<p>*Meigs' syndrome is the association of a right pleural effusion with or without ascites and a benign ovarian tumour. The ascites resolves on removal of the tumour.</p>	

Fig. 23.16 Pathogenesis of ascites.

23.20 Ascitic fluid: appearance and analysis

Cause/appearance

- Cirrhosis: clear, straw-coloured or light green
- Malignant disease: bloody
- Infection: cloudy
- Biliary communication: heavy bile staining
- Lymphatic obstruction: milky-white (chylous)

Useful investigations

- Total albumin (plus serum albumin) and protein*
- Amylase
- Neutrophil count
- Cytology
- Microscopy and culture

*To calculate the serum–ascites albumin gradient (SAAG).

distinguish a transudate from an exudate. Cirrhotic patients typically develop a transudate with a total protein concentration below 25 g/L and relatively few cells. However, in up to 30% of patients, the total protein concentration is more than 30 g/L. In these cases it is useful to calculate the SAAG by subtracting the concentration of the ascites fluid albumin from the serum albumin. A gradient of more than 11 g/L is 96% predictive that ascites is due to portal hypertension. Venous outflow obstruction due to cardiac failure or hepatic venous outflow obstruction can also cause a transudative ascites, as indicated by an albumin gradient above 11 g/L, but unlike in cirrhosis the total protein content is usually above 25 g/L.

Exudative ascites (ascites protein concentration above 25 g/L or a SAAG of less than 11 g/L) raises the possibility of infection (especially tuberculosis), malignancy, hepatic venous obstruction, pancreatic ascites or, rarely, hypothyroidism. Ascites amylase activity above 1000 U/L identifies pancreatic ascites, and low ascites glucose concentrations suggest malignant disease or tuberculosis. Cytological examination may reveal malignant cells (one-third of cirrhotic patients with a bloody tap have a hepatoma). Polymorphonuclear leucocyte counts above 250×10^6 /L strongly suggest infection (spontaneous bacterial peritonitis, see below). Laparoscopy can be valuable in detecting peritoneal disease.

Management

Successful treatment of ascites relieves discomfort but does not prolong life, and if over-vigorous, can produce serious disorders of fluid and electrolyte balance and precipitate hepatic encephalopathy (p. 938). Treatment of transudative ascites is based on restricting sodium and water intake, promoting urine output with diuretics and, if necessary, removing ascites directly by paracentesis. Exudative ascites due to malignancy should be treated with paracentesis but fluid replacement is generally not required. In ovarian cancer, however, paracentesis usually needs to be guided by ultrasound, as the need for frequent paracentesis often results in the fluid becoming loculated. During management of ascites, the patient should be weighed regularly. It is important to avoid removing more than 1 L of fluid daily, so body weight should not fall by more than 1 kg daily if fluid depletion in the rest of the body is to be avoided.

23.21 Some drugs containing relatively large amounts of sodium or causing sodium retention

High sodium content

- Antacids
- Alginates
- Antibiotics
- Phenytoin
- Sodium valproate
- Effervescent preparations (e.g. aspirin, calcium, paracetamol)

Sodium retention

- Carbenoxolone
- Corticosteroids
- Metoclopramide
- NSAIDs
- Oestrogens

Sodium and water restriction

Restriction of dietary sodium intake is essential to achieve negative sodium balance in ascites, and a few patients can be managed satisfactorily on this treatment alone. Restriction of sodium intake to 100 mmol/day ('no added salt diet') is usually adequate. Drugs containing relatively large amounts of sodium and those promoting sodium retention, such as non-steroidal anti-inflammatory drugs, must be avoided (Box 23.21). Restriction of water intake to 1.0–1.5 L/day is necessary only if the plasma sodium falls below 125 mmol/L.

Diuretics

Most patients require diuretics in addition to sodium restriction. Spironolactone (100–400 mg/day) is the drug of choice for long-term therapy because it is a powerful aldosterone antagonist; unfortunately, it can cause painful gynaecomastia and hyperkalaemia. Some patients also require loop diuretics, such as furosemide, but these can cause fluid and electrolyte imbalance and renal dysfunction. Diuresis is improved if patients are rested in bed, perhaps because renal blood flow increases in the horizontal position. Patients who do not respond to doses of 400 mg spironolactone and 160 mg furosemide are considered to have refractory or diuretic-resistant ascites and should be treated by other therapeutic measures.

Paracentesis

The first-line treatment of refractory ascites is large-volume paracentesis with intravenous albumin replacement. Paracentesis to dryness or the removal of 3–5 L daily is safe, provided the circulation is supported with an intravenous colloid such as human albumin (6–8 g per litre of ascites removed, usually as 100 mL of 20% human albumin solution (HAS) for every 3 L of ascites drained) or another plasma expander. Paracentesis can therefore be used as an initial therapy or when other treatments fail.

Peritoneo-venous shunt

The peritoneo-venous shunt is a long tube with a non-return valve running subcutaneously from the peritoneum to the internal jugular vein in the neck; it allows ascitic fluid to pass directly into the systemic circulation. It is effective in ascites resistant to conventional treatment but complications, including infection, superior vena caval thrombosis, pulmonary oedema, bleeding from oesophageal varices and disseminated intravascular

coagulopathy, limit its use and insertion of these shunts is now rare.

Transjugular intrahepatic portosystemic stent shunt (TIPSS)

TIPSS (pp. 941–942) can relieve resistant ascites but does not prolong life; it may be an option where the only alternative is frequent, large-volume paracentesis. It can be used when liver function is reasonable or in patients awaiting liver transplantation.

Renal failure

Renal failure can occur in patients with ascites. It can be pre-renal due to vasodilatation from sepsis and/or diuretic therapy, or due to hepatorenal failure, which is discussed on page 944.

Spontaneous bacterial peritonitis

Patients with cirrhosis are highly susceptible to spontaneous bacterial peritonitis (SBP). This usually presents suddenly with abdominal pain, rebound tenderness, absent bowel sounds and fever in a patient with obvious features of cirrhosis and ascites. Abdominal signs are mild or absent in about one-third of patients, and in these patients hepatic encephalopathy and fever are the main features. Diagnostic paracentesis may show cloudy fluid, and an ascites neutrophil count above $250 \times 10^6/L$ almost invariably indicates infection. The source of infection cannot usually be determined, but most organisms isolated from ascitic fluid or blood cultures are of enteric origin and *Escherichia coli* is the organism most frequently found. Ascitic culture in blood culture bottles gives the highest yield of organisms. SBP needs to be differentiated from other intra-abdominal emergencies, and the finding of multiple organisms on culture should arouse suspicion of a perforated viscus.

Treatment should be started immediately with broad-spectrum antibiotics, such as cefotaxime. Recurrence of SBP is common but may be reduced with prophylactic quinolones such as norfloxacin (400 mg daily) or ciprofloxacin (250 mg 12-hourly) (Box 23.22).

Prognosis

Only 10–20% of patients survive 5 years from the first appearance of ascites due to cirrhosis. The outlook is not universally poor, however, and is best in those with well-maintained liver function and a good response to therapy. The prognosis is also better when a treatable cause for the underlying cirrhosis is present or when a precipitating cause for ascites, such as excess salt intake, is found. The mortality at 1 year is 50% following the first episode of bacterial peritonitis.

EBM 23.22 Antibiotics and spontaneous bacterial peritonitis (SBP)

'In patients with a previous episode of SBP and continued ascites, norfloxacin 400 mg/day prevents recurrence (NNT_B 4.5).'

'In patients with cirrhosis who have had a gastrointestinal haemorrhage, prophylactic antibiotics reduce the risk of bacterial peritonitis (NNT_B 12.5) and improve survival (NNT_B 11).'

Hepatic encephalopathy

Hepatic encephalopathy is a neuropsychiatric syndrome caused by chronic liver disease. As encephalopathy progresses, confusion is followed by coma. Confusion needs to be differentiated from delirium tremens and Wernicke's encephalopathy, and coma from subdural haematoma which can occur in alcoholics after a fall (Box 23.23). Features include changes of intellect, personality, emotions and consciousness, with or without neurological signs. The degree of encephalopathy can be graded from 1 to 4, depending on these features, and this is useful in assessing response to therapy (see Box 23.14, p. 933). When an episode develops acutely, a precipitating factor may be found (Fig. 23.17). The earliest features are very mild and easily overlooked but, as the condition becomes more severe, apathy, inability to concentrate, confusion, disorientation, drowsiness, slurring of speech and eventually coma develop. Convulsions sometimes occur. Examination usually shows a flapping tremor (asterixis, p. 921), inability to perform simple mental arithmetic tasks (Fig. 23.18) or to draw objects such as a star (constructional apraxia, Fig. 23.19), and, as the condition progresses, hyper-reflexia and bilateral extensor plantar responses. Hepatic encephalopathy rarely causes focal neurological signs, and if these are present, other causes must be sought. Feto hepaticus, a sweet musty odour to the breath, is usually present but is more a sign of liver failure and portosystemic shunting than of hepatic encephalopathy. Rarely, chronic hepatic encephalopathy (hepatocerebral degeneration) gives rise to variable combinations of cerebellar

- Primary psychiatric disorders (p. 240)
- Hypoglycaemia (p. 812)
- Neurological Wilson's disease (p. 1203)
- Post-ictal state

Fig. 23.17 Factors precipitating hepatic encephalopathy.

