intestinal resection or an ostomy placed high in the intestinal tract will require a protein hydrolysate or elemental formula. As formula intake increases, wean the infant from PN. Careful monitoring is important to ensure adequate growth and weight gain, as well as GI tolerance.

Monitoring and supporting the infant's physiologic needs are important during the postoperative period. Assess fluid status carefully, including all losses from gastric drainage, stools, and an ostomy, if present. Monitoring GI function, including return of bowel sounds, gastric residuals, and feeding tolerance, is a key aspect of care. Support and educate the parents. Hospitalization may be prolonged, and the parents may need support and guidance in establishing their parental role with their sick newborn. Social services often is necessary to help the parents deal with the crisis of the birth of an infant with health problems and the stress of the child's prolonged hospitalization.

Community Care

Incorporate parent education regarding home care for their infant into the plan of care from the start. Address gastrostomy and ostomy care, administration of feedings, and signs of intestinal dysfunction. If PN will be required for a prolonged period, the parents will need extensive preparation to manage administration of PN and a central venous catheter care at home (see Chapter 17).

Hernias and Hydroceles

A hernia is a protrusion of an organ, or part of an organ, or other structure through the wall of the cavity in which it is contained. Inguinal and umbilical hernias are two of the most common types. Omphalocele, gastroschisis, and diaphragmatic hernias are types of hernias that require

special considerations. They are discussed later in this chapter

A hernia in the abdominal region is considered *reducible* when its contents are easily manipulated back into the peritoneal cavity. An *incarcerated* hernia occurs when the abdominal contents become trapped and difficult to reduce. A *strangulated* hernia occurs when the herniated intestines become twisted and edematous, compromising blood flow. Intestinal obstruction and ischemia may occur.

A hydrocele results from peritoneal fluid communicating with the scrotal area through a patent processus vaginalis, collecting in the tunica vaginalis. Inguinal hernias and hydroceles are among the most common congenital anomalies in infants that require surgical repair.

Pathophysiology

The processus vaginalis is an outpouching of the peritoneum that develops during the third month of gestation. In males, it descends along the inguinal canal to the area of the scrotum. In females, it terminates in the area of the labia majora. During the seventh month of gestation, the testes descend through the processus vaginalis into the scrotum. The processus vaginalis typically remains patent until birth and closes at birth or during early infancy. Protrusion of abdominal contents through the patent processus vaginalis into the inguinal area causes the hernia.

Inguinal hernias (Fig. 18–12A) are caused by abdominal contents exiting the peritoneal cavity and protruding into the processus vaginalis. An umbilical hernia results from imperfect closure or weakness of the umbilical ring that allows portions of intestine or omentum to protrude. This type is more common in low-birth-weight, female, and African American infants. Umbilical hernias usually cause no problems and often regress spontaneously. Surgical repair is not indicated unless the hernia becomes strangulated or incarcerated, persists beyond age 3 years, or continues to enlarge after age 2 years.

Inguinal hernias occur in about 1% to 4% of children and more frequently in infants (Mollen & Kane, 2007). Indirect inguinal hernias, which are developmental defects rather than a direct inguinal hernia caused by a weakened wall, are most common. Unilateral right-sided hernias are more common (60%) than left-sided ones, a difference thought to result from the fact that the right testis descends later than the left. Hernias may also occur in children with conditions characterized by increased intra-abdominal pressure, which forces the abdominal contents into the processus vaginalis, a peritoneal sac that normally closes early during infancy. These children include those with ventriculoperitoneal shunts, those with chronic cough secondary to cystic fibrosis, and those receiving peritoneal dialysis.

Hydroceles are caused by peritoneal fluid communicating with the scrotal area through a patent processus vaginalis. A hydrocele may be communicating (processus vaginalis remains patent and allows peritoneal fluid to

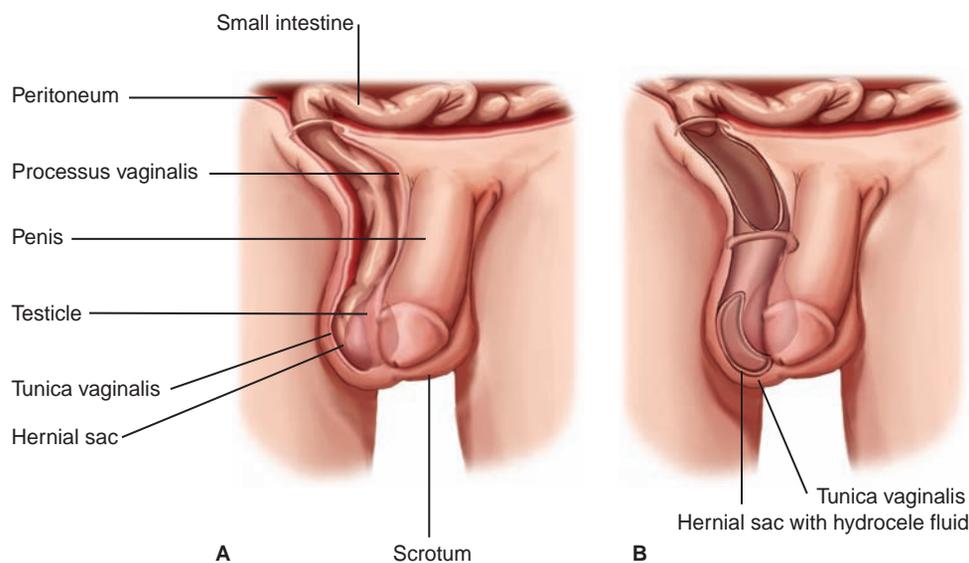

FIGURE 18–12. (A) In an inguinal hernia, the bowel protrudes into the patent processus vaginalis. (B) A noncommunicating hydrocele has no connection with the abdominal cavity, so the amount of scrotal swelling does not fluctuate with activity. In a communicating hydrocele, the processus vaginalis remains patent and the amount of scrotal swelling may vary with the child's activity.

cause intermittent scrotal swelling that waxes and wanes (related to activity) or noncommunicating (processus vaginalis is completely obliterated, with fluid collecting in the scrotal area that does not increase in size). A noncommunicating hydrocele usually disappears by age 1 year (Fig. 18–12B).

Assessment

The diagnosis of hernia or hydrocele is most commonly made by history and physical examination. The parents of the child with an inguinal hernia typically report seeing a bulge in the groin area that occurs only when the child cries, strains, or coughs. Pain is not typically reported unless the hernia becomes incarcerated or strangulated. In this case, the child may be irritable, with cramping abdominal pain and vomiting that may progress from nonbilious to feculent as obstruction of the trapped bowel progresses.

The swelling associated with a hydrocele is not painful. The scrotal sac is translucent on transillumination (shining a light through the scrotum). For the child with a communicating hydrocele, observe for a scrotal bulge or swelling that increases with crying or straining and decreases when the child is at rest.

On physical examination, an inguinal hernia appears as a bulge in the inguinal or scrotal area. In an inguinal hernia, thickening of the structures of the inguinal canal may be felt with palpation. The examination may include attempts to palpate the hernial sac over the cord structures in the inguinal region. This sliding sensation of the sac and cord structures over the pubic bone is described as a positive “silk glove sign.” It is not diagnostic of a hernia, but is suggestive of one. An umbilical hernia is observed as an intermittent bulging of the umbilicus. It is typically not associated with pain.

WORLDVIEW: Teach parents that home remedies, such as using belly bands or taping a coin over the umbilicus, will not prevent or cure an umbilical hernia. If parents insist on using such remedies, encourage them to use a small coin and clean the umbilical area well.

Interdisciplinary Interventions

Manual reduction of an incarcerated hernia of any type is attempted before surgical repair. The child is sedated, the lower torso is elevated, and the incarcerated contents of the hernia are gently manipulated back into the peritoneal cavity. If the reduction is successful, elective surgical repair is scheduled 24 to 48 hours later. Delaying the surgery allows time for resolution of any edema of the bowel resulting from the incarceration, and substantially reduces the potential for postoperative complications. If manual reduction is unsuccessful or the hernia shows evidence of strangulation, immediate surgical repair is indicated, because the blood supply to the bowel is compromised.

Surgical repair of the hernia, called *inguinal herniorrhaphy*, usually is done in term infants and children as an outpatient procedure. Preterm infants may require 24 hours of acute care observation in the hospital postoperatively because of their increased risk of apnea with anesthesia. The herniorrhaphy is done through an incision through the inguinal crease. The processus vaginalis is identified and ligated. Contralateral exploration and herniorrhaphy are done in children younger than age 1 year who are at high risk for occurrence of “second-side” hernia after repair of the initial hernia.

Surgical intervention for a hydrocele is similar to that for a hernia with a high ligation of the processus vaginalis. The distal portion of the excess sac may be carefully trimmed down to and around the testis (Alexander, 2006a).

Preoperatively, assess the hernia site and the child's vital signs. Be alert for signs of incarceration or strangulation. These signs include an increase in behaviors that indicate pain and the presence of a firm, tender mass in the inguinal region. Vomiting and abdominal distension may also be present.

caREminder

Carefully assess the skin condition in the inguinal area. Diaper rash or skin breakdown may lead to poor wound healing or wound infection and can necessitate delay of elective surgery.

Postoperatively, assess the surgical site for bleeding or drainage, recurrence of the hernia, and any vascular compromise to the gonads. Monitor for apnea and desaturation of oxygen for infants younger than 1 year of age with a history of prematurity. Educate parents regarding the surgical procedure, preoperative routines, postoperative care, signs and symptoms of recurrence or complications, and avoidance of constipation. Usual activities can be resumed after several days; contact sports are restricted for at least 2 weeks.

Gastroschisis and Omphalocele

Abdominal wall defects include gastroschisis (a full-thickness defect of the abdominal wall, usually to the right of the umbilical cord, through which loops of bowel eviscerate) and omphalocele (herniation of intestines into the base of the umbilical cord covered with a large peritoneal sac; Fig. 18–13). These defects are increasing worldwide. This increase is attributed to the rise of gastroschisis occurring in 1.6 to 4.6 per 10,000 live births (Islam, 2008). The rate of omphalocele has remained stable at 2 per 10,000 live births. The cause for the increase in gastroschisis is not clear. However, it has been

FIGURE 18–13. Omphalocele in a newborn. Note the large protruding sac.

associated with young maternal age, use of recreational and illicit substances, and use of ibuprofen and aspirin. Gender distribution is not a factor. The etiology of these abdominal wall defects is poorly understood. A mechanical or teratogenic event early during fetal development is hypothesized.

Infants born with gastroschisis have a survival rate of 90% to 95% whereas those born with isolated cases of omphalocele have a reported survival rate between 75% and 90% (Islam, 2008). Mortality is usually related to associated congenital anomalies and life-threatening complications.

Pathophysiology

The defect associated with gastroschisis is believed to occur between the fourth and eighth weeks of fetal development. Although the exact mechanism is unclear, gastroschisis may be the result of an early tear in the umbilical cord before the umbilical ring closes. The bowel eviscerates into the amniotic cavity, where prolonged contact with amniotic fluid creates a fibrous peel over the exposed loops of bowel. The fibrous peel apparently contributes to the intestinal dysmotility often seen in infants with gastroschisis. A more recent hypothesis advances that a failure exists of one or more folds of the abdominal wall to fuse properly and completely, leading to a defect and herniation into the amniotic fluid (Islam, 2008). Associated anomalies are usually confined to the GI tract, with intestinal atresia occurring in 5% to 15% of all cases. Intestinal malrotation may also be seen.

The pathophysiology that leads to the development of omphalocele is poorly understood. An early defect in abdominal wall development may result in a disparity between the size of the abdominal cavity and the abdominal viscera, leaving inadequate space for the midgut to return to the abdominal cavity during the 10th week of gestation, after its normal extracolonic phase of development. All infants with omphalocele have a malrotation because of the nature of the developmental defect. It is often associated with other congenital defects. In contrast to gastroschisis, omphalocele is associated with advanced maternal age and abnormal karyotypes. Associated malformations are present in 30% to 80% of these infants. Trisomy 13 and 18 are the most common chromosomal anomalies (McNair, Hawes, & Urquhart, 2006). Cardiac anomalies are found in 30% to 50% of cases. The size of the defect can be classified as small or as giant. It is also described by the integrity of the membranes as being intact or ruptured. The defect may contain small and large intestine, liver, and other abdominal structures. There is not agreement in the definition of a giant omphalocele; however, some classify it as larger than 5 cm and as a large as 8 cm (Islam, 2008).

Assessment

Both gastroschisis and omphalocele are evident immediately in the delivery room. With a planned delivery,

interdisciplinary health team members are present in the delivery room, such as neonatologist and surgeon. If the defect was undetected prenatally, the infant is stabilized and transported to a tertiary care nursery. The nurse assesses the color of the viscera and may approximate the degree of the defect related to the volume of externalized viscera.

Diagnostic Tests

Abdominal wall defects may be detected prenatally. Elevated maternal serum α -fetoprotein is detected through routine surveillance. The amount of α -fetoprotein secreted is directly proportional to the size of the defect (McNair et al., 2006). In addition, most abdominal wall defects are diagnosed with routine ultrasound. Differentiating the type of abdominal wall defect is important to direct other prenatal testing such as an echocardiogram. Prenatal diagnosis allows the family and medical team to plan for the delivery in a tertiary-level hospital, where a team of specialized healthcare providers can manage the infant postnatally.

Prenatal diagnosis also allows for family counseling and for a decision to terminate or proceed with the pregnancy after all the prenatal studies are completed. Studies have not been conclusive regarding the benefits between a vaginal or C-section delivery.

In some centers, the infant with gastroschisis may be delivered electively at 36 weeks' gestation to reduce the exposed bowel's contact with amniotic fluid, thereby minimizing formation of the fibrous peel. There is no evidence that elective early delivery changes the outcome.

Nursing Diagnoses and Outcomes

In addition to those listed in Nursing Plan of Care 18-1, the following nursing diagnoses and outcomes may apply to the child with an abdominal wall defect:

Ineffective breathing pattern related to the effects of diaphragmatic elevation by bowel

Outcome: The child will demonstrate adequate lung expansion and blood oxygenation.

Hypothermia related to effects of increased heat loss through exposed viscera

Outcomes: The child will exhibit signs and symptoms of minimal heat loss.

The child's body temperature will remain within normal limits.

Risk for infection related to presence of exposed viscera

Outcome: The child will remain free of signs and symptoms of infection.

Risk for injury related to presence of exposed viscera and potential for torsion of bowel or supporting vessels

Outcome: The child will remain free of injury, including maintenance of bowel position and blood supply.

Interdisciplinary Interventions

At birth, handle the exposed bowel or peritoneal sac carefully to prevent twisting or torsion of the mesentery. Protect the bowel by wrapping the exposed viscera with warm saline-soaked gauze, and cover and seal with a plastic wrap or place in a "bowel bag," which should contain the defect, torso, and legs, to prevent heat and fluid loss from the exposed viscera. Monitor and maintain a normothermic environment. Obtain IV access. Give fluid resuscitation and correct any electrolyte abnormalities. Administer broad-spectrum antibiotics as ordered. Provide hemodynamic and respiratory support, including mechanical ventilation, as needed. Insert an orogastric or NG tube to prevent aspiration and decrease abdominal distention. Anticipate insertion of a urinary catheter to monitor urine output.

Surgical intervention is necessary to close the abdominal wall defect. Small defects may be treated with reduction of the eviscerated bowel into the abdominal cavity, followed by primary closure of the abdominal wall. Larger defects require a staged repair. A Silastic silo is placed around the exposed viscera (Fig. 18-14) and the protruding bowel is slowly reduced into the abdominal cavity every 12 to 24 hours until complete reduction is achieved. This technique enables the cavity to expand gradually to accommodate the bowel. After the bowel is fully reduced into the abdominal cavity, the abdominal wall is surgically closed.

If a silo has been placed, monitor for signs of hypothermia and for shock from fluid depletion caused by heat loss and insensible water loss through the exposed viscera. Position and move the infant with extreme caution, to avoid tension on the site or torsion of the mesentery. Monitor for respiratory distress, which may be caused by elevation of the diaphragm from returning too much bowel to a small abdominal cavity. Also monitor for cyanosis of the lower extremities, which may indicate pressure on the descending aorta and its femoral branches. The infant is usually sedated before reduction to minimize movement.

Continue to protect the abdominal wall after surgical closure. Patient goals include monitoring respiratory and hemodynamic status, managing fluids, maintaining vascular access, facilitating gastric decompression, managing pain (see Chapter 10), and preventing infection. Providing parenteral support is a priority. Nutritional support with PN through a central venous catheter is usually initiated 1 or 2 days after surgery, after fluids and electrolytes stabilize. Feedings are initiated when the child is medically stable and bowel function has returned. Bilious vomiting and occult blood in the stools and gastric residuals may indicate necrotizing enterocolitis or obstruction; report these findings to the surgeon.

The child with gastroschisis may have a prolonged postoperative ileus and may require parenteral support for several weeks before feedings can be initiated. In some cases, enteral drip feedings by NG or gastrostomy tube are necessary because of persistent intestinal dysmotility that causes intolerance to oral or bolus feedings. A

FIGURE 18–14. If an omphalocele or gastroschisis is too large to repair immediately, a Silastic silo is placed over the exposed viscera and the intestines are gradually reduced into the abdominal cavity over a period of days.

semielemental formula typically is used when initiating enteral feedings. In cases in which intestinal atresias are associated with gastroschisis, short bowel syndrome results from bowel resection and requires prolonged dependence on PN.

Maintaining parent involvement in the care of the infant is central to the plan of care. Discharge planning and parent education must be coordinated for the home enteral feeding program, oral–motor stimulation, skin care, and home PN, including central venous catheter care (see Chapters 12 and 17).

Community Care

The infant discharged with these conditions has the same need as all other infants for follow-up to ensure optimal growth and development. Ensuring family function is intact, with appropriate bonding for high-risk infants, must be considered in the discharge plan. Teach parents to report signs of complications early. Bilious vomiting, abdominal distention, poor appetite, constipation, diarrhea, or fever may be associated with bowel complications, such as intestinal obstruction. Continued support and care for the infant is directly related to the extent of bowel resected and the function of remaining bowel. Infants may require a discharge plan for a home enteral program, a home parenteral program, or a combined program. Extensive planning and education are needed for transition to home care when this intensive support is required. Evaluate ongoing therapy for developmental and oral–motor function and make appropriate referrals to optimize outcomes.

Congenital Diaphragmatic Hernia (CDH)

CDH is the protrusion of abdominal contents into the chest cavity through a defect in the diaphragm. The

reported incidence varies from 1 in 3,000 to 1 in 4,000 births. Associated anomalies such as cardiac defects, trisomy 18, EA, omphalocele, and disorders of the central nervous system have been reported. CDH may be an isolated anomaly or associated with multiple malformations. Delayed presentations have been reported and account for 5% to 10% of all CDHs (Becmeur et al., 2007).

The overall survival rate for live births varies with the severity of the defect but has reached as much as 80% in some reports as a result of advances in preoperative physiologic stabilization and changes in medical and surgical advances; early term infants have the greatest survival rate (Stevens et al., 2009).

Pathophysiology

CDH results from the failure of the pleuroperitoneal canal (the opening between the chest and abdomen) to close completely during fetal development or from an early return of the intestines to the abdomen after the normal herniation into the umbilicus during fetal development.

The defect in the diaphragm may be large or small, allowing proportional amounts of abdominal contents to herniate. The herniation is most commonly on the left side, through the posterolateral foramen of Bochdalek. Bilateral hernias are rare and are typically fatal.

More threatening to the infant's survival are the associated effects on the pulmonary system. The ipsilateral lung is usually hypoplastic, with decreased numbers of airway generations, alveoli, and arterioles. The arterioles also show increased muscular mass. The contralateral lung has similar abnormalities, but to a lesser extent, from pressure from a shift to the mediastinum. Compression of the lungs by the herniated viscera during fetal development may contribute to the hypoplasia and persistent

pulmonary hypertension. Abnormal development of the mesenchyme is another possible cause.

Assessment

Most infants with CDH experience respiratory distress at birth or within the first few hours of life. As the infant swallows air, the herniated segment distends and further compromises lung and diaphragmatic excursion. Assessment findings include decreased or absent breath sounds on the affected side, although bowel sounds may be heard. If the defect is on the left, which is most common, heart sounds are shifted to the right. Chest sounds are dull on percussion. Tachypnea and cyanosis are present. Assess the need to assist with or initiate resuscitation in the delivery room; which is often required. A high incidence of pneumothorax with left-sided defects is observed. Blood gas analysis reveals acidosis.

Physical examination reveals a barrel-like chest, particularly on the affected side. In contrast to the normal protruding abdomen, the abdomen of the infant with CDH looks scaphoid, or sunken, because of the absence of abdominal contents.

Diagnostic Tests

CDH is often diagnosed during pregnancy by fetal ultrasound. After birth, chest radiograph is usually diagnostic, showing gas-filled intestinal loops in the chest, displacement of the cardiac silhouette, and a gasless abdomen.

Nursing Diagnoses and Outcomes

In addition to the nursing diagnoses listed in Nursing Plan of Care 18–1, the following nursing diagnoses and outcomes may apply to the infant with CDH:

Impaired gas exchange related to effects of lung hypoplasia and lung compression

Outcome: The infant will demonstrate oxygen saturation levels adequate to sustain life and prevent the sequelae of oxygen deprivation.

Grieving (family) related to child's high risk of death

Outcomes: Family will verbalize feelings related to infant's high-risk condition.

Family will spend as much time as possible with the infant.

Family will demonstrate understanding of the infant's condition and prognosis

Alert! Ventilatory support is usually required. Support includes insertion of an endotracheal tube if the infant requires ventilatory assistance. Infants with CDH should not receive bag-and-mask ventilatory support because air insufflation causes further distention of the intestinal loops in the chest, causing further lung compression and thus decreasing the infant's ability to oxygenate.

Interdisciplinary Interventions

CDH is a life-threatening emergency. Initially, the primary concern is to stabilize cardiopulmonary status.

Intubate and ventilate using a low peak pressure and gentle ventilation (<30 cm H₂O) if possible. The infant may be treated with paralytic agents to avoid further swallowing of air and further pulmonary compromise. An umbilical artery catheter or arterial line is usually placed to monitor blood gas values. A central venous catheter may be inserted to provide full hemodynamic and pulmonary support. A dual lumen (vented) orogastric tube is passed to decrease the amount of air in the hernia, decrease the lung compression, and allow for continuous suction. Keep the infant NPO and administer and monitor IV fluids and antibiotics.

Surgical Intervention

Traditionally, surgery was done on an emergency basis. Today, the current approach in most medical centers is with nonemergent surgery; however, there is no clear evidence to support nonemergent versus immediate surgical repairs (Harting & Lally, 2007). The parameters for surgical readiness are center dependent but generally include hemodynamic stability, acid–base balance within physiologic range, and ability to tolerate convention ventilation with adequate oxygenation.

Preoperative treatment with extracorporeal membrane oxygenation is one management option when the infant fails conventional medical therapy. Extracorporeal membrane oxygenation is similar to cardiopulmonary bypass, which allows the cardiopulmonary system to rest while allowing oxygen and carbon dioxide to be exchanged mechanically outside the body. The goal of initial stabilization is to address the cardiorespiratory compromise caused by pulmonary hypertension and hypoplasia before surgery is attempted. Pharmacologic treatment of the pulmonary hypertension has proved to be of limited value.

The hernia is most commonly reduced using a subcostal incision on the ipsilateral side. The defect in the diaphragm is corrected using primary closure, if possible. If primary closure will cause excessive tension on the intestines, diaphragm, and large vessels and thereby compromise total thoracic compliance, then a synthetic patch or an abdominal muscle flap procedure is used. Minimal invasive surgery has been described and may be gaining more acceptance (Becmeur et al., 2007)

Postoperatively, an infant with CDH usually remains critically ill and a challenge to manage. The infant's respiratory status continues to be of primary concern. The goal is to prevent persistent pulmonary hypertension caused by vasoconstriction and acidosis, and to preserve the “good lung” from barotrauma. Oxygen therapy is continued; infants are weaned carefully from mechanical ventilation. The infant remains at high risk for pneumothorax because of the pulmonary abnormalities. The use of tube thoracostomy to treat pneumothorax has fallen

out of favor because it is postulated to cause iatrogenic pulmonary injury via a mediastinal shift after pleural suction. The lungs usually will gradually displace fluid and air as they enlarge.

Monitor and assess breath sounds and respiratory status for signs of pneumothorax. If such signs occur, notify the physician or advanced practice nurse promptly. Routine postoperative care includes pain management, careful monitoring for changes in the infant's status, and administering IV fluids and antibiotics. The orogastric tube remains in place for gastric decompression. A gastrostomy tube may be placed during surgery to facilitate postoperative GI decompression and feeding.

Provide developmentally supportive care (dim the lights, decrease noise, handle gently) to decrease stress on the infant. Involve social services or clergy as appropriate to help support the family.

Nutritional Interventions

Initiate feedings gradually and wean the infant from PN as tolerance to feeding progression is demonstrated. Infants with CDH frequently have GERD. Monitor for signs of GERD and use appropriate positioning and feeding techniques. Problems with sucking and swallowing, and aversion to oral stimulation may be observed, resulting from prolonged NPO status. Consult the occupational therapist to provide assessment and interventions for oral-motor dysfunction. Early involvement with the occupational therapist may help to reduce some of the oral-motor problems. Feedings should be small and frequent; avoid overfeeding. Feed the infant in a semiupright position and burp frequently. Enteral nutrition may be continued to support growth and development, because FTT is a common complication. Other complications include chronic lung disease, chronic aspiration pneumonia, and GERD that requires surgical intervention.

Alert! The infant with CDH is prone to abdominal obstruction. Vomiting, abdominal distention, or a change in bowel elimination pattern should be reported immediately.

Community Care

Involve the parents in the infant's care to the greatest extent possible. Before discharge, ensure that the parents can demonstrate appropriate feeding techniques. Also teach the parents how to recognize signs of respiratory distress, respiratory infection, and bowel obstruction, and to notify their healthcare provider if such signs occur. Emphasize the need for long-term follow-up to identify and intervene for any long-term sequelae.

Meckel's Diverticulum

The most common congenital malformation of the GI tract, Meckel's diverticulum, is asymptomatic in most cases, but it may cause disease in approximately 4% to

6% of those affected (Menezes et al., 2008). Incidence is greater in males than females by a ratio of 3:1. With early identification and surgical intervention, Meckel's diverticulum is usually resolvable.

Pathophysiology

Meckel's diverticulum arises from a vestigial segment of the embryonic yolk sac that fails to separate from the primitive intestine during the fifth and seventh week of gestation. Meckel's diverticulum can occur anywhere in the abdomen but is most commonly found in the right lower quadrant. It is found on the antimesenteric border of the ileum, usually within 40 to 50 cm of the ileocecal valve. A range of distances from the ileocecal valve may occur as well as the size of the Meckel's diverticula, depending on the age and size of the child at time of diagnosis. Ectopic tissue, most commonly gastric tissue, may be found in the distal tip of a Meckel's diverticulum. Secretion of acid and pepsin from the ectopic gastric tissue causes peptic ulceration and, ultimately, bleeding in the lower GI tract.

Assessment

Most symptomatic children present younger than age 2 years. Intermittent, painless rectal bleeding is the most common clinical manifestation of Meckel's diverticulum. The blood is most often bright red or maroon and may be passed independent of stool resulting from ulceration at the junction of the ectopic tissue and the normal ileal mucosa. Emphasize to the family that they must save all output so a full assessment can be completed. Careful assessment and measurement of blood loss will determine further interventions. Bleeding may be so severe as to cause severe anemia or hemorrhagic shock.

Physical assessment findings may include pallor, lethargy, and hemodynamic instability. Intestinal obstruction (secondary to intussusception or volvulus) can occur and presents with bilious vomiting, abdominal pain, and distention. Perforation is a potential complication, but uncommon. Presentation of symptoms may also be similar to acute appendicitis with nausea, vomiting, and right-sided abdominal pain.

Diagnostic Tests

Depending on the degree of bleeding, a CBC may reveal severe anemia. Standard radiographic imaging and barium studies of the GI tract are of little value in identifying Meckel's diverticulum. Definitive diagnosis is most commonly made with a Meckel's scan (technetium-99m pertechnetate scan), which uses IV injection of a technetium isotope to visualize the ectopic gastric mucosa commonly found in bleeding Meckel's diverticulum. If the Meckel's scan is not diagnostic, a tagged red blood cell study may be done to localize the bleeding site.

Interdisciplinary Interventions

Because rectal bleeding is the most common manifestation of Meckel's diverticulum, assessing and restoring

circulating fluid volume is the most important initial step in patient management. Administer IV fluids and possibly a transfusion of packed red blood cells to restore circulating fluid volume. After the child is stabilized, further diagnostic workup can take place. Place the child on NPO status and give antibiotics if peritoneal signs present, as ordered.

A diverticulectomy is performed via an open approach or laparoscopically. Under most circumstances, intestinal resection is not required, recovery is complete, and complications are uncommon. Laparoscopic surgery is frequently used and is helpful in evaluating the child with unusual symptoms (Chan et al., 2008).

Promoting the child's comfort during both the preoperative and postoperative periods are an important aspect of care. Provide information and support to the child and family regarding diagnostic procedures and therapeutic interventions to help allay anxiety during the course of the hospitalization. Postoperatively, monitor for the return of bowel function, encourage early ambulation, and monitor tolerance to progression of diet. The hospital stay is usually short, and the child will go home when there is no evidence of fever and when ambulation and a regular diet are tolerated.

Community Care

Instruct parents to report any signs of infection to their surgeon. The child's return to school and to full activities may vary, depending on the surgeon.

Malrotation and Volvulus

Although the incidence of malrotation is reported to be approximately 1 in 500 live births, its true incidence is difficult to ascertain, because many affected infants are asymptomatic. Volvulus occurs most commonly during the first month of life, but it can occur anytime during childhood. The male to female ratio is 2:1 (McCullough & Sharieff, 2006).

Malrotation is the result of incomplete or deviated rotation of the midgut during embryologic development between the eighth and 10th week of gestation, which causes incomplete fixation of the mesentery on the posterior abdominal wall at the duodenum and proximal colon. *Volvulus* is a life-threatening complication of malrotation, in which the malrotated bowel twists in a clockwise direction on itself, causing vascular compromise and, ultimately, necrosis of the bowel. Omphalocele, gastroschisis, and congenital diaphragmatic hernia, because of the nature of their structural defects, all are associated with volvulus. Other associated conditions include intestinal atresias, Hirschsprung disease, and Meckel's diverticulum.

Infants who lose little or no intestine have an excellent prognosis. The infant or child will recover from surgery with minimal problems. The outcome for the child with associated medical complications such as infarcted bowel, or complicated with associated congenital anomalies or is younger than 1 month of age has increased risks for morbidity.