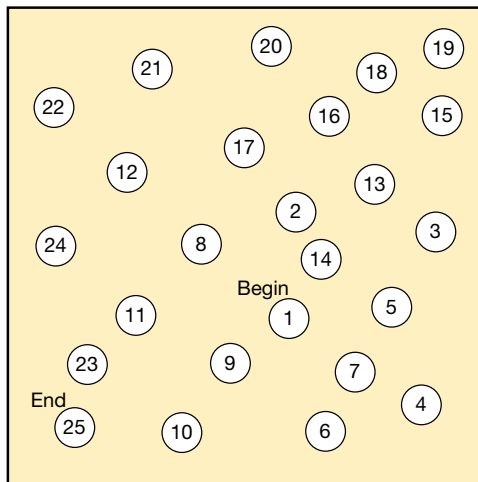

Fig. 23.18 Number connection test used in assessing encephalopathy. These 25 numbered circles can normally be joined together within 30 seconds. Serial observations may provide useful information as long as the position of the numbers is varied to avoid the patient learning their pattern.

Fig. 23.19 Constructional apraxia in encephalopathy. Drawing stars and clocks may reveal marked abnormality.

dysfunction, Parkinsonian syndromes, spastic paraplegia and dementia.

Pathophysiology

Hepatic encephalopathy is thought to be due to a disturbance of brain function provoked by circulating neurotoxins that are normally metabolised by the liver. Accordingly, most affected patients have evidence of liver failure and portosystemic shunting of blood, but the balance between these varies from individual to individual. Some degree of liver failure is a key factor, as portosystemic shunting of blood alone hardly ever causes encephalopathy. Little is known of the biochemical 'neurotoxins' causing the encephalopathy, but they are thought to be mainly nitrogenous substances produced in the gut, at least in part by bacterial action. These substances are normally metabolised by the healthy liver and therefore excluded from the systemic circulation. Ammonia has traditionally been considered an important factor and ammonia-

induced alteration in astrocyte glutamine and glutamate concentrations may be important. Recent interest has focused on γ -aminobutyric acid as a mediator, along with other factors such as octopamine, amino acids, mercaptans and fatty acids which can act as neurotransmitters. Some factors appear to precipitate hepatic encephalopathy by increasing the availability of these substances; in addition, the brain in cirrhosis may be sensitised to other factors such as drugs that are able to precipitate hepatic encephalopathy (see Fig. 23.17). Disruption of the function of the blood-brain barrier is a feature of acute hepatic failure and may lead to cerebral oedema.

Investigations

The diagnosis can usually be made clinically, but when doubt exists, an electroencephalogram (EEG) shows diffuse slowing of the normal alpha waves with eventual development of delta waves. The arterial ammonia is usually increased in patients with hepatic encephalopathy. However, increased concentrations can occur in the absence of clinical encephalopathy, so this investigation is of little or no diagnostic value.

Management

The principles of management are to treat or remove precipitating causes (see Fig. 23.17) and to suppress the production of neurotoxins by bacteria in the bowel. Dietary protein restriction is rarely needed and is no longer recommended as first-line treatment because it is unpalatable and can lead to a worsening nutritional state in already malnourished patients. Lactulose (15–30 mL 8-hourly) is a disaccharide which is taken orally and reaches the colon intact, to be metabolised by colonic bacteria. The dose is increased gradually until the bowels are moving twice daily. It produces an osmotic laxative effect, reduces the pH of the colonic content, thereby limiting colonic ammonia absorption, and promotes the incorporation of nitrogen into bacteria. Lactitol is a rather more palatable alternative to lactulose, with a less explosive action on bowel function. Neomycin (1–4 g 4–6-hourly) is an antibiotic which acts by reducing the bacterial content of the bowel. It can be used in addition or as an alternative to lactulose if diarrhoea becomes troublesome. Neomycin is poorly absorbed from the bowel but sufficient gains access to the body to contraindicate its use when uraemia is present. It is less desirable than lactulose for long-term use; ototoxicity is the main deleterious effect and so neomycin is now rarely used. Chronic or refractory hepatic encephalopathy is one of the main indications for liver transplantation.

Variceal bleeding

Acute upper gastrointestinal haemorrhage from oesophago-gastric varices (Fig. 23.20) is a common manifestation of chronic liver disease. However, gastrointestinal bleeding can also occur as the result of peptic ulceration, which is more common in patients with liver disease than in the general population. The investigation and management of gastrointestinal bleeding are dealt with in more detail on pages 852–856, but the specific management of variceal bleeding is discussed here.

Fig. 23.20 Varices: endoscopic views. **A** Oesophageal varices (arrows) at the lower end of the oesophagus. **B** Gastric varices (arrows).

Management

Principles

The priority in acute bleeding from oesophageal varices is to restore the circulation with blood and plasma, not least because shock reduces liver blood flow and causes further deterioration of liver function. Even in patients with known varices, the source of bleeding should always be confirmed by endoscopy because about 20% of patients are bleeding from some other lesion, especially acute gastric erosions. Management of acute variceal bleeding is described in Box 23.24 and illustrated in Figure 23.21. All patients with cirrhosis and gastrointestinal bleeding should receive prophylactic broad-spectrum antibiotics, such as oral ciprofloxacin or intravenous cephalosporin, because sepsis is common and treatment with antibiotics has been shown to improve outcome. The measures used to control acute variceal bleeding include endoscopic therapy (banding or sclerotherapy), balloon tamponade and oesophageal transection.

23.24 Emergency management of bleeding

Management	Reason
0.9% saline (1–2 L)	Extracellular volume replacement
Vasopressor (terlipressin)	Reduces portal pressure, acute bleeding and risk of early rebleeding
Prophylactic antibiotics (cephalosporin i.v.)	Reduces incidence of SBP
Emergency endoscopy	Confirm variceal rather than ulcer bleed
Variceal band ligation	To stop bleeding
Proton pump inhibitor	To prevent peptic ulcers
Phosphate enema and/or lactulose	To prevent hepatic encephalopathy

Fig. 23.21 Management of acute bleeding from oesophageal varices. (TIPSS = transjugular intrahepatic portosystemic stent shunt)

Banding ligation and sclerotherapy

This is the most widely used initial treatment and is undertaken if possible at the time of diagnostic endoscopy (Fig. 23.22). It stops variceal bleeding in 80% of patients and can be repeated if bleeding recurs. Band ligation involves the varices being sucked into a cap placed on the end of the endoscope, allowing them to

Fig. 23.22 Appearance of oesophageal varices following application of strangulating bands (band ligation, arrow).

be occluded with a tight rubber band. The occluded varix subsequently sloughs with variceal obliteration. Banding is repeated every 1–2 weeks until the varices are obliterated. Regular follow-up endoscopy is required to identify and treat any recurrence of varices. Band ligation has fewer side-effects than sclerotherapy, a technique in which varices are injected with a sclerosing agent, which has now been largely abandoned in preference to banding ligation. Banding is associated with less risk of oesophageal perforation and oesophageal strictures. Prophylactic acid suppression with proton pump inhibitors reduces the risk of secondary bleeding from banding-induced ulceration.

Active bleeding at endoscopy may make endoscopic therapy difficult; in such cases, bleeding should be controlled by balloon tamponade prior to endoscopic therapy. Protection of the patient's airway with endotracheal intubation may allow an improved endoscopic view, facilitating endoscopic therapy, and significantly reduce the risk of pulmonary aspiration.

Pharmacological reduction of portal venous pressure

Pharmacological reduction of portal pressure is less important than banding in preventing rebleeding, but is useful in reducing active bleeding while endoscopy is being arranged. Terlipressin is the current drug of choice and releases the vasoconstrictor, vasopressin, over several hours in amounts sufficient to reduce the portal pressure without producing systemic effects. It is given in a dose of 2 mg i.v. 6-hourly until bleeding stops, and then 1 mg 6-hourly for a further 24 hours.

Balloon tamponade

This technique employs a Sengstaken–Blakemore tube possessing two balloons which exert pressure in the fundus of the stomach and in the lower oesophagus respectively (Fig. 23.23). Current modifications incorporate additional lumens to allow material to be aspirated from the stomach and from the oesophagus above the oesophageal balloon.

Fig. 23.23 Sengstaken–Blakemore tube.

The tube should be passed through the mouth and its presence in the stomach should be checked by auscultating the upper abdomen while injecting air into the stomach and by radiology. Gentle traction is essential to maintain pressure on the varices. Initially, only the gastric balloon should be inflated with 200–250 mL of air, as this will usually control bleeding. Inflation of the gastric balloon must be stopped if the patient experiences pain because inadvertent inflation in the oesophagus can cause oesophageal rupture. If the oesophageal balloon needs to be used because of continued bleeding, it should be deflated for about 10 minutes every 3 hours to avoid oesophageal mucosal damage. Pressure in the oesophageal balloon should be monitored with a sphygmomanometer and should not exceed 40 mmHg. Balloon tamponade will almost always stop oesophageal and gastric fundal variceal bleeding, but only creates time for the use of more definitive therapy. Particular care should be taken to avoid pulmonary aspiration whilst inserting the tube; as mentioned above, patients unable to protect their airway should be intubated.

Self-expanding removable oesophageal stents are a new alternative to the Sengstaken tube in patients with bleeding oesophageal, in contrast to gastric, varices.

Transjugular intrahepatic portosystemic stent shunting (TIPSS)

This technique uses a stent placed between the portal vein and the hepatic vein within the liver to provide a

portosystemic shunt and therefore reduce portal pressure (Fig. 23.24). The procedure is carried out under radiological control via the internal jugular vein; prior patency of the portal vein must be determined angiographically, coagulation deficiencies may require correction with fresh frozen plasma, and antibiotic cover is provided. Successful shunt placement stops and prevents variceal bleeding. Further bleeding necessitates investigation and treatment (e.g. angioplasty) because it is usually associated with shunt narrowing or occlusion. Hepatic encephalopathy may occur following TIPSS and is managed by reducing the shunt diameter. Although TIPSS is associated with less rebleeding than endoscopic therapy, survival is not improved (Box 23.25).

Portosystemic shunt surgery

Surgery prevents recurrent bleeding, but carries a high mortality and often leads to encephalopathy. Non-selective portacaval shunts can divert the majority of the portal blood away from the liver, rendering patients liable to post-operative liver failure and hepatic encephalopathy. This led to the development of more selective shunts (such as the distal splenorenal shunt); such devices are associated with less post-operative encephalopathy, but with the passage of time liver portal blood flow falls and encephalopathy may supervene. Furthermore, survival is not prolonged, as death from liver failure may occur.

Fig. 23.24 Transjugular intrahepatic portosystemic stent shunt (TIPSS). X-ray showing placement of TIPSS within the portal vein (PV), allowing blood to flow from the portal vein into the hepatic vein (HV) and then the inferior vena cava (IVC). (H = heart)

EBM 23.25 Secondary prevention of variceal bleeding in patients with cirrhosis

'While TIPSS is more effective than endoscopic treatment in reducing variceal rebleeding, it does not improve survival and is associated with more encephalopathy.'

- Laine L. *Hepatology* 1995; 22:663–665.

For further information: www.bsg.org.uk

In practice, portosystemic shunts are now reserved for patients in whom other treatments have not been successful and are offered only to those with good liver function.

Oesophageal transection

Transection of the varices can be performed with a stapling gun, although this carries some risk of subsequent oesophageal stenosis and is normally combined with splenectomy. The operation is used when TIPSS is not available and when bleeding cannot be controlled by the other therapies described. The operative morbidity and mortality are considerable and the procedure is now rarely used.

Prognosis

In the presence of portal hypertension, the risk of a variceal bleed occurring within 2 years varies from 7% for small varices up to 30% for large varices. The mortality following a variceal bleed has improved to around 15% overall but still is about 45% in those with poor liver function, i.e. Child–Pugh C patients.

CIRRHOSIS

Hepatic cirrhosis is a common disease characterised by diffuse hepatic fibrosis and nodule formation. It can occur at any age, has significant morbidity and is an important cause of premature death. World-wide, the most common causes of cirrhosis are chronic viral hepatitis and prolonged excessive alcohol consumption. Cirrhosis is the most common cause of portal hypertension and its associated complications.

The causes of cirrhosis are listed in Box 23.26; any condition leading to persistent or recurrent hepatocyte death, such as chronic hepatitis C infection, may lead to cirrhosis. It may also occur in prolonged biliary damage or obstruction, as is found in primary biliary cirrhosis, primary sclerosing cholangitis and post-surgical biliary strictures. Persistent blockage of venous return from the liver, such as occurs in veno-occlusive disease and Budd–Chiari syndrome, can also result in liver cirrhosis.

23.26 Causes of cirrhosis

- Alcohol
- Chronic viral hepatitis (B or C)
- Non-alcoholic fatty liver disease
- Immune
 - Primary sclerosing cholangitis
 - Autoimmune liver disease
- Biliary
 - Primary biliary cirrhosis
 - Secondary biliary cirrhosis
 - Cystic fibrosis
- Genetic
 - Haemochromatosis
 - Wilson's disease
 - α_1 -antitrypsin deficiency
- Cryptogenic (unknown—15%)
- Chronic venous outflow obstruction

Pathophysiology

The cardinal feature of cirrhosis is an increase in fibrous tissue, progressive and widespread death of liver cells, and inflammation leading to loss of the normal liver architecture. Following liver injury, stellate cells in the space of Disse (see Fig. 23.3, p. 923) are activated by cytokines produced by Kupffer cells and hepatocytes. This transforms the stellate cell into a myofibroblast-like cell, capable of producing collagen, pro-inflammatory cytokines and other mediators which promote hepatocyte damage and cause tissue fibrosis (see Fig. 23.4, p. 924).

Destruction of the liver architecture causes distortion and loss of the normal hepatic vasculature with the development of portosystemic vascular shunts and the formation of nodules. Cirrhosis evolves slowly over years to decades, and normally continues to progress even after removal of the aetiological agent (e.g. abstinence from alcohol, venesection in haemochromatosis). Cirrhosis is a histological diagnosis characterised by diffuse hepatic fibrosis and nodule formation (Fig. 23.25). These changes usually affect the whole liver, but in biliary cirrhosis (e.g. primary biliary cirrhosis) they can be patchy.

Cirrhosis can be classified histologically into two types:

- *Micronodular cirrhosis*, characterised by small nodules about 1 mm in diameter and seen in alcoholic cirrhosis.
- *Macronodular cirrhosis*, characterised by larger nodules of various sizes. Areas of previous collapse of the liver architecture are evidenced by large fibrous scars.

Clinical features

The clinical presentation of cirrhosis is highly variable. Some patients are completely asymptomatic and the diagnosis is made incidentally at ultrasound or at surgery. Others present with isolated hepatomegaly, splenomegaly or signs of portal hypertension (p. 945). When symptoms are present, they are often non-specific and include weakness, fatigue, muscle cramps, weight loss, anorexia, nausea, vomiting and upper abdominal discomfort (Box 23.27). Occasionally, cirrhosis presents with features of hepatic insufficiency. Cirrhosis will occasionally present to a chest physician because of shortness of breath and a large right pleural effusion, without accompanying ascites or with hepatopulmonary syndrome (p. 973).

Hepatomegaly is common when the cirrhosis is due to alcoholic liver disease and haemochromatosis. Progressive hepatocyte destruction and fibrosis gradually reduce liver size as the disease progresses in other causes of cirrhosis. A reduction in liver size is especially common if the cause of cirrhosis is viral hepatitis or autoimmune liver disease. The liver is often hard, irregular and non-tender. Jaundice is usually mild when it first appears and is due primarily to a failure to excrete bilirubin. Mild haemolysis may occur due to hypersplenism but is not a major contributor to the jaundice. Palmar erythema can be seen early in the disease but is of limited diagnostic value, as it occurs in many other conditions associated with a hyperdynamic circulation including normal pregnancy, as well as being found in some normal people. Spider telangiectasias occur and comprise a central arteriole (which occasionally raises the skin surface), from which small vessels radiate. They vary in

Fig. 23.25 Histological features in normal liver, hepatic fibrosis and cirrhosis. **[A]** Normal liver. Columns of hepatocytes 1–2 cells thick radiate from the portal tracts (PT) to the central veins. The portal tract contains a normal intralobular bile duct branch of the hepatic artery and portal venous radical. **[B]** Bridging fibrosis (stained pink, arrows) spreading out around the hepatic vein and single liver cells (pericellular), and linking adjacent portal tracts and hepatic veins. **[C]** A cirrhotic liver. The liver architecture is disrupted. The normal arrangement of portal tracts and hepatic veins is now lost and nodules of proliferating hepatocytes are broken up by strands of pink/orange-staining fibrous tissue (arrows) forming cirrhotic nodules (CN).

size from 1 to 2 mm in diameter, are usually found only above the nipples, and can occur early in the disease. One or two small spider telangiectasias can be found in about 2% of healthy people and can occur transiently in greater numbers in the third trimester of pregnancy, but otherwise they are a strong indicator of liver disease. Florid spider telangiectasia, gynecomastia and parotid enlargement are most common in alcoholic cirrhosis. Pigmentation is most striking in haemochromatosis and in any cirrhosis associated with prolonged cholestasis. Pulmonary arteriovenous shunts also develop, leading to hypoxaemia and eventually to central cyanosis, but this is a late feature.

23.27 Clinical features of hepatic cirrhosis

- Hepatomegaly (although liver may also be small)
- Jaundice
- Ascites
- Circulatory changes
 - Spider telangiectasia, palmar erythema, cyanosis
- Endocrine changes
 - Loss of libido, hair loss
 - Men: gynaecomastia, testicular atrophy, impotence
 - Women: breast atrophy, irregular menses, amenorrhoea
- Haemorrhagic tendency
 - Bruises, purpura, epistaxis
- Portal hypertension
 - Splenomegaly, collateral vessels, variceal bleeding
- Hepatic (portosystemic) encephalopathy
- Other features
 - Pigmentation, digital clubbing, Dupuytren's contracture

Endocrine changes are noticed more readily in men, who show loss of male hair distribution and testicular atrophy. Gynaecomastia is common and can be due to drugs such as spironolactone. Easy bruising becomes more frequent as cirrhosis advances. Epistaxis is common and sometimes severe; it can mimic upper gastrointestinal bleeding if the blood is swallowed.