Pathophysiology

The midgut comprises the duodenum distal to the entry of the bile duct, jejunum, ileum, appendix, cecum, and colon up to the midtransverse segment. Between the fifth and 10th weeks of gestation, the midgut grows rapidly and, because of lack of space, is forced to rotate out of the abdominal cavity into the umbilical cord. Between the 10th and 11th weeks of gestation, the abdominal cavity enlarges to a point that allows the midgut to reenter the abdominal cavity. The midgut normally rotates 270 degrees counterclockwise as it returns to the abdominal cavity. If the midgut fails to complete this rotation, the mesentery usually cannot fix completely onto the posterior abdominal wall, and a foreshortened mesenteric base forms. This foreshortening results in a stalklike, "poorly fixed" structure, creating a risk for the bowel to twist on itself, kinking and knotting the intestinal loops and causing abdominal pain and intestinal obstruction. Congenital bands of adhesions, known as *Ladd's bands*, are usually present. These bands extend from the right upper quadrant across the duodenum to the cecum and may cause duodenal obstruction.

Malrotation can present as a chronic problem, with intermittent abdominal pain and vomiting alternating with asymptomatic periods. Infants with malrotation and midgut volvulus present acutely with intense symptoms, and their condition can deteriorate rapidly.

Assessment

Assess the patient's general color, activity level, and the volume and characteristics of emesis, which is usually bilious and possibly more pronounced in young infants. Assess the abdomen for progressive distention accompanied by constant versus intermittent pain. Presentation of symptoms may be less pronounced in older children. Signs of acute or intermittent intestinal obstruction, crampy abdominal pain, FTT, constipation, bloody diarrhea, and hematemesis may be observed in the older child with malrotation. In some cases of malrotation, the presentation of symptoms can be intermittent with few obvious physical findings.

Alert! To avoid serious complications of malrotation with volvulus, any acute onset of bilious emesis in an otherwise healthy infant requires immediate workup that includes malrotation with volvulus in the differential. This symptom must be treated as an emergency situation.

Infants with volvulus usually present through the emergency room with a history of a healthy infant experiencing sudden onset of vomiting, progressing to bilious vomiting. When substantial vascular compromise has occurred, the child may demonstrate abdominal distention and tenderness, signs of peritonitis, with rapid deterioration leading to hypovolemic shock. The presence of blood in the stool is a serious sign, because it indicates vascular compromise of the intestine.

Diagnostic Tests

Diagnosis of malrotation is supported by radiographic evaluation. A plain radiograph of the abdomen may demonstrate an air-filled stomach and duodenum with a proximal obstruction (commonly termed a *double-bubble sign*), or gas-filled intestinal loops with distal obstruction. Free air in the peritoneum may be seen if perforation has occurred. An upper GI barium swallow contrast study is the gold standard for diagnosing volvulus. The classic finding is the small intestine rotated to the right side of the abdomen, indicating the malrotation, with contrast narrowing at the obstruction site, causing a “corkscrew” appearance (Lampl et al., 2009). Ultrasound is also used as a diagnostic tool.

Interdisciplinary Interventions

Surgical correction of malrotation with signs of obstruction or volvulus is necessary in symptomatic infants. Preoperatively, a NG tube is inserted for gastric decompression and IV fluids are administered to aggressively correct any fluid volume deficits. IV antibiotics are also given. During surgery, the malrotation is identified and “untwisted.” All adhesive bands are divided, and the cecum is placed in the left abdomen.

If a volvulus is identified, emergency surgery is necessary to minimize intestinal necrosis, untwist the bowel, and reestablish the blood supply. Nonviable bowel is resected. If bowel necrosis is extensive, or viability of the bowel is questionable after the volvulus has been untwisted, “second-look” surgery may be done 24 to 48 hours after the initial surgery, to achieve maximal salvage of bowel.

Postoperative management is affected by the amount of bowel that is resected. The child with volvulus and extensive bowel necrosis may be critically ill during the immediate postoperative period and may require prolonged hospitalization. Care is similar to that for other intestinal surgeries. Monitor vital signs and hydration status, and provide pain management. Provide scrupulous care of the NG tube, including assessment of the skin condition of the nares, to avoid complications related to skin breakdown. If the infant required a significant length of bowel resection resulting in short bowel syndrome, a gastrostomy tube and a central venous catheter may be placed at the time of surgery.

Volvulus needs to be considered as a catastrophic event for the child and family. Provide physiologic and educational interventions within a framework of emotional support that recognizes and responds to the family’s reaction to this acute and extreme change in the child’s health. A social worker or psychologist may be of help to the child and family in dealing with the acute crisis of the child’s illness and in making long-term adjustments. Child life specialists may provide developmentally appropriate play experiences to help the child cope with the effects of hospitalization and changes in health and bodily function.

Community Care

Education is essential. Teach parents to recognize signs of bowel obstruction resulting from the increased risk for

adhesions. Educate the parents in the care specific to their infant’s needs. Some infants may require enteral feeding through a gastrostomy tube; education may be required for parenteral therapy and for central line management, depending on the extent of the resection and the amount of bowel remaining. Teach parents routine care and problem-solving skills that will help them to cope with nonroutine situations.

Intussusception

Intussusception is a common cause of intestinal obstruction; more than 75% of cases occur in children 3 to 24 months old, predominantly males (Waseem & Rosenberg, 2008). It occurs when a proximal segment of bowel prolapses or telescopes into the lumen of an immediately distal segment of bowel. This prolapse results in vascular compromise, edema, and, eventually, mechanical obstruction. The ileocecal junction is a common site of intussusception (Fig. 18–15).

It can be classified as idiopathic, which is seen in most cases, or pathologic. The idiopathic form is believed to be a result of a viral illness, during which hypertrophied lymphoid tissue develops (Peyer’s patches) in the bowel (an identified change in the intestinal mucosa). This becomes a lead point, accounting for the majority of infant presentations. Usually in older children, a pathologic lead point can be identified, most commonly as a Meckel’s diverticulum, polyp, or hemangioma to name a few from a lengthy list of potential triggers. An individual with cystic fibrosis may develop intussusception resulting from the thick, inspissated stool that may result from inconsistent ingestion of replacement pancreatic enzymes.

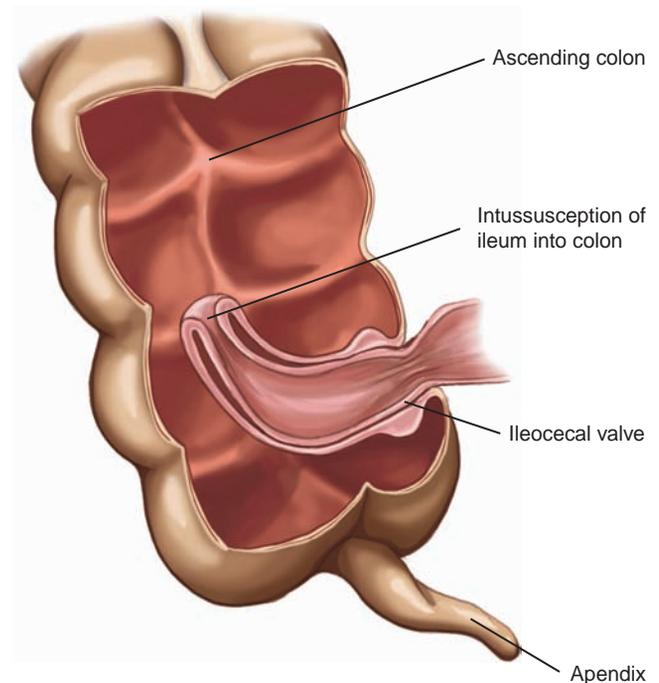

FIGURE 18–15. In intussusception, a portion of the bowel telescopes into itself, causing signs and symptoms of intestinal obstruction.

The prognosis for the child with intussusception is good if detection and treatment are prompt. Recurrence occurs in 0.5% to 15% of cases after nonoperative reduction and is usually within the first 24 hours. Therefore, these children are admitted and observed. Long-term sequelae are uncommon.

Pathophysiology

Edema develops within the telescoped bowel wall secondary to vascular and lymphatic compression. Bleeding occurs, resulting in the passage of blood and mucus in the stool. As the bowel becomes more edematous, mechanical obstruction of the bowel occurs. If left untreated, this obstruction may lead to gangrene and perforation.

Assessment

The child with intussusception classically presents as a usually healthy infant with severe abdominal pain that is crampy and intermittent, causing the knees to be drawn up to the chest. Vomiting is nonbilious at first but may become bilious as the disease progresses and complete intestinal obstruction occurs. Check the child's diaper or underpants. Dark-red blood and mucus are passed through the rectum; this discharge is commonly described as *currant jelly stools*. Although this type of stool is classically described in the literature, it is a late sign, and absence of bloody stools does not alter the workup.

During the early stages of intussusception, the physical findings from assessment may reveal no abnormalities other than episodic pain. The infant or child's level of consciousness may reveal increased irritability progressing to lethargy and listlessness as the disorder progresses. Monitoring the temperature may reveal a low-grade fever. Palpate the abdomen, which should be soft and nontender. A sausage-shaped mass is commonly palpable in the mid to upper right quadrant, with bowel signs absent in the right lower quadrant. With progressive obstruction, the abdomen may become more distended and tender, and the mass may become nonpalpable. Palpate the groin for incarcerated hernia or testicular torsion, which must be ruled out as a possible cause of intermittent acute pain.

Diagnostic Tests

A CBC and electrolyte panel may be part of the evaluation. The CBC may show a slight increase in white blood cells, reflecting inflammation, and the electrolyte panel may reflect some degree of dehydration if the child has had excessive fluid losses from vomiting. The urinalysis shows signs of dehydration with elevation of specific gravity.

Radiographic evaluation begins with a plain radiograph of the abdomen, which often reveals nonspecific findings but may demonstrate some density in the area of the intussusception. A contrast enema, done with air alone or with barium, is used as both a diagnostic and therapeutic tool in treating intussusception. Today, the air enema under fluoroscopy is widely used because air is safer than contrast media, exposes the child to less radiation, and

avoids further peritoneal complications if perforation occurs. The contrast enema is done after the child has received NG decompression, IV access with fluid resuscitation, and IV antibiotics. A surgeon stands by in the event of bowel perforation during enema administration. The child is sedated before the procedure. The contrast material infused during the enema delineates the area of intussusception on radiograph, which appears like a coiled spring within the lumen of the bowel. The pressure of the contrast material is maintained for as long as 5 minutes, which causes reduction of the intussusception in 70% to 84% of cases (Waseem & Rosenberg, 2008). The radiograph technician is able to visualize the reflux of air into the small bowel as the tissue mass is successfully reduced. The child is observed for 24 to 36 hours for signs of recurrence. Ultrasound may also be used for the diagnosis.

Interdisciplinary Interventions

Surgical reduction of intussusception is required in cases in which overt signs of peritonitis, bowel perforation, or septic shock are present or when radiographic interventional methods fail. Fluid resuscitation and IV broad-spectrum antibiotics are given preoperatively. A laparotomy is performed through a transverse right lower quadrant incision. Manual reduction of the intussusception is attempted after the bowel is mobilized. If this approach is not successful, the affected bowel is resected, with end-to-end anastomosis. If bowel perforation is detected during surgery, a temporary ostomy may be created.

A key intervention in the care of the child with intussusception is teaching the family about the signs and symptoms of recurrent intussusception. Recurrence may also develop months later in a small percentage of patients even after a surgical reduction. Early recognition and treatment are important to avoid severe illness.

Community Care

Instruct the parents to return to the medical facility if vomiting, abdominal pain, or bloody stools recur. If a surgical procedure was performed, provide instruction on signs of wound infection, such as fever, redness, swelling, or drainage from the incision.

Hirschsprung Disease

Hirschsprung disease, or congenital megacolon, is a congenital absence of ganglion cells (ganglia) from variable lengths of the terminal bowel. Short-segment Hirschsprung disease accounts for as many as 90% of cases and affects the rectum and rectosigmoid colon; long-segment Hirschsprung disease (approximately 10% of cases) affects the entire colon and portions of the small intestine. Ultrashort-segment Hirschsprung disease, which involves less than 5 cm of colon, occurs in a small number of patients (Imseis & Garipey, 2004).

Hirschsprung disease occurs in 1 in 5,000 live births; short-segment Hirschsprung disease has a 4:1 predominance in males (Dasgupta & Langer, 2008). Both familial and sporadic cases have been identified through

molecular genetics, and specific genes have been identified as the cause of Hirschsprung disease in some patients. The RET proto-oncogene on chromosome 10 accounts for 50% of familial cases and is most common in long-segment disease (Garipey, 2003). As many as 12% of children with Hirschsprung disease have associated chromosomal anomalies, most commonly trisomy 21, and 15% present with at least one other congenital anomaly, such as heart defects (Garipey, 2003).

Long-term follow-up studies report that these children overcome postoperative problems and do well over time (Dasgupta & Langer, 2008). Social satisfaction, quality of life, and sexual function are reported to be relatively normal for most individuals living with Hirschsprung disease. Children with coexisting conditions are at greater risk for complications, but this risk decreases over time as well.

Pathophysiology

During the fifth to 12th weeks of gestation, neuroblasts (precursors of the intestinal ganglia) migrate to the GI tract. Neurons arise from the embryonic neural crest cells that normally populate the distal colon during this time. The portion of the enteric nervous system in the gut wall consists of two major plexuses of ganglia connected by bundles of axons: the myenteric intermuscular (Auerbach), and submucous (Meissner) plexuses, located between the circular and longitudinal muscle layers and the submucous layer. The absence of these plexuses leads to inadequate relaxation in the affected bowel. In response to stool in the rectum, the internal sphincter of the rectum contracts instead of relaxing. This abnormal response obstructs passage of the stool and results in

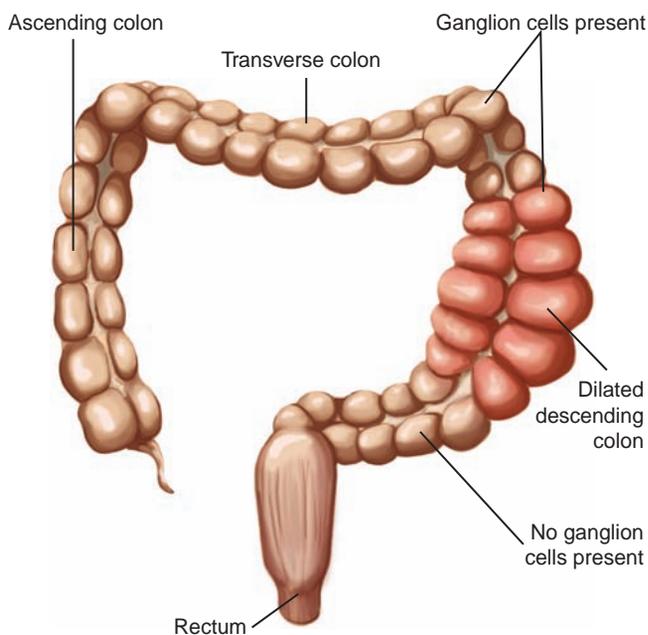

FIGURE 18–16. In Hirschsprung disease, dilation of the colon occurs proximal to the aganglionic section.

dysmotility, bacterial overgrowth, and enterocolitis. In response to the obstruction, the proximal normal bowel distends, thus the term *megacolon* (Fig. 18–16). As the bowel distends, intraluminal pressure increases, putting pressure on the bowel wall. This pressure decreases blood flow, causing ischemia and deterioration of the mucosal barrier. Stasis also allows bacterial overgrowth, through which bacteria proliferate with translocation into the abdominal wall. Inflammation and infection of the bowel wall (enterocolitis) can result—a potentially life-threatening complication.

Assessment

Clinical manifestations of Hirschsprung disease vary depending on the extent of the bowel segment involved and the child's age at the time of diagnosis (Developmental Considerations 18-1). Suspect Hirschsprung disease when the newborn does not pass meconium during

DEVELOPMENTAL CONSIDERATIONS 18–1

Presentation of Hirschsprung Disease

Newborn

Breast-fed infants may present with less severe manifestations:

- Failure to pass meconium within 48 hours after birth
- Abdominal distention
- Bilious vomiting
- Liquid stool (from seepage around fecal impaction, must be differentiated from diarrhea of enterocolitis)
- Enterocolitis
 - Abdominal distention
 - Diarrhea
 - Fever
- Hematochezia

Older Infants and Children

- Chronic constipation
- Characteristic stools
 - Foul smelling
 - Consistency varies: small pellets, ribbonlike, or liquid (from seepage around fecal impaction, must be differentiated from diarrhea of enterocolitis)
- Abdominal distention
- Enterocolitis
 - Abdominal distention
 - Diarrhea
 - Fever
 - Hematochezia
- Failure to thrive

the first 24 hours after birth and has bilious vomiting or has abdominal distention, feeding intolerance, with bilious aspirates and vomiting. For the older child, a history of severe constipation from birth, FTT, abdominal distention, and an empty rectal ampulla on digital rectal examination are clinical indicators for Hirschsprung disease.

Fifty to 90% of cases are diagnosed within the neonatal period as a result of increased awareness (Langer, 2004). Enterocolitis is the presenting symptom in approximately 6% of newborns with Hirschsprung disease. Risk factors for enterocolitis in this group include delay in diagnosis beyond age 1 week and Down syndrome.

Physical examination most often reveals a distended abdomen and the absence of stool in the rectum. During the rectal examination, upon withdrawal of the digit, there may be an explosive release of foul-smelling liquid stool and air as a result of decompression of the proximal normal bowel.

Diagnostic Tests

Abdominal radiographs can be helpful to determine the air patterns present in the colon. A water-soluble contrast enema is commonly the first step in establishing the diagnosis of Hirschsprung disease. In most cases, the study demonstrates a characteristic transition zone where the aganglionic segment of bowel and the dilated proximal segment meet. Contrast enemas are avoided when a patient presents with suspicion of enterocolitis. Rectal manometry may be used as a diagnostic tool, particularly in the older child. Definitive diagnosis is made by histologic evaluation with suction rectal biopsy from multiple sites demonstrating the absence of ganglion cells in the submucosa and myenteric plexus. If insufficient tissue is obtained, a full-thickness biopsy is done in the operating room.

Nursing Diagnoses and Outcomes

In addition to the nursing diagnoses listed in Nursing Plan of Care 18-1, the following nursing diagnoses and outcomes may apply to the infant with Hirschsprung disease:

Constipation related to effects of aganglionic bowel

Outcome: The child and family will verbalize understanding of signs of altered elimination and implement appropriate interventions.

Risk for infection related to potential complication of postoperative atelectasis and enterocolitis

Outcomes: The child will be free of infection.

The child and family will recognize the signs of enterocolitis and contact the healthcare provider when such signs are present.

Interdisciplinary Interventions

Preparing and supporting the child during tests and procedures and providing parent education and support are important activities throughout the diagnostic workup. Surgery is the definitive treatment. The aganglionic segment of bowel is removed, and the normal bowel is

anastomosed to the rectum. Historically, this surgery was done in two stages, an approach still used at some institutions. With two-stage surgery, the child undergoes a diverting colostomy just proximal to the transition zone. This procedure allows the normal bowel to decompress and return to normal size. At a later date, usually when the child is 6 to 12 months old or has reached a body weight of 5 to 10 kg and is medically stable, a second-stage pull-through procedure is done to reestablish bowel continuity. Surgical approaches have undergone numerous revisions, and debate continues over the best surgical approach. The most common approach is the Soave endorectal pull-through procedure. This surgery is a primary pull-through in which the aganglionic rectum is stripped of its mucosa, and normal innervated colon is pulled through the muscular layer (“muscular cuff”) of the rectum and anastomosed 1.0 to 1.5 cm above the dentate line. Colostomy is indicated in a subgroup of patients, such as a very sick child with enterocolitis, a child with massive megacolon, a neonate with pneumoperitoneum, a child with developmental delay, or a child with total colonic aganglionosis.

Surgical correction also may be done laparoscopically. A laparoscopic biopsy is initially done to identify the transition zone, and then the procedure is performed. Another more recent approach is the transanal (perineal) pull-through, first described in 1999. This technique consists of a transanal mucosectomy, followed by a full-thickness transanal resection of the aganglionic rectum and sigmoid colon and coloanal anastomosis.

Initial preoperative care of the child diagnosed with Hirschsprung disease includes the standard care for any child with suspected bowel obstruction. The child is kept NPO, and gastric decompression is instituted. IV fluids and electrolytes are administered to meet maintenance requirements and correct any deficits, along with IV antibiotics. If enterocolitis is suspected, additional interventions include rectal irrigations and possibly a colostomy (Langer, 2004). Neonates do not require a preoperative bowel prep, but older children may require extensive preparation. This prep may be subject to surgeon preference. If the child must have an ostomy, the certified wound, ostomy, continence nurse (CWOCN) will be involved during the preoperative period. The CWOCN will mark the site for the stoma and provide education and support to the child, family, and clinical nurse while preparing the family for surgery.

Provide routine postoperative care for the child after surgery. The CWOCN will collaborate with the bedside nurse to monitor the appearance and function of the colostomy, and to select appropriate pouching appliances. After the pull-through, monitor the child closely for signs of intra-abdominal abscess, such as fever, irritability, and abdominal distention. Assessing skin condition is important with patients having a pull-through procedure, because they will have frequent liquid stools postoperatively. Aggressive skin care using skin barrier creams to avoid maceration or skin breakdown is required. Early involvement of the CWOCN to assist with skin care recommendations and a skin care program is an essential part of the plan of care, both postoperative and home

care. Rectal dilations are initiated at 2 to 3 weeks after surgery to reduce the risk of stenosis. These are continued for about 6 months until the anastomotic scar tissue becomes supple. Many children are placed on a home bowel program to maintain full evacuation of the colon. Other therapies may include rectal washouts (similar to enemas) for 3 to 4 months to reduce the incidence of enterocolitis.

Alert! Do not administer anything per rectum for the first 2 to 3 weeks after a pull-through procedure, including suppositories, thermometers, or catheters. Place a sign on the patient's bed so that others will avoid these measures.

Community Care

The child with Hirschsprung disease has special care needs at home after both primary and staged surgeries. Assess the family's understanding of Hirschsprung disease and the treatment plan. Prepare the family to meet the child's anticipated care needs at home. When two-stage surgery is performed, the family will need instruction in colostomy care. Include the child in all teaching, as developmentally appropriate. Provide instruction in skin care, pouch application and management, and signs of complications. The CWOCN will collaborate with the bedside nurse in the teaching process and in referring the family to community resources, such as a home health agency, for support and to reinforce family education. The family should receive needed ostomy care supplies at discharge and should be given information regarding where to obtain ongoing supplies.

After pull-through, the child and family will need to be taught about postoperative complications. Emphasize signs of anastomotic stricture, bowel obstruction, and enterocolitis. Provide them with the appropriate follow-up contacts. Teach parents to contact their physician for signs of enterocolitis (see Developmental Considerations 18–1). In addition, teach the parent and patient signs of bowel obstruction, which include abdominal distention, bloating, vomiting, or severe constipation and pain. These complications can occur at any time.

Long-term problems may include delays in toilet training, staining, fecal incontinence, constipation, and an overall negative effect of the disease on the quality of life. Many of the complications of Hirschsprung disease have been reported to decrease significantly after the age of 15 years (Engum & Grosfeld, 2004). Although many children attain satisfactory bowel function, parents need to be prepared for these problems, supported during toilet training of the child, and encouraged to have realistic expectations about the child's ability to achieve continence.

Children and families may benefit from peer support in dealing with Hirschsprung disease (see [thePoint](#) for additional information about organizations). Community organizations such as the local ostomy association offer opportunities for children and families to interact with others who have been similarly affected.

Anorectal Malformations

Anorectal malformations encompass disruptions in anal development that result from altered prenatal development of the GI and genitourinary tracts during the fourth to 16th weeks of gestation. Anorectal agenesis (also referred to as *imperforate anus*), anal stenosis, and fistulas (rectovaginal fistula or fistulas in females and rectourethral fistula in males) are examples of anorectal malformations. Persistent cloaca is a complex congenital malformation in which the rectum, vagina, and urinary tract are fused together in a single common channel communicating externally through a single perineal orifice located at the normal urethral site. The posterior sagittal anorectoplasty (PSARP) is the most common surgical approach (Rintala & Pakarinen, 2008).

Anorectal malformations occur in 1 in 4,000 live births and are slightly more common in males than females. Although their precise etiology is not known, anorectal malformations are frequently associated with the presence of other congenital anomalies, often as a part of VACTERL association.

Anorectal malformations are classified as high, when the infant has no perineal fistula, and low, when a perineal bowel opening is present (Rintala & Pakarinen, 2008). Specific malformations are generally common to each classification (Table 18–4). Genitourinary anomalies, other than fistulas, are associated with low lesions in 20% of cases and with high lesions in 50% of cases.

The prognosis for a child with an anorectal malformation depends on the type of malformation and the presence of other congenital anomalies. Morbidity usually results from associated defects and the complexity of the lesion.

Pathophysiology

During the fourth week of gestation, the cloaca (a transitory embryologic cavity) forms at the end of the primitive

TABLE 18–4

Classification of Anorectal Malformations

Classification	Male	Female
High	Anorectal agenesis Anorectal agenesis with rectourethral fistula Rectal atresia	Anorectal agenesis Anorectal agenesis with rectovaginal fistula Rectal atresia
Intermediate	Rectobulbar urethral fistula Anal agenesis	Rectovestibular fistula Rectovaginal fistula Anal agenesis
Low	Anocutaneous fistula Anal stenosis	Anocutaneous fistula Anal stenosis Anovestibular fistula

hindgut. The cloaca serves as the early common channel of the rectum and the urogenital structures. The urorectal septum develops at 4 to 6 weeks' gestation, descending in a cephalocaudal direction to unite with the cloacal membrane that divides the rectum from the urogenital structures. Rupture of the cloacal membranes at 8 weeks' gestation forms the urogenital and anal orifices. Further differentiation takes place during the next 8 weeks to form the bladder, the urethra, and seminal vesicles in males, and the urethra and vagina in females. Failure of embryologic development at any point in this process can result in anorectal anomaly. The form of the anomaly is closely related to the timing of the disruption in embryologic development, with high anomalies occurring around the fourth week of gestation and low anomalies occurring between the 10th and 12th weeks.

Assessment

Anorectal malformations are usually immediately obvious at birth. On the initial physical examination, the anus is absent or displaced (Fig. 18–17). Affected females may have a variable number and configuration of openings noted in the perineal area. The presence of a fistula may be noted when gas or stool is expelled from the urethra or vagina. In males, fistulas may be seen anywhere along the tract between the usual location of the anus and the tip of the penis, appearing as epithelial pearls or spots of meconium. Meconium may be seen in the urine if a fistula is present between the bowel and urinary tract.

An anal malformation that is not immediately noted may present with signs of lower intestinal obstruction, such as abdominal distention and bilious vomiting within the first 18 to 24 hours after birth. The presence of a midline groove with well-formed buttocks and an obvious anal dimple indicates a good prognostic sign and that the malformation is low, in contrast to flattened buttocks (with no midline groove) and the absence of an anal dimple, which indicates a high malformation.

Diagnostic Tests

Male infants need a urinalysis to detect the presence of meconium in the urine. Radiographic evaluation is necessary to determine the extent of the malformation. A cross-table lateral radiograph with the infant positioned prone with the pelvis elevated, can be used to differentiate a high lesion from a low lesion. It can also disclose the presence of gas in the bladder or urethra, which indicates the presence of a fistulous connection with the bowel. Ultrasound of the abdomen and pelvis determines whether the malformation includes the urinary tract. If the study is positive, a more detailed urologic evaluation is conducted.

CT or magnetic resonance imaging may also be used to visualize the anorectal anatomy. Radio-opaque dye studies of any obvious fistulous tracts may be done to determine the exact anatomy of the tract.

Interdisciplinary Interventions

The infant with anorectal malformation requires a careful physical examination to determine the presence of other anomalies that may be life threatening. The more complex and the higher the defect, the greater the chance for an associated anomaly. In addition, a determination is made if the defect present requires a colostomy. Immediate stabilization focuses on relieving intestinal obstruction by NG decompression. The infant is put on NPO status, and IV fluids and antibiotics are administered. Strict monitoring of intake and output is recorded. Provide standard preoperative care.

Surgical intervention depends on the nature of the malformation. Children with low lesions require anoplasty (creation of an anal opening) in a single-stage procedure.

Perform routine postoperative care with special attention to prevention of perineal skin excoriation from passing small, frequent liquid-type stools. Antibiotic ointment is applied to this area after each diaper change for 2 weeks and as indicated. The plan of care includes nothing per rectum. Signage may be posted on the crib to

FIGURE 18–17. An anal dimple may be present in low types of anal agenesis but not in high types.

communicate this to the healthcare team. Two to 3 weeks after surgery, anal dilations are begun and continued for approximately 2 months to prevent stenosis of the operative site. Dilatations may be continued on a tapering schedule.

Children with high lesions require a diverting colostomy within the first 24 to 48 hours of life. Definitive repair is done in two subsequent stages. The first stage is done after 1 month of age, although some surgeons may wait until an older age, when the rectovaginal or rectourethral fistula (if present) is repaired. The PSARP procedure is done to create an anal opening. A laparotomy is performed with a PSARP when the rectum is too high and cannot be visualized from the posterior approach. Postoperative care is more complex after an open abdominal procedure with the PSARP. Dilations of the newly created anus begin 2 weeks after surgery and continue for approximately 6 to 8 weeks, at which time the desired size is achieved. The second stage of the surgery, final closure of the colostomy, is then planned. Dilatations continue on a tapering schedule for a total of 6 months (Guardino, 2007). In recent years, pediatric surgeons have attempted one-stage repairs to avoid a colostomy, future surgeries, and thus additional trauma to the patient. Decisions are individualized based on many factors, such as the complexity of the malformation and peripheral circumstances (Zheng, Xiao, & Huang, 2008).

Besides the usual postoperative care, inspect the anoplasty site for mucosal prolapse, which may occur if an inadequate amount of sphincter has been preserved. The postoperative plan of care includes administering IV antibiotics and fluids, and managing pain. A urinary catheter is placed if a cloacal repair was required to correct the malformation. This measure protects the suture line in the urethra; notify the surgeon if the catheter becomes dislodged.

Interventions for skin care generally are surgeon specific but may include applying antibiotic ointment to the perineum with each diaper change for at least 2 weeks (Guardino, 2007). Stool-softening agents may be administered. The surgeon initially carries out anal dilations. Before the patient's discharge, the parents are instructed (either by the surgeon or by the surgical nurse at the follow-up visit) to continue anal dilations at home.

After closure of the colostomy, the child is not discharged until he or she has passed stools and demonstrated diet tolerance. Frequent, small liquid stools resulting in perineal excoriation must be addressed. Many skin barriers are available. Consult with the CWOCN to determine the most effective skin barrier and skin care program.

Constipation is a long-term problem after PSARP and may also be experienced with low lesions. The spectrum of problems experienced directs bowel management interventions. Interventions may include diet, increased activity, oral agents, enemas, biofeedback, and bowel management programs. When children reach school age, and a bowel program with daily enemas is ineffective in controlling soiling or constipation, an antegrade continence enema procedure may be considered as an option.