Splenomegaly and collateral vessel formation are features of portal hypertension, which occurs in more advanced disease (see below). Ascites is due to a combination of liver failure and portal hypertension (p. 945), and signifies advanced disease. Evidence of hepatic encephalopathy also becomes increasingly common with advancing disease. Non-specific features of chronic liver disease include clubbing of the fingers and toes. Dupuytren's contracture is traditionally regarded as a complication of cirrhosis, but the evidence for this is weak. Chronic liver failure develops when the metabolic capacity of the liver is exceeded. It is characterised by the presence of encephalopathy and/or ascites. The term 'hepatic decompensation' or 'decompensated liver disease' is often used when chronic liver failure occurs.

A variety of clinical and laboratory features may be present (Box 23.28), in addition to encephalopathy and ascites; these include peripheral oedema, renal failure, jaundice, and hypoalbuminaemia and coagulation abnormalities due to defective protein synthesis.

Management

This includes treatment of the underlying cause, maintenance of nutrition and treatment of complications,

23.28 Features of chronic liver failure

- | | |
|--------------------------------------|-------------------------------------|
| • Worsening synthetic liver function | • Variceal bleeding |
| • Prolonged prothrombin time | • Hepatic encephalopathy |
| • Low albumin | • Ascites |
| • Jaundice | • Spontaneous bacterial peritonitis |
| • Portal hypertension | • Hepatorenal failure |

which are discussed in detail below. Chronic liver failure due to cirrhosis can also be treated by orthotopic liver transplantation, which currently accounts for about three-quarters of all liver transplant operations (p. 976).

Ascites

Management of ascites is discussed on page 937. In patients with cirrhosis, ascites may be complicated by renal failure and also by spontaneous infections which are often precipitated by a variceal bleed. Blood in the gastrointestinal tract appears to affect permeability of the gastrointestinal tract to bacteria. Both of these complications have adverse prognostic significance and may prompt referral for transplantation.

Hepatorenal syndrome

This occurs in 10% of patients with advanced cirrhosis complicated by ascites. There are two clinical types; both are mediated by renal vasoconstriction due to underfilling of the arterial circulation.

- *Type 1 hepatorenal syndrome* is characterised by progressive oliguria, a rapid rise of the serum creatinine and a very poor prognosis (without treatment, median survival is less than 1 month). There is usually no proteinuria, a urine sodium excretion below 10 mmol/day and a urine/plasma osmolality ratio of > 1.5 . Other non-functional causes of renal failure must be excluded before the diagnosis is made. Treatment consists of albumin infusions in combination with terlipressin and is effective in about two-thirds of patients. Haemodialysis should not be used routinely because it does not improve the outcome. Patients who survive should be considered for liver transplantation.
- *Type 2 hepatorenal syndrome* usually occurs in patients with refractory ascites, is characterised by a moderate and stable increase in serum creatinine, and has a better prognosis.

Varices and hepatocellular carcinoma surveillance

Once the diagnosis of cirrhosis is made, endoscopy should be performed to screen for oesophageal varices (p. 947) and ultrasound performed to check for hepatocellular carcinoma (p. 968).

Prognosis

The overall prognosis in cirrhosis is poor. Many patients present with advanced disease and/or serious complications that carry a high mortality. Overall, only 25% of patients survive 5 years from diagnosis but, where liver function is good, 50% survive for 5 years and 25% for up to 10 years. The prognosis is more favourable when the underlying cause of the cirrhosis can be corrected, as in alcohol misuse, haemochromatosis and Wilson's disease.

Laboratory tests give only a rough guide to prognosis in individual patients. Deteriorating liver function, as evidenced by jaundice, ascites or encephalopathy, indicates a poor prognosis unless a treatable cause such as infection is found. Increasing bilirubin, falling albumin (or an albumin concentration < 30 g/L), marked hyponatraemia (< 120 mmol/L) not due to diuretic therapy, and a prolonged prothrombin time are all bad prognostic features (Boxes 23.29 and 23.30). The

i 23.29 Child–Pugh classification of prognosis in cirrhosis			
Score	1	2	3
Encephalopathy	None	Mild	Marked
Bilirubin (μmol/L)*			
PBC/sclerosing cholangitis	< 68	68–170	> 170
Other causes of cirrhosis	< 34	34–50	> 50
Albumin (g/L)	> 35	28–35	< 28
Prothrombin time (seconds prolonged)	< 4	4–6	> 6
Ascites	None	Mild	Marked
Add the individual scores: < 7 = Child's A, 7–9 = Child's B, > 9 = Child's C			
*To convert bilirubin in μmol/L to mg/dL, divide by 17.			

i 23.30 Survival in cirrhosis				
Child–Pugh grade	Survival (%)			Hepatic deaths (%)
	1 year	5 years	10 years	
A	82	45	25	43
B	62	20	7	72
C	42	20	0	85

Child–Pugh score and, more recently, the MELD (Model for End-stage Liver Disease) score can be used to assess prognosis. The MELD is more difficult to calculate at the bedside but, unlike the Child–Pugh score, includes renal function; if this is impaired, it is known to be a poor prognostic feature in end-stage liver disease (Box 23.31). Although these scores give a guide to prognosis, the course of cirrhosis can be unpredictable, as unforeseen complications such as variceal bleeding may unexpectedly lead to death.

i 23.31 1-year survival rate depending on MELD score		
MELD score	1-year survival (%)	
	No complications	Complications*
< 9	97	90
10–19	90	85
20–29	70	65
30–39	70	50
MELD from SI units		
$10 \times (0.378[\ln \text{ serum bilirubin } (\mu\text{mol/L}) + 1.12[\ln \text{ INR}] + 0.957[\ln \text{ serum creatinine } (\mu\text{mol/L})] + 0.643)$		
MELD from non-SI units		
$3.8 [\ln \text{ serum bilirubin } (\text{mg/dL})] + 11.2 [\ln \text{ INR}] + 9.3 [\ln \text{ serum creatinine } (\text{mg/dL})] + 6.4$		
ln = natural log. To calculate online, go to www.unos.org/resources/meldPeldCalculator.asp .		
*Complications are the presence of ascites, encephalopathy or variceal bleeding.		

PORTAL HYPERTENSION

Portal hypertension is an invariable complication of cirrhosis but also can occur as the result of other causes. It is defined as a portal venous pressure above 7 mmHg; however, clinical features or complications do not usually develop until the portal venous pressure exceeds 12 mmHg. Increased vascular resistance is the cause in most cases, but the underlying causes are classified in accordance with the main sites of obstruction to blood flow in the portal venous system (Fig. 23.26). Extrahepatic portal vein obstruction is the usual source of portal hypertension in childhood and adolescence, while cirrhosis causes at least 90% of cases of portal hypertension in adults in developed countries. Schistosomiasis is the most common cause of portal hypertension world-wide but is infrequent outside endemic areas (e.g. Egypt; p. 370).

Clinical features

The clinical features of portal hypertension result principally from portal venous congestion and collateral vessel formation (Box 23.32). Splenomegaly is a cardinal finding, and a diagnosis of portal hypertension is unusual when splenomegaly cannot be detected clinically or by ultrasonography. The spleen is rarely enlarged more than 5 cm below the left costal margin in adults, but more marked splenomegaly can occur in childhood and adolescence. Collateral vessels may be visible on the anterior abdominal wall and occasionally several radiate from the umbilicus to form a caput medusae. Rarely, a large umbilical collateral vessel has a blood flow sufficient to give a venous hum on auscultation (Cruveilhier–Baumgarten syndrome). The most important collateral vessel formation occurs in the oesophagus and stomach, and this can be a source of severe bleeding. Rectal varices also cause bleeding and are often mistaken for haemorrhoids, which are no more common in portal hypertension than in the general population. Feter hepaticus results from portosystemic shunting of blood, which allows mercaptans to pass directly to the lungs.

Ascites can occur as a result of portal hypertension when intrahepatic sinusoidal distension is present, as occurs with post-hepatic portal hypertension (hepatic outflow obstruction, p. 973) or cirrhosis. Pre-sinusoidal portal hypertension does not cause ascites, as there is no distension of the sinusoids.

The most important clinical feature of portal hypertension is variceal bleeding, which commonly arises from oesophageal varices located within 3–5 cm of the oesophagogastric junction, or from gastric varices. The size of the varices, endoscopic variceal features such as red spots and red stripes, high portal pressure and liver failure are all general factors that predispose to bleeding. Drugs capable of causing mucosal erosion, such as salicylates and other non-steroidal anti-inflammatory drugs (NSAIDs), can also precipitate bleeding. Variceal bleeding is often severe, and recurrent bleeding occurs if preventative treatment is not given. Bleeding from varices at other sites is comparatively uncommon but most often occurs from varices in the rectum or intestinal stomas.

Pathophysiology

Increased portal vascular resistance leads to a gradual reduction in the flow of portal blood to the liver and simultaneously to the development of collateral vessels,

Fig. 23.26 Classification of portal hypertension according to site of vascular obstruction. *Most common cause. Note that splenic vein occlusion can also follow pancreatitis leading to gastric varices.

23.32 Complications of portal hypertension

- Variceal bleeding: oesophageal, gastric, other (rare)
- Congestive gastropathy
- Hypersplenism
- Ascites*
- Iron deficiency anaemia
- Renal failure
- Hepatic encephalopathy

*Except in post-hepatic.

allowing portal blood to bypass the liver and enter the systemic circulation directly. Portosystemic shunting occurs, particularly in the gastrointestinal tract and especially the distal oesophagus, stomach and rectum, in the anterior abdominal wall, and in the renal, lumbar, ovarian and testicular vasculature. Stomal varices can also occur at the site of an ileostomy. Normally, virtually all the portal blood flows through the liver but, as collateral

vessel formation progresses, more than half of the portal blood flow may be shunted directly to the systemic circulation. Increased portal flow contributes to portal hypertension but is not the dominant factor.