This procedure involves creating a one-way conduit between the skin and the cecum using the appendix. An abdominal stoma is created to allow easier access for daily flushes/enemas with evacuation through the rectum to achieve more efficient bowel management (Tobias et al., 2008).

Community Care

Management for the infant with an anorectal malformation includes family education about colostomy care. Refer the family for home health nursing follow-up as needed. Concerns related to fecal incontinence have long-term implications in both the clinic and school settings. Provide anticipatory guidance for parents, including support with bowel management programs. The goal of bowel management is "social continence" for children who are unable to be fully continent. Follow-up care is essential for the coordination of individualized interventions and for the provision of long-term support needed to progress toward normalization of elimination patterns.

ANSWER: A primary difference of GI surgery among infants through school-aged children such as

Cory is the parent-child relationship. For many infants with a malformation, surgery occurs before a parent-child relationship is well established. Nurses should spend additional time supporting the parent-infant relationship and encouraging the parent to master caregiver skills.

INFLAMMATORY DISORDERS

Inflammatory disorders of the GI tract include gastroenteritis, appendicitis, IBD, and pancreatitis, which are covered in this chapter.

Gastroenteritis

Gastroenteritis, inflammation of the GI tract, may be caused by GI irritants such as bacteria, viruses, and toxins produced by fish, mushrooms, and chemicals (such as food additives; Table 18-5). Outbreaks of gastroenteritis routinely occur in daycare centers, schools, institutions for the handicapped, and other places where overcrowding is prevalent and hygiene is inadequate. Food-borne outbreaks occur fairly regularly. Hospital-acquired infections resulting in gastroenteritis involve two main organisms: rotavirus and *Clostridium difficile*. Both organisms can linger in the environment for a long time and can be easily transmitted from child to child on the unwashed hands of healthcare workers. Acute diarrhea may also result from overfeeding with hyperosmolar fluids, use of antibiotics, and extraintestinal infections such as pneumonia, urinary tract infection, or otitis media, which are usually self-limited and mild in severity. Generally, acute gastroenteritis has about a 5-day duration. Life-threatening gastroenteritis seldom occurs in the United States.

Second only to pneumonia, diarrheal diseases are a worldwide leading cause of illness and death among

TABLE 18-5
Causes of Gastroenteritis

children younger than 5 years of age in developing countries (World Health Organization, 2008). Infants are particularly vulnerable to gastroenteritis with subsequent dehydration. Treatment for these children includes breast-feeding, oral rehydration solution, and zinc supplementation. Studies have shown benefits from probiotics when added to the formula of healthy infants up to 6 months of age (Kligler et al., 2007).

Pathophysiology

Microbes that cause gastroenteritis are transmitted by the fecal–oral route. Hands are contaminated with stool by not washing them after toileting or changing an infant’s diapers. These contaminated hands are then placed directly into the mouth or on foods, then the contaminated food is consumed. The bacteria or viruses either remain unchanged in the food or continue to grow and multiply, possibly producing toxins.

Assessment

Typical signs and symptoms include diarrhea, nausea, vomiting, and abdominal pain. However, specific findings vary with the causative organism. For example, some organisms produce watery diarrhea; others produce bloody diarrhea. Fever, nausea, and vomiting may be present with some infections and missing with others.

History regarding duration of symptoms, underlying or preexisting condition including an immunocompromised status, sick contacts, dietary changes, presence of blood in stool, recent travel, exposure to pets, recent use of antibiotics, and history of fever may assist in directing the workup. A physical examination is done to rule out other extraintestinal causes, such as a urinary tract infection or otitis media. The physical examination also allows the healthcare provider to assess for clinical evidence of dehydration. Signs such as capillary refill less than 2 seconds, dry mucous membrane, absence of tears, and ill general appearance are associated with a greater sensitivity to fluid volume deficit.

Diagnostic Tests

Examination of the stool both physically (noting color, consistency, odor, and volume) and microscopically (leukocytes, ova or parasites, culture) is essential. Fresh stool is sent to the laboratory for culture. However, in a healthy infant or child who presents without fever and no blood in the stools, stool cultures may not be ordered. The laboratory reports positive culture results for *Salmonella*, *Shigella*, *Campylobacter*, *Yersinia*, or hemorrhagic *Escherichia coli*. Other tests include enzyme immunoassay for *C. difficile* toxins and *rotavirus*, as well as neutralizing antibody for other viral agents. Many laboratories use

DNA probes and polymerase chain reaction for certain organisms.

If the child is febrile, a urine culture may be considered to rule out urinary tract infection, and serum electrolytes may be obtained for evaluation of dehydration.

Interdisciplinary Interventions

Treatment consists of rehydration and correcting any electrolyte imbalances (see [thePoint](#) for Care Path: An Interdisciplinary Plan of Care for the Child With Gastroenteritis). Antibiotic therapy depends on the severity of the illness or whether a specific pathogen is isolated. Often, antibiotics do not alter the course of the illness significantly and contribute to the development of resistant strains and/or a carrier state of infection. However, antibiotics may be useful for life-threatening infections.

Assess and monitor the child for signs of fluid and electrolyte imbalance (see Chapter 17 for an in-depth discussion of assessment and treatment). Oral rehydration therapy is the method of choice for treatment of children with gastroenteritis who have mild to moderate depletion. Oral rehydration therapy does not necessitate hospitalization, so it is advantageous in maintaining family cohesion. Provide parents with detailed teaching about how to implement oral rehydration therapy—what fluid to use, how long to continue, how to advance the child's diet, signs of worsening status in the child, and when to notify the healthcare provider. If the child is severely dehydrated, or fails to improve on oral rehydration, hospitalization may be necessary for IV hydration. Observe contact precautions when handling stool or stool-contaminated items. When caring for patients with gastroenteritis, educate all caregivers to clean hands with soap and water until an organism is identified. Waterless alcohol-based products for hand hygiene do not kill the spores of *C. difficile*.

Probiotic use has been extensively studied for acute diarrhea. Recommendations to use probiotics are gaining much attention because of their safety and minimal side effects. Some practitioners recommend using probiotics in the treatment of rotavirus. Studies, in general, have limitations in the methodology; thus, more controlled studies are needed to validate this practice. Nonetheless, the use of probiotics may play a treatment role in some cases and has been shown to decrease the duration of acute diarrhea (Kligler et al., 2007).

Diarrheal stools are irritating to the perianal area. Instruct the older child to wipe gently but thoroughly. If the area is excoriated, use moist, soft towelettes. If not toilet trained, change children's diapers as soon as possible after stooling. Wash with a moist, soft cloth and apply a thick layer of petroleum jelly, zinc oxide ointment, or other skin barrier product.

Community Care

Poultry is often positive for *Campylobacter* and *Salmonella*; therefore, teach parents and others to wash their hands and cooking implements thoroughly after handling poultry. Often, daycare centers are sources of outbreaks for

Campylobacter, *Salmonella*, *Shigella*, and rotaviral gastroenteritis. Again, teach effective hand hygiene, especially after diapering an infant, and proper disposal of diapers in occlusive bags prior to disposing outside the home. Emphasize separating food preparation areas and diaper-changing areas. Serve as a liaison between the daycare center and the parents by providing accurate information. Advise parents to keep infants not yet toilet trained out of the daycare center until diarrhea stops.

Report food-borne outbreaks of gastroenteritis to the local health department for tracing and prevention of further cases of food poisoning.

Currently there are two rotavirus vaccines available (Rotrix and RotaTeq), administered as oral preparations with schedules set forth by the Centers for Disease Control. There is much hope that these vaccines will reduce the burden of rotavirus disease in children in the United States. There is also great promise, as the details of availability to areas outside the United States are processed, for advancement of greater global healthcare issues to reduce the number of deaths from gastroenteritis.

Appendicitis

QUESTION: How typical is Cory's experience with appendicitis?

Appendicitis is an obstruction of the vermiform appendiceal lumen at the end of the cecum. It is the most common condition, with approximately 4 appendectomies per 1,000 children performed annually (Goldin et al., 2007). It is most common in children between age 6 and 14 years, with peak incidence at age 9 to 11 years. Appendicitis is rare in children younger than age 2 years. Diagnosis of acute appendicitis in children younger than 7 years may be difficult, because they may not have the typical presentation. In general, children may deviate from the classic presentation and may be more challenging to diagnose (Morrow & Newman, 2007).

The prognosis for appendicitis is good with early recognition and surgical intervention. Perforation is most common in children. Perforation rates vary, with 36% reported as a median frequency (Morrow & Newman, 2007). Perforation leads to potential complications such as wound infection, intra-abdominal abscess, and peritonitis, in addition to increased length of stay and costs. Mortality from appendicitis is rare.

Pathophysiology

Appendicitis begins with obstruction of the lumen of the appendix by a fecalith (a concrete mass of fecal material) or by lymphocytic hyperplasia. With obstruction, the flow of normal mucosal secretions is inhibited, resulting in increased intraluminal pressure and compromised venous drainage. Ischemic breakdown with simultaneous bacteria of the lumen wall occurs. These events lead to appendicitis, which may become complicated by gangrene and perforation.

Assessment

The health history and physical assessment provide valuable information in the diagnosis of appendicitis and often are the only diagnostic tools needed. Focus the history on determining the time of onset and location of the pain. The parent or child may describe the pain as initially being periumbilical, then migrating to the lower right quadrant. Younger children may describe the pain as more generalized, whereas older children are better able to localize the pain. The pain is initially crampy as the appendix distends against obstruction, but it becomes more constant as inflammation increases and the appendix distends further. Also elicit any recent history of nausea, anorexia, vomiting, and fever. In appendicitis, low-grade fever, nausea, anorexia, and vomiting typically occur after the onset of abdominal pain. Diarrhea may be present in very young children.

Alert! With perforation of the appendix, abdominal pain is suddenly relieved; however, it returns (along with signs of a generalized acute abdomen) as peritonitis develops. Therefore, sudden cessation of appendicitis pain is an ominous sign.

During the physical examination, observe whether the child guards the area of pain or winces with movement, such as walking or climbing onto the examination table or hospital bed. The abdomen appears flat with imperforated appendicitis; abdominal distention may be present after perforation occurs. The child with imperforated appendicitis may have only mild temperature elevation. After perforation, the temperature may rise to 101 to 104 °F (38.3–40 °C), and the child may appear dehydrated. Signs of shock may be present if peritonitis is advanced.

On auscultation, bowel sounds are normal to hyperactive early during the course of appendicitis, but become hypoactive with perforation. Percussion reveals irritation and pain in the right lower quadrant. Rebound tenderness is present with palpation in the right lower quadrant, referred to as *McBurney's point* (point of tenderness, one-third of the distance from the right anterior superior iliac spine along a line extending to the umbilicus).

caREminder

Palpate the right lower quadrant last during the physical assessment of the child with suspected appendicitis. Doing so enables you to assess the child's response more accurately in comparison with the response in quadrants that should be free of pain.

Diagnostic Tests

A CBC and urinalysis are obtained as a part of the workup of the child with suspected appendicitis. Although laboratory tests may not be helpful in establishing a definitive diagnosis of appendicitis, they are important tools

in ruling out other potential causes of illness. White blood cell counts are elevated in 80% of patients with acute appendicitis. These counts may be normal early during the course of the disease, but increase as inflammation progresses. Therefore, a second CBC is often done for comparison. Urinalysis may reveal a small number of white blood cells in the urine as a result of urethral irritation from the proximity of the urethra to the inflamed appendix.

Ultrasound is also used as a first-line imaging tool. Some reports state it is less sensitive and more operator dependent, and thus not as helpful as a diagnostic tool. Some institutions have adopted the practice to use ultrasound first, to reduce the child's exposure to ionizing radiation and to determine whether additional imaging is necessary when a confident diagnosis cannot be made (Schwartz, 2008).

Radiographic evaluation is not a standard part of the workup of the child with suspected appendicitis, but may be useful if the diagnosis is uncertain. When a plain radiograph of the abdomen is obtained, it is not diagnostic. Imaging studies assist the surgeon in making an accurate diagnosis when the clinical findings are inconsistent. CT scanning is often used because of its high sensitivity. It provides a complete assessment of the imaged region, defining a perforated appendix or, with a complicated appendectomy, identifies abscess formation. However, there is growing concern over the widespread use of CT scanning and the radiation risk it poses to children.

Interdisciplinary Interventions

Surgical appendectomy through a right lower quadrant transverse incision is the definitive treatment for appendicitis. In some centers, laparoscopic appendectomy may be a treatment option for the child with uncomplicated, imperforated appendicitis. For those children in whom the diagnosis is in doubt, such as adolescent females, or for obese children, a laparoscopic approach may be advantageous. This approach avoids a larger incision than may be needed with the traditional open approach. The laparoscopic approach enables intraperitoneal exploration and a wider visual field. All children with suspected appendicitis receive preoperative IV antibiotics. Postoperative administration of antibiotics after an uncomplicated appendectomy for appendicitis without perforation is thought to reduce the incidence of wound infection. The hospital stay may be 1 to 2 days.

Management includes comfort measures, pain control, and IV hydration until an oral diet is tolerated. Discharge criteria include a normalized white blood count, afebrile status, tolerance of oral diet, and adequate pain control with oral medicines (Morrow & Newman, 2007) (see [thePoint](#) for Care Path: An Interdisciplinary Plan of Care for the Child With Nonperforated Appendicitis). Traditionally, pain management for simple imperforated appendicitis included acetaminophen with codeine. About 10% of children are now known to lack the receptors for converting codeine into a bioavailable form (see Chapter 10). When poor relief is obtained from this medication, other analgesics are recommended.

In the event of complicated appendicitis by perforation, intraoperative debridement of necrotic material and lavage of the peritoneal cavity are performed. The optimal antibiotic treatment has not been determined. The use of narrow-spectrum antibiotics that achieve adequate coverage for the most common organisms and reduce the incidence of antibiotic resistance has traditionally been used, such as aminoglycoside-based triple-antibiotic therapy. There is a growing trend toward broad-spectrum monotherapy (piperacillin/tazobactam or ceftiofloxacin) with at least equal efficacy to the traditional method and may offer benefits of decreases in length of hospital stay and hospital costs (Goldin et al., 2007).

Intestinal ileus may persist for 3 to 5 days after surgery, making it necessary for the child to remain NPO and receive NG decompression and IV fluids until oral intake can be resumed. In some cases, the child may be discharged early and may complete the IV antibiotics at home.

When children present with a perforated appendix that has become a localized abscess with right lower quadrant peritoneal irritation, an interval appendectomy may be considered in a select group of patients (Morrow & Newman, 2007). These children are treated with IV antibiotics following CT-guided drainage of the abscess. The appendectomy is scheduled for several weeks after this treatment.

Complications of appendicitis occur more frequently after appendectomy for a perforated appendix. The most common complication is a wound infection and abscess. When this complication occurs, opening the wound to achieve healing by secondary intention is the treatment. Wound cultures and antibiotics may be ordered. A wound abscess may be drained under CT guidance.

Preoperative management of the child with appendicitis requires careful and ongoing assessment of the child's vital signs, pain, and hydration status. Promptly report changes in vital signs, and any changes in the character of the child's pain that are consistent with the onset of perforation and peritonitis, to the medical team. Traditionally, pain medication has been held until the diagnosis is firmly established to avoid masking symptoms.

More recently, studies have reported that administration of analgesics to children able to report pain levels did not seem to interfere with identifying a diagnosis of appendicitis (Green et al., 2005). Other reports indicate that the physical examination may be altered with administration of analgesics, but does not result in an increase of incorrect management decisions (Ranji et al., 2006). More randomized, controlled studies are needed to support a practice change and to address comfort in this population.

Allow the child to assume the position that permits greatest comfort; incorporate relaxation techniques. The child will be NPO and will have an IV for antibiotics and fluids. Teach the child about patient-controlled analgesia, if it may be used postoperatively (see Chapter 10).

Both child and parents may be fearful and anxious about the child's pain, multiple procedures, examinations, and the impending surgery. Offering clear, developmentally appropriate explanations of all interventions, and

providing emotional support to the child and family may help alleviate their fear and anxiety (Fig. 18–18; see Chapter 11).

After surgery, the child requires routine postoperative care and comfort measures. Monitor the child who has been treated for a perforated appendix for signs of wound infection. Routinely assess for return of bowel function and respiratory complications such as atelectasis or pneumonia. Provide interventions to maintain the proper function of the NG tube, and administer and monitor IV fluids and antibiotics. A drain may be placed to promote excretion of infected peritoneal fluid.

Reinforce preoperative instruction with the child and parents on the use of patient-controlled analgesia and the incentive spirometer. Analgesia is administered before use of the incentive spirometer or ambulation to progress the child toward recovery with maximum cooperation from the child.

Community Care

Parents of a child who is eligible for early discharge require instruction regarding wound care and administration of IV antibiotics. Request a referral for home health nursing and home pharmacy services to support the family in the home transition. Instruct the parents to contact the surgeon if signs of infection, fever, anorexia, abdominal pain, vomiting, or diarrhea occur. Clarify the child's permitted activity level with the surgeon. Often children can return to school in a week and resume normal activities, such as participating in physical education, within 4 weeks.

ANSWER: Much of Cory's experience with appendicitis is typical; however, Cory is younger than most children who have appendicitis. Remember the peak ages are 9 to 11 years of age. Cory's inflammation also progressed until the appendix ruptured, which occurs in only 35% of cases.

Inflammatory Bowel Disease (IBD)

IBD is actually a group of diseases characterized by inflammation of the GI tract. Crohn's disease and ulcerative colitis are the most common forms of IBD and account for more than 80% of all cases. Ulcerative colitis results in an inflammation of the mucosal layer of the large intestine and rectum. Inflammatory disease associated with Crohn's disease can occur in any part of the GI tract, from the mouth to the anus, and is transmural. More recently, the classification of indeterminate colitis has been used to describe those children who have ambiguous characteristics and cannot be accurately designated as having Crohn's disease or ulcerative colitis (Gramlich & Petras, 2007).

The precise incidence and prevalence of IBD in the United States is unknown; however, recent reports indicate the frequency is increasing in both pediatric and adult populations. It is now estimated that more than

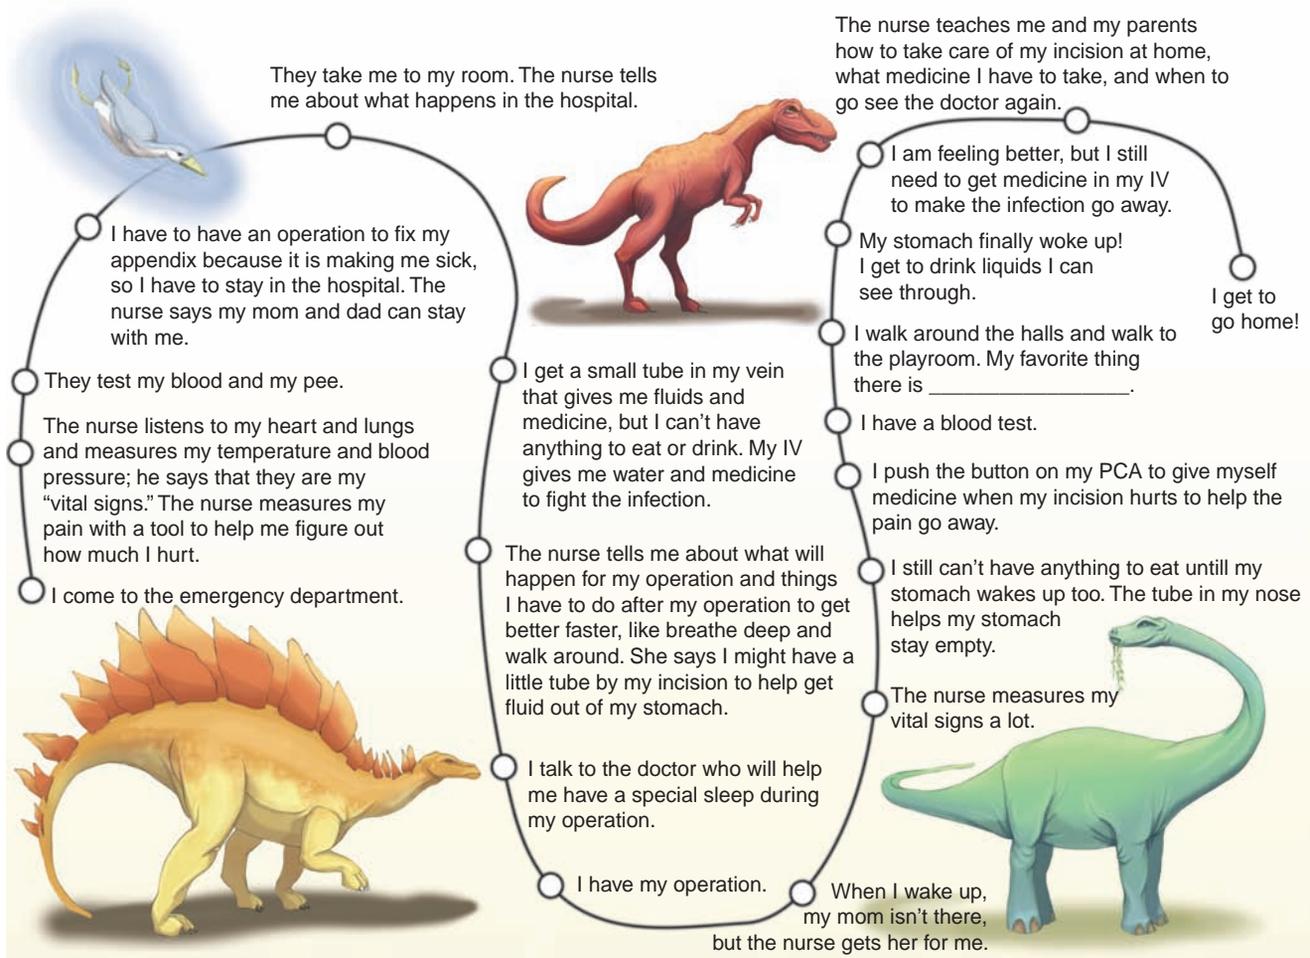

FIGURE 18–18. A care path for a child with perforated appendix.

1 million people are affected by IBD in the United States, with 10% to 25% in the pediatric age range (Carvalho & Hyams, 2007; Rufo and Bousvaros, 2007). The most important risk factor for developing IBD is a positive family history. IBD will develop in 10% of individuals with a first- or second-degree relative who has IBD (Hanauer, 2006). Genetic, immunologic, and environmental factors have been cited in the etiology of IBD. Although the precise interaction between these factors is not well understood, individuals with IBD are thought to have a genetic predisposition to an immunologically mediated inflammatory response to certain environmental triggers.

WORLDVIEW: Increased incidence and prevalence has been documented worldwide. One explanation is the "hygiene hypothesis," which advances a fundamental lifestyle change has resulted in a low microbial exposure from a formerly high microbial exposure. Exposure to fewer microbial antigens during early years leads to a less robust immune system. This ultimately results in the body's inability to mount a strong immunologic response to potential exogenous challenges to offending agents in later years, and thus may consequently lead to chronic inflammation (Kugathasan & Fiocchi, 2007).

The prognosis for all forms of IBD depends on the type, severity, and extent of disease, and the response to medical therapy. Surgery is ultimately curative for ulcerative colitis. Over the long term, however, individuals affected with ulcerative colitis have demonstrated a higher than normal risk of developing colorectal cancer and require ongoing monitoring. Crohn's disease is a recurrent disease. Long-term complications may include stricture, fistula, and intra-abdominal abscess formation. Individuals with severe disease who require extensive resection of diseased bowel may be left with short bowel syndrome and long-term dependence on PN.

Pathophysiology

The exact pathophysiology of IBD is not known, but it is believed to involve defective regulation of the intestine's immune-mediated response to an environmental trigger, resulting in varying degrees of injury to the inner lumen of the GI tract. The patterns of injury vary by disease, both grossly and histopathologically (Table 18–6). The inflammation associated with ulcerative colitis is confined to the rectum and large intestine. The inflammatory lesions are continuous and involve only the mucosal layer. The inflammation associated with Crohn's disease

TABLE 18-6
Characteristics of Inflammatory Bowel Disease

Characteristic	Ulcerative Colitis	Crohn's Disease
<i>Gross Morphologic</i>		
Areas of involvement	Rectum and variable length of colon	Any area of GI tract, terminal ileum, and colon are common sites
Distribution of lesions	Continuous, uniform	Intermittent, "skip" lesions with healthy tissue between areas of inflammation
Fistulas, strictures	Absent	May occur
<i>Histologic</i>		
Ulcerations	Shallow; limited to mucosal, sub-mucosal layers	Transmural, penetrating all layers of GI tract
Granulomas	Absent	Present in more than 50% of histologic specimens

may occur in any part of the GI tract, but commonly involves the terminal ileum and colon. Lesions are intermittent and transmural, with areas of healthy tissue between areas of inflammation. Linear ulcerations, aphthous ulcers, and granulomatous lesions are all associated with Crohn's disease.

Assessment

Clinical manifestations of IBD can be seen not only in the GI tract but systemically as well. The characteristic GI manifestation of ulcerative colitis is bloody diarrhea accompanied by crampy, typically left-sided lower abdominal pain. Disease severity is assessed based on stool frequency and the severity of abdominal pain, along with the degree of fever, weight loss, anemia, and hypoalbuminemia. The diarrhea associated with Crohn's disease is often watery, as opposed to bloody. Abdominal pain is a common complaint and is usually located in the right lower quadrant. Perianal disease with fistula, skin tags, or granulomas is often present.

Systemic symptoms such as delayed growth and anorexia may precede GI symptoms by months to years in many cases of IBD. Delayed growth and weight loss in IBD arise from decreased nutrient intake secondary to anorexia; early satiety; malabsorption of nutrients; and deficiencies of vitamins, minerals, and trace elements. Extraintestinal manifestations include arthritis, arthralgias, oral ulcerations, dermatologic changes (erythema nodosum), ophthalmologic changes, and osteopenia.

Diagnostic Tests

Diagnostic evaluation of the child with suspected IBD is done to rule out other potential causes of disease and to classify the type of IBD the child has. Laboratory studies are used as an initial screening measure. The CBC of the child with IBD frequently demonstrates leukocytosis and

microcytic anemia. The erythrocyte sedimentation rate is elevated in active Crohn's disease; this finding is less common in ulcerative colitis. Low serum albumin and iron levels are common, as are other nutritional markers that indicate malabsorption and malnutrition from GI losses and inflammation, such as total protein, total albumin, and fat-soluble vitamin levels. Stool samples are obtained to look for gross or occult blood and to rule out the presence of enteric pathogens and fecal markers (proteins released from activated neutrophils in the bowel mucosa) for inflammation. Baseline liver enzyme levels are obtained to monitor for potential side effects of pharmacologic management.

Other serologic tests may include an assay for C-reactive protein, which is an inflammatory marker. Positive results on antibody tests using perinuclear antineutrophil cytoplasmic antibodies and anti-*Saccharomyces cerevisiae* antibodies immunoglobulin G (IgG) and IgA have been found to be highly associated with ulcerative colitis and Crohn's disease, respectively. When these test results are positive, further studies are indicated. In cases difficult to diagnose, these studies may help to differentiate between ulcerative colitis and Crohn's disease (Carvalho & Hyams, 2007).

Radiographic studies are done to visualize the pattern and extent of lesions and to screen for strictures or fistulas. An abdominal plain film radiograph, barium enema, and upper GI series with small bowel follow-through are usually done. Endoscopy and intestinal biopsy, which are the gold standard, are done to establish and differentiate the diagnosis of IBD with histologic confirmation. Subsequent endoscopic evaluation may be done during the course of treatment to assess the child's response to therapy.

Ultrasound and magnetic resonance imaging may be used to document complications such as abscess formation and bowel wall thickening.

Nursing Diagnoses and Outcomes

In addition to those listed in the Nursing Plan of Care 18–1, the following nursing diagnoses and outcomes may apply to the child with IBD:

Risk for impaired skin integrity related to effects of diarrhea

Outcomes: Child will be free from perineal erythema or excoriation.

Child's skin will remain intact.

Disturbed body image related to perceptions of disease and effects of therapy, restricted diet, effects of medications, retarded growth, and delayed sexual maturation

Outcome: Child will verbalize a positive self-image.

Ineffective coping related to chronicity of the condition

Outcomes: Child will verbalize feelings and identify own strengths.

Child will develop alternative, positive coping strategies.

Child will identify and use external resources, such as peer support, group participation, one-on-one support, camp for teens with special needs or IBD, or counseling with a mental health practitioner.

Interdisciplinary Interventions

Interventions for managing IBD involve a variety of treatment methods, including medical, nutritional, and surgical therapies. IBD is a chronic condition with symptoms that are frequently distressing and may alter the child's usual activities of daily living. Ongoing psychosocial assessment and support, as well as sensitivity to the stresses that the disease and its treatment place on the child and family, are essential.

Medical therapy for IBD uses various agents. Treatment regimens are individualized depending on the type, location, and severity of the disease, and the presence of extraintestinal or systemic manifestations. Patient and family education, and monitoring for response to therapy and side effects are important nursing activities.

Pharmacologic Therapy

Corticosteroids are the pharmacologic mainstay of medical therapy in treating both Crohn's disease and acute moderate to severe ulcerative colitis. Although their specific mechanism of action in IBD is not precisely understood, the manner in which they modulate cell-mediated immunity produces an anti-inflammatory effect that can induce remission of IBD symptoms. These medications are not optimal for long-term therapy, because they fail to prevent relapse and they cause adverse side effects. Thus, other medications are used with corticosteroids, with the goal of weaning the patient off the corticosteroids as soon as possible. Corticosteroids are administered as oral prednisone or prednisolone, or as IV methylprednisolone. In severe disease, in which malabsorption may be present, corticosteroids are initiated in the IV form and then transitioned to the oral form when

enteric absorption becomes more reliable. These agents are administered at high doses initially, followed by a slow-tapered schedule until a maintenance dose is achieved. Continual tapering of steroids is a goal. These medications are adjusted according to the child's response to therapy. Children require ongoing monitoring for side effects while receiving corticosteroid therapy. Acute side effects during high-dose therapy include glucose instability, hypertension, fluid and sodium retention, and mood swings. Long-term side effects of special concern in children include growth impairment and bone demineralization. The cushingoid changes associated with corticosteroid use (moon facies, hirsutism, acne) may create body image concerns for the adolescent that can affect adherence to drug therapy.

KidKare ■ Educating adolescents about the management of oral medications (e.g., steroids) and not to quit "cold turkey" or abruptly stop these medicines is vital for this developmental age, which is characterized by "omnipotence" as a central theme in psychosocial development.

Sulfasalazine and other aminosalicilate-containing medications, such as 5-aminosalicylic acid (5-ASA), are used to treat mild to moderate ulcerative colitis and colonic disease in Crohn's disease. 5-ASA is the active agent in sulfasalazine and is primarily activated in the colon. 5-ASA inhibits prostaglandin synthesis in the colon, leading to a localized anti-inflammatory effect. 5-ASA-containing products are available in oral, enema, or suppository forms.

Metronidazole, an antibiotic with both antibacterial and antiprotozoal properties, has been used in to treat IBD. Its primary benefit is in treating Crohn's disease when perianal complications are present. Ciprofloxacin has also been used to reduce the microbial intestinal flora associated with inflammation.

Immunosuppressive and immunomodulating agents are used to treat severe corticosteroid-resistant Crohn's disease. These drugs are also used with low-dose corticosteroids to induce and maintain remission in both Crohn's disease and ulcerative colitis. Azathioprine and 6-mercaptopurine are commonly used for their steroid-sparing properties to reduce inflammation and maintain remission. Therapy must be administered for at least 3 months before efficacy can be established. Close monitoring for side effects, including suppressed bone marrow function, pancreatitis, and hepatitis, is necessary.

Methotrexate can be administered weekly by intramuscular or subcutaneous injection in patients who have not responded to other first-line therapies. Side effects include nausea, stomatitis, diarrhea, and pulmonary interstitial pneumonitis, although this last effect is rare.

Biologic agents may be used in immune-mediated inflammatory disorders that are characterized by immune dysregulation resulting in acute or chronic inflammation, organ damage, and increased morbidity and mortality. Inappropriate activation of inflammatory cytokines, such

as interleukin 12 (IL-12), IL-6, or tumor necrosis factor alpha (TNF- α), comprises a shared manifestation of these disorders (Vizcarra & Belcher, 2006). The monoclonal antibody infliximab (Remicade), a TNF antagonist, is the first antibody approved for treating Crohn's disease. It works by blocking the body's production of TNF- α , a form of TNF present in increased amounts in the intestinal lining of people with Crohn's disease, which intensifies inflammation. Infliximab reduces inflammation and helps the tissue to heal, as evidenced by endoscopic and histologic evaluation. It thereby induces and maintains remission. This agent is a breakthrough therapy, because other agents have achieved improvement that can be seen with endoscopic evaluation, but not healing at the cell level. This medication is administered intravenously and repeated at scheduled intervals. Monitoring is required for acute infusion reactions, such as flushing, chills, chest pain, shortness of breath, and pruritus. Most infusion reactions are managed with antihistamines or corticosteroids and by slowing the infusion rate (Carvalho & Hyams, 2007).

Other biologic agents are becoming available to treat those patients who have either lost response or are intolerant to infliximab. There has been an association of these agents with lymphoproliferative disease, necessitating close monitoring and further investigation.

Nutritional Interventions

The goal of nutritional intervention is to provide adequate nutrient intake to optimize normal growth and development, including pubertal development (which is frequently delayed), and to prevent and correct nutrient deficiencies. Dietary management focuses on enhancing protein and calorie intake. Generally, a high-protein, high-calorie diet is recommended. During an exacerbation, the child may require dietary restrictions, such as a lactose-free or low-fiber, low-residue diet to facilitate intestinal recovery. Many patients will self-restrict their diets as a result of nausea, abdominal pain, vomiting, and anorexia, creating more vulnerability to growth failure and poor nutrition.

Patients with IBD, especially those with Crohn's disease, are at risk for fat-soluble vitamin deficiency from malabsorption caused by bile salt deficiency and inadequate intake. Iron deficiency anemia is common from blood loss or impaired use of iron. Steroid use may increase urinary excretion of minerals. Recent attention focused on bone mineralization and bone density has revealed that the incidence of osteopenia is high (Jose et al., 2009). Monitor oral intake and assess for deficiencies. Routine supplementation includes a daily multivitamin and calcium. Vitamins D and B₁₂, plus folate, zinc, and iron, should be given as necessary along with fat-soluble vitamins in their water-soluble forms. The use and application of omega-3 fatty acids in the treatment of Crohn's disease has been studied for its anti-inflammatory role. Results indicate that it is safe to administer and may play a role in maintenance of remission when enteric-coated capsules are used (Turner et al., 2007). These conclusions were from small study populations and further studies are indicated.

Modulen IBD (by Nestle) is the only specialized nutrition product for IBD. The acid casein protein source contains transforming growth factor, a polypeptide naturally found in human and cow's milk (Hattner, 2004). It has been shown to enhance epithelial cell growth and promote healing. It can be used as a nutritional supplement or a sole source of nutrition. Enteral supplementation through an NG or gastrostomy tube may be used in cases of growth failure or to support calorie requirements during the adolescent growth spurt. An elemental or semielemental formula is commonly used, because it is most easily absorbed. PN may be used for children who require bowel rest, to alleviate acute symptoms of disease. Evidence suggests that enteral nutritional supplementation using elemental or polymeric (Modulen) formulas may be effective for maintenance of remission in Crohn's disease, as an alternative or adjunctive therapy (Akobeng & Thomas, 2007). Additional literature suggests that enteral therapy with a polymeric formula can be used as a primary therapy for Crohn's diseases with select candidates (Wisikin, Wootton, & Beattie, 2007). Larger randomized, controlled studies are needed to validate this approach. For children with Crohn's disease who require prolonged bowel rest for the treatment of fistulas or who have lost substantial amounts of intestine because of resection, long-term PN in the home may be necessary (see Chapter 17).

Surgical Interventions

Indications for surgical intervention in IBD vary depending on the type of disease present. For the child with ulcerative colitis, surgery is indicated in the presence of the following conditions: colonic perforation or hemorrhage, toxic megacolon, and growth failure from corticosteroids. Removing the diseased colon cures ulcerative colitis. In the past, colectomy with a standard ileostomy was the traditional operative approach. During the past 15 years, the ileo pouch anal anastomosis has become more common. With this approach, after colectomy, an internal pouch is constructed from the distal ileum and is anastomosed to the anus (Fig. 18–19). Complications of this procedure include pouch stenosis, which results in the obstruction of the outflow of stool from the pouch, and pouchitis, an inflammation of the pouch, resulting from stool stasis. Various therapies are used for treatment, including antibiotics, probiotics, and topical agents. Although 90% of children achieve acceptable stool continence and frequency after the surgery, a small number may experience soiling or nighttime fecal staining.

Surgical intervention does not cure Crohn's disease, because Crohn's disease is a recurrent disease. Surgical intervention thus is reserved to treat complications of Crohn's disease. As with ulcerative colitis, emergency surgical intervention is necessary in the case of bowel perforation or hemorrhage. Intestinal obstruction from chronic inflammation and fibrosis may be treated with bowel resection and primary anastomosis. Strictureplasty may be used in cases of partial obstruction. Surgical intervention may be indicated to treat a fistula or abscess that does not respond to medical therapy. If colectomy is

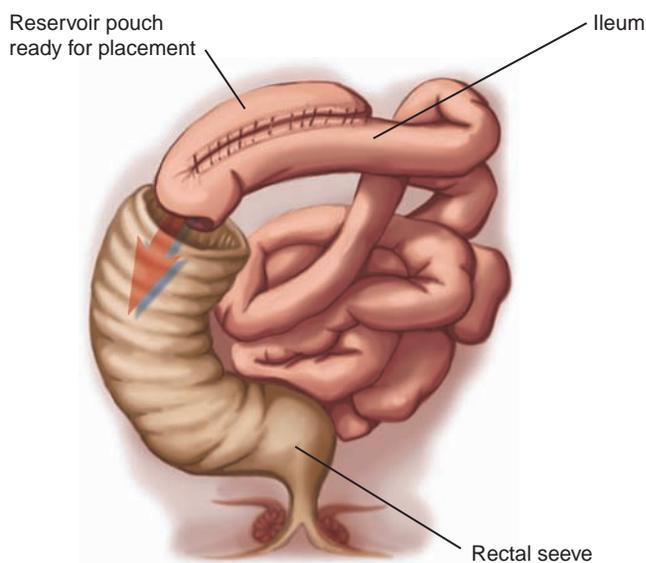

FIGURE 18–19. Ileoanal anastomosis with a pouch reservoir is commonly used for ulcerative colitis.

required for intractable disease, a standard ileostomy is performed. The ileoanal pull-through is contraindicated for individuals with Crohn's disease because of the risk of recurrent disease.

Community Care

The symptoms of IBD, as well as the side effects of therapy, may affect the daily life of the child and adolescent considerably. Shame and secrecy regarding GI symptoms, body image concerns, anxiety, and depression may all occur in the child with IBD. Supportive relationships with family, peers, and healthcare workers may be very therapeutic. Provide ongoing education and encourage open discussion of concerns relating to symptoms, treatments, and side effects. Referral to community support organizations for target psychosocial interventions, such as specialized camps (Shepanski et al., 2005), has been shown to reduce overall psychosocial morbidity. Coordination with the school nurse for restroom privileges, as needed, and to use the school clinic bathroom for privacy and preservation of self-esteem is helpful.

Pancreatitis

Pancreatitis in children is characterized by inflammation of the pancreas that causes clinical signs of acute abdominal pain and vomiting, and is accompanied by elevated pancreatic enzymes. It is categorized as acute, chronic, severe acute, and hereditary. These types are classified by their clinical and diagnostic findings. Although the causes are numerous, the clinical pattern in all types is similar. The intensity of the disease, and its complications, may vary depending on the etiology.

The prevalence of acute pancreatitis is reportedly increasing, but the reason for this increase is unclear. In children, acute pancreatitis is caused by numerous fac-

tors. Major causes include systemic disease, drugs, and trauma. Gallstones, structural and congenital abnormalities, and heredity are all possible etiologies. Acute pancreatitis that is associated with systemic disease occurs in approximately 20% of cases. Multisystem diseases such as pulmonary disease and hemolytic uremic syndrome are most commonly associated with acute pancreatitis in children younger than 3 years of age (Kandula & Lowe, 2008).

Idiopathic acute pancreatitis occurs in approximately 25% of cases (Kandula & Lowe, 2008). Causes may include

- Infections from bacteria (occasionally) or viral agents, such as Coxsackie B, Epstein-Barr virus, cytomegalovirus, and influenza (more common); helminth infections (in less developed countries)
- Medications, most commonly valproic acid (Werlin & Fish, 2006)
- Trauma, such as blunt trauma from an automobile or bicycle accident (from handlebars); suspicion of child abuse if findings of blunt trauma are inconsistent with the history
- Gallstones and structural abnormalities, such as an abnormal common bile duct

Chronic pancreatitis can originate from a hereditary form, be idiopathic in nature, or be associated with cystic fibrosis, more commonly in individuals who are pancreatic sufficient.

Most children with uncomplicated pancreatitis do well with supportive care. Chronic pancreatitis can begin acutely, then develops complications that progress to end-stage pancreatitis as a result of recurrent and chronic inflammation. Septic complications may contribute to an unfavorable outcome; severe sepsis can result in multiorgan failure and death.

Pathophysiology

Pancreatitis is an inflammatory process brought on by premature activation of pancreatic enzymes that causes destruction of ductal structures and pancreatic cells. This process results in fibrosis and autodigestion. Acute pancreatitis (most common) is usually self-limited. Recurrent acute pancreatitis can occur with normal pancreatic function in between cycles of inflammation. This type of acute pancreatitis is most commonly seen in children with underlying structural alterations and in those with familial or idiopathic pancreatitis. Pseudocysts or abscesses can develop, although these complications are infrequent.

Assessment

The child admitted with the suspicion of pancreatitis typically has a complaint of abdominal pain, either epigastric, upper left, or upper right quadrant pain (or some combination) that may radiate to the back. In the younger child, abdominal pain may not be as evident, but rather may be manifested as irritability (Kandula & Lowe, 2008). Nausea and vomiting are common,

particularly with ingestion of food. A history of anorexia is common. Fever, tachycardia, hypotension, and jaundice may be present. Abdominal signs, such as abdominal distention, decreased bowel sounds, rebound tenderness, and guarding also may be noted.

Diagnostic Tests

Routine laboratory tests are done, including a CBC and blood chemistry panel. An elevated white blood cell count may be seen, and serum amylase and lipase levels are usually more than three times the normal value. Both amylase and lipase levels are monitored frequently for trending patterns throughout the course of the illness but do not correlate with the severity of illness (Kim et al., 2008). Total bilirubin, alkaline phosphatase, and blood glucose are also elevated. CT and abdominal ultrasound are done to confirm diagnosis, determine severity, and identify complications. These studies assist in identifying a pancreas enlarged by inflammation, dilated pancreatic ducts, cysts in the common bile and intrahepatic bile ducts, or abscess formation. Endoscopic retrograde cholangiopancreatography and magnetic resonance cholangiopancreatography are done more frequently in children today than in the past to evaluate the biliary and pancreatic ducts. Endoscopic retrograde cholangiopancreatography is used for both diagnosis and therapeutic interventions, such as a biliary sphincterotomy, dilation of a stricture, stone removal, stent placement, or drainage of pseudocysts. Magnetic resonance cholangiopancreatography is useful for identifying structural abnormalities such as stenotic or dilated ducts, or cholelithiasis. It offers the promise for even more frequent use in pediatrics, because it is less invasive.

Nursing Diagnoses and Outcomes

Nursing diagnoses and outcomes for the child with a GI alteration are identified in Nursing Plan of Care 18–1. Pain management is a major issue for the child with pancreatitis, because the inflamed pancreas causes severe pain. The following nursing diagnoses thus may also apply to the child with pancreatitis:

Ineffective breathing pattern related to splinting (guarding) because of severe pain

Outcome: Child will demonstrate a breathing pattern that maintains oxygenation within the child's normal range.

Dysfunctional GI motility related to irritation of the GI system leading to nausea

Outcomes: Child and family will discuss and use methods to decrease nausea.

The child will report relief of nausea.

Interdisciplinary Interventions

The main interventions for pancreatitis are supportive, including administration of antibiotics, stress ulcer prophylaxis, pain relief by analgesic administration, fluid management, glycemic control, promotion of pancreatic rest during the acute phase until the child is stabilized (pancreatic enzyme levels are not increasing and pain is

controlled), and monitoring for complications. Keep the child NPO to rest the pancreas. When severe emesis is present, an NG tube may be placed to decompress the stomach to prevent gastric distention. When the child is stabilized, nasojejunal feeding is started. This type of feeding is associated with improved immune function in adult studies (Marik, 2009) and, subsequently, is used in the treatment of children. PN via a central venous catheter (e.g., peripherally inserted central catheter) may be administered to support nutrition through recovery. Feedings are advanced slowly. A low-fat diet is used when nausea, abdominal pain, and decreased levels of amylase and lipase occur.

Patient positioning may play a role in nonpharmacologic comfort measures. Remind the patient to try a fetal position to minimize stretching or tension of the peritoneum. Pseudocysts and abscesses, if present, may require surgical drainage and antibiotic therapy.

Chronic pancreatitis treatment is also supportive, but may evolve into a debilitating condition. Ongoing need for analgesics, loss of school attendance, and depression may be experienced as a result of the chronic nature of the condition.

Community Care

Educate the child and parents about managing a low-fat diet, and ways of incorporating the diet into the child's lifestyle when the child returns to school and in other social circumstances.

DISORDERS OF GASTROINTESTINAL MOTILITY AND FUNCTION

Disorders of GI motility and function involve a diverse group that includes functional abdominal pain and irritable bowel syndrome (types of chronic abdominal pain), colic, GERD, constipation, and encopresis.

QUESTION: Identify ways in which disorders of GI motility and function are different from the acute illness Cory experienced. What is the role of the nurse when children are cared for at home?

Functional Abdominal Pain and Irritable Bowel Syndrome (IBS)

Numerous definitions exist in the literature that describe chronic abdominal pain using terms such as *recurrent abdominal pain*; and *chronic, functional, nonorganic, and psychogenic abdominal pain*. Efforts have focused not only on defining and clarifying terminology for the clinician, but also on developing guidelines for evaluating and treating the spectrum of conditions based on extensive literature review, consensus of the expertise of the committee members and evidence-based practice when available.

Chronic abdominal pain, formerly called *recurrent abdominal pain*, is one of the most common complaints of

school-aged and adolescent children. In 1999, symptom-based criteria, known as the Rome II criteria were developed to define functional bowel disorders associated with abdominal pain. Revisions were published again in 2006, known as *Pediatric Rome III Criteria for Functional GI Disorders* (Rasquin et al., 2006). These criteria address the following disorders (Di Lorenzo et al., 2005; McOmber & Shulman, 2008):

1. Abdominal pain related functional GI disorders, including irritable bowel syndrome, functional dyspepsia, abdominal migraine, and functional abdominal pain
2. Cyclic vomiting syndrome, aerophagia, and rumination
3. Functional constipation and nonretentive fecal incontinence

The term *functional* is used to differentiate GI symptoms of a chronic or recurrent nature that cannot be explained by structural or biochemical studies (Rasquin et al., 2006).

This discussion is limited to functional abdominal pain and irritable bowel syndrome. Functional abdominal pain is defined as weekly occurrences of intermittent or continuous abdominal pain for at least 8 weeks. Functional pain syndrome includes the previous definition with the addition of pain occurring 25% of the time and either some loss of daily function or additional somatic complaints such as headache, extremity pain, or sleep problems. Irritable bowel syndrome is defined as at least weekly abdominal discomfort or pain for 8 weeks. At least two of the following three conditions must be present at least 25% of the time:

1. Abdominal pain or discomfort improved with defecation
2. Abdominal pain or discomfort associated with a change in the frequency of stool
3. Abdominal pain or discomfort associated with a change in form (appearance) of stool
4. In addition, no indication of an inflammatory, metabolic, structural, or neoplastic condition that may explain the patient's symptoms

Functional abdominal pain is most prevalent in children 8 to 15 years of age (Scholl & Allen, 2007) and irritable bowel syndrome is reported in about 10% to 15% of children. In adult studies, IBS is more prevalent in women, but no such pattern has been found in pediatric studies. Although the etiology is not as clearly defined as conditions having an organic etiology, one must keep in mind that the pain is not imaginary. The child's experience of pain is *real*.

Pathophysiology

Complex factors influence GI function, including inflammation, positive family history of GI conditions, allergy, and psychoemotional states that can result in altered sensory experiences arising from these stimuli on the gut. The current understanding of pathophysiology in these disorders includes a disordered brain–gut communication between efferent and afferent pathways that signal

messages between the central nervous system and the intestine. These disrupted signals may result from a postinfectious state disrupting the mucosal nerves, a genetically susceptible individual related to serotonin reuptake abnormalities, altered intestinal microflora, ineffective coping with perceived stressors, and associated psychiatric disorders that may influence the individual's experience but do not cause the symptoms (Clark & DeLegge, 2008). The child experiences an abnormal perception of GI function, which results in visceral hypersensitivity and pain. Sites of visceral hyperalgesia are differentiated between functional abdominal pain and irritable bowel syndrome. Patients with irritable bowel syndrome demonstrated more rectal hypersensitivity than children with functional abdominal pain whereas children with functional abdominal pain demonstrated more gastric hypersensitivity (McOmber & Shulman, 2008).

Assessment

Diagnosis of functional abdominal pain and irritable bowel syndrome is based on typical health history data and normal physical assessment findings. Assess carefully to identify red flags that may indicate the need for a more extensive workup to rule out organic etiologies (Chart 18-2) (Di Lorenzo et al., 2005). Elicit specific information about the nature of the pain and associated factors. Obtain a thorough diet history to evaluate for food allergies or intolerances. Include the child in the interview in a developmentally appropriate manner to elicit his or her perceptions of the cause of pain, as well as exacerbating and alleviating factors.

Functional abdominal pain typically manifests in children as episodic attacks of abdominal pain. Pain episodes may cluster in the morning or the evening. They may delay the onset of sleep at night, but typically do not awaken the child from sleep. The episodes are not consistently associated with activities such as meals or bowel movements. Pain is usually localized in the periumbilical area without radiation and is nonspecific in character. A history of frequent school absences is common in

CHART 18-2 SOME INDICATORS OF ORGANIC CAUSES OF ABDOMINAL PAIN

- Unexplained fever
- Weight loss
- Deceleration of linear growth velocity
- Evidence of GI blood loss
- Severe vomiting
- Chronic severe diarrhea
- Persistent pain in right upper or lower quadrants
- Family history of inflammatory bowel disease

functional abdominal pain. In some cases it may be associated with physical, emotional, or sexual abuse.

Irritable bowel syndrome is characterized with pain and either diarrhea-predominant or constipation-predominant symptoms. The pain is generally relieved by defecation. The individual experiences cycles of increased symptoms and symptom-free periods. Triggers that exacerbate the symptoms are identified, such as food, stress, and hormonal changes. Environmental stressors are frequently reported. Alterations in family dynamics may be present. For both conditions, physical assessment reveals no obvious abnormalities. Growth is not impaired, and weight loss is not seen.

Diagnostic Tests

A simple laboratory evaluation may be done to screen for organic disease. This evaluation includes a CBC, erythrocyte sedimentation rate, and urinalysis and culture, because urinary tract infections can present as symptoms of abdominal pain. Stool specimens may be obtained to test for ova and parasites, *Giardia* (by enzyme-linked immunosorbent assay), and occult blood. A basic liver panel and albumin with amylase and lipase may be obtained. If lactose intolerance is suspected, a lactose hydrogen breath test may be done. If results are normal in the presence of a normal physical examination, further testing is likely not necessary to determine a diagnosis of functional abdominal pain or irritable bowel syndrome.

Interdisciplinary Interventions

After a positive diagnosis of functional abdominal pain or irritable bowel syndrome is determined, education and reassurance of the child and parents are the key elements in the treatment plan. As with many GI conditions, an interdisciplinary team approach is most beneficial for these complex problems. The physician, nurse, social worker, dietitian, and other healthcare professionals work with the family to outline the plan of care and goals. Reassure the child and family that the symptoms are not uncommon and explain the underlying mechanism of the abdominal pain. An analogy can be made to the treatment approach for a headache. A headache can be from a variety of causes, including diet, stress, fatigue, or tension. Most people recognize that many things cause headaches, and that an individual's tolerance to headache discomfort also varies. Explain that the pain arises from a heightened excitability of the nerves that communicate to the brain, which is expressed by a feeling of stretching or spasm in the gut, to validate their pain experience. Assist the child and family to identify triggers that exacerbate bowel symptoms and pain, and ways to eliminate or modify them. Evaluate the child's and parents' specific perceptions and concerns about the pain, explore their coping skills, and help them develop methods to manage anxiety when pain is present (Clinical Judgment 18–2). One study reported that the intervention of distraction by their parent during pain episodes made the child feel better compared with the parent providing additional attention, reassurance, and sympathy (Walker et al., 2006).

Diet modification to avoid identified triggers has been suggested. Evidence that increased fiber in the diet provides a benefit is inconclusive. There is evidence that cognitive behavioral therapy may provide the skills to reframe, and thereby modify, the pain experience and reduce disability on a short-term basis (Di Lorenzo et al., 2005). Family therapy may be helpful to assist parents to reinforce adaptive and positive behaviors. There is also evidence that a 2-week treatment with peppermint oil may benefit the child with irritable bowel syndrome because of its properties to relax smooth muscles (Kline et al., 2001).

Tricyclic antidepressants have been used to reduce central pain perception. They are used in lower doses than for the treatment of depression. Selective serotonin reuptake inhibitors have also been used in the treatment of functional abdominal pain. With increased acknowledgment of the mind–body–spirit connection, multimodal therapies may become the strongest approach to long-term treatment. More studies are needed to tease out those interventions that are of most benefit.

Community Care

If school absence has been an issue, help the child and parents develop a plan for school reentry and for handling episodes of pain in the school setting. With parental permission, involve the school nurse and teacher in the plan to ensure a consistent approach. The nurse in the outpatient setting can serve as a valuable support and communication link for the family in treating these disorders.

Children with chronic abdominal pain may be at risk for later emotional symptoms and psychiatric disorders (Di Lorenzo et al., 2005). More research is needed to direct the care of children and families affected by these common problems.

Colic

Colic, also known as the *irritable infant* (Keefe et al., 2006), is a term used to describe a constellation of infant behaviors characterized primarily by prolonged periods of inconsolable crying in an otherwise healthy, thriving infant. The condition has been recognized for decades, yet complete understanding continues to elude the experts.

Colic is reported to occur in 10% to 25% of infants (Keefe et al., 2006). Differences in the incidence of colic by sex, cultural background, breast-feeding versus bottle-feeding, or birth weight have not been identified.

Colic is thought to be a multifactorial phenomenon. Its exact etiology remains unclear, although many theories, both physiologic and psychological, have been proposed. Physiologic factors that apparently play a role in colic include the immaturity of the infant nervous system (which makes it difficult for the infant to screen out sensory stimuli). Another theory includes GI disorders ranging from such minor conditions as gas, cramps, and overeating to major disorders such as food allergy and gastroesophageal reflux disease. Psychosocial factors that

CLINICAL JUDGMENT 18–2

A Child With Functional Abdominal Pain

Rose is a 9-year-old girl, brought in by her mother to the clinic, complaining of abdominal pain. This pain has occurred before.

Questions

1. What other history would the nurse want to obtain?
2. What factors in the history are significant?
3. Does Rose have symptoms of organic disease?
4. What is the next step in the evaluation?
5. All laboratory results are normal. Rose and her mother are taught about functional abdominal pain, pain relief interventions (warm baths, distraction, talking about stressors), and Rose is referred for counseling to help her cope with her parents' divorce. What are symptoms of organic disease that warrant further follow-up?

Answers

1. *Past medical history*, including previous and current illnesses, immunizations, fever, allergies, food intolerances, normal weight, has Rose started puberty (occasional colds, otitis media, diarrhea, immunizations up to date, typical weight is 62 lb, she has not started puberty); *daily routines*, including patterns of elimination (describe number, amount, appearance); diet history, sleep patterns (voids four to six times per day; yellow urine; no dysuria; 1 stool every 1 to 2 days; brown, formed, no pain with evacuation; abdominal pain unrelated to stooling pattern; no change in sleep habits); *pain history*, including how long the pain has been occurring, how often, when does it occur (time of day, location such as school or home), where is it located, what is done when the pain occurs, does anything relieve or exacerbate it, has it been interfering with activities of daily living or school attendance or performance, Rose's and family's response to the pain, what does the family think is wrong (pain has been occurring one to two times per week for about 5 months, is crampy pain, located in the periumbilical region lasting 1 to 3 hours, usually in the evening, no medications are given, mother sits with Rose and distracts her with "talking about happy times" until the pain resolves, does not impact activities of daily living, Rose and her mother think Rose may have some disease); *family history*, including IBD, ulcer disease, recurrent or chronic pain, anxiety disorders (unremarkable except mother suffers from occasional migraines); and *psychosocial history*, including family functioning, school performance, peer relationships, previous stressors and typical coping style and response (parents are getting a divorce, Rose is doing her typical B and C work in school, has many friends, no major stressors previously, Rose usually reads or goes out to play when she is stressed).
2. History is predominately unremarkable except for recurrent abdominal pain, mother's history of migraines, and impending parental divorce.
3. No.
4. Explain to Rose and her mother that this type of pain may be caused by dysfunctional motility and things other than disease, and that some laboratory tests will be done. A CBC, sedimentation rate, urinalysis, and possibly stool for Hematest will be done. Extensive testing may indicate to Rose and her mother that the healthcare team thinks something is seriously wrong and can increase their anxiety further.
5. Weight loss, fever, blood in emesis or stool, abdominal distention, or fatigue

have been cited include parental anxiety and variations in infant temperament. Most cases of colic apparently result from some interaction between physiologic and psychosocial factors. More recently, a newer theory has been advanced, termed the *fourth trimester* (Karp, 2004). This theory suggests that the infant essentially is born too soon, with all functions still immature. It proposes that the infant does not "wake up" and actively respond to the environment until the third month after birth.

Pathophysiology

Like the etiology of colic, the pathophysiology of colic also is unclear. In most cases, crying is a normal physio-

logic response on the part of the infant to distress or discomfort and serves to communicate the infant's needs to the parents. The normal 6-week-old infant may cry up to 3 hours a day, decreasing to 1 hour per day by age 3 months (Brazelton, 1962). In the case of colic, unexplained crying will generally begin at about 2 weeks of age with a peak at 6 weeks to 2 months of age. The inconsolable crying lasts about 3 to 4 hours and can continue to 4 to 6 months of age. The episodes usually occur around the same time of day, often in the evening. No long-term negative physiologic sequelae are associated with colic. Although studies have supported all of the theories mentioned here as having a role in the pathophysiology of colic, none of them totally explained colic. Keefe

et al. (2006) proposed an etiology as a delay or disturbance in the sleep–wake cycle of the infant’s ability to self-regulate. The “fourth trimester” theory (Karp, 2004) is also compatible with previously described colic characteristics. Karp’s research identified a “calming reflex” that occurs in utero that forms the foundation for his proposed interventions.

Assessment

A thorough history and physical examination rules out any organic sources of discomfort or distress. The infant with colic has prolonged episodes of crying but appears otherwise healthy and demonstrates appropriate weight gain. The crying episodes are often accompanied by abdominal distention and flatus. The infant may be noted drawing the knees in toward the chest. The colicky symptoms are consistent over time, unlike those of other GI conditions in infancy, which may present with abdominal pain but progress with other signs such as vomiting, diarrhea, abdominal distention, and fever. Parents may report that simple soothing measures are ineffective during the crying episodes. Note what methods have been used to calm the baby or to help the parents cope.

Alert! Assess the effect of the infant’s behavior on the parent’s feelings about parenting and on the family and marital relationship. The stress of caring for a colicky baby can result in shaken baby syndrome (see Chapter 29). It has been implicated as a trigger for infant maltreatment and parental dysfunction, such as neglect or inattentiveness (Keefe et al., 2006).

Nursing Diagnoses and Outcomes

In addition to those listed in Nursing Plan of Care 18–1, the following nursing diagnoses and outcomes may apply to the family of an infant with colic:

Risk for impaired parenting related to effects of prolonged, distressed crying

Outcomes: Parents will demonstrate an ability to read their infant’s cues and respond quickly and appropriately.

Infant will demonstrate a decrease in the amount of daily crying.

Parent will identify sources of support for feelings of increased stress.

Interdisciplinary Interventions

Parent education and counseling are the key interventions in managing infant colic. Teach the parents to read the infant’s cues to determine what infant need is being communicated. Teach them to determine what is normal infant crying and to understand the importance of meeting the infant’s needs in a timely fashion. Make parents aware that by dealing with the crying episodes, they can also avoid escalation of crying to a point at which the infant cannot be consoled. Teaching soothing techniques and ways to handle the infant offers the parents a sense of control (Nursing Interventions 18–1). Reassure the parents that too much holding will not spoil the infant.

Caring for the infant with colic can be very stressful and frustrating. Parents may feel a sense of failure because they cannot calm their infant. Acknowledge the parents’ feelings and provide support. Assist the parents to identify family and community resources for respite. Emphasize the time-limited nature of colic, which usually diminishes by 3 to 4 months of age. This knowledge may help the parents cope with their immediate frustrations.

WORLDVIEW: Many populations use star anise tea as a treatment for infant colic. Star anise tea has been documented to have neurologic and GI toxicities and should not be administered to infants because of its potential danger in this population.