Investigations

The diagnosis is often made on clinical grounds. Portal venous pressure measurements are rarely needed for clinical assessment or routine management, but can be used to confirm portal hypertension and to differentiate sinusoidal and pre-sinusoidal forms. Pressure measurements are usually made by using a balloon catheter inserted using the transjugular route (via the inferior vena cava into a hepatic vein and then hepatic venule) to measure the wedged hepatic venous pressure (WHVP). This is used as an indirect measurement of portal vein pressure. Thrombocytopenia is common due to hypersplenism, and platelet counts are usually in the region of $100 \times 10^9/L$; values below $50 \times 10^9/L$ are uncommon. Leucopenia

occurs occasionally but anaemia is seldom attributed directly to hypersplenism; if anaemia is found, a source of bleeding should be sought.

The most useful investigation is endoscopic examination of the upper gastrointestinal tract to determine whether gastro-oesophageal varices are present (see Fig. 23.20, p. 940). This establishes the presence of portal hypertension but not its cause. Ultrasonography often shows features of portal hypertension, such as splenomegaly and collateral vessels, and can sometimes indicate the cause, such as liver disease or portal vein thrombosis. CT and MRI angiography can identify the extent of portal vein clot and are used to identify hepatic vein patency.

Management

Management of variceal bleeding

This is discussed on page 940.

Primary prevention of variceal bleeding

Propranolol (80–160 mg/day) or nadolol is effective in reducing portal venous pressure. Administration of these drugs at doses which reduce the heart rate by 25% has been shown to be effective in the primary prevention of variceal bleeding, which is the most important complication of portal hypertension (Box 23.33). The efficacy of β -adrenoceptor antagonists (β -blockers) in primary prevention is similar to that of prophylactic banding.

Secondary prevention of variceal bleeding

Beta-blockers have also been used as a secondary measure to prevent recurrent variceal bleeding following banding.

EBM 23.33 Primary prevention of variceal bleeding

'In patients with cirrhosis, treatment with propranolol reduces variceal bleeding by 47% (NNT_B 10), death from bleeding by 45% (NNT_B 25) and overall mortality by 22% (NNT_B 16).'

• Hayes PC, et al. Lancet 1990; 336:153–156.

For further information:  www.bsg.org.uk

Congestive gastropathy

Long-standing portal hypertension causes chronic gastric congestion recognisable at endoscopy as multiple areas of punctate erythema ('snake skin gastropathy'). Rarely, similar lesions occur more distally in the gastrointestinal tract. These areas may become eroded, causing bleeding from multiple sites. Acute bleeding can occur, but repeated minor bleeding causing iron-deficiency anaemia is more common. Anaemia may be prevented by oral iron supplements but repeated blood transfusions can become necessary. Reduction of the portal pressure using propranolol 80–160 mg/day is the best initial treatment. If this is ineffective, a TIPSS procedure can be undertaken.

INFECTIONS AND THE LIVER

Viral hepatitis

Viral hepatitis is a common cause of jaundice and must be considered in anyone presenting with hepatitic liver blood tests (high transaminases). The causes are listed in Box 23.34.

All these viruses cause illnesses with similar clinical and pathological features and which are frequently anicteric or even asymptomatic. They differ in their tendency to cause acute and chronic infections. The features of the major hepatitis viruses are shown in Box 23.35.

23.34 Causes of viral hepatitis

Common

- Hepatitis A
- Hepatitis B \pm hepatitis D
- Hepatitis C
- Hepatitis E

Less common

- Cytomegalovirus
- Epstein–Barr virus

Rare

- Herpes simplex
- Yellow fever

23.35 Features of the main hepatitis viruses

	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D	Hepatitis E
Virus					
Group	Enterovirus	Hepadna virus	Flavivirus	Incomplete virus	Calicivirus
Nucleic acid	RNA	DNA	RNA	RNA	RNA
Size (diameter)	27 nm	42 nm	30–38 nm	35 nm	27 nm
Incubation (weeks)	2–4	4–20	2–26	6–9	3–8
Spread					
Faeces	Yes	No	No	No	Yes
Blood	Uncommon	Yes	Yes	Yes	No
Saliva	Yes	Yes	Yes	Unknown	Unknown
Sexual	Uncommon	Yes	Uncommon	Yes	Unknown
Vertical	No	Yes	Uncommon	Yes	No
Chronic infection	No	Yes	Yes	Yes	No
Prevention					
Active	Vaccine	Vaccine	No	Prevented by	No
Passive	Immune serum globulin	Hyperimmune serum globulin	No	hepatitis B vaccination	No
Note All body fluids are potentially infectious, although some (e.g. urine) are less infectious than others.					

Clinical features of acute infection

A non-specific prodromal illness characterised by headache, myalgia, arthralgia, nausea and anorexia usually precedes the development of jaundice by a few days to 2 weeks. Vomiting and diarrhoea may follow, and abdominal discomfort is common. Dark urine and pale stools may precede jaundice. There are usually few physical signs. The liver is often tender but only minimally enlarged. Occasionally, mild splenomegaly and cervical lymphadenopathy are seen. These are more frequent in children or those with Epstein-Barr virus infection.

Jaundice may be mild and the diagnosis may be suspected only after finding abnormal liver blood tests in the setting of non-specific symptoms. Symptoms rarely last longer than 3–6 weeks. Complications may occur, as listed in Box 23.36, but these are rare.

**23.36 Complications of acute viral hepatitis**

- Acute liver failure
- Cholestatic hepatitis (hepatitis A)
- Aplastic anaemia
- Chronic liver disease and cirrhosis (hepatitis B and C)
- Relapsing hepatitis

Investigations

A hepatic pattern of LFTs develops, with serum transaminases typically between 200 and 2000 U/L. The plasma bilirubin reflects the degree of liver damage. The ALP rarely exceeds twice the upper limit of normal. Prolongation of the prothrombin time indicates the severity of the hepatitis but, except in rare cases of acute liver failure, rarely exceeds 25 seconds. The white cell count is usually normal with a relative lymphocytosis. Serological tests confirm the aetiology of the infection.

Management

Most individuals do not need hospital care. Drugs such as sedatives and narcotics, which are metabolised in the liver, should be avoided. No specific dietary modifications are needed. Alcohol should be avoided during the acute illness. Elective surgery should be avoided in cases of acute viral hepatitis, as there is a risk of post-operative liver failure.

Liver transplantation is very rarely indicated for acute viral hepatitis complicated by liver failure, but is commonly performed for complications of cirrhosis resulting from chronic hepatitis B and C infection.

Hepatitis A

The hepatitis A virus (HAV) belongs to the picornavirus group of enteroviruses. HAV is highly infectious and is spread by the faecal-oral route. Infected individuals, who may be asymptomatic, excrete the virus in faeces for about 2–3 weeks before the onset of symptoms and then for a further 2 weeks or so. Infection is common in children but often asymptomatic, and so up to 30% of adults will have serological evidence of past infection but give no history of jaundice. Infection is also more common in areas of overcrowding and poor sanitation. In occasional outbreaks water and shellfish have been the vehicles of transmission. In contrast to hepatitis B, a chronic carrier state does not occur.

Investigations

Only one HAV antigen has been found; individuals infected with HAV make an antibody to this antigen (anti-HAV). Anti-HAV is important in diagnosis, as HAV is only present in the blood transiently during the incubation period. Excretion in the stools occurs for only 7–14 days after the onset of the clinical illness and the virus cannot be grown readily. Anti-HAV of the IgM type, indicating a primary immune response, is already present in the blood at the onset of the clinical illness and is diagnostic of an acute HAV infection. Titres of this antibody fall to low levels within about 3 months of recovery. Anti-HAV of the IgG type is of no diagnostic value as HAV infection is common and this antibody persists for years after infection, but it can be used as a marker of previous HAV infection. Its presence indicates immunity to HAV.

Management

Infection in the community is best prevented by improving social conditions, especially overcrowding and poor sanitation. Individuals can be given substantial protection from infection by active immunisation with an inactivated virus vaccine.

Immunisation should be considered for individuals with chronic hepatitis B or C infections. Immediate protection can be provided by immune serum globulin if this is given soon after exposure to the virus. The protective effect of immune serum globulin is attributed to its anti-HAV content. Immunisation should be considered for those at particular risk, such as close contacts, the elderly, those with other major disease and perhaps pregnant women.

Immune serum globulin can be effective in an outbreak of hepatitis, in a school or nursery, as injection of those at risk prevents secondary spread to families. People travelling to endemic areas are best protected by vaccination.

Acute liver failure is rare in hepatitis A (0.1%) and chronic infection does not occur. However, HAV infection in patients with chronic liver disease may cause serious or life-threatening disease. In adults a cholestatic phase with elevated ALP levels may complicate infection.

Hepatitis B

The hepatitis B virus consists of a core containing DNA and a DNA polymerase enzyme needed for virus replication. The core of the virus is surrounded by surface protein (Fig. 23.27). The virus, also called a Dane particle, and an excess of its surface protein (known as hepatitis B surface antigen) circulate in the blood. Humans are the only source of infection.