NURSING INTERVENTIONS 18–1

The Crying Infant

- Reduce sensory stimuli: Minimize noise, light, extraneous movements; handle infant with firm, deliberate movements
- Contain the infant: Keep extremities close to the body, swaddle tightly, use caution to avoid overheating
- Provide opportunities for sucking: Nonnutritive or feeding
- Position on side or stomach for calming (not for sleeping), or hold infant with stomach pressed against your shoulder or in a football hold (infant’s stomach against your forearm, infant’s crotch at your antecubital fossa and your hand supporting the head); the last two positions provide warmth and pressure against the infant’s stomach, which may help calm
- Use low, calming, rhythmic voice; mimic (verbally or with commercially produced tapes) the “shhh” sounds infants hear in utero; play rhythmic 60-cycle music (e.g., *Pachelbel’s Canon in D*)
- Use rhythmic movement: Rocking, swaying, or swinging; use jiggly, rapid, small movements two to three times a second, interspersed with slow, broad swaying; teach parents never to shake an infant

Gastroesophageal Reflux Disease (GERD)

Gastroesophageal reflux (GER) is effortless passage of gastric contents into the mouth (regurgitation) or esophagus (silent or occult reflux). Postprandial GER is a normal physiologic phenomenon, without negative sequelae in most cases. GERD occurs when symptoms or complications are present.

GER occurs in an estimated 1 in 500 infants. Healthy, full-term infants are affected in 50% of cases, commonly associated with delays in the normal maturation of the lower esophageal sphincter (LES). Conditions that carry a high frequency of association for the development of GERD include esophageal atresia (30%–80%), neurologic impairment (65%–70%), cystic fibrosis, motor dysfunction, increased intragastric pressure, delayed gastric emptying, and central nervous system disorders. Other high-risk groups of children include those who have a repaired omphalocele, or a repaired CDH and chronic lung disease (Pacilli, Chowdhury, & Pierro, 2005).

The prognosis for the child with GERD is related to the severity of symptoms and whether associated anomalies are present. By 1 year of age, most infants with mild to moderate reflux will become symptom free and able to discontinue medications (Craig et al., 2004). When medical therapy has failed or the symptoms are severe, surgery is indicated.

Pathophysiology

The body has a natural barrier system at the gastroesophageal junction to prevent the reflux of gastric contents into the esophagus that includes both anatomic and physiologic elements. Anatomically, the length of the esophagus, its orientation with the surrounding intra-abdominal ligaments, and the angle of His (made by the esophagus and axis of the stomach) play a role as a barrier to reflux. The LES is not an anatomic structure, but a zone at the lower esophageal segment that generates a greater pressure than that of the gastric luminal pressure. Physiologically, esophageal motility and gravity facilitate clearance of refluxed material as well as saliva. Other factors include effective gastric emptying. The major component of this barrier system is a competent LES. Under normal circumstances, the LES remains functional as a result of the combined anatomic and physiologic elements. The LES relaxes and opens during swallowing, belching, and vomiting.

Conditions that cause a decrease in LES pressure lead to the development of GERD. Continuous LES hypotonia, incompetent LES, transient LES relaxation, inappropriate LES relaxation independent of swallowing, and anatomic disruption of the esophagogastric junction (e.g., hiatal hernia) are the most common mechanisms of decreased LES pressure. Esophageal motor dysfunction, increased intragastric pressure, and delayed gastric emptying are other contributing factors.

Both intrinsic and extrinsic factors can cause decreased LES. Children with central nervous system disorders have demonstrated an increased incidence of LES hypo-

tonia. Medications such as theophylline and foods containing fat, chocolate, or caffeine, or those that are highly spiced, may cause transient decreases in LES pressure. Children who are fed enterally are at risk for reflux related either to gastric distention from bolus feedings or the presence of an NG tube.

When the esophagus is repeatedly exposed to gastric secretions, esophagitis results. The associated inflammation can cause pain (often called *heartburn* by older children), dysphagia, ulcerations, and chronic occult blood loss leading to anemia. Chronic esophagitis can result in stricture formation and altered esophageal motility. Barrett's esophagitis is a rare related condition that, even in children, can eventually lead to adenocarcinoma. Long-term studies on the sequelae experienced by adults when GERD is diagnosed in childhood are needed to provide a life span view of this condition.

Severe GERD can cause vomiting, which over time may lead to inadequate nutrient intake and FTT. Vomiting may also put the child at risk for pulmonary aspiration of gastric contents. Reflexive responses to the presence of refluxed material in the esophagus may trigger bronchospasm, laryngospasm, and, in some cases, apnea.

Assessment

Conduct a thorough history and physical examination when evaluating a child with suspected GERD to assess for causative factors and severity of symptoms, and to rule out other pathologic conditions. A spectrum of symptoms is associated with GERD and presentation may vary with age (Chart 18–3).

A careful feeding history and direct observation of feeding technique may be helpful in distinguishing GERD from more benign problems, such as overfeeding or inadequate burping technique. Additional history includes disruption of sleep pattern and behavioral changes.

Ascertain whether the child is experiencing regurgitation or vomiting. Parents may describe regurgitation and vomiting as the same entity. However, vomiting is forceful expulsion of gastric contents.

Diagnostic Tests

Radiographic evaluation commonly includes a barium swallow or upper GI series to assess for anatomic or structural abnormalities, such as strictures. A gastric emptying study may be done to assess for delayed function. Upper GI endoscopy may be done, with biopsies to assess for esophageal erosions, the presence of a hiatal hernia, and histologic changes from esophagitis. Continuous intraesophageal pH monitoring (for 24–48 hours) is the gold standard diagnostic test. It is used to determine the frequency and duration of reflux episodes and their temporal relationship with the child's activity and symptoms. The parent or nurse must maintain a thorough record of all the child's activities and symptoms during the study, including the beginning and ending of feedings, sleep-wake periods, position changes, and any GI or respiratory

CHART 18-3 CLINICAL MANIFESTATIONS OF GERD

GI Manifestations

- Effortless regurgitation or vomiting after feeding in infants (this symptom is also seen with normal GER without any other symptoms present)
- Weight loss or FTT from decreased nutrient intake associated with vomiting
- Irritability
- Feeding refusal
- Older children may not experience vomiting, but may report episodes of chest pain or heartburn associated with reflux
- Dysphagia and anemia associated with esophagitis
- Hematemesis

Pulmonary Manifestations

- Chronic cough, frequently noted at night when the child is supine
- Recurrent bronchopulmonary infections
- Bronchospasm, laryngospasm, apnea, bradycardia can be associated with reflux episodes
- Reactive airway disease
- Chronic hoarseness

Other

- Sandifer syndrome: The child assumes a spasmodic posture, often after feeding, to facilitate esophageal clearance with neck extension and rotation of the head and neck to one side; typically the back is arched with spine hyperextension

symptoms. Carefully observe the child to ensure that the pH probe is not dislodged. The study may be done in the hospital or in the outpatient setting. In either setting, educate and support parents in their role in monitoring and recording their child's activity during the study period; parental monitoring and accurate record keeping contribute to meaningful test outcomes.

A more advanced technology for the pH study is available at some centers. This technology uses multichannel intraluminal impedance monitoring, which detects all reflux episodes, those with acid and those with nonacid material. It uses the principle of low voltage between placed electrodes on a multichannel intraesophageal catheter and measures differences in conductivity of refluxed contents that are either gas, liquid, or mixed material between different esophageal segments. Early studies have shown that infants reflux nonacidic material more than acidic contents. Studies thus far have shown that reflux occurs about half of the time with acidic contents. They also show there are additional episodes of reflux with nonacidic contents (Condino et al., 2006). More studies and standardized parameters are needed for the pediatric population. This approach will provide

valuable information for clinical correlation as its use becomes more mainstream in the clinical arena.

Interdisciplinary Interventions

Various treatment strategies are used to manage GERD. The choice of treatment depends on the severity of the child's symptoms and associated medical problems.

Conservative Management

Conservative management is a common approach taken for infants with mild GERD symptoms. Parental reassurance regarding a thriving, healthy infant is a critical intervention. Additionally, time-honored approaches involve modifications in positioning, diet, and feeding.

Evidence that infants have substantially fewer GER symptoms in the prone position has been demonstrated with pH monitoring. Positioning the infant with GERD is challenging, because the prone position is associated with sudden infant death syndrome (SIDS). The recommendations from the North American Society for Pediatric Gastroenterology and Nutrition Practice Guidelines (Rudolph et al., 2001) advise parents to use a nonprone position for sleep. Prone position for GERD is only considered when the risk of death from GERD complications outweighs the potential risk for SIDS. For children who are older than 1 year, including adolescents, the guidelines state that there is a likely benefit to left-side positioning during sleep and elevation of the head of the bed. There is not sufficient evidence to support elevation of the head, although this is widely practiced, perhaps because many children with GERD also may be fed via an enteral tube. Positioning with the right side down promotes gastric emptying and can be used after feedings when the infant is well supported. Car seats hold an infant in a position that induces reflux. If a car seat is used, teach parents to ensure that the infant is not slouching, thus increasing intra-abdominal pressure.

Alert! The Academy of Pediatrics' Back to Sleep campaign recommends that infants (from birth to 12 months) sleep supine. Prone sleep is recommended only when the risk of complications from GERD outweighs the risk for SIDS. When the prone position is necessary, advise parents not to use soft bedding.

A meta-analysis demonstrated that thickened feedings are moderately effective in reducing GER in infants and is not associated with serious adverse effects (Horvath, Dziechciarz, & Szajewsha, 2008), thus they are often recommended. Teach parents to thicken feedings with rice cereal (1 tbl/oz with standard 20-cal/oz formula) and implement a feeding schedule with smaller feeding volumes at more frequent intervals. Formula thickened with rice cereal is commercially available.

Pharmacologic Therapy

For moderate and severe cases of GERD, pharmacologic therapy is used in conjunction with conservative management strategies. Antacid preparations and histamine-2

blocking agents (e.g., cimetidine, ranitidine), are used to provide symptomatic relief of esophagitis and to reduce the damaging effects of refluxed gastric contents on the esophageal mucosa. Proton pump inhibitors (omeprazole, lansoprazole) are effective acid-suppressing agents and are superior in relieving symptoms. Prokinetic agents such as metoclopramide, low-dose erythromycin, and cisapride (available in the United States under extremely limited conditions because of the drug's potential for cardiotoxicity) are used to enhance gastric emptying.

Educating the parent about side effects of these medications is important. For example, metoclopramide can produce central nervous system side effects such as extrapyramidal reactions and dystonia. Accordingly, provide the parent with verbal and written instructions regarding medication administration, drug interactions, and ways to recognize untoward reactions promptly.

Surgical Interventions

Surgical intervention for GERD is indicated when symptoms do not respond to medical therapy, when severe complications exist, or when episodes are life threatening. The goal of surgical intervention is to create an anatomic barrier to reflux. The most common surgical antireflux procedure in children is the Nissen fundoplication. The fundoplication creates a one-way “valve” by wrapping the gastric fundus 360 degrees around the lower end of the esophagus. Traditionally, fundoplication has been performed as an open operative procedure, requiring a 5- to 7-day hospitalization. More recently, laparoscopy is being used. This approach offers a more rapid recovery period, earlier initiation of feedings, less postoperative pain, and is more cosmetically pleasing. Patients are discharged earlier than with the traditional open approach.

Immediately after the fundoplication, the junction between the stomach and esophagus (the “wrap”) may be “tight” as a result of postoperative swelling such that belching and vomiting are initially impossible. A temporary gastrostomy tube is often placed at the time of surgery to vent air from the stomach during the immediate postoperative period. The gastrostomy tube may be removed approximately 6 to 8 weeks after surgery, unless the child has a continued indication for enteral nutrition through the gastrostomy tube, which may be a common scenario.

Postoperative management includes assessing the effectiveness of gastric decompression by either NG or gastrostomy tube and assessing the surgical incision. Intake and output are monitored. Pain management is scheduled to optimize comfort so progression of recovery is maximized. Effective pain management enables the child to perform activities to promote ambulation and to prevent pulmonary complications.

Feedings are initiated when bowel function returns. If a gastrostomy tube is in place, vent it before and after feedings, and for retching and abdominal distention. Monitor and intervene early for constipation to avoid the child straining to stool. Collaboration with a pediatric registered dietitian and physical therapist may be beneficial when the child's condition is complicated by obesity.

Discharge planning and family education are important. Assess the parents' knowledge of postoperative care, management of the gastrostomy tube, and feeding schedule. Consider any underlying disease of the child when planning discharge and family education regarding treatment strategies. Instruct the family regarding dietary modifications, feeding techniques, positioning, and medication administration. Direct observation while the parents feed and position the child helps provide meaningful feedback. Provide education about medications, dosing schedules, and potential side effects verbally and in writing.

The child undergoing surgical intervention for GERD will need instruction regarding gastrostomy tube home management in addition to routine preoperative and postoperative instructions. Teach the child, as developmentally appropriate, and family about gastrostomy tube site care, use of the gastrostomy tube for gastric venting, and feeding as indicated. Additional education includes problem solving for mechanical, feeding, and infectious complications, as well as safety issues related to the child's developmental level. The family also needs education about gastrostomy tube replacement if accidental dislodgment occurs. Most surgeons and gastroenterologists identify a safe postplacement time frame during which this procedure may be done at home. Collaborating with hospital-based or healthcare insurance case managers is important to link the family to appropriate community resources for obtaining supplies and equipment necessary for home care.

Community Care

Home health follow-up is helpful to support the family during the initial postoperative period and to help the parents transfer their knowledge successfully to the home setting. Ongoing monitoring of response to medical therapy is done in both the outpatient and home settings. Develop a plan for the child to return to daycare or school during the discharge process. When a child requires a gastrostomy tube, direct the parents to contact the school and to complete required school forms to avoid delays in school attendance. Consider including child care and school personnel, or other caregivers in the discharge plan. The school nurse is an important collaborator in this effort.

Constipation

Constipation is a delay or difficulty in defecation that has been present for longer than 2 weeks and causes considerable distress (Philichi, 2008). In the past there has been a lack of a generally accepted definition. A consensus of experts defined a spectrum of disorders of defecation in attempts to provide uniform definitions to classify these problems for diagnosis and treatment, and to collect information that directs outcomes based on consistent definitions. An elaboration of the previous simple definition also includes the following characteristics of constipation as pebblelike or hard stools for a majority of stools, firm stools two or fewer times a week, and no evidence of

structural, endocrine, or metabolic disease (van den Berg, Benninga, & Di Lorenzo, 2006). Normal stool frequency varies developmentally, so the definition of constipation must be made relative to the expected developmental norm. *Encopresis* is defined as the involuntary loss of formed, semiformal, or liquid stool into the child's underwear after the child has achieved a developmental level of 4 years (Loening-Baucke, 2002).

Constipation is a common pediatric problem, presenting as the complaint in 3% of pediatric outpatient visits and in 25% of children referred to pediatric gastroenterologists (Philichi, 2008). Constipation prevalence reports vary by age and gender. One epidemiologic review reported an increased prevalence around the preschool age, which is a typical time for toilet training (van den Berg et al., 2006), yet overall prevalence gender rates are considered to be similar. Encopresis is more common in males (van den Berg et al., 2006).

Constipation may arise from a variety of disorders, both organic and nonorganic (Table 18–7). Most commonly, it is the result of functional causes. After other underlying causes such as structural, metabolic, or endocrine have been ruled out, constipation may be called *functional constipation*. Encopresis most commonly arises from functional constipation in a child with no evidence of physical abnormality. It is manifested by the history of an expulsion of a normal bowel movement, usually involuntary, in an inappropriate place or inappropriate social context (van der Wal, Benninga, & Hirasing, 2005). Fecal incontinence, with or without constipation, arising from organic disease is less common. Children with special needs or chronic conditions are at higher risk than others for constipation and may experience constipation as a complication of their condition. This section covers only the topic of constipation.

Pathophysiology

The process of normal defecation depends on the interaction between numerous sensory and motor mechanisms. The rectum forms a right angle with the anal canal. The urge to defecate is initiated by distention of the rectum with stool. This event induces a reactive relaxation of the internal anal sphincter and contraction of the external anal sphincter. Squatting or sitting straightens out the angle between the rectum and the anal canal, enabling stool to pass easily. Increasing intra-abdominal pressure, as with the Valsalva maneuver, and voluntarily relaxing the contracted external anal sphincter permits feces to be expelled.

Constipation is a symptom and in children is commonly the result of voluntary fecal withholding, resulting from an experience of painful or frightening defecation. Another frequently cited time for constipation to emerge is during toilet training. Change in diet, illness, stress, beginning school, and not taking time from play to defecate have all been implicated as causes to functional constipation. Painful lesions, such as fissures of the anal or perianal region, or hardened stools may result in pain when feces are passed, causing the child to withhold stool to avoid pain. Psychosocial or behavioral factors also may

**Causes of Constipation in Children
(Continued)**

Situational

- Febrile or prolonged illness
- Surgery or bed rest
- Anal fissure or diaper dermatitis
- Change in child's diet or routine

contribute to constipation. Overly aggressive toilet training, childhood anxieties that cause the child to avoid school bathrooms, or intrusive parental interventions surrounding toileting habits may all result in stool withholding.

After a pattern of withholding is begun, a vicious cycle develops. As defecation is delayed, progressively larger amounts of stool are built up in the rectum for longer periods of time, resulting in more pain and more withholding. Fecal soiling results when a large stool mass stretches the walls of the colon and rectum, desensitizing the rectum, and involuntary leakage of semiformal or liquid stool occurs around the fecal mass.

Assessment

The goals of the initial history and physical examination of the child with functional constipation or encopresis are to assess causative factors and to rule out any potential organic causes. Note information regarding stool frequency, size and stooling pattern; time first stool was passed after birth; and associated symptoms, such as fever, abdominal distention, anorexia, nausea or vomiting, weight loss, or failure to gain weight (Philichi, 2008). Obtain a thorough diet and toilet training history, noting any pertinent psychosocial stressors.

Complaints of abdominal pain may be expressed. Assess the contour of the abdomen and note distention. Palpate for fecal masses, particularly in the left lower quadrant. Appetite may be poor. After passage of stool, parents may note that the child's mood and appetite improve. Question about urinary tract symptoms and incontinence, which can also be seen in the child with functional constipation and encopresis. Symptoms occur as a result of the dilated rectum placing pressure on the bladder, causing spasms. Recurrent urinary tract infections have been reported, particularly in females, usually related to ascending bacteria from fecal soiling.

Assess the sacral area for dimpling, which may indicate a spinal abnormality. Inspect the perianal area to note fissures, position of the anus, dermatitis, and rectal prolapse.

Diagnostic Tests

Barium enema or anorectal manometry may be done when problems persist or an organic etiology is suspected, such as Hirschsprung disease. Stools are tested

for occult blood. A flat abdominal film allows the extent of the constipation to be evaluated and response to clean out, if performed.

Interdisciplinary Interventions

The treatment plan for the child with constipation is individualized depending on the severity of symptoms and on the child's developmental level. For simple constipation, increasing hydration; incorporating more fiber, fruits and vegetables, and whole grain foods; discontinuing medications associated with constipation; and using laxatives may be effective (Montgomery & Navarro, 2008). Constipation in children with specialized chronic conditions requires additional evaluation and treatment that may be beyond the scope of primary care. For the child whose symptoms are more severe, the treatment plan is generally designed in three stages: (1) disimpaction (bowel cleanout) and patient education, (2) prevention of reimpaction/maintenance, and (3) establishment of regular bowel habits.

During the initial phase of education, the goal is to "demystify" the process of defecation and to help decrease feelings of guilt or blame. Describe the normal process of defecation and explain the pathophysiologic alterations associated with constipation. Using the abdominal radiograph to provide a visual image may reinforce the extent of the problem and understanding of the treatment plan with the parents and child. Explain the treatment, approach, providing options when able, and include the purpose of each therapeutic intervention, anticipated outcomes, and potential problems. Disimpaction is necessary to eliminate any fecal mass from the rectum that may be present. Disimpaction may be achieved with large doses of lubricants such as mineral oil or, in severe cases, a colonic lavage solution. The colonic lavage may be administered through an NG tube by a continuous drip method (Philichi, 2008). Some clinicians may routinely use enemas in severe cases, although this method may be traumatic for both child and parent, and can contribute to the cycle of aversive experiences the child associates with defecation. Enemas are also difficult for the parents to carry out at home. High doses of oral medications have been shown to be an effective cleanout method.

Children with special needs or chronic illness may require enemas in combination with oral agents. They may require admission to acute care for more aggressive interventions, such as administration of polyethylene glycol–electrolyte solution (GoLYTELY) via an NG tube plus use of an enema preparation. These children may be at increased risk for complications from administering enemas. When enemas are deemed necessary, the child should have small volumes with short retention times to reduce the risk for potential complications. Cardiopulmonary and intravascular volume status should be evaluated before administering hypertonic enemas (Walker et al., 2003).

The goal of phase 2 is to prevent reimpaction or maintenance. Treatment is designed to overcome the child's tendency to withhold stool. Various agents are used for

this purpose, most commonly mineral oil and osmotic agents such as milk of magnesia, lactulose, or sorbitol. Polyethylene glycol, electrolyte free (Miralax), has been found to safely treat chronic constipation. This drug is not readily absorbed and is therefore an excellent bowel evacuating agent. It is better accepted than older agents because it is tasteless, odorless, and colorless and has no grit. It can be mixed with liquids such as Kool-aid or Gatorade. Therefore, it is the agent of choice both for treating disimpaction and for maintaining stooling patterns (Benninga, Candy, & Taminiau, 2005). If mineral oil is used, it should not be given to children at risk for pulmonary aspiration; it is also contraindicated in infants younger than 1 year. Oral agents are usually continued until 4 to 6 months after the last painful stool. The child must be weaned off the laxative slowly.

KidKare ■ Give the child choices regarding how the Miralax or mineral oil is taken. Miralax can be mixed with beverages (water, juice, soda) and offered chilled. Serving mineral oil cold or mixing it with orange juice or carbonated beverages enhances its palatability. Emulsified mineral oil should be shaken before use and given with meals. It is more palatable than nonemulsified mineral oil.

The role of fiber is controversial; however, educating the child and parents about the importance of a balanced diet that includes whole grains, fruits, and vegetables promotes overall health. Increasing fluid intake will not correct the problem unless dehydration is present. A program to encourage regular toileting behaviors is also initiated at this time. Behavioral management is more helpful in conjunction with oral agents than oral agents alone. Children are asked to sit on the toilet for 5 to 10 minutes 20 to 30 minutes after every meal and attempt to evacuate the rectum. This practice takes advantage of the natural gastrocolic reflex. A system of positive reinforcements/incentives, such as stickers, can be instituted to reward adherence to medications and toileting sessions. Proper alignment and positioning is important to flatten the anorectal angle and facilitate the passage of stool by supporting young children's dangling feet on a footrest. Encourage the parents to communicate the treatment plan to appropriate school and child care personnel to promote consistency. Psychological and behavioral issues can present ongoing concerns for the child and family, and may require intervention from a psychologist, social worker, or child development professional. Biofeedback may be beneficial for a select subgroup of children with persistent symptoms. The child is weaned off the medications as regular bowel habits become reestablished.

Community Care

The child with chronic constipation and fecal soiling can experience many negative psychologic and social sequelae. Low self-esteem, poor school performance, and impaired peer relations have been reported. Family rela-

tionships can be affected negatively. Parents who do not understand the physiologic mechanisms that cause constipation with fecal soiling may become frustrated and angry with their child's recurrent soiling.

A collaborative effort between the child, family, and healthcare team therefore is essential to successful outcomes during the treatment phase. The nurse, in the outpatient and school settings, plays an important role in the treatment plan. Child and family evaluation, education, and support, along with phone and clinic follow-up to monitor progress and make necessary modifications in the treatment plan, are key. Educate and support the family through the treatment phase, because a great deal of patience and time may be required to achieve successful outcomes. Follow-up is recommended for at least 1 year after initial successful treatment, to reinforce success and provide treatment with laxatives if relapse occurs.

ANSWER: In many chronic conditions, parents assume the responsibilities of caregiving. In these instances, the role of the nurse centers on the family unit. The nurse provides education, reassurance, and support through telephone follow-up or outpatient visits.

DISORDERS OF MALABSORPTION

Disorders of malabsorption include chronic diarrhea, short bowel syndrome, celiac disease, and lactose intolerance.

Chronic Diarrhea

Chronic diarrhea is defined as diarrhea that persists for more than 3 weeks. Because normal stool consistency and frequency varies developmentally, diarrhea is defined as an increase in stool frequency and alteration in stool consistency compared with the child's norm.

The incidence of chronic diarrhea varies depending on the etiology (Chart 18-4). In Munchausen syndrome by proxy, a rare form of child abuse (see Chapter 29), diarrhea may be induced by the administration of laxatives.

The prognosis of a child with chronic diarrhea depends on the underlying etiology. Some causes of chronic diarrhea are easily resolved, such as eliminating the offending agent and treating an infectious process, whereas other causes such as inflammatory bowel disease or diarrhea related to pancreatic insufficiency may have serious, life-long consequences for the child.

Pathophysiology

The pathophysiology of chronic diarrhea depends on the cause of the diarrhea. Numerous physiologic mechanisms can result in diarrhea. Osmotic diarrhea results from malabsorption of an absorbable solute. This event creates a solute load in the intestine that results in increased fluid losses. Malabsorption of carbohydrates, whether because of mucosal injury or congenital defects of carbohydrate absorption, results in osmotic diarrhea. Overfeeding or

excessive fruit juice consumption creates a high solute load in the intestine that also will result in osmotic diarrhea.

Certain intestinal infections, severe GI mucosal injury, or tumors may result in secretory diarrhea. The hallmark characteristic of secretory diarrhea is large volumes of watery diarrhea despite complete bowel rest. Other causes of diarrhea include mechanical obstruction and bowel resection. In the case of mechanical obstruction, formed stool cannot pass beyond the area of blockage, but liquid stool may leak around it. Massive resection of intestine reduces the absorptive surface area of the bowel and decreases bowel transit time, resulting in diarrhea.

Assessment

The child with chronic diarrhea requires a comprehensive diagnostic evaluation to establish the etiology of the illness.

When taking the history, ask questions to identify risk factors for infection. Carefully review the child's diet history and history of growth and weight gain. Assess for signs of dehydration, malnutrition, or other indicators of GI dysfunction during the focused physical assessment. Ask the child or family to save the stool so direct observation and quantification of the stool can be done.

Clinical manifestations of chronic diarrhea can vary, depending on its etiology. Assess the appearance (consistency, size, and color), frequency, odor, and urgency of stool, which can provide clues regarding the underlying cause. Assess for blood in the stool and ask about associated symptoms such as abdominal pain, fever, and vomiting. Assess and query about the stool pattern, because stools may cycle between normal and abnormal daily or intermittently. The child with chronic diarrhea secondary to pancreatic insufficiency will have the large, bulky, foul-smelling stools characteristic of fat malabsorption. The child with diarrhea secondary to an inflammatory illness, such as ulcerative colitis, may have liquid stool with mucus and bright-red blood.

Physical assessment findings also vary. Although some children may appear quite well, others may appear acutely or chronically ill. The child's pattern of growth and weight gain will reflect the duration and severity of the diarrhea. Some children do not exhibit any alteration in growth and weight gain, whereas others demonstrate delayed growth, substantial weight loss, and FTT. Overt signs of nutrient deficiencies may be present in these cases. If the child has experienced severe fluid and electrolyte losses from the diarrhea, dehydration and metabolic imbalances may be evident on physical examination.

Diagnostic Tests

Laboratory evaluation of the stool can help differentiate between infectious, inflammatory, or malabsorptive causes. Stool culture for bacteria and for ova and parasites are obtained to assess for infection. Stool specimens for white blood cell counts, occult blood, and alpha 1-antitrypsin

assess for inflammatory causes. Screening for malabsorptive disorders is done by measuring stool pH, reducing substances, and fecal fat. A sweat test is done to rule out cystic fibrosis. DNA analysis may also be done in conjunction with a sweat test to further evaluate for genetic mutations associated with cystic fibrosis.

Blood specimens are taken to evaluate for systemic disease, fluid and electrolyte imbalance, and nutritional status. A CBC with erythrocyte sedimentation rate or C-reactive protein, chemistry panel with electrolytes, liver and renal function tests, and serum protein level determination are done. Trace mineral and vitamin levels may be assessed. A hydrogen breath study may be done if malabsorption is suspected. Immunologic studies may be included in the workup, such as serum Ig's with IgA and IgG subsets.

Radiographic studies are usually used only in situations in which the results of the history and physical examination suggest an anatomic defect, obstruction, or IBD. Endoscopic evaluation with intestinal biopsy, which includes small intestinal biopsy, is reserved for the child with suspected IBD, infection from a source not identified by stool culture, suspected mucosal injury of unidentified origin, or unexplained chronic diarrhea.

Interdisciplinary Interventions

Treatment of the child with chronic diarrhea involves treating the underlying organic source of the diarrhea, along with nutritional intervention to optimize digestion and absorption of nutrients, and to foster growth and weight gain. For the child with chronic diarrhea related to overfeeding or excessive juice consumption, treatment consists of nutritional counseling to normalize the child's diet. Modifying formula or diet may be necessary in malabsorptive disorders. Casein hydrolysate formulas, amino acid-based formulas, and modified protein-based formulas are commonly used in these cases. In cases of severe mucosal injury, enteral or PN may be necessary to support the child's fluid and nutritional requirements until mucosal healing takes place. The child with secretory diarrhea may require complete bowel rest and support with PN until the cause of the diarrhea resolves.

Management of the child with chronic diarrhea involves meticulous attention to fluid and electrolyte balance. Carefully assess and document all of the child's intake, whether oral, enteral, or by IV, and all output, including stool volume and characteristics. Ongoing assessment and management of any venous access device is essential to maintain delivery of parenteral therapies.

caREminder

Assess infant stool volumes by weighing diapers. If mixing of urine and stool makes accurate assessment difficult, separate stool and urine by use of an infant urine bag. To obtain a stool specimen, a disposable diaper can be applied inside out. The plastic barrier will not absorb the stool, which can then be removed and placed in the specimen container.

Replacement of fluid losses should be considered when stool volumes exceed 15 to 20 g/kg body weight per day. Carefully assess the child's hydration status and feeding tolerance. Skin integrity may be impaired secondary to frequent diarrheal stools. Prompt, frequent diaper changes and meticulous skin care are important. Collaboration with the CWOCN may be helpful to ensure that optimal skin barrier products are available for use. Educate the parents regarding medical and dietary management of the child's diarrhea. Also provide instruction in specialized nutrition support therapy techniques and home monitoring.

Short Bowel Syndrome

Short bowel syndrome is a condition in which extensive resection of small bowel results in malabsorption, fluid and electrolyte loss, and malnutrition. Short bowel syndrome in neonates is associated with congenital anomalies of the GI tract such as jejunoileal atresia, gastroschisis, and omphalocele. Preterm infants with severe necrotizing enterocolitis may undergo intestinal resections that result in short bowel syndrome. Infants and older children who experience malrotation with midgut volvulus may sustain severe ischemic injury to the small intestine that requires massive intestinal resection. Children with Crohn's disease who undergo repeated resections of diseased bowel also may be left with a short bowel.