Hepatitis B infection affects 300 million people and is one of the most common causes of chronic liver disease and hepatocellular carcinoma world-wide.

Hepatitis B may cause an acute viral hepatitis; however, the acute infection is often asymptomatic, particularly when acquired at birth. Many individuals with chronic hepatitis B are also asymptomatic. Chronic hepatitis, associated with elevated serum transaminases, may occur and can lead to cirrhosis, usually after decades of infection (Fig. 23.28).

The risk of progression to chronic liver disease depends on the source of infection (Box 23.37). Vertical transmission from mother to child in the perinatal period

Fig. 23.27 Schematic diagram of hepatitis B virus. Hepatitis B surface antigen (HBsAg) is a protein which makes up part of the viral envelope. Hepatitis B core antigen (HBcAg) is a protein which makes up the capsid or core part of the virus (found in the liver but not in blood). Hepatitis B e antigen (HBeAg) is part of the HBcAg which can be found in the blood and indicates infectivity.

23.37 Source of hepatitis B infection and risk of chronic infection

Horizontal transmission (10%)

- Injection drug use
- Infected unscreened blood products
- Tattoos/acupuncture needles
- Sexual (homosexual and heterosexual)
- Close living quarters/playground play as a toddler (may contribute to high rate of horizontal transmission in Africa)

Vertical transmission (90%)

- HBsAg-positive mother

is the most common cause of infection world-wide and carries the highest risk.

In this setting, adaptive immune responses to HBV may be absent initially, with apparent immunological tolerance. Several mechanisms contribute towards this.

- Firstly, the introduction of antigen in the neonatal period is tolerogenic.
- Secondly, the presentation of such antigen within the liver, as described above, promotes tolerance; this is particularly evident in the absence of a significant innate or inflammatory response.
- Finally, very high loads of antigen may lead to so-called 'exhaustion' of cellular immune responses.

Fig. 23.28 Natural history of chronic hepatitis B infection. There is an initial immunotolerant phase with high levels of virus and normal liver biochemistry. An immunological response to the virus then occurs, with elevation in serum transaminases which causes liver damage: chronic hepatitis. If this response is sustained over many years and viral clearance does not occur promptly, chronic hepatitis may result in cirrhosis. In individuals where the immunological response is successful, viral load falls, HBe antibody develops and there is no further liver damage. Some individuals may subsequently develop HBV-DNA mutants, which escape from immune regulation, and viral load again rises with further chronic hepatitis. Mutations in the core protein result in the virus's inability to secrete HBe antigen despite high levels of viral replication; such individuals have HBeAg-negative chronic hepatitis. (ALT = alanine aminotransferase; AST = aspartate aminotransferase)

However, the state of tolerance is not permanent and may be reversed as a result of therapy, or through spontaneous changes in innate responses such as interferon-alpha and NK cells, accompanied by host-mediated immunopathology.

Investigations

Serology

HBV contains several antigens to which infected persons can make immune responses (Fig. 23.29); these antigens and their antibodies are important in identifying HBV infection (Box 23.38).

- The *hepatitis B surface antigen* (HBsAg) is an indicator of active infection, and a negative test for HBsAg makes HBV infection very unlikely. In acute liver failure from hepatitis B the liver damage is mediated by viral clearance and so HBsAg is negative, with evidence of recent infection shown by the presence of hepatitis B core IgM. HBsAg appears in the

Fig. 23.29 Serological responses to hepatitis B virus infection.

(HBsAg = hepatitis B surface antigen; anti-HBs = antibody to HBsAg; HBeAg = hepatitis B e antigen; anti-HBe = antibody to HBeAg; anti-HBc = antibody to hepatitis B core antigen)

23.38 How to interpret the main investigations used in the serological diagnosis of hepatitis B virus infection

Interpretation	Anti-HBc			
	HBsAg	IgM	IgG	Anti-HBs

Occasional	–	–	+	–
Immunisation without infection	–	–	–	+

+ Positive; – negative; ± present at low titre or absent.

blood late in the incubation period but before the prodromal phase of acute type B hepatitis; it may be present for a few days only, disappearing even before jaundice has developed, but usually lasts for 3–4 weeks and can persist for up to 5 months. The persistence of HBsAg for longer than 6 months indicates chronic infection. Antibody to HBsAg (anti-HBs) usually appears after about 3–6 months and persists for many years or perhaps permanently. Anti-HBs implies either a previous infection, in which case anti-HBc (see below) is usually also present, or previous vaccination, in which case anti-HBc is not present.

- The *hepatitis B core antigen* (HBcAg) is not found in the blood, but antibody to it (anti-HBc) appears early in the illness and rapidly reaches a high titre, which subsides gradually but then persists. Anti-HBc is initially of IgM type with IgG antibody appearing later. Anti-HBc (IgM) can sometimes reveal an acute HBV infection when the HBsAg has disappeared and before anti-HBs has developed (see Fig. 23.29 and Box 23.38).
- The *hepatitis B e antigen* (HBeAg) is an indicator of viral replication. In acute hepatitis B it may appear only transiently at the outset of the illness; its appearance is followed by the production of antibody (anti-HBe). The HBeAg reflects active replication of the virus in the liver.

Chronic HBV infection (see below) is marked by the presence of HBsAg and anti-HBc (IgG) in the blood. Usually, HBeAg or anti-HBe is also present; HBeAg indicates continued active replication of the virus in the liver. Although the presence of anti-HBe usually implies low viral replication, the exception is HBeAb-positive replicating chronic hepatitis B (also called 'pre-core mutant' infection and discussed below), in which high levels of serum HBV-DNA are seen, despite negative HBeAg.

Viral load

HBV-DNA can be measured by polymerase chain reaction (PCR) in the blood. Viral loads are usually in excess of 10^5 copies/mL in the presence of active viral replication, as indicated by the presence of e antigen. In contrast, in those with low viral replication, HBsAg- and anti-HBe-positive, viral loads are less than 10^5 copies/mL. The exception is in patients who have a mutation in the pre-core protein, which means they cannot secrete e antigen into serum (Fig. 23.30). Such individuals will be anti-HBe-positive but have a high viral load and often evidence of chronic hepatitis. These mutations are common in the Far East and those patients affected are classified as having e antigen-negative chronic hepatitis. They respond differently to antiviral drugs from those with classical e antigen-positive chronic hepatitis.

Measurement of viral load is important in monitoring antiviral therapy and identifying patients with pre-core mutants. Specific HBV genotypes can also be identified using PCR. Genotypes B and C appear to have more aggressive disease that responds less well to interferon.

Management

Acute hepatitis B

Treatment is supportive with monitoring for acute liver failure, which occurs in less than 1% of cases. There is no definitive evidence that antiviral therapy (e.g. lamivudine) reduces the severity or duration of acute hepatitis B.

Fig. 23.30 The site of HBV-DNA mutations. HBV-DNA encodes four proteins: a DNA polymerase needed for viral replication (P), a surface protein (S), a core protein (C) and an X protein. The pre-C and C regions encode a core protein and an e antigen. Although mutations in the hepatitis B virus are frequent, certain mutations have important clinical consequences. Pre-C encodes a signal sequence needed for the C protein to be secreted from the liver cell into serum as e antigen. A mutation in the pre-core region leads to a failure of secretion of e antigen into serum, and so individuals have high levels of viral production but no detectable e antigen in the serum. Mutations can also occur in the surface protein and may lead to the failure of vaccination to prevent infection since surface antibodies are produced against the native S protein. Mutations also occur in the DNA polymerase during antiviral treatment with lamivudine.

Full recovery occurs in 90–95% of adults following acute HBV infection. The remaining 5–10% develop a chronic infection which usually continues for life, although later recovery occasionally occurs. Infection passing from mother to child at birth leads to chronic infection in the child in 90% of cases and recovery is rare. Chronic infection is also common in immunodeficient individuals, such as those with Down's syndrome or HIV infection. Fulminant liver failure due to acute hepatitis B occurs in less than 1% of cases.

Recovery from acute HBV infection occurs within 6 months and is characterised by the appearance of antibody to viral antigens. Persistence of HBeAg beyond this time indicates chronic infection. Combined HBV and HDV infection causes more aggressive disease.

Chronic hepatitis B

Treatments are still limited, as no drug is able to eradicate hepatitis B infection completely (i.e. render the patient HBsAg-negative). The goals of treatment are HBeAg seroconversion, reduction in HBV-DNA and normalisation of the LFTs. The indication for treatment is a high viral load in the presence of active hepatitis, as demonstrated by elevated serum transaminases and/or histological evidence of inflammation and fibrosis. The oral antiviral agents are more effective in reducing viral loads in patients with e antigen-negative chronic hepatitis B than in those with e antigen-positive chronic hepatitis B, as the pre-treatment viral loads are lower.

Most patients with chronic hepatitis B are asymptomatic and develop complications such as cirrhosis and hepatocellular carcinoma only after many years (see Fig. 23.28). Cirrhosis develops in 15–20% of patients with chronic HBV over 5–20 years. This proportion is higher in those who are e antigen-positive.