Necrotizing enterocolitis, midgut volvulus, or congenital anomalies such as jejunal or ileal atresia and gastroschisis are the most common reasons for intestinal resection resulting in short bowel syndrome. Reported survival rates for the child with short bowel syndrome exceed 85% to 90%; 80% to 95% of children who require intestinal transplantation become independent of parenteral nutrition (PN) (Lopushinsky et al., 2007).

Pathophysiology

The small bowel is the primary site for digestion and absorption of nutrients. At 26 to 38 weeks' gestation, the small bowel undergoes extensive development, doubling in length. The full-term neonate is born with 200 to 300 cm of small bowel, which has an absorptive surface area of 950 cm. By adulthood, small bowel length grows to 600 to 900 cm with an absorptive surface area of 7,500 cm. These facts are important in understanding the infant's response to massive small bowel loss.

Short bowel syndrome occurs when extensive resection of small bowel reduces the absorptive surface area, causing malabsorption of nutrients, fluid, and electrolytes. During a process called *intestinal adaptation*, the remaining bowel develops the capability to do the work of digesting and absorbing adequate fluid and nutrients to support life. Although the very small infant does not initially tolerate resection of large segments of small bowel as well as an adult does, over the long term the infant has greater potential for intestinal adaptation because of the greater capacity for growth of the small bowel.

A number of factors affect the small intestine's ability to adapt. The length of remaining bowel, the site of the

resection, and whether the ileocecal valve is intact after the resection all play an important role in determining long-term outcomes. As a general rule, infants with as little as 15 cm of small bowel with an ileocecal valve, or 40 cm of small bowel without an ileocecal valve at the time of their neonatal resections have a greater chance to become independent of parenteral nutrition (PN) (Harris, 2007). Prognosis with older children with this bowel length would be worse.

Resection of the jejunum is less well tolerated than resection of the ileum, because the ileum has greater capacity for adaptation. The presence of the ileocecal valve is an important prognostic factor, because this valve functions to slow the intestinal transit time and prevent reflux of bacteria from the large bowel into the small bowel. The quality and function of the child's residual bowel is also an important factor, with residual disease and surgical complications such as strictures, fistulas, and dysmotility having a negative influence.

Intestinal adaptation in short bowel syndrome occurs through various mechanisms. The presence of nutrients in the lumen of the small intestine leads to dilation of the residual bowel and mucosal hyperplasia, which results in increased villous height and crypt depth. This reconfiguration increases the absorptive surface area in the small bowel. The very young neonate's inherent capacity for intestinal growth may also contribute to the process of adaptation. The process of adaptation can take from months to years. Providing adequate nutritional support during this process is essential. Full or partial support with PN is required until intestinal adaptation to full enteral feedings takes place.

Assessment

Clinical manifestations of untreated short bowel syndrome include profuse, watery diarrhea; malabsorption; and failure to thrive (FTT). Dehydration, electrolyte imbalances, and vitamin and mineral deficiencies may also occur. Skin breakdown may occur on the buttocks and perineum because of ongoing contact with diarrheal stools. Infants with short bowel syndrome are also at risk for oral feeding aversions because of prolonged nutritional support with parenteral and enteral feedings.

Children with short bowel syndrome are at risk for hepatobiliary complications. **Cholestasis** (stasis of bile flow) and cholelithiasis (gallstones) can result from malabsorption of bile salts and gallbladder stasis. Prolonged PN may put the child with short bowel syndrome at risk for cirrhosis, liver failure, and death. Liver disease in the parenterally fed child is believed to be multifactorial, yet is poorly understood. Prematurity, lack of enteral nutrition, and recurrent infection are all believed to play a role in the development of PN-associated liver disease. A contributing factor is thought to be related to fat emulsion. Currently, the fat emulsions are comprised of soy/safflower or soy oil alone, high in omega-6 fatty acids. This formulation is thought to contribute to the proinflammatory effect from the omega-6 fatty acids. Studies are currently being conducted to

investigate the use of omega-3 fish oil to formulate fat emulsions (Gura et al., 2008). Initial reports are promising.

Diarrhea and malabsorption in the child with short bowel syndrome may be exacerbated by bacterial overgrowth syndrome, a condition involving abnormal bacterial colonization of the small bowel. This condition can result from impaired motility secondary to adhesions or strictures and absence of the ileocecal valve.

Diagnostic Tests

At the time of surgery, the surgeon notes the length of remaining bowel and the presence or absence of the ileocecal valve. Other diagnostic studies may be needed to further define the functional status of the remaining bowel related to GI complications. These studies may include (but are not limited to) upper and lower endoscopy. Radiographic studies are used to determine growth of bowel length. Additional studies are done periodically to determine patient progress or to define ongoing problems.

Interdisciplinary Interventions

The basic principles of managing the child with short bowel syndrome are to initiate early and aggressive use of enteral nutrition to facilitate small bowel adaptation and to provide ongoing support with PN until adaptation takes place. Careful management of fluids, electrolytes, and nutrition along with prevention, early identification, and treatment of complications are also essential. Care of the child with short bowel syndrome is a collaborative effort across the continuum of care. In addition to nurses, the team includes the pediatrician, pediatric gastroenterologist, pediatric surgeon, dietitian, pharmacist, occupational therapist, and social worker.

The initial diagnosis of short bowel syndrome is established at the time of operative intervention for the underlying intestinal anomaly or disease state. During the initial postoperative period, the immediate goal is to stabilize fluid and electrolyte levels. Accurately measure and document all output, including urine, stool, NG or gastrostomy tube drainage, and ostomy output. Careful ongoing replacement of excess fluid loss is vital.

Gastric hypersecretion is typical during the early stages after intestinal resection and is treated by administering a histamine-2 blocker (e.g., ranitidine) or a proton pump inhibitor (e.g., lansoprazole). Frequent laboratory evaluation of electrolyte balance is done. PN is initiated after the initial postoperative stabilization and is advanced gradually until the child's nutritional requirements are met (see Chapter 17). Meticulous care of the central venous access device, the child's lifeline, is essential to minimize the potential for catheter-related bloodstream infections. Baseline PN laboratory values, including liver and renal function tests, calcium, magnesium, phosphorus, total protein, and albumin, are done at the time PN is initiated and on a regular basis throughout the course of therapy.

When the child's GI function returns postoperatively, enteral feedings are started at low volumes by continuous

drip through an NG tube, for the short term, or gastrostomy tube to promote nutritional tolerance. The primary goal of enteral nutrition during the immediate postoperative period is to stimulate the intestine's adaptive response. Elemental or casein hydrolysate formulas are frequently used, although in some cases breast milk is given, if available. Provide maternal support to establish and maintain a breast milk supply while the infant is NPO or unable to feed by mouth. Small-volume oral feedings and oral stimulation through a pacifier are established as early as possible to prevent oral feeding aversion.

Assess the infant's tolerance of PN and enteral feedings by careful, ongoing evaluation of weight gain, fluid and electrolyte balance, and stool output. Evaluate stools for malabsorption by testing for occult blood, pH, and reducing substances. Replace excess fluid losses with IV electrolyte solutions. Advance enteral feedings slowly and wean the child from PN proportionally as tolerance to enteral feeding progresses.

Bowel tapering and lengthening procedures for long-term functional improvement is considered when the remaining bowel segment is impaired. During intestinal adaptation, the remaining bowel may become dilated with subsequent dysmotility from attempts to increase the surface area. The Bianchi procedure is a procedure during which the dilated bowel is resected longitudinally and anastomosed end to end from the divided bowel. The end result is a bowel segment that is half the former diameter and twice the length. A newer procedure—serial transverse enteroplasty—is performed by stapling the bowel segment in a “Z” or zig-zag pattern, which effectively increases the absorptive surface area while also tapering the bowel. The benefit of this procedure reduces the risk of an anastomotic leak because the bowel lumen is not disrupted (Harris, 2007).

Community Care

Infants and children transitioned to home require coordinated services to provide optimal growth and development, and to direct successful home care. Home health nurses play a pivotal role to assist parents in applying principles of safety appropriate to the infant's or child's developmental level as individual milestones in growth and development occur. When the infant or child is medically stable, discharge to home on PN and enteral nutrition can be considered. Teach the parents to become expert in PN administration and central venous access care. Continually reinforce infection prevention techniques because catheter-related bloodstream infections are a common, but preventable, complication. Provide instruction on the home enteral program, gastrostomy tube care, skin care, and oral stimulation. An occupational therapist monitors and follows the progress of oral-motor skills.

The infant's complex medical needs must be balanced by opportunities for normal growth and development. Social services and home care nursing provide ongoing support. Evaluation of the family's and child's coping styles and functioning is ongoing and necessary, because the duration of complex home therapy is often unpredictable.

Celiac Disease (CD)

Celiac disease, also known as *celiac sprue* or *gluten enteropathy or intolerance*, is a malabsorptive disorder caused by a lifelong intolerance to dietary gluten. The incidence of celiac disease varies greatly geographically. In the United States, celiac disease was thought to be relatively rare when the presentation relied on the classic malabsorptive symptoms of diarrhea and growth failure. Recent reports have confirmed that it is more common than once believed, with an estimated prevalence in the United States of approximately 1 in 100 children (Tully, 2008). The prevalence of celiac disease is higher among children with diabetes mellitus type 1, Down syndrome, Turner's syndrome, and autoimmune thyroiditis, and among children with a first-degree relative diagnosed with celiac disease (Barker & Liu, 2008). The prognosis for the child with celiac disease is good with the institution of a life-long gluten-free diet. Symptoms typically improve within the first week of starting the diet, and mucosal damage resolves within 6 months.

Pathophysiology

The child with celiac disease demonstrates villous atrophy of the proximal small intestine. The mucosal layer of the small intestine appears “flat” instead of having the normal fingerlike projections of healthy villi. Lack of functional villi results in impaired digestion and absorption of nutrients. The damage to the intestinal mucosa is believed to be mediated by immunologic mechanisms, with mucosal injury arising from an adverse immunologic reaction to gliadin, a polypeptide protein fraction of gluten. Injury to the mucosa of the small intestine and malabsorption is manifested after gluten from wheat, oats, barley, or rye is introduced into the diet. Symptoms resolve when the child is placed on a gluten-free diet.

Assessment

The workup of the child with suspected celiac disease includes an initial history and physical examination that contains a detailed nutritional assessment to evaluate the child's pattern of growth and diet history, and to look for signs and symptoms of malabsorption and nutritional deficiencies. Diagnostic tests are also performed.

The clinical presentation of celiac disease may vary, depending on the child's age and the degree of injury to the intestinal mucosa. Assess the child's general appearance and color, along with growth parameters. Classically, a young child, after demonstrating normal growth during the first months of life, typically presents between 6 and 24 months of age, after gluten products are introduced into the diet, with a history of FTT. Chronic diarrhea, with foul-smelling, bulky, greasy stools, is typical, although in some cases constipation is present and is accompanied by dilation of the colon and rectal prolapse. Abdominal distention, pain, vomiting, muscle wasting, and hypotonia are common. Anorexia, irritability, and

lassitude are also common. In severe cases, overt signs of nutritional deficiencies may be present on physical examination. In adolescence, celiac disease may present as growth retardation with delayed puberty or menses, or short stature. Anemia is frequently present.

Assessment beyond the GI system also provides indicators of celiac disease. Assess the skin, particularly the trunk and the interior aspects of the elbows and knees, for an intensely itchy, vesicular rash (dermatitis herpetiformis). Inspect the oral cavity for the presence of aphthous ulcers and for dental enamel irregularities. Question the child and family about these extraintestinal manifestations in the history, including neurologic complaints. Evaluation for osteomalacia and osteoporosis is recommended. Iron deficiency anemia unresponsive to iron therapy is the most common non-GI manifestation.

Diagnostic Tests

Laboratory tests evaluate for malabsorption and nutritional deficiencies. Blood cell counts and serum iron, protein, mineral, and vitamin levels may all be decreased in chronic malabsorption, and total IgA levels are measured to rule out selective IgA deficiency (Tully, 2008). Serum levels of antiendomysial antibodies, antitissue transglutaminase antibody are recommended in the workup and are indicated for those at increased risk for celiac disease (Hill et al., 2005). However if the selective total IgA level is deficient, then the antitissue transglutaminase antibody and antiendomysial levels are unreliable. Testing may also be done to assess lactose tolerance and to detect malabsorption of dietary fat.

If suspicion of celiac disease is high after initial screening and from the results of serologic tests, a referral to a pediatric gastroenterologist is indicated. An upper GI endoscopy with small bowel biopsy from multiple sites is recommended while the child is receiving a typical oral intake of gluten. To conclusively make the diagnosis of celiac disease, multiple biopsy specimens of the small intestine must demonstrate the characteristic histiologic appearance of celiac disease, and the child must demonstrate a clinical response to a gluten-free diet. Reevaluation by small bowel biopsy within 4 to 6 months of initiating a gluten-free diet is no longer recommended; however, this may be indicated for those individuals who have an unsatisfactory clinical response. Capsule endoscopy may become a tool to evaluate mucosal healing and to screen for intestinal complications (Shamir & Eliakim, 2008).

Testing is available for genetic markers to identify a high- or low-risk propensity for developing celiac disease. The presence of *HLA-DQ2* or *HLA-DQ8* markers indicates the potential for disease development. Not all individuals who have the markers will develop the disease (Tully, 2008).

Nursing Diagnosis and Outcomes

In addition to those presented in Nursing Plan of Care 18–1, the following nursing diagnosis and outcomes may apply to the family of a child with celiac disease:

Ineffective family therapeutic regimen management related to lifelong maintenance of dietary restrictions

Outcomes: Child will demonstrate avoidance of products that contain gluten.

Child remain free of injury to the intestinal mucosa.

Child and family will list palatable alternatives to gluten products.

Child and family will confirm receipt of information and resources on how to identify gluten-containing products.

Child and family will verify knowledge of how to connect with a support group to assist with effective coping and management.

Interdisciplinary Interventions

The goal of therapy is to resolve the symptoms and minimize the complications using the best known strategies. Initiating the gluten-free diet as early as possible and adhering to it for life are essential to symptom management. The main offending proteins are wheat, barley, and rye. In the past, oats were also identified as causing intestinal damage. More recently, pure oats have been determined to be safe, although concerns regarding wheat contamination during harvest and milling of oats renders their safety questionable, and avoidance is still recommended. See and Murphy (2006) summarize the management approach using CELIAC as an acronym:

Consultation with a skilled dietitian

Education about CD

Lifelong adherence to a gluten-free diet

Identification and treatment of nutrition deficiencies

Access to a support group

Continuous long-term follow-up

Education regarding the diet is an essential part of the treatment plan and is a collaborative endeavor that includes the physician, dietitian, nurse, patient, family, and community members. An experienced dietitian who is knowledgeable about gluten-free diets is essential to the child's and parents' education and understanding. The teaching plan emphasizes information about the following aspects of care: the importance of adhering to the diet, sources of gluten (both food and nonfood), alternatives to gluten foods, places to obtain gluten-free products, label reading and shopping, managing eating away from home (whether at school, with friends, or in restaurants), support groups, and follow-up.

Gluten, in the form of malt, modified food starches, or dextrins, is used as a stabilizer or preservative in many processed foods and nonfood products. The Food Allergen Labeling and Consumer Protection Act of 2004 helped to identify ingredients in processed foods and make them safer for people on restricted diets. This law requires that peanuts, tree nuts, soy, fish, shellfish, milk, eggs, and wheat be listed on all food labels. The Food and Drug Administration has also defined and permitted the use of "GF" (gluten free) on labels (See & Murphy, 2006).

COMMUNITY CARE 18-1

Maintaining a Gluten-Free Diet

- All forms of wheat, rye, barley, and usually oats (some people can tolerate) should be omitted.
- Other foods are permitted as desired or as specified by the physician.
- *Caution:* Always read labels on commercially prepared foods. When in doubt, contact the producer.

Foods	Allowed	Not Allowed
Beverages	Milks Fruit juices Carbonated beverages Cocoa (read label to check that no wheat flour has been added) Coffee (ground, read label on instant) Tea	Malted milk Ovaltine Beer
Bread/cereal	Breads made from rice, corn, soybean, potato, tapioca, sago, or gluten-free wheat flour Dry cereals made only with rice or corn; cornmeal, hominy	Breads, rolls, crackers, cakes, cookies, cereals, noodles, spaghetti, and so forth, made from wheat, rye, wheat germ, barley, bran, oats
Fruit	As desired	
Meat/fish/fowl/eggs/cheese/nuts	As desired, plain Peanut butter	None with breading, cream sauce, thickened gravy Cold cuts (unless labeled “all meat”) None with cream sauce or breading Commercial salad dressings (read label)
Vegetables	As desired	
Fats	Butter, margarine, oil, pure mayonnaise Salad dressing thickened with allowed flours	
Condiments/sweets	Salt, pure spices Sugar, honey, molasses, syrup, jam, jelly, candy (read label) Gelatin, homemade ice cream, rice pudding, pudding thickened with allowed flours	Some candies are dusted with flour to prevent sticking, or made with flour Ice cream, sauce, and gravy mixes may contain wheat flour without listing on label Soy sauce

Provide ongoing education to reinforce that damage may occur, despite a lack of overt symptoms, with nonadherence to the diet. Refer the family to community resources for gluten-free foods and to peer support organizations such as the Celiac Sprue Association (see [thePoint](#) for information on organizations).

In addition to a gluten-free diet, the child is monitored for vitamin deficiencies such as calcium, iron, zinc, magnesium, and fat-soluble vitamins. Supplements are provided as indicated. It is important to ensure that all prescription and over-the-counter medications are gluten free.

Community Care

Ongoing monitoring is necessary to evaluate the child's response to therapy. Failure to respond to the gluten-free diet or exacerbation of symptoms may be the result of nonadherence. Developmental factors in younger children and social pressure on older children and adolescents may make adhering to the diet difficult (Community Care 18-1). Because adherence is so difficult, finding developmentally sensitive ways to include

children in all dietary counseling is important, to increase their sense of involvement and responsibility in the treatment plan. The child and parents must understand the importance of the lifelong diet and the ramifications of nonadherence.

KidKare ■ ■ Remind children and parents that wheat free does not always equate with gluten free.

Follow-up is necessary to determine whether goals are achieved and to reinforce the plan of care. Encourage parents to work with school food service personnel to identify gluten-free foods that the child can enjoy with peers. Parents can also contact those adults who host “play dates” or serve food at school parties about the need for gluten-free foods, and can send gluten-free snacks and treats with the child. Caution parents about well-intended people who may offer the child gluten-containing food because they do not understand the importance of medical diets. Encourage parents to reinforce

education and empower the child by having him or her make appropriate choices at the market and at restaurants, and by including the child in meal planning and preparation.

Lactose Intolerance

Lactose intolerance, also known as *primary lactase deficiency*, is the most common cause of carbohydrate malabsorption. Symptoms may begin in early childhood, may be subtle, and may progress over many years. The incidence of primary lactase deficiency varies greatly by ethnic group. Up to 80% of African American and Ashkenazi Jewish adults, and approximately 50% to 80% of Hispanics experience primary lactase deficiency. It approaches almost 100% in Asian and American Indian adults (Heyman, 2006), whereas only about 2% of northern Europeans experience this condition, despite having a diet rich in dairy products.

WORLDVIEW: In parts of the world such as Asia and Africa, where primary lactase deficiency is very common, milk products are not a large part of the usual adult diet, so symptoms of lactose intolerance are relatively rare.

Pathophysiology

Lactose is the primary carbohydrate found solely in mammalian milk. Lactase, an enzyme located on the brush border near the tip of the intestinal villi, breaks down lactose so that its component parts can be absorbed. When lactase activity is inadequate, lactose is malabsorbed. An increased osmotic load to the gut is generated where fluids and electrolytes are drawn into the intestinal lumen, resulting in loose stools. The likelihood of developing symptoms depends on the amount of residual lactase activity, the amount of lactose ingested, and the composition of the meal. Premature infants have substantially lower levels of lactase activity until at least 34 weeks' gestation. White children may not demonstrate symptoms of primary lactase intolerance until ages 4 to 5 years of age whereas 20% of Hispanic, Asian, and African American children may show some relative signs of deficiency (Heyman, 2006). GI disease can adversely affect lactase activity. Acute infectious gastroenteritis, such as that caused by rotavirus, can cause partial villous atrophy, resulting in a transient lactase deficiency. Individuals with disease characterized by inflammation of the GI tract, such as Crohn's disease, ulcerative colitis, or celiac disease may also experience secondary lactase deficiency. At-risk infants, younger than 3 months old, who develop gastroenteritis and suffer from subsequent lactase deficiency may experience a complicated recovery process.

Primary lactase deficiency results from the normal physiologic decline in lactase activity that usually begins during childhood at various ages and across different racial groups. Secondary lactase deficiency results from small bowel mucosal injury resulting from insults from infection (e.g., *Giardia*, chemotherapy, or bacterial over-

growth). The intestinal disease or inflammation can cause transient lactose intolerance. Developmental lactase deficiency is defined as relative lactase deficiency seen in infants younger than 34 weeks' gestation. True congenital lactase deficiency, in which symptoms are present shortly after birth, is extremely rare.

Assessment

A thorough history is the initial step in evaluating the child with suspected lactose intolerance, to correlate the relationship of lactose ingestion to clinical symptoms. A detailed diet history may not offer accurate information because of the relative variance of lactose consumed and the degree of lactase deficiency. Primary lactose intolerance is manifested by one of the following symptoms: abdominal pain, bloating, diarrhea, nausea, and flatulence (Heyman, 2006). In some cases, complaints of recurrent abdominal pain may be the only presenting symptom. Those with low lactase activity may be able to tolerate some lactose intake, particularly when it is part of a meal.

The most reliable diagnostic tool in establishing the diagnosis of lactose intolerance is the hydrogen breath test. An increase in breath hydrogen levels after ingestion of a load of lactose indicates lactose malabsorption. When secondary lactase deficiency is suspected, additional studies are performed related to the differential diagnosis, such as stool specimens and serology to rule out an infectious process and celiac disease, respectively (Heyman, 2006).

Interdisciplinary Interventions

Lactose intolerance is treated by reducing or eliminating lactose-containing foods in the diet. The amount of lactose that can be tolerated is highly variable. Dietary counseling focuses on helping children and parents identify both obvious and hidden sources of lactose in processed foods. Milk products treated with a microbially derived lactase may be used. Lactase enzymes are also available in tablets or drops, which may be ingested with lactose-containing foods to improve tolerance. Many children can tolerate small amounts of lactose such as yogurt, hard cheeses, and ice cream without discomfort.

Dietary counseling also includes ensuring that daily calcium and vitamin D requirements are adequately met through other sources, particularly when a strict diet is recommended. The nurse, in collaboration with the dietitian, makes sure that counseling is developmentally and culturally sensitive, to enhance adherence.

HEPATIC DISORDERS

Hepatic disorders that alter GI function include biliary atresia, cirrhosis, and end-stage liver disease.

Biliary Atresia

Biliary atresia is characterized by obstruction of bile flow out of the liver caused by absence of, or progressive

sclerosis of, the extrahepatic bile ducts. Biliary atresia is currently the most common indication for liver transplant in children. It occurs in 1 of 14,000 births in the United States, an incidence that results in 250 to 400 new diagnoses annually (Stringer, 2008). The process begins during the prenatal period and is slightly more predominant in females than males.

If recognized and treated early, biliary atresia carries a good prognosis. If not treated, the child will succumb to end-stage liver disease by age 12 to 24 months. Advances in the surgical management of biliary atresia and liver transplantation have greatly improved the outlook for the child with biliary atresia.

Pathophysiology

Biliary atresia is postulated to stem from five possible causes: (1) a defect in the development of the biliary tract, (2) a defects in the prenatal circulation, (3) viral infection or toxin exposure, (4) genetic predisposition, or (5) inflammatory or immunologic dysregulation (Bezerra, 2006). A proposed working model provides insight into the disease mechanism and progression. The model divides the causes of biliary atresia into two types: those that are toxic or environmental and those that act directly on the host, including defects in fetal or prenatal circulation, immunologic dysregulation, and defects in morphogenesis (Campbell & Bezerra, 2004). It proposes that biliary atresia is initiated by an insult that leads to an inflammatory response. In a normal host, the tissue is repaired, with resumption of physiologic homeostasis, and the host becomes disease free. In genetically susceptible hosts, progression of injury to the biliary tract results in biliary atresia. Approximately 10% to 20% of infants with biliary atresia have associated malformations (situs inversus, polysplenia, congenital heart defects, and absent inferior vena cava [splenic malformation syndrome]) (Kelly & Davenport, 2007) that suggest a defect during early embryologic development.

The child with biliary atresia experiences chronic obstruction of bile flow that results in progressive damage to the liver. Cholestasis leads to edema and inflammation of the portal tracts of the liver, destruction of the portal bile ducts by bile plugs, secondary proliferation of intralobular bile ducts, and inflammation of the parenchyma of the liver. Progressive fibrosis and, eventually, cirrhosis of the liver tissue result in end-stage liver disease (described later in this chapter).

Assessment

Infants with biliary atresia typically present with jaundice between 3 and 8 weeks of age. The jaundice is persistent and progressive. Stools are acholic (pale, clay colored), and the urine is usually dark. The abdomen is usually enlarged early during the course because of hepatomegaly. On physical examination, the liver feels large and firm. Splenomegaly may develop after the first 6 weeks. Infants with biliary atresia often thrive and appear well during the first month of life, but then demonstrate progressive malnutrition and growth failure as the disease

progresses. As liver function deteriorates, the child demonstrates the manifestations of end-stage liver disease, including **ascites** (accumulation of large amounts of serous fluid in the peritoneal cavity), splenomegaly, portal hypertension, and decrease in liver size as fibrosis progresses.

Diagnostic Tests

Laboratory evaluation is used to rule out causes of jaundice that are unrelated to the biliary tract and to establish the degree of liver damage sustained (Chart 18–5). Imaging studies are used to visualize the architecture and function of the biliary tract. Liver biopsy and cholangiography may be done percutaneously or intraoperatively as a means to definitively establish the diagnosis. A hepatoinodiacetic acid scan is an imaging study during which an IV-administered radioactive material is taken up by the liver and normally excreted by the biliary system into the intestine, and eventually excreted in the stool. If bile flow is undetected, a 24-hour follow-up scan is done. When there is bile obstruction, as in the case of biliary atresia, excretion of bile is not detectable. Efforts are underway to determine a sensitive screening method for early detection (Kelly & Davenport, 2007).

CHART 18–5 DIAGNOSTIC EVALUATION OF THE CHILD WITH LIVER DYSFUNCTION

Laboratory Evaluation

Alanine aminotransferase, aspartate aminotransferase
Alkaline phosphatase
Bilirubin, total/direct
Hepatitis A, B, C serologies
“TORCH” titers
HIV screen
Alpha 1-antitrypsin
Metabolic screen
CBC
Prothrombin time, partial thromboplastin time
Sweat chloride

Radiographic Studies

Abdominal ultrasound
Hepatoinodiacetic acid scan
Cholangiogram (intraoperative)
Magnetic resonance cholangiopancreatography

Liver Biopsy

Percutaneous or intraoperative

Nursing Diagnoses and Outcomes

In addition to those presented in Nursing Plan of Care 18–1, the following nursing diagnoses and outcomes may apply to the child with biliary atresia:

Risk for infection related to impaired liver function and poor nutritional status

Outcome:

Child will remain free of acquired infection.

Risk for impaired skin integrity related to pruritus secondary to liver dysfunction

Outcomes:

Child will exhibit intact skin.

Child will verbalize a reduction in complaints of pruritus.

Interdisciplinary Interventions

Because jaundice and liver failure have many possible causes (see the section on cirrhosis), a comprehensive evaluation is needed to establish the diagnosis. Care during the diagnostic period focuses on supporting the child's physiologic and psychosocial needs, as well as on meeting the parent's information needs throughout the many diagnostic procedures.

Surgical Interventions

Hepatic portoenterostomy, also known as the *Kasai procedure*, is the first-line operative intervention. Historically, portoenterostomy has been done before 2 months of age for optimal results; however, surgery may be of benefit beyond the recognized 60-day parameter to “bridge” the infant until transplant is arranged. Infants diagnosed later are referred directly for liver transplant. Numerous modifications have been made to the Kasai procedure, but the principle remains the same: a conduit is made to bypass the fibrotic extrahepatic biliary tree and reestablish bile drainage. Anastomosis of a jejunal bowel segment to the transected surface of the porta hepatis creates a “roux-en-Y” structure that provides a pathway for bile drainage. Postoperative goals include stimulating bile flow and providing nutritional therapy to promote growth and development, and to prevent complications, such as ascending cholangitis.

Postoperative care is similar to other surgical conditions of the abdomen. Fluid management, IV antibiotics, abdominal decompression via NG tube, and pain management are central to the infant's recovery. Monitor the NG output and ensure that the system is effectively functioning. The NG tube may require irrigation to keep it patent. Management also includes administering agents such as phenobarbital or ursodeoxycholic acid to stimulate secretion of bile. Corticosteroids are administered in many centers for their well recognized anti-inflammatory effects.

Nutritional Interventions

Aggressive nutritional support is critical to postoperative and long-term management. The infant is at high risk for FTT and malnutrition because of malabsorption of dietary fat and fat-soluble vitamins caused by decreased

intraluminal concentrations of bile acids. Infant formulas are given that provide a high percentage of fats as medium chain triglycerides and therefore are readily absorbed (e.g., Portagen, Pregestimil). NG feedings or IV fat emulsions may also be used to ensure adequate caloric intake. PN may be administered if the infant is not showing progress toward meeting nutritional goals. Supplements of fat-soluble vitamins A, D, E, and K are given in their water-soluble forms. Collaboration between the dietitian, nurse, physician, and family is essential in ongoing monitoring of nutrition, liver function, and other parameters.

Interventions to Prevent or Manage Complications

Bacterial ascending cholangitis is a frequent complication after hepatic portoenterostomy, with an incidence of 30% to 50%, most commonly during the first year after surgery (Davenport, 2005). Bacterial organisms ascending from the intestinal tract are frequently implicated along with bile stasis. Prophylactic antibiotic therapy with trimethoprim-sulfamethoxazole is given as long-term therapy to minimize these episodes. Fever, increased jaundice, and acholic stools are the overt clinical signs of ascending cholangitis. If ascending cholangitis occurs, treatment is with broad-spectrum IV antibiotics. Teach parents to recognize the signs and symptoms of bacterial ascending cholangitis to ensure that their child receives prompt medical attention. Instruct parents to notify their physician if they observe fever, decreased appetite, or increased jaundice (evidenced by skin color, color of sclera, and return of pale, acholic stools).

Another complication is portal hypertension from impaired blood flow. This complication progresses to hypersplenism, ascites, and bleeding from esophageal varices, which can be life threatening. Variceal bleeding is treated by sclerotherapy or, in older children, with variceal banding (Davenport, 2005).

Pruritus is a bothersome result of cholestasis. Rifampin has been found to alter bile acid metabolism and reduce systemic and intrahepatic levels of bile acid levels, thus lending relief from cholestatic pruritus. This medication must be monitored carefully during long-term use because of the potential for side effects. Inform parents that this medication turns the urine orange. Ensure that the child's fingernails are clipped, to avoid damaged skin integrity (see Chapter 25 for other appropriate nursing interventions). These children may also experience altered sleep patterns, because the pruritus is intense. Discuss methods that may help parents cope, such as alternating times (or nights) that they get up to tend to the child, sleeping when the child sleeps, or having family and friends sleep over to provide respite.