Interferon-alfa. This is most effective in selected patients with a low viral load and serum transaminases greater than twice the upper limit of normal, in whom it acts by augmenting a native immune response. In HBeAg-positive chronic hepatitis, 33% lose e antigen after 4–6 months of treatment, compared to 12% of controls. Response rates are lower in HBeAg-negative chronic hepatitis, even when patients are given longer courses of treatment. Interferon is contraindicated in the presence of cirrhosis, as it may cause a rise in serum transaminases and precipitate liver failure. Longer-acting pegylated interferons which can be given once weekly have been evaluated in both HBeAg-positive and HBeAg-negative chronic hepatitis (Box 23.39). Other antiviral therapies are required because many patients with chronic hepatitis B have high levels of viraemia and/or low transaminase levels, and are therefore not candidates for interferon. Side-effects are common and include fatigue, depression, irritability, bone marrow suppression and thyroid disease. The drug appears to be better tolerated in patients with hepatitis B compared to those with hepatitis C.

Lamivudine. This is a nucleoside analogue which inhibits DNA polymerase and suppresses HBV-DNA levels. It is effective in improving liver function in patients with decompensated cirrhosis and may prevent the need for transplantation. Long-term therapy is complicated by the development of HBV-DNA polymerase mutants (known as 'YMDD variants'), which may occur after 9 months of treatment and is characterised by a rise in viral load during treatment. These viral mutants are less hepatotoxic than native virus. Elevations in transaminases occur when lamivudine is stopped if mutant virus is present, as native virus replaces mutant virus. In the event of mutations occurring, other antiviral agents can be added (add-on therapy) but are less effective than when used in lamivudine-naïve patients.

Adefovir. This is a nucleotide analogue that is phosphorylated to yield active drug which inhibits HBV-DNA polymerase. It reduces HBV-DNA levels by 3–4 logs, enhances the frequency of HBeAg seroconversion and leads to histological improvement, but is contraindicated in renal failure. The HBV-DNA mutants develop at a lower rate than with lamivudine; 2% are identified after 2 years of treatment but this figure increases to 18% after 3 years. Relapse occurs on stopping treatment, and the optimum length of treatment remains unknown. Adefovir is effective in suppressing most of the lamivudine-induced DNA polymerase mutant viruses.

EBM 23.39 Pegylated interferons in chronic hepatitis B infection

'In HBeAg-positive chronic hepatitis, treatment with pegylated interferon for 6 months eliminates HBeAg in 35%, and normalises liver biochemistry in 25% of patients. In HBeAg-negative chronic hepatitis, treatment with pegylated interferon for 12 months leads to normal liver biochemistry in 60%, and sustained suppression of hepatitis B virus load below 400 copies/mL in 20% of patients.'

- Marcellin P. *N Engl J Med* 2004; 351:1206–1217.

For further information:  www.aasld.org

 www.nice.org.uk

EBM 23.40 Entecavir and telbivudine in chronic hepatitis B infection

'In HBeAg-positive patients, 48 weeks of treatment with entecavir suppresses HBV-DNA levels in 67%, compared to 36% with lamivudine and 60% with telbivudine. Anti-HBe seroconversion occurs in 21% following a year of entecavir, lamivudine or telbivudine. In HBeAg-negative chronic hepatitis, HBV-DNA negativity is achieved in 90% with entecavir, compared to 72% with lamivudine and 88% with telbivudine at 1 year. Treatment also improves histology and liver biochemistry.'

- Lai C-L. N Engl J Med 2007; 357:2576–2588.
- Lai C-L. N Engl J Med 2006; 354:1011–1020.

For further information:  www.aasld.org

Entecavir and telbivudine. These drugs are more effective than lamivudine and adefovir in reducing viral load in HBeAg-positive and HBeAg-negative chronic hepatitis (Box 23.40). Antiviral resistance mutations occur in only 1% after 3 years of entecavir drug exposure. Entecavir, unlike telbivudine, may have anti-HIV action and is contraindicated in HIV patients who are not on antiretroviral therapy.

Tenofovir and other drugs. Other drugs which also have action against chronic hepatitis B include tenofovir and emcitabine; these also have anti-HIV efficacy. Tenofovir has recently been shown to be superior to adefovir in the treatment of chronic hepatitis B (Box 23.41). The role of combination antiviral therapy, as used in HIV infection, is still unclear.

Liver transplantation. Historically, liver transplantation was contraindicated in the presence of hepatitis B because infection often recurred in the graft. However, the use of post-liver transplant prophylaxis with lamivudine and hepatitis B immunoglobulins has reduced the reinfection rate to 10% and increased 5-year survival to 80%, making transplantation an acceptable treatment option in selected cases.

Prevention

Individuals are most infectious when markers of continuing viral replication, such as HBeAg, and high levels of HBV-DNA are present in the blood; they are least infectious when only anti-HBe is present with low levels of virus. HBV-DNA can be found in saliva, urine, semen and vaginal secretions. The virus is about ten times more infectious than hepatitis C, which in turn is about ten times more infectious than HIV.

A recombinant hepatitis B vaccine containing HBsAg is available (Engerix) and is capable of producing active

immunisation in 95% of normal individuals. The vaccine gives a high degree of protection and should be offered to those at special risk of infection who are not already immune, as evidenced by anti-HBs in the blood (Box 23.42). The vaccine is ineffective in those already infected by HBV. Infection can also be prevented or minimised by the intramuscular injection of hyperimmune serum globulin prepared from blood containing anti-HBs. This should be given within 24 hours, or at most a week, of exposure to infected blood in circumstances likely to cause infection (e.g. needlestick injury, contamination of cuts or mucous membranes). Vaccine can be given together with hyperimmune globulin (active-passive immunisation).

Neonates born to hepatitis B-infected mothers should be immunised at birth and given immunoglobulin. Hepatitis B serology should then be checked at 12 months of age.

23.42 At-risk groups meriting hepatitis B vaccination in low endemic areas

- Parenteral drug users
- Men who have sex with men
- Close contacts of infected individuals
 - Newborn of infected mothers
 - Regular sexual partners
- Patients on chronic haemodialysis
- Patients with chronic liver disease
- Medical, nursing and laboratory personnel

Hepatitis D (Delta virus)

The hepatitis D virus (HDV) is an RNA-defective virus which has no independent existence; it requires HBV for replication and has the same sources and modes of spread. It can infect individuals simultaneously with HBV, or can superinfect those who are already chronic carriers of HBV. Simultaneous infections give rise to acute hepatitis, which is often severe but is limited by recovery from the HBV infection. Infections in individuals who are chronic carriers of HBV can cause acute hepatitis with spontaneous recovery, and occasionally simultaneous cessation of the chronic HBV infection occurs. Chronic infection with HBV and HDV can also occur, and this frequently causes rapidly progressive chronic hepatitis and eventually cirrhosis.

HDV has a world-wide distribution. It is endemic in parts of the Mediterranean basin, Africa and South America, where transmission is mainly by close personal contact and occasionally by vertical transmission from mothers who also carry HBV. In non-endemic areas, transmission is mainly a consequence of parenteral drug misuse.

Investigations

HDV contains a single antigen to which infected individuals make an antibody (anti-HDV). Delta antigen appears in the blood only transiently, and in practice diagnosis depends on detecting anti-HDV. Simultaneous infection with HBV and HDV followed by full recovery is associated with the appearance of low titres of anti-HDV of IgM type within a few days of the onset of the illness. This antibody generally disappears within 2 months but persists in a few patients. Superinfection

EBM 23.41 Tenofovir for chronic hepatitis B

'Among patients with chronic HBV infection, tenofovir at a daily dose of 300 mg had superior antiviral efficacy with a similar safety profile as compared with adefovir 10 mg daily. In HBeAg-positive patients, tenofovir suppressed HBV DNA to < 400 copies/mL in 76% of patients, compared with 13% of those given adefovir ($p < 0.001$).

- Marcellin P, et al. NEJM 2008; 359:2442–2445.

of patients with chronic HBV infection leads to the production of high titres of anti-HDV, initially IgM and later IgG. Such patients may then develop chronic infection with both viruses, in which case anti-HDV titres plateau at high levels.

Management

Effective management of hepatitis B effectively prevents hepatitis D.

Hepatitis C

This is caused by an RNA flavivirus. Acute symptomatic infection with hepatitis C is rare. Most individuals are unaware of when they became infected and are only identified when they develop chronic liver disease.

Eighty per cent of individuals exposed to the virus become chronically infected and late spontaneous viral clearance is rare.

Hepatitis C is the cause of what used to be known as 'non-A, non-B hepatitis', a syndrome of acute hepatitis often with jaundice seen after a transfusion of blood or blood products. Following the identification of the virus in 1990, blood donors are now screened for infection in many parts of the world. New cases of post-transfusion hepatitis C no longer occur in the UK.

Hepatitis C infection is usually now identified in asymptomatic individuals screened because they have risk factors for infection such as previous injection drug use (Box 23.43) or they have incidentally been found to have abnormal liver blood tests. Although most individuals remain asymptomatic until progression to cirrhosis occurs, fatigue can complicate chronic infection and appears to be unrelated to the degree of liver damage.

Investigations

Serology and virology

The HCV protein contains several antigens that give rise to antibodies in an infected person, and these are used in diagnosis. It may take 6–12 weeks for antibodies to appear in the blood following acute infection such as a needlestick injury. In these cases hepatitis C RNA can be identified in the blood as early as 2–4 weeks after infection. Active infection is confirmed by the presence of serum hepatitis C RNA in anyone who is antibody-positive. Anti-HCV antibodies persist in serum even after viral clearance, whether spontaneous or post-treatment.