Community Care

The family of the child with biliary atresia faces multiple psychosocial stressors resulting from the chronic and often degenerative nature of the disease. Complicated medical care in the home, multiple acute hospitalizations,

and, for many, the prospect of liver transplant may present a source of ongoing anxiety, and may strain family and personal relationships, work performance, and finances. The family's coping can be enhanced by ongoing involvement with a social worker or other mental health professional, and by referral to peer support organizations.

Cirrhosis and End-Stage Liver Disease

Cirrhosis is defined by the World Health Organization as a diffuse liver process characterized by fibrosis and the conversion of normal liver tissue into structurally abnormal nodules. The end result of most forms of liver disease, cirrhosis has many possible causes (Table 18–8). The precise incidence of cirrhosis in children is difficult to ascertain.

Currently, the national increase in childhood obesity has led to an increase in the condition of nonalcoholic fatty liver disease. It is defined as a chronic liver disease with excessive accumulation of hepatic fat representing a spectrum of liver disease. The manifestations may range from steatosis (fat accumulation in the hepatocyte without inflammation) to steatohepatitis. Nonalcoholic steatohepatitis marks a more progressive disease that manifests also with fat accumulation along with inflammation and fibrosis. Cirrhosis can be a long-term complication. There is some controversy regarding whether the origin of nonalcoholic fatty liver disease is the first step toward nonalcoholic steatohepatitis or whether they exist as two separate conditions (Lerret & Skeleton, 2008).

TABLE 18–8

Diseases Leading to Cirrhosis

Etiology	Disease
Infectious	Viral hepatitis Herpesvirus
Metabolic disorders	Alpha 1-antitrypsin deficiency Cystic fibrosis Glycogen storage disease Hemochromatosis Wilson's disease
Biliary malformations	Biliary atresia Alagille syndrome Choledochal cyst
Toxic exposure	Acetaminophen Isoniazid Natural toxins (mushrooms)
Vascular disease	Budd-Chiari syndrome Congestive heart failure Veno-occlusive liver disease
Other	Parenteral nutrition liver disease Neonatal hepatitis Primary sclerosing cholangitis

The long-term outlook for the child with cirrhosis varies, depending on the nature and severity of the disease. Although the child with compensated cirrhosis may experience very little impairment, the child with active cirrhosis or fulminant hepatic failure will require liver transplant to achieve long-term survival.

Pathophysiology

Cirrhosis and end-stage liver disease are the end result of the liver's response to injury. The mechanisms of injury may vary, but the liver's response follows a typical pattern. Injury to the hepatocyte leads to cell necrosis. Cell necrosis releases factors that lead to fibrous regeneration of connective tissue. Normal liver structures are disrupted by fibrosis and nodule formation, leading to compression and distortion of intrahepatic vascular structures. This distortion and compression, in turn, causes further ischemic and hypoxic injury to the hepatocytes.

In compensated cirrhosis, cirrhosis presents without biochemical or clinical evidence of impairment in liver function. In active cirrhosis, the signs and symptoms of cirrhosis are manifest and progressive. In fulminant hepatic failure, sudden impairment in liver function with acute massive necrosis leads to hepatic encephalopathy within 8 weeks of symptom onset.

Assessment

Clinical manifestations of cirrhosis and end-stage liver disease depend on the etiology of the injury to the liver and on how rapidly hepatic failure progresses. General manifestations of cirrhosis often mimic other systemic illnesses. FTT may be noted, along with anorexia and easy fatigability. Jaundice may be present but is not always evident. Nausea, vomiting, and abdominal pain and distention may occur. Children with compensated cirrhosis may have few findings on physical examination or laboratory evaluation. Children in fulminant hepatic failure demonstrate multiple alterations, both physically and biochemically.

On physical examination, with advanced disease, muscle wasting may be noted. The liver may be large and tender during the early stages of cirrhosis, but progresses to becoming small and shrunken as it becomes increasingly nodular. Hepatomegaly may be difficult to appreciate when obesity coexists. Marked enlargement of the spleen and abdominal ascites are noted when portal hypertension is present. Ascites may also be noted when hypoalbuminemia is present. Cyanosis and digital clubbing occur in the presence of chronic hypoxemia from pulmonary systemic collateral shunting. Easy bruising or overt signs of bleeding may be seen, related to clotting factor deficiencies and low platelets.

Diagnostic Tests

Laboratory evaluation is done to detect serologic evidence of causative factors. Evaluation of liver function tests, blood indices such as CBC with differential,

clotting parameters, and visceral protein status help to establish the degree to which liver function is impaired. These studies are abnormal with advanced disease. Radiographic and imaging studies detect any structural abnormalities within the liver and biliary duct system. Liver biopsy provides histologic evidence to confirm the diagnosis and the severity of the fibrosis or cirrhosis.

Interdisciplinary Interventions

The goal of the initial diagnostic evaluation of the child with suspected cirrhosis is to establish the underlying cause of liver disease and to determine the degree of injury to the liver. Similar to the management of the child undergoing evaluation for suspected biliary atresia, the goal during the diagnostic phase is to support the child's physiologic and psychosocial needs and to meet the parent's information needs throughout the many diagnostic procedures.

Care of the child with cirrhosis is geared toward preventing and treating the complications associated with cirrhosis and end-stage liver disease. Therapy to treat the underlying cause of the liver disease is undertaken with the goal of eliminating or modifying whatever agent or mechanism is causing injury to the liver.

Supportive Interventions

Nutritional therapy is geared toward optimizing calorie and protein intake without exacerbating the underlying symptoms of cirrhosis. Ascites is managed with fluid and sodium restrictions; diuretics are commonly administered to enhance fluid excretion. However, diuretic therapy may cause fluid and electrolyte imbalances and can also impair renal function. Hypoalbuminemia can contribute to the accumulation of ascites and edema in the child with end-stage liver disease and may necessitate intermittent albumin transfusions. Portal hypertension can lead to the development of esophageal or gastric varices that are potential sites of upper GI bleeding. Coagulopathies related to abnormal prothrombin production and associated thrombocytopenia put the child at risk for GI bleeding, particularly when varices are present. Endoscopic sclerotherapy or a banding procedure may be used to treat such varices. Monitoring the child for changes in the level of consciousness is key to identifying the development of hepatic encephalopathy. Hepatic encephalopathy is treated by reducing and modifying protein intake and by administering neomycin or lactulose.

Surgical Interventions

Liver transplantation, offered at specific tertiary care centers, offers definitive treatment for the life-threatening complications of cirrhosis and end-stage liver disease. The liver transplant team manages the child through all phases of transplant, from evaluation to the ongoing follow-up care after surgery. The nurse coordinator on the team plays a vital role in coordinating the child's care, and providing child and family education during the preoperative and postoperative periods.

The Child With Altered Genitourinary Status

Case History

Remember B. J. and J. D. Johnson from Chapter 5? They are African American fraternal twins with one older sister. When they were born, J. D. was noted to have a glanular hypospadias without chordee. His brother was circumcised the day after he was born, but the healthcare provider recommended that J. D. not be circumcised

until his surgery to repair the hypospadias. The boys' father, James Johnson, has expressed concerns about the anomaly, the surgical repair of his son's penis, and about the delay of circumcision. Now J. D. is 9 months old and is scheduled to have hypospadias repair as an outpatient.

CHAPTER OBJECTIVES

1. Correlate the child's history, symptoms, and physical signs with manifestations of genitourinary abnormalities.
2. Identify various diagnostic procedures and their applications in genitourinary evaluation.
3. Describe the treatment options available to children with alterations in genitourinary status.
4. Describe common alterations in health patterns related to the genitourinary system.
5. Identify the teaching needs of the child experiencing challenges related to urinary elimination.
6. Describe the types of renal replacement therapies available for the child experiencing acute renal failure or chronic renal disease.
7. Choose nursing interventions that support the interdisciplinary plan of care for the child with a genitourinary disorder.

See [thePoint](#) for a list of Key Terms.

Pediatric urology and nephrology are complementary, but distinct, practice disciplines. Urology studies the structure and function of all parts of the urinary tract. Nephrology studies kidney function: how the kidneys regulate serum chemistries, maintain fluid balance, and produce hormones.

Urologic and nephrologic disorders in children run the gamut from such problems as hydrocele, proteinuria, and urinary tract infections (UTIs), to complex disorders including bladder exstrophy and renal failure. Recurrent UTIs, enuresis, and dysfunctional voiding are the most

common genitourinary conditions affecting children. Urologic and nephrologic sequelae often result from neurologic disorders such as myelomeningocele, neuromuscular dysfunction, or accompanying abdominal or sacral tumors, like rhabdomyosarcoma or sacral teratoma. Trauma to the genitourinary tract, or shock resulting from trauma, can cause renal or urologic problems. Malformations of the genitalia and urinary system structures can occur during fetal development. Although some of these malformations are life threatening, many can be surgically corrected when the child is young.

Medical advances have led to development of more types of diagnostic tools, improvement in surgical techniques, and refinements in the equipment used to treat genitourinary abnormalities. As a result, the lives of many children have been prolonged and improved by treatment of these disorders.

DEVELOPMENTAL AND BIOLOGIC VARIANCES

The genitourinary system begins to form during the first month of gestation with the rudimentary development of the kidneys. Between the 11th and 12th weeks of gestation, the fetal kidneys begin to produce urine. In utero, the placenta serves as a “pseudo-kidney,” helping the fetus regulate fluid and electrolyte balance. The kidneys do not function independently until after birth, and they do not reach maturity until age 2 years (Fig. 19–1). Bladder capacity increases with age (Jansson et al., 2005).

During fetal development, the failure of structures to form, or the abnormal or duplicate formation of structures results in congenital genitourinary abnormalities

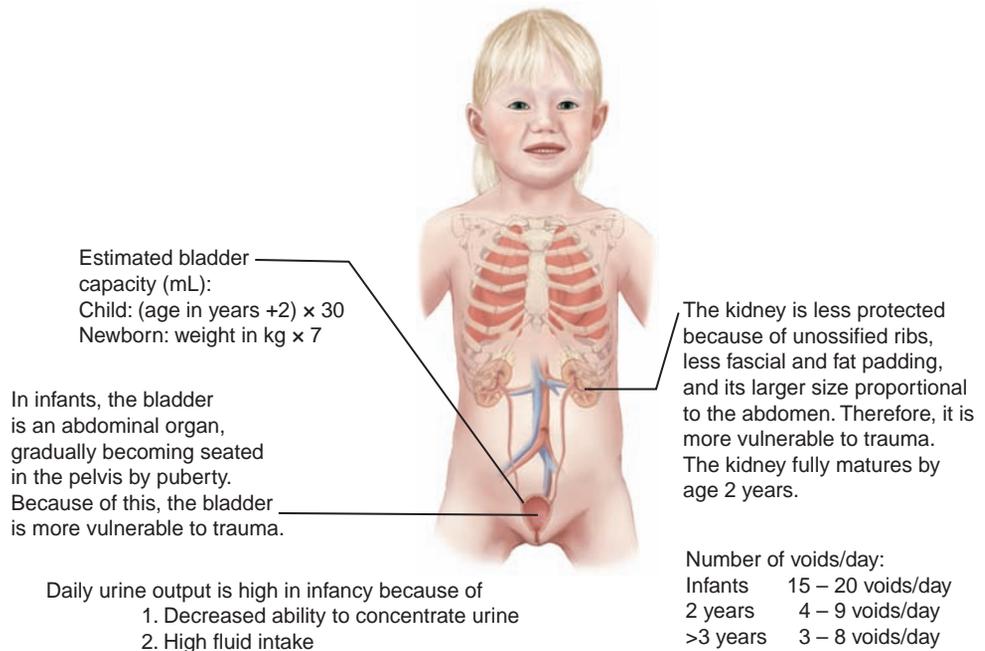

FIGURE 19–1. Developmental and biologic variances: genitourinary system.

Normal urinary output is 1 – 2mL/kg/hr

(see [thePoint](#) for Supplemental Information: Congenital Anomalies and Associated Genitourinary Defects). Obstruction of urine flow, as a result of misplaced vessels or abnormal innervation, can cause back-pressure of urine and damage to renal tissue before birth. This pressure may result in **hydronephrosis**, a condition in which urine backs up into the renal pelvis and calyces, which dilate and impair renal function.

In young children, renal blood flow is slow, the reabsorption of amino acids is limited, autoregulation is not fully developed, and concentration of urine is not as effective as in an adult. Thus, during periods of fluid loss (caused by diarrhea, fever, fluid restrictions, or reduced fluid intake), the child is at increased risk for dehydration.

Most children with genitourinary disorders are younger than 7 years old, because the most common disorders are usually congenital, with symptoms manifesting early in life. The most common noncongenital genitourinary condition is UTI. UTIs are common in girls until they reach school age, because they have short urethras; thereafter, UTIs decrease dramatically in incidence until either puberty or the commencement of sexual activity (Smyth, Moore, & Goldsmith, 2006).

Diseases in children younger than 5 years that result in end-stage renal disease (ESRD) are generally congenital (Warady & Chadha, 2007). Those leading to ESRD in older children are usually the result of other urologic abnormalities. At puberty, children with renal impairment often experience a decline in renal function, possibly related to the demand of increasing muscle mass exceeding the function of the remaining functional nephrons or related to sex hormones, or both (Warady & Chadha).

Although genitourinary abnormalities occur in males and females, certain disorders have a distinct gender-associated distribution. For example, UTIs and vesicoureteral reflux (VUR) are far more prevalent in females. Structural defects of the genitourinary organs, however, are found almost exclusively in males. These defects include hypospadias, epispadias, cryptorchidism, inguinal hernia, hydrocele, varicocele, and posterior urethral web or valve.

QUESTION: Which aspects of J. D.'s focused health history would be most important to obtain?

ASSESSMENT OF THE CHILD WITH ALTERED GENITOURINARY STATUS

Signs and symptoms of genitourinary and renal conditions, such as mild abdominal pain, low-grade fever, slow weight gain, and edema, are often subtle. Determining when symptoms began may be difficult, because clinical signs may have gone unnoted for some time before the child presents for evaluation.

Focused Health History

In the focused health history, collect data that may indicate a primary or secondary condition that affects genito-

urinary function (Focused Health History 19–1). Obtain a detailed history of the child's voiding pattern (Chart 19–1). A bowel history helps to evaluate constipation, which can be connected to incontinence and UTIs.

Note any recent colds or other respiratory or dermatologic infections. Streptococcal infections may lead to antigen–antibody reactions that can affect renal function as much as 2 to 3 weeks after the infection has resolved (see the sections in this chapter on acute glomerulonephritis and hemolytic–uremic syndrome [HUS]).

Gather a comprehensive family medical history; many genitourinary abnormalities in children are more likely to occur if other family members have had the same condition. For instance, enuresis, urinary tract anomalies, and renal calculi have familial distributions.

ANSWER: When obtaining J. D.'s health history, important aspects would include information about any familial issues related to genitourinary function, including a family history of anomalies. In addition, the information related to the mother's pregnancy and labor, and J. D.'s birth, as well as information about any other anomalies would be important.

Focused Physical Assessment

Although direct examination of the kidneys and urinary tract is difficult, inspecting, auscultating, percussing, and palpating parts of the genitourinary system and other body systems may provide information about renal function (Focused Physical Assessment 19–1). Direct special attention toward the abdomen, spine, and external genitalia, and to neuromuscular status of the lower extremities. Genitourinary conditions, renal disease, and renal failure have particularly far-reaching effects on different body systems because of the renal system's critical role in regulating fluid and electrolyte balance. Furthermore, abnormalities in other body systems are often associated with genitourinary disorders because gestational events that affect genitourinary development may also affect other developing systems. In addition, evaluate bowel habits, because urinary dysfunction is sometimes brought on by bowel dysfunction.

While obtaining the health history, formulate a general impression of the child's renal health. Observe for poor skin color, fatigability or lethargy, bony configurations, and abnormal speech patterns, all of which can occur in urinary conditions or renal failure. In particular, assess for signs of fluid overload and electrolyte imbalance, including changes in vital signs and the presence of edema and ascites. Electrolyte imbalance can lead to skeletal and cardiac manifestations, such as fractures and murmurs. Chapter 17 presents more information on fluid and electrolyte imbalances, and their effects on all body systems.

On physical examination, the child's abdomen should appear flat when the child is lying supine. On percussion, dullness or flatness should be heard along the left costal

FOCUSED HEALTH HISTORY 19–1

The Child With Altered Genitourinary Status*

Current history

Poor growth
 Weight gain/edema, most recent weight
 Malaise, fatigue
 Intermittent fevers, chronic infections and treatment of
 Seizures (may be a sign of electrolyte abnormalities)
 Changes in or abnormal voiding patterns
 - Frequency of urination, urgency
 - Presence of pain or burning during voiding
 - Quality of urinary stream, dribbling
 - Straining with voiding
 - Pre- and postvoid leaking
 - Holding maneuvers (in which the child sits on the heels in such a way to suppress the urge to void)
 - Color and odor of the urine
 - Presence of day or nighttime enuresis
 Discharge from urethra or genitals
 Hematuria, proteinuria, hypertension
 Changes in consistency and frequency of stools, chronic constipation or encopresis
 Enlargements, lumps, or masses in groin, abdomen, or scrotum
 Abdominal or flank pain (duration, intensity, precipitating factors, anything that improved or increased the symptoms)
 Current medications and recreational drugs (nonsteroidal anti-inflammatory drugs can be particularly nephrotoxic)
 Home remedies for current genitourinary/renal conditions and their success or failure
 Presence and treatment of any chronic genitourinary/renal disease or other conditions

Past medical history

Prenatal/Neonatal History

Maternal

Polyhydramnios or oligohydramnios
 Diabetes or hypertension
 Toxemia
 Alcohol ingestion or cocaine exposure
 Use of nephrotoxic drugs
 Abnormal antenatal ultrasounds (if present, what gestational age the alterations were noted)

Infant

Birth weight
 Gestational age
 Asphyxia
 Ear abnormalities
 Presence of a single umbilical artery (often associated with renal abnormalities)
 Abdominal mass
 Abnormal newborn screening test results
 Chromosome anomaly
 Malformations (spina bifida, cardiac, esophageal, rectal, pulmonary)

Previous Health Challenges

Bleeding disorders
 Streptococcal infections and treatment
 Varicella

(Continued)

FOCUSED HEALTH HISTORY 19–1

The Child With Altered Genitourinary Status* (Continued)

	Hospitalizations or surgeries, circumcision at birth
	Status of current immunizations, especially varicella
	Latex sensitivity
	If prior genitourinary or renal problem: information about the condition, any ongoing treatments, medications, or special appliances that the child is using as a result of the condition
Nutritional assessment	Types and quantity of fluid and food intake
	Sodium intake
	Dietary preferences or difficulties; episodes of thirst, anorexia, nausea, vomiting, craving for salty foods
Family medical history	Familial renal disease or uropathology
	Familial type 1 insulin-dependent diabetes
	Hypertension
	Hematuria, proteinuria
	Systemic lupus erythematosus/lupus nephritis
	Dialysis or renal transplantation may signify inheritable renal disorder
	Deafness (Alport's syndrome)
	Chronic UTIs
	Renal or urinary tract calculi
	Parental enuresis and age at resolution
	If any of these are present, presentation, evaluation, and treatment
Social and environmental history	Any recent life changes (e.g., in school, family, death, parental divorce or separation)
Growth and development	Normal growth trajectory, failure to thrive, short stature
	Age at which child achieved daytime and nighttime bowel and bladder control
	Delayed puberty, age of onset of menses
	Sleep habits (e.g., does child sleep deeply and not arouse to void)
	School performance, as age appropriate

*This history focuses on the genitourinary system. See Chapter 8 for a comprehensive format.

margin over the spleen and kidneys, and 1 to 3 cm below the right costal margin over the liver. Dullness heard above the symphysis pubis indicates a full bladder. Tympany should normally be heard throughout the rest of the abdomen.

It is difficult to palpate most genitourinary organs. The kidneys are rarely palpable, except in neonates. A distended bladder may be palpated above the symphysis pubis. Palpation that elicits complaints of abdominal tenderness is common in UTI.

Examine genitalia for structural anomalies, such as labial fusion in a female and hypospadias or epispadias in a male. In an uncircumcised male older than age 3, the foreskin of the penis is usually retractable without difficulty; narrowing of the preputial opening of the foreskin that prevents it from being retracted over the glans penis is called **phimosis**. Palpate the testes to ensure that they have descended. Chapter 8 presents a more detailed description of abdominal and genital assessment.

QUESTION: Would J. D. have had to undergo any diagnostic tests or procedures to confirm his condition?

Diagnostic Criteria for Evaluating Genitourinary Status

Various diagnostic procedures and laboratory tests are used to evaluate genitourinary function. Tests and Procedures 19–1 describes common diagnostic studies for evaluating the genitourinary system. Procedures can be invasive and frightening, particularly for the young child. Catheterization is especially feared because of the coinciding features of urologic function and sexual expression that shape the child's concept of the genital organs. Current teachings of "good touch/bad touch" sexual abuse programs further compound the child's apprehension.

CHART 19-1 A VOIDING PROFILE

1. How often does your child urinate? During the day? _____ During the night? _____
2. Is the urine stream Strong, Weak, Dribbling, Small? (circle applicable answers)
3. Does your child have difficulty initiating the urine stream? Yes No
4. Can your child tell when he or she needs to void during the day? Sometimes Always Never
What does your child do when he or she needs to void? Ignore the sensation Go to the bathroom Squat or cross legs to avoid going to the bathroom
5. Does your child experience pain with urination? Yes No
How old was your child when they were toilet trained (dry during the day)? _____ years _____ months
6. Does your child have any daytime wetting accidents? Yes No
If yes, how many a day? ____
How long has this been going on? ____ months
____ years
7. Does your child soak his or her underwear when they wet? Yes No
8. Have you tried any treatment? Yes No
9. Does your child leak urine (dribble) after going to the bathroom? Yes No
10. Does your child have dribbling caused by activities like coughing, sneezing, laughing, running, playing sports? Yes No
11. Does your child have damp underwear during the day? Yes No
12. Does your child wear protective pads for any wetting accidents? Yes No
13. Does your child wet the bed? Yes No
If yes, how many times a night does he or she wet the bed? _____
14. How long has your child wet the bed? _____
15. Has there ever been a time when your child was dry at night? Yes No
16. Have you ever tried treatment? Yes No
If yes, what treatment? _____
17. Has your child ever had a UTI? Yes No
If yes, what were the symptoms? _____
18. Has your child had unexplained fevers? Yes No
19. Does your child have frequent stomachaches? Yes No
20. How often does your child have a bowel movement? _____
21. What is the consistency of the bowel movements? Hard, round balls Soft and log shaped
22. How much fluid does your child drink during day? _____
23. What fluids does your child drink during the day? _____
24. How does your child bathe? Shower Bath

KidKare ■ Before the procedure, prepare the child and parents by describing the internal structures that will be examined. Helpful steps include giving demonstrations using anatomically correct dolls; showing pictures of or touring the radiology department; and describing the visual, auditory, and somatic experiences the child will encounter during the study or procedure. Be honest with the child and use age-appropriate information.

Teach the child coping skills (e.g., guided imagery, relaxation and deep breathing, use of music or distraction techniques) and reinforce use of these skills during the procedure.

Collecting Urine Specimens

Several methods are used to obtain urine samples. The choice of method is based on the reason for testing the urine and on the child's ability to void.

caREminder

Many children have difficulty voiding on command (Nursing Interventions 19-1). When a urine sample will be needed during an examination, remind the parent to offer fluids to the child on the trip to the office or clinic, or have the specimen collected at home, using the appropriate collection technique.

In toilet-trained children, clean-catch midstream urine samples are the easiest samples to obtain and are satisfactory for most routine urinalysis and culture and sensitivity studies. Obtaining a urine sample from a nontilet-trained child presents a major challenge. Methods to collect urine include using a urine collection bag, urethral catheterization, and suprapubic aspiration (Tradition or Science 19-1; see also **thePoint** for Procedures/Interventions: Urine Collection: Routine Voided; Urine Collection: Urinary Catheterization: Insertion and Removal; Urine Specimen Collection Methods).

Bacterial count criteria used to establish the diagnosis of UTI are determined by the method used to collect the sample (see Tradition or Science 19-2). Freshly voided samples are preferred for routine urine tests, and they are necessary for urine culture and sensitivity tests.

caREminder

If the sample cannot be sent to the laboratory within 30 minutes, refrigerate it to prevent false-positive results.

ANSWER: In most cases, hypospadias is diagnosed by physical examination. Further diagnostic testing would be warranted if J. D. was experiencing difficulty voiding or if additional anomalies of the genitourinary tract or other body systems were suspected.

FOCUSED PHYSICAL ASSESSMENT 19–1

The Child With Altered Genitourinary Status

Assessment Parameter	Alterations/Clinical Significance
General appearance	<p>Child may be listless because of electrolyte imbalance or anemia.</p> <p>Chronic kidney disease, UTI, or renal failure may cause poor growth.</p> <p>Poor skin turgor, dry mucosa, or recent weight loss may indicate dehydration.</p> <p>Sudden weight gain may indicate fluid excess.</p> <p>Child may have vague complaints or none, because the decrease in renal function progresses slowly.</p>
Integumentary system (skin, hair, nails)	<p>Pallor suggests anemia resulting from decreased erythropoietin levels.</p> <p>Dry, pruritic skin with petechiae can be caused by uremia.</p> <p>“Doughiness” can be caused by poor nutrition or fluid excess.</p> <p>Hypopigmented spots, seen in tuberous sclerosis, can be associated with polycystic kidney disease.</p> <p>Café-au-lait spots may indicate neurofibromatosis, which is associated with renal artery stenosis.</p> <p>Dysplasia of nails may be a sign of nail–patella syndrome, which is associated with nephrotic syndrome.</p> <p>Malar rash, photosensitivity, and discoid rash is associated with systemic lupus erythematosus, which may include lupus nephritis.</p> <p>Purpura is seen in Henoch-Schonlein purpura.</p>
Head and neck	<p>Microcephaly is a syndromal feature that can be associated with obstructive uropathy or chronic renal failure in infants.</p> <p>Potter’s facies can occur with renal agenesis and oligohydramnios.</p> <p>Periorbital edema is caused by fluid retention from nephritic syndrome or renal failure.</p> <p>Low-set ears or high-arched palate may be indicators of multisystem syndrome with associated urologic abnormalities.</p> <p>Short neck and low hairline is associated with Klippel-Feil syndrome, which may include renal adysplasia.</p> <p>Pale mucosa can indicate anemia.</p> <p>Circumoral cyanosis can indicate a heart defect with associated renal anomalies.</p> <p>Webbed neck occurs with Turner’s or Noonan syndromes; genetic conditions also associated with renal or gonadal malformations.</p>
Eyes	<p>Cataracts, Leisch nodules, and colobomata are associated with retinitis pigmentosa; renal disease may be associated.</p> <p>Splinter hemorrhages, cotton-wool patches are indicative of hypertension.</p>
Ears	<p>Structural abnormalities (e.g., preauricular pits) of the ears or deafness are associated with renal malformation.</p>
Face, nose, and oral cavity	<p>Caries and tooth discoloration are common in chronic renal disease.</p>
Thorax and lungs	<p>Rapid or deep breathing may be a sign of respiratory compensation for acidosis.</p> <p>Rales may indicate fluid excess.</p> <p>Widely spaced nipples are associated with Turner’s syndrome, which may include horseshoe kidneys.</p>
Cardiovascular system	<p>Rapid, irregular pulse may indicate fluid excess.</p> <p>Elevated blood pressure can occur with renal failure, fluid excess, or certain medications; alternately, improper cuff size may have been used to obtain measurement.</p> <p>Murmurs are associated with anemia as well as cardiac defects.</p> <p>A friction rub can indicate pericarditis caused by uremia, inadequate dialysis, or infected hemodialysis access (catheters, grafts, fistulas).</p>
Abdomen	<p>Fluid excess can lead to edema, ascites, and descent of the liver margin.</p> <p>A protuberant abdomen may suggest fluid retention, organomegaly, peritonitis, or ascites.</p> <p>Distended veins may indicate abdominal or vascular distention.</p>

Assessment Parameter	Alterations/Clinical Significance
Lymphatic system	<p>Flank masses may be unilateral or bilateral, and in children are usually of renal origin: multicystic kidney disease, hydronephrosis, autosomal recessive polycystic kidney disease, Wilm’s tumor.</p> <p>Slack abdominal muscles may indicate prune-belly syndrome.</p> <p>Fever and local swelling, redness, and discharge at exit sites for urinary drainage tubes and peritoneal dialysis catheters are signs of infection.</p> <p>Hydronephrotic kidneys or distended bladder may be palpable.</p> <p>Chronic constipation/encopresis correlates with UTI and voiding dysfunction.</p> <p>Lymphedema may be related to Turner’s syndrome, which may include horseshoe kidneys.</p>
External genitalia and breasts (includes anus)	<p>Unusual genital appearance may result from birth defects and other anomalies.</p> <p>Masses, lesions, inability to palpate testes on palpation of scrotal sac suggest testicular anomalies, undescended testicles.</p> <p>Tanner stage of puberty can be delayed in chronic kidney disease.</p> <p>Amenorrhea, anovulation, impotence, and sterility are common in postpubertal young people with chronic renal disease.</p>
Musculoskeletal system	<p>“Renal rickets” (changes and pathologic fractures of ribs and long bones of arms and legs) occurs with renal osteodystrophy in children; bones are weakened by changes in calcium and phosphorus metabolism with renal failure.</p> <p>Short stature associated with numerous conditions that involve kidney abnormalities.</p> <p>Postaxial polydactyly, absent or small patella seen in nail-patella syndrome, which may include nephrotic syndrome.</p> <p>Muscle wasting occurs in advanced chronic renal disease.</p> <p>Muscle weakness occurs in many renal conditions.</p>
Neurologic system	<p>Developmental delay may result from chronic condition and its treatment.</p> <p>Fatigability, muscle wasting, and lethargy can occur with renal failure.</p> <p>Level of consciousness may be decreased in renal failure.</p> <p>Temporary psychosis with hallucinations can result from very high levels of blood urea nitrogen.</p> <p>Gait can change as a result of fluid in abdomen for peritoneal dialysis.</p> <p>Sacral abnormalities such as deformed gluteal cleft, tuft of hair, vascular markings, a dimple, or lipomeningocele are associated with myelodysplasia, the most common cause of neuropathic bladder dysfunction in children.</p> <p>Fine/gross motor development delay may be associated with enuresis.</p>

TREATMENT MODALITIES

Treatment to maintain or restore genitourinary function is aimed at compensating for alterations in gravity flow or muscular contraction that impede normal urine flow and reestablishing the free flow of liquid waste (urine) from the body. When renal failure occurs, multifaceted treatment must be initiated to rid the body of toxins and perform the work of the nonfunctioning kidneys.

Urinary Diversion

Urine normally flows unimpeded from the kidneys through the ureters and collects in the bladder. At a time that is physiologically and socially appropriate, the sphincter relaxes to allow micturition by a bladder contraction (by the smooth muscle component of the bladder). Anomalies or conditions that restrict urine flow, such as ureteral strictures or kinking, massive vesicoureteral reflux (VUR), or spinal cord trauma, may require urologic management by urinary diversion. Diversion

techniques either incorporate the use of tubes or are tubeless. Urinary diversion is most often a temporary measure, although some functional disabilities require permanent diversion.

Drainage Tubes

Various drainage tubes are used to divert urine flow. Foley catheters, ureteral stents, and nephrostomy or ureterostomy tubes provide an exit for urine from the body either proximal to an obstruction or through a section that may be occluded after surgical manipulation. In some cases, a stent or catheter is also used to create hemostasis within incised urinary mucosa or to act as a splint after ureteral reconstruction.

Advantages of externalized urinary drainage tubes are their uncomplicated design, their multiple applications, and their easy removal. However, because of their drawbacks, such as increased risk for infection, mucous plugs, and urolithiasis, plus the potential for accidental dislodgment, intubated urinary diversion is used for short-term management.

Tests and Procedures 19–1 or Evaluating Genitourinary Status

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
<i>Blood Studies</i>			
Complete blood cell count (CBC), white blood cell count (WBC)	Determines number of white blood cells in blood	Normal Newborn: 9,000 to 30,000 cells/mm ³ 0 to 2 years: 6,000 to 17,000 cells/mm ³ >2 years: 5,000 to 10,000 cells/mm ³ Elevated in presence of infection or inflammation Decreased in lupus/viral illnesses	Deliver specimen to laboratory within 4 hours of drawing blood
Hemoglobin	Determines total concentration of hemoglobin in peripheral blood; tests for anemia	Newborn: 14 to 24 g/dL Infant: 10 to 15 g/dL Child: 11 to 16 g/dL Lower in presence of renal parenchymal disease, obstructive uropathy, chronic kidney disease	Shortened red cell life span and decreased erythropoiesis with renal disease
Hematocrit	Determines percentage of red blood cells to total volume of blood	Newborn: 44% to 64% Infant: 30% to 40% Child: 31% to 43% Lower in presence of renal parenchymal disease, obstructive uropathy, chronic kidney disease	
Clotting studies: Prothrombin time (PT) partial thromboplastin time (PTT) (INR)	Determines prothrombin and partial thromboplastin time, thus evaluating the extrinsic coagulation system	Prothrombin time: Newborn: 12 to 17 seconds Child: 11 to 13 seconds Partial thromboplastin time: Newborn: 25 to 45 seconds Child: 30 to 45 seconds Thrombin time: Newborn: 12 to 16 seconds Child: 7 to 12 seconds Prolonged in children experiencing renal complications Thrombocytopenia	If insufficient blood is added to a citrate-containing tube, a falsely elevated prothrombin time may result Do not obtain blood sample for test within 3 hours of a heparin dose
Serum chemistries (blood urea nitrogen [BUN] creatinine, electrolytes, glucose)	Evaluates fluid and electrolyte status in presence of acute renal failure or chronic renal disease	Elevated levels indicative of renal disease	Sodium can be decreased with polyuria or urinary concentrating defects
Cholesterol, triglycerides	Evaluates for hyperlipidemia	Elevated in children with acute renal failure or chronic renal disease and nephrotic syndrome	Child should fast 12 to 14 hours before sample is drawn
Erythrocyte sedimentation rate (ESR)	A nonspecific test to detect inflammatory or infectious disease	Newborn: 0 to 2 mm/hour Child: 0 to 20 mm/hour Elevated levels suggest inflammatory state	

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
C-reactive protein (CRP)	Nonspecific test to diagnose infection or inflammation	<0.8 mg/dL Elevated levels indicate presence of inflammatory process	
Antinuclear Antibody (ANA) C3	Evaluates abnormal levels in the complement system	High level of false-positive ANA levels Low C3 level indicative of postinfectious glomerulonephritis or systemic lupus erythematosus	
<i>Urinalysis</i>			
Specific gravity	Measures the concentration of particles in the urine to evaluate the concentrating and excretory ability of the kidneys	Newborn: 1.001 to 1.015 Child: 1.001 to 1.025 Low: diabetes insipidus, pyelonephritis, renal damage High: dehydration	To accurately determine specific gravity, use first morning void If not analyzed immediately, refrigerate the urine
pH	Indicates acid–base balance of patient	4.6 to 8.0 (average, 6.0) Increased in presence of bacteriuria	Urine becomes alkaline upon standing Foods may affect pH: citrus fruits, dairy products, vegetables cause alkaline urine; meat and fruits (e.g., cranberry) cause acidic urine
Blood*	Determines presence of red blood cells in urine	Normal: 0 to 2 red blood cells per high-powered field Elevated levels indicate possible UTI, calculus, trauma, urethral obstruction, renal parenchymal disease; in the presence of protein, is indicative of glomerulonephritis and requires immediate intervention.	When obtaining urine sample from adolescent females, question about presence of menstruation
Protein*	Indicates renal disease	Negative: <8 mg/dL Positive test indicates renal disease; in the presence of blood is indicative of glomerulonephritis and requires immediate intervention.	False-positive result occurs after strenuous activity or stress Obtain first morning void A 24-hour specimen is more accurate than a spot urine and is usually paired with a similarly collected urine creatinine to standardize the results Keep refrigerated
Glucose	Determines presence of sugar in urine	Presence of glucose may indicate diabetes mellitus, a potential cause for nocturnal enuresis Also associated with renal tubular damage	
Leukocyte esterase (LE)	Detects leukocyte esterase, an enzyme that breaks down white blood cells	Negative Positive dipstick testing indicates probable UTI	Obtain midstream clean-catch urine sample Test may not be accurate for children False-positive results are seen in urine mixed with vaginal secretions

(Continued)

Tests and Procedures 19–1 or Evaluating Genitourinary Status (Continued)

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
			False-negative results are seen in urine with high protein levels or increased ascorbic acid levels
Nitrites	Indicates conversion of nitrate to nitrite by bacteria	Negative Positive test may indicate bacteriuria	False-negative result occurs often with children Obtain midstream clean-catch sample from adolescent females
<i>Urine Microscopic Studies</i>			
White blood cells	Detects white blood cells in urine	Normal: 0 to 4 cells per high-powered field More than 5 cells indicates pyuria	Obtain midstream clean-catch urine from females
Red blood cells	Detects red blood cells in urine	Normal: 0 to 3 cells per high-powered field	
Casts	Detects “clumps” of cells; can be white blood cells, red blood cells, hyaline casts	Hyaline casts: 0 to 3 cells per low-powered field, normal; any other cast are abnormal Red blood cell casts need further investigation for acute glomerulonephritis	
Bacteria	Detects UTI	Normal: negative Positive: visible bacteria	Difficult to detect Obtain midstream clean-catch sample to avoid contamination
<i>Microbiologic Studies</i>			
Urine culture and sensitivity	Determines the presence of bacterial pathogens Determines the type of bacteria Determines how effectively various antibiotics will inhibit bacterial growth	Normal: no growth More than 100,000 cfu/mL are indicative of UTI Sensitivity reported by zone of inhibition or by degree of sensitivity/resistance per antibiotic	Obtain midstream clean-catch samples Young or nontilet-trained children may require suprapubic aspiration or catheterization If unable to process urine within 30 minutes, refrigerate sample Obtain sample before initiating antibiotic therapy
<i>24-Hour Urine Collection</i>			
Creatinine clearance	Assesses glomerular filtration rate from timed urine collection and blood sampling	Creatinine clearance values should be close to glomerular filtration rate values Increased levels indicate chronic kidney disease	Refrigerate urine collection as retrieved Attach to the collection bottle a sticker indicating the date and times urine collection started and stopped, and the child’s height and weight

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
<i>Radiographic Studies</i>			
Kidney, ureter, and bladder (KUB, or flat plate) radiograph	Screening study to check for urinary calculi and to assess location, size, and shape of urinary organs	Normal organ placement and size, no calculi, normal gas pattern Abnormal findings require further testing	Barium from other radiographic studies may interfere Older children may be asked to hold their breath for a part of the picture
Ultrasound (sonogram)	Use of reflected sound waves to evaluate kidney, bladder, ureters, and fetal urinary system	Useful initial study to evaluate urinary structures, abdominal masses, hydronephrosis, urinary calculi, cysts, and renal tumors Used during shock wave lithotripsy to focus on the urinary stone	No preparation No radiation No contrast material used
Intravenous pyelogram (IVP) or excretory urogram	Evaluates kidneys and internal drainage structures; renal function demonstrated by contrast material being filtered and excreted by kidney	Can diagnose multiple congenital anomalies, calculi, obstruction, tumors	Bowel preparation is required Barium in bowel interferes with study Contraindication is allergy to iodine or shellfish Increase fluids after study
Voiding cystourethrogram (VCUG)	Visualizes bladder and urethra, evaluates urine flow during bladder emptying, grades the severity of reflux	Normal: complete emptying, no reflux, smooth bladder, no urethral anomalies Vesicoureteral reflux, lower urinary tract trauma, tumors, pelvic masses, urethral obstruction, posterior urethral valves and strictures	Not to be performed in the presence of a UTI Requires catheterization
Renal scan (scintigraphy) Dimercaptosuccinic acid (DMSA) Diethylenetriamine pentaacetic acid (DTPA, ^{99m} C-DTPA) Mercaptoacetyltriglycine (MAG 3, ^{99m} Tc-MAG 3)	Injected radioisotope evaluates anatomy and function of renal parenchyma Defines the parenchymal tissue and outlines defects in the cortex, detects renal scarring Evaluates split renal function and renal blood flow; used to detect kidney obstruction when diuretic medication is included with the scan	Normal renal function, normal time to excrete dye Pyelonephritis, urinary obstruction, nonfunctioning kidney (which may not be visualized by an intravenous pyelogram), tumor, abscess, trauma	Do not schedule within 24 hours after intravenous pyelogram Minimal radiation exposure Child should be well hydrated Radioactive tracer is excreted within 24 hours Requires intravenous injection
Computed tomography (CT)	Visualizes horizontal or vertical cross-section of kidney to determine nature of tissue material Use of iodine contrast dye enhances the image	Renal trauma, tumor, cyst, hematoma, calculi, congenital anomalies	Patient must not move during procedure; child or infant is sedated CT with contrast requires intravenous injection Inquire about allergy to shellfish or iodine
Computed tomographic angiography	Depicts renal vessels, often used in evaluation of hypertension	Renovascular disease	

(Continued)

Tests and Procedures 19–1 or Evaluating Genitourinary Status (Continued)

Diagnostic Test or Procedure	Purpose	Findings and Indications	Healthcare Provider Considerations
Renal angiography	Evaluates the renal blood vessels	Renal vascular malformation, definitive or preoperative embolization of vascular tumors	Requires intravenous injection Patient must not move during procedure — child or infant is sedated Inquire about allergy to shellfish or iodine
Magnetic resonance imaging (MRI)	Characterizes and stages renal lesions	Acute pyelonephritis	Equipment may induce feelings of claustrophobia
<i>Additional Tests</i>			
Cystoscopy	Directly visualizes urethra and bladder, bladder trigone, ureteral orifices	Urethral strictures, urethral webs, posterior urethral valves, cystitis, ectopic or displaced ureteral orifice, calculi	Requires anesthesia Preoperative preparation Dysuria noted up to 24 hours, may be intense with initial void
Urodynamics	A series of tests evaluates bladder and urethral function and innervation Cystometrogram measures bladder capacity and pressure during the filling phase Urinary flow rate measures volume of urine voided in a specific time Urethral pressure profile measures urethral and sphincter competency Electromyography measures neurologic activity of sphincter Postvoid residual	Detrusor sphincter, dyssynergia, urethral obstruction, hyperreflexia, hyporeflexia, uninhibited bladder contractions, neurogenic bladder, congenital sphincter anomaly (e.g., bladder exstrophy)	Requires externally placed perineal electrodes Requires catheterization Requires cooperation of child, who is asked to void on command and to lie still
Percutaneous renal biopsy	Determines type of kidney disease or cause of renal failure and likelihood of recovery or disease progression	Abnormal cellular structure, inflammation, scarring, immunofluorescent staining, or electron microscopy	Sedation required Observe for signs of bleeding for 18 hours after biopsy

Nursing care for the child with tubed urinary diversion focuses on preventing infection, maintaining tube patency, avoiding dislodgment of the apparatus, and providing comfort measures. For a child with urinary drainage tubes, teach all aspects of home care to the parents (and child as appropriate), demonstrate, and observe their performance before the child is discharged. Review the signs and symptoms of complications, emergency procedures, and methods of telephone contact in case of emergency. Home care nursing visits, as needed, and telephone follow-up ensure consistent care and provide additional reassurance to the family.

Stents

An indwelling stent facilitates continuous flow of urine within the ureter, so one may be used after corrective ureteral procedures or as an adjunct to shock wave lithotripsy in treating large renal calculi. Children with internalized urinary diversion require no special care or activity restrictions, although a repeat cystoscopic procedure is necessary to remove the stent. When a double-J stent is used for short-term diversion (e.g., after removal of stones), a string is left protruding from the urethra (taped to the child) to allow the stent to be removed in the healthcare provider's office.

NURSING INTERVENTIONS 19–1

General Considerations for Urine Specimen Collection

Consideration	Intervention
Language used by the nurse may be misunderstood by the child.	Use the child's words (e.g., "pee-pee") to make a request.
Adolescent may be reluctant to have test completed because of concerns over body image, body functions, privacy, suspicion that specimen is requested for drug testing.	Inquire about concerns; try to elicit specific information.
Child may have difficulty complying with request.	Explain why test is needed.
	Provide potty chair or urine collector in toilet.
	Run water in sink to trigger urge to void.
	Offer child something to drink; most infants void shortly after feeding. Offer moderate amounts of fluid (too much fluid may dilute the specific gravity of the urine).
	Enlist the assistance of parents, which may increase the child's cooperation.
Disposable diapers with absorbent gel are difficult to aspirate from and yield inaccurate results.	See thePoint for Procedure: Urine Collection: Routine Voided

Stomal Diversion

Nonintubated diversion is accomplished by externalizing a urinary structure, allowing urine to drain through a stoma. This technique is the treatment of choice for long-term management of children with urologic mal-function secondary to neurologic compromise, trauma, or severe congenital outlet defects. Short-term tubeless urinary diversion is useful to quickly drain the hydro-nephrotic kidney and to stabilize renal function before definitive corrective surgery. The stoma is located proxi-

mal to the diseased, obstructed, or atonic urinary structure, most commonly as an *ureterostomy* (detaches the ureter from the bladder and brings it to the surface of the abdomen), *pyelostomy* (creates an opening to the kidney pelvis), or *vesicostomy* (creates an opening to the bladder) (Fig. 19–2).

Once hailed as a life-saving procedure, permanent urinary diversion through a stoma led to such overwhelming negative consequences that the management of children who would previously have been treated with stomal diversion has shifted. (For more information, see [thePoint](#) for Supplemental Information: Urinary Diversion Through a Stoma.) The current trend is to combine surgical and pharmacologic approaches to restore function to the lower urinary structures while conserving the upper tracts. For most children, the potential to become continent is great. A key positive factor has been the introduction of clean intermittent catheterization to maintain regular and complete bladder emptying.

TRADITION OR SCIENCE 19–1

Should lidocaine gel be used routinely for urinary catheterization?

**MORE INQUIRY
NEEDED**

Some studies show that the use of lidocaine lubricant does significantly decrease pain and distress with pediatric urethral catheterization (Gerard et al., 2003) and decreases pain in adult males (Siderias et al., 2004). Other studies demonstrate no difference in pain scores between nonanesthetic lubricant and 2% lidocaine gel as lubricant during bladder catheterization in young children (Vaughan et al., 2005) or adult females (Tanabe et al., 2004), or during cystoscopy in adult males (Chen et al., 2005). The use of lidocaine lubricant may increase the child's anxiety and the duration of the procedure. Assess each child individually for appropriateness of use. More inquiry is needed to determine an optimal standard of practice.

Urinary Reconstruction

Evaluating bladder capacity, contractility, and sphincteric competency is essential to determine a treatment plan. A small, inelastic bladder must be enlarged to provide an adequate reservoir. Bladder augmentation material is typically supplied by ileum, sigmoid, or (rarely) gastric tissue. If the bladder has normal capacity and good detrusor (bladder muscle) contractility, it is left alone. Urethral resistance is considered next in attempting to determine the capability for continence and complete bladder emptying. High sphincteric resistance,

TRADITION OR SCIENCE 19–2

What is the best method of obtaining urine to evaluate for UTI?

MORE INQUIRY NEEDED

In an extensive systematic review to determine the accuracy of tests to detect UTI in children younger than 5 years of age, Whiting et al. (2006) determined that, in toilet-trained children, clean, voided midstream urine (CVU) samples had similar accuracy to those obtained by suprapubic aspiration. Although urethral catheterization has been considered a reliable method to diagnose UTI, newer research indicates that samples obtained by catheterization should be interpreted similar to CVU (Lau et al., 2007). Agreement between CVU and catheterized specimens analyzed by the presence/absence of growth was good in boys but poor in girls; agreement was poor when samples were analyzed by colony counts, with CVU having higher counts than catheter (Lau et al., 2007). Catheterized specimens produced fewer false positives than CVU, but both rates were unacceptably high (Lau et al., 2007).

In nontoilet-trained children, the evidence is not conclusive. Suprapubic aspiration is reliable and has been considered the gold standard, but many parents and healthcare providers consider it unacceptably invasive, and it may not always be successful (American Academy of Pediatrics, 1999b; Whiting et al., 2006). American Academy of Pediatrics guidelines recommend urethral catheterization as a reliable method to diagnose UTI in children younger than age 2 years (American Academy of Pediatrics). Catheterization is also invasive, requires technical expertise, and risks introducing bacteria into the bladder. Non-invasive methods are preferable, but typically yield less accurate results. If a sample collected by a urine collection bag is negative, one may feel confident about the results. If, however, the urine sample is positive, this result may be from contamination, especially if the urine collection bag was left in place for an extended time. Therefore, reliability of such results is questionable. Specimens obtained using urine collection bags are susceptible to contamination, with a false-positive rate of 85% to 99% (Ma & Shortliff, 2004), and yield more ambiguous culture results (Schroeder et al., 2005). Contamination can be decreased by frequent changing (Rao et al., 2004). Urine recovered from urine collection pads yields culture results similar to those obtained with urine collected from urine bags (Farrell et al., 2002), although white blood cell count might be lower in urine collected from a pad than in that collected from a bag (Ahmad et al. 1991; Farrell et al., 2002; Feasey, 1999; Macfarlane et al., 2005). The limited data available suggest that bag and pad specimens may be suitable for obtaining culture specimens, but definitive conclusions cannot be drawn, and further studies are needed (Whiting et al., 2006).

which blocks urine flow, is managed by clean intermittent catheterization. Insufficient resistance requires either a procedure to reconstruct the bladder neck or surgical implantation of an artificial sphincter to prevent dribbling. Clean intermittent catheterization may be instituted to ensure complete bladder emptying. Any impairment to catheterization, such as poor fine motor control or extreme skeletal deformity, may necessitate the creation of a continent catheterizable stoma (Mitrofanoff procedure). Pharmacologic agents that mediate detrusor function may be administered as adjuncts to achieve the goal of continence.

Benefits from reconstructing the urinary tract rather than creating an external stomal diversion include less disfigurement, no need for an external collection device, improved preservation of the upper tracts, and improved continence. Disadvantages are either procedure dependent or related to poor patient adherence to the postoperative regimen or lax patient follow-up. Complications related to the augmented bladder or the associated gastrointestinal resection include electrolyte disturbances, mucous plugs, calculi in the bladder, bladder cancer, reflux, and ascending pyelonephritis (from chronically neglected catheterization). Stomal problems include stomal stenosis, leakage, false passage, atrophy, and stomal breakdown (Barqawi et al., 2004).

Clean Intermittent Catheterization

Clean intermittent catheterization has revolutionized the management of voiding dysfunction related to neurogenic or congenital causes. By reversing the cycle of chronic bladder distention, which creates mucosal ischemia, urinary stasis, and an environment conducive to bacterial colonization, clean intermittent catheterization substantially lowers UTI rates. Additionally, clean intermittent catheterization alleviates the persistently elevated intravesical pressure, a precursor for vesicoureteral reflux (VUR) and upper tract damage. An added benefit of clean intermittent catheterization involves the therapeutic effects on detrusor function. A regularly emptied bladder, drained before distention occurs, maintains detrusor contractility and prevents overflow incontinence.

Technique

Clean intermittent catheterization can be performed on children of any age, using a 6 to 14-French-diameter catheter. A variety of catheters is available, including latex, latex-free, and hydrophilic catheters.

Alert! To prevent a possible urethral allergic reaction, do not use latex catheters.

Clean technique is used by the parent and child when catheterizing. Most people who catheterize routinely will have bacteria in the bladder, but this condition is not treated as a UTI unless the child also has symptoms such as fever, abdominal pain, or back pain.

FIGURE 19–2. A vesicostomy creates an opening to the bladder to divert urine flow.

Teach the parents and child, as appropriate, how to perform clean intermittent catheterization (TIP 19–1). Before teaching the child or parent how to perform clean intermittent catheterization, review the pelvic and perineal anatomy, clearly highlighting the urethral pathway. Depending on the child's gender, demonstrate how the normal male urethra is much straighter when held erect and perpendicular to the abdomen, or that the female urethral tract is angled toward the umbilicus. Have the family perform the procedure on an anatomically correct doll until proficiency is achieved, before attempting the procedure on the child. Boys have little difficulty locating the external meatus, but girls often need to use a mirror. When the child is able to easily locate and enter the urethra with a tube, the mirror can be removed.

The age to teach a child self-catheterization depends on developmental and emotional factors, such as attention span, fine motor and manipulative control, family support, emotional readiness, and ability to perform sequential behaviors. Individualized judgment and procedural adaptation are required for children who are physically, emotionally, or developmentally challenged. Full independence with the procedure occurs when the child acquires a concept of time and record keeping, typically around age 6 to 8 years (Clinical Judgment 19–1).

Helping the Child to Accept Clean Intermittent Catheterization

Poor adherence to clean intermittent catheterization is often seen during adolescence and is associated with increased rates of epididymitis and recurrent UTIs (Holmdahl et al., 2007). The psychosocial chaos of adolescence may impinge on the teen's acceptance of clean intermittent catheterization and on the teen's willingness to commit to a long-term bladder-emptying routine. Driven to fit in with peers, teens who have never previously balked at the technique may refuse to perform clean intermittent catheterization. Teens will often deny their

need for assisted bladder emptying in a self-deceptive attempt to be like other teens. Offer parents anticipatory guidance about this problem as the child approaches puberty. The following suggestions can enhance the teen's cooperation:

- Acknowledge and validate the teen's conflicting feelings about his or her body.
- Maintain privacy and confidentiality.
- Avoid shaming the teen, especially around peers.
- Help the teen create a contract of responsibility.
- Offer either developmentally appropriate rewards or negative feedback to promote expected behavior.

Pharmacologic Management

Managing many genitourinary and renal conditions involves the use of pharmacologic agents. Medications may be curative, as in the administration of an antibiotic to treat UTI, or used as adjuncts to other treatment modalities, as in the management of voiding disorders. Thus, the nurse needs to be familiar with common genitourinary medications used in children, and their urologic and renal applications (see [thePoint](#) for Medications: Medications Used to Manage Genitourinary Conditions). Steroid therapy is used to treat several renal conditions, as described in this chapter's section on nephrotic syndrome (NS). (See Chapters 22 and 25 for more information regarding steroid therapy.)

Renal Replacement Therapies

Altered laboratory values or fluid imbalance from renal causes that cannot be controlled with conservative measures such as diet or medication require some form of renal replacement therapy. These therapies include peritoneal dialysis (PD), hemodialysis, and kidney transplant.

TIP 19-1 A Teaching Intervention Plan for the Child Requiring Clean Intermittent Catheterization

Nursing diagnosis and outcomes

- Effective therapeutic regimen management

Outcomes

- Child and family will perform clean intermittent catheterization proficiently.
- Child and family will catheterize in a timely manner to prevent urine leakage and skin breakdown.
- Child and family will identify signs and symptoms of stomal stenosis and infection.

Teach the child/family

To Catheterize via Urethra or a Continent

Diversion (Stoma)

- Educate regarding the importance of regular bladder drainage and the consequences of negligence. Strategize with the family to devise a workable catheterization routine for the child. Timing of clean intermittent catheterization should be every 3 to 4 hours, although more frequent drainage may be needed initially for continence. Because the child with a neurogenic bladder lacks sensory pathways to detect a full bladder, an alarm can be set to provide the needed cue for bladder emptying. Ask the surgeon/primary provider if the child needs to awaken at night to catheterize. It may be sufficient to catheterize before bedtime and immediately upon waking. If it is necessary to awaken the child at night, have the child set an alarm and remind him or her that most people awake at least once at night to urinate; this is more common in older children.
- Some children will need to use an indwelling Foley catheter during the night if hydronephrosis is a concern. If so, instruct them on Foley insertion and the use of a night drainage bag.
- Cleanse the perineum with mild soap and water once a day.* Menstruating females may wish to cleanse prior to each clean intermittent catheterization. Females should use three front-to-back swipes with clean wipes each time, males should use a circular motion around the meatus. If the child has a stoma, cleanse around the stoma using three strokes in a circular motion and not “scrubbing” back and forth. In uncircumcised males, pull back the foreskin to clean the head of the penis.
- Assemble all supplies as needed (e.g., catheter, lubricant, wipes, container to collect urine if not draining into toilet). Carry disposable towelettes and lubricant with the catheter for adequate meatal hygiene. For an infant, placing a protective pad under the child’s bottom can help minimize mess.
- Perform hand hygiene using soap and water or alcohol-based hand gel.

- Position urine collection container if needed, or sit on, stand, sit in wheelchair facing the toilet using a catheter extension tube if needed (available through medical supply companies).
- Lubricate the catheter with a water-based gel. If a hydrophilic catheter is being used, the catheter may come prelubricated with water in its package or water may need to be added to the package. Exposing the hydrophilic catheter to water activates the special coating and the entire catheter is slippery. Gel is not necessary when using hydrophilic catheters.
- Insert the catheter gently into the urethra (stoma) until urine begins to flow. After urine is flowing, insert the tube a little farther and instruct the child to keep holding catheter and to watch for urine to stop. Urine flows more readily when the child raises intra-abdominal pressure, using methods such as the Valsalva technique, laughing, or blowing (e.g., blowing bubbles or a pinwheel). Teach the child/family to use the Credé maneuver to massage the vesical dome only if the child has no VUR, per physician approval.
- When urine flow stops, slowly remove the catheter, stopping to wait if the urine begins to drain again. When finished draining the bladder, teach the child to pinch the tube so that as he or she removes it, urine will not drip on clothing.

Catheter Care

- Rinse the tube with soap and water after catheterization, and dry and place it in a breathable container such as a plastic zip-lock bag with holes in it, a toothbrush holder, or a paper bag. It may be helpful to use a syringe filled with water to flush the catheter.
- Once a week, either soak the tube in a 1:3 solution of vinegar and water, rinsing well before use, or boil in water for 5 to 10 minutes.
- Plastic tubes last for 2 to 4 weeks.

For Children Attending Daycare/School

- Upon parental request/approval, teach designated staff clean intermittent catheterization techniques and/or how to support the child in self clean intermittent catheterization.
- Help staff/child to provide flexibility in the school day schedule and identify a private area to store supplies and perform clean intermittent catheterization.

To Monitor Urinary Function

- Evaluate amount of urine output; note consistent decrease in volume.

- Observe urine for mucus, odor, or discoloration.
- Check stoma for signs of irritation, bleeding, shrinkage, protrusion, or other change in appearance.

Contact Healthcare Provider if:

- Child has high temperature or persistent or unexplained fever more than 101 °F (38.3 °C).

- There is a foul odor, consistent discoloration, or excess mucus in the urine.
- Child has flank pain or aching, extreme fatigue, or loss of appetite.
- Child has abdominal pain or pain when catheterizing stoma.
- Child has difficulty passing the catheter or there is a large amount of blood when catheterizing.

*Some practitioners recommend cleansing before each clean intermittent catheterization, but there is limited evidence to support this practice (Bray & Sanders, 2007).

Peritoneal Dialysis (PD)

PD may be used to provide renal replacement therapy in acute renal failure (ARF) or chronic renal disease. Methods for children include intermittent PD, continuous ambulatory PD, and continuous cycling PD (also called automated PD).

All PD methods use the same physiologic principles of metabolic and fluid control, and require similar nursing care. Diffusive and convective clearance (solute and fluid clearance) occur when the peritoneal membrane's rich blood supply comes into apposition with sterile dialysate instilled into the child's abdominal (peritoneal) cavity through the dialysis catheter. The dialysate stays in the

CLINICAL JUDGMENT 19–1

The Child With Spina Bifida Seen for a Self-Catheterization Program

Five-year-old Michelle was born with myelomeningocele at the L1 level. She is seen in the rehabilitation outpatient clinic for an instructional program in self clean intermittent catheterization. Until now, Michelle has been incontinent and has continued to wear diapers. This has not presented a problem in the past, but she is now preparing to enter a public school.

Questions

1. What information will you need regarding Michelle's elimination patterns?
2. What self-care techniques should be introduced to Michelle?
3. How would you determine that Michelle is ready to participate in this program?
4. What steps would be followed in introducing self clean intermittent catheterization to Michelle?
5. How would you determine that Michelle is ready for discharge?

Answers

1. How much fluid does Michelle usually drink per day, especially in the evening? How frequently does she wet diapers? When changed, is the diaper damp, wet, or fully saturated? Is she aware of voiding and does she seem bothered if wet?
2. Perineal care, recognition of relationship of volume of intake and types of fluids to output of urine
3. Michelle shows interest in "keeping dry" and wearing underwear, Michelle is able to understand

4. that she will be able to "go to the bathroom" using the catheter and will not be wet in between times
4. A clean intermittent catheterization program should be initiated by the nurse, explaining the purpose and technique to Michelle step by step (a visual aid, handout, picture book, or videotape/DVD may be helpful). An anatomically correct doll can be used to introduce the topic and explain how the body works. This can also be used to have Michelle "try" the techniques. Michelle should assist in gathering supplies and in setting up for the procedure, and watch the catheterization using a mirror. Michelle should initiate steps of the procedure (cleansing with soap and water, identifying urethral opening with mirror). Michelle should try to insert the catheter after she has been cleansed and prepared by the nurse. Michelle should try the procedure while sitting on the toilet.
5. Michelle is able to perform each step of the procedure independently with only occasional reminders or verbal cues. Michelle's parents demonstrate independence in performing the procedure. Michelle's parents support their daughter in completing each task and understand the steps that Michelle must practice to gain complete independence. The family can solve different scenarios and complications (management of limited supplies, UTIs, scheduling catheters around community social activities).