Molecular analysis

There are six common viral genotypes whose distribution varies world-wide. Genotype has no effect on progression of liver disease but does affect response to treatment. Genotype 1 is most common in north-

ern Europe and is less easy to eradicate with current treatments.

Liver function tests

LFTs may be normal or show fluctuating serum transaminases between 50 and 200 U/L. Jaundice is rare and only usually appears in end-stage cirrhosis.

Liver histology

Serum transaminase levels in hepatitis C are a poor predictor of the degree of liver fibrosis, and so a liver biopsy is often required to stage the degree of liver damage. Non-invasive methods of assessing liver fibrosis in hepatitis C infection remain an area of active research. The degree of inflammation and fibrosis can be scored histologically. The most common scoring system used in hepatitis C is the Metavir system, which scores fibrosis from 1 to 4, the latter equating to cirrhosis.

Management

The aim of treatment is to eradicate infection. The treatment of choice is pegylated α -interferon given weekly subcutaneously, together with oral ribavirin, a synthetic nucleotide analogue (Box 23.44). The main side-effect of ribavirin is haemolytic anaemia. Side-effects of interferon are significant and include flu-like symptoms, irritability, and depression which can affect quality of life. Virological relapse can occur in the first 3 months after stopping treatment, and cure is defined as loss of virus from serum 6 months after completing therapy (sustained virological response, or SVR). The length of treatment and efficacy depend on viral genotype (12 months' treatment for genotype 1 results in a 40% SVR, whereas 6 months' treatment for genotype 2/3 leads to an SVR in > 70%). Response to treatment is better in patients who have an early virological response, as defined by negativity of HCV-RNA in serum 1 month after starting therapy, and it may be possible to shorten the duration of therapy in this patient group. Protease inhibitors are currently in clinical trials; when given in combination with interferon and ribavirin, they appear to increase efficacy.

Liver transplantation should be considered when complications of cirrhosis occur, such as diuretic-resistant ascites. Unfortunately, hepatitis C almost always recurs in the transplanted liver and up to 15% of patients will develop cirrhosis in the liver graft within 5 years of transplantation.

There is no active or passive protection against HCV. Progression from chronic hepatitis to cirrhosis occurs over 20–40 years. Risk factors for progression include male gender, immunosuppression (such as co-infection with HIV) and heavy alcohol misuse. Not everyone with hepatitis C infection will necessarily develop cirrhosis, but approximately 20% do so within 20 years. Once cirrhosis

23.43 Risk factors for the acquisition of chronic hepatitis C infection

- Intravenous drug misuse (95% of new cases in the UK)
- Unscreened blood products
- Vertical transmission (3% risk)
- Needlestick injury (3% risk)
- Iatrogenic parenteral transmission, (i.e. contaminated vaccination needles)
- Sharing toothbrushes/razors

EBM 23.44 Treatment of hepatitis C

'The addition of ribavirin to pegylated α -interferon therapy improves the overall sustained virological response from 33% to 55%.'

For further information: www.nice.org.uk

has developed, the 5- and 10-year survival rates are 95% and 81% respectively. One-quarter of people with cirrhosis will develop complications within 10 years and, once complications like ascites have arisen, the 5-year survival is around 50%. Once cirrhosis is present, 2–5% per year will develop primary hepatocellular carcinoma.

Hepatitis E

Hepatitis E is caused by an RNA virus which is endemic in India and the Middle East. An increase in prevalence has recently been noted in northern Europe and infection is no longer seen only in travellers from an endemic area.

The clinical presentation and management of hepatitis E are similar to that of hepatitis A. Disease is spread via the faecal–oral route; in most cases, it presents as a self-limiting acute hepatitis and does not cause chronic liver disease.

Hepatitis E differs from hepatitis A in that infection during pregnancy is associated with the development of acute liver failure, which has a high mortality. In acute infection, IgM antibodies to HEV are positive.

Other forms of viral hepatitis

Non-A, non-B, non-C (NANBNC) or non-A–E hepatitis is the term used to describe hepatitis thought to be due to a virus that is not HAV, HBV, HCV or HEV. Other viruses which affect the liver probably do exist, but the hepatitis viruses described above now account for the majority of hepatitis virus infections. Cytomegalovirus and Epstein–Barr virus infection causes abnormal LFTs in most patients, and occasionally icteric hepatitis occurs. Herpes simplex is a rare cause of hepatitis in adults, and most of these patients are immunocompromised. Abnormal LFTs are also common in chickenpox, measles, rubella and acute HIV infection.

HIV infection and the liver

Several causes of abnormal LFTs occur in HIV infection, as shown in Box 23.45. This topic is discussed in more detail on page 394.

23.45 Causes of abnormal liver blood tests in HIV infection

Hepatitis blood tests

- Chronic hepatitis C

- Tuberculosis
- Atypical mycobacterium
- Sclerosing cholangitis due to *Cryptosporidia*

ALCOHOLIC LIVER DISEASE

Alcohol is one of the most common causes of chronic liver disease. In the UK mortality from alcoholic liver disease is rising, with over 3000 deaths/year; the mean age at presentation is falling.

The risk of alcoholic liver disease is variable and not everyone who drinks heavily will develop liver disease. Only 10% of alcoholics have evidence of cirrhosis at post-mortem. Alcoholic liver disease does not occur below a threshold of 21 units/week in women and 28 units/week

23.46 Amount of alcohol in an average drink

Alcohol type	% alcohol by volume	Amount	Units*
Beer	3.5	440 mL (1 pint)	2
	9	440 mL (1 pint)	4
Wine	10	125 mL	1
	12	750 mL	9
'Alcopops'	6	330 mL	2
Sherry	17.5	750 mL	13
Vodka/um/gin	37.5	25 mL	1
Whisky/brandy	40	700 mL	28

*1 unit = 8 g.

in men (Box 23.46). Most individuals with liver disease will have drunk heavily for more than 5 years.

Although the average alcohol consumption of an individual with cirrhosis is 160 g/day for an average of 8 years, there is no clear linear relationship between dose and liver damage.

Some of the risk factors for alcoholic liver disease are:

- *Drinking patterns.* The type of beverage does not affect risk, but liver damage is more likely to occur in continuous rather than binge drinkers.
- *Gender.* The incidence of alcoholic liver disease is increasing in women, who often conceal alcohol misuse and have higher blood ethanol levels than men after drinking because their body mass is lower.
- *Genetics.* Alcoholism is more common in monozygotic than dizygotic twins. However, polymorphisms in the genes involved in alcohol metabolism, such as aldehyde dehydrogenase (ALD), have yet to be linked to alcoholic liver disease.
- *Nutrition.* Animals given a choline-deficient diet are more likely to develop alcoholic liver disease.

Pathophysiology

Alcohol is metabolised almost exclusively by the liver via one of two main pathways (Fig. 23.31).

- Eighty per cent of alcohol is metabolised to acetaldehyde by the mitochondrial enzyme, alcohol dehydrogenase (ADH). Acetaldehyde forms adducts with cellular proteins in hepatocytes which activate the immune system, leading to cell injury. Acetaldehyde is then metabolised to acetyl-CoA and acetate by ALD. This generates NADH from NAD (nicotinamide adenine dinucleotide), which changes the redox potential of the cell.
- The remaining 20% is metabolised by the mixed function oxidase enzymes of the smooth endoplasmic reticulum. Cytochrome CYP2E1 is an enzyme which oxidises ethanol to acetate. It is induced by alcohol, and during metabolism of ethanol it releases oxygen free radicals, leading to lipid peroxidation which can induce mitochondrial damage. The CYP2E1 enzyme also metabolises acetaminophen and hence chronic alcoholics are more susceptible to hepatotoxicity from low doses of paracetamol.

Fig. 23.31 Factors involved in the pathogenesis of alcoholic liver disease.

It is thought that pro-inflammatory cytokines may also be involved in inducing hepatic damage in alcoholic hepatitis, since endotoxin is released into the blood because of increased gut permeability, leading to release of TNF- α , IL-1, IL-2 and IL-8 from immune cells. All of these cytokines have been implicated in the pathogenesis of liver fibrosis (see Fig. 23.4, p. 924).

The pathological features of alcoholic liver disease are shown in Box 23.47. In about 80% of patients with severe alcoholic hepatitis, cirrhosis will coexist at presentation. Iron deposition is common and does not necessarily indicate haemochromatosis. Figure 23.33 (p. 958) shows the histological features of alcoholic liver disease, which are identical to those of non-alcoholic steatohepatitis.

Clinical features

Alcoholic liver disease has a wide clinical spectrum ranging from mild abnormalities of LFTs on biochemical testing to advanced cirrhosis. The liver is often enlarged in alcoholic liver disease, even in the presence of cirrhosis. Peripheral stigmata of chronic liver

23.48 Clinical syndromes of alcoholic liver disease

Fatty liver

- Asymptomatic abnormal liver biochemistry
- Normal/large liver

Alcoholic hepatitis

- Jaundice
- Malnutrition
- Hepatomegaly
- Features of portal hypertension (e.g. ascites, encephalopathy)

Cirrhosis

- Stigmata of chronic liver disease
- Ascites/varices/encephalopathy
- Large, normal or small liver
- Hepatocellular carcinoma

disease, such as palmar erythema, are more common in alcoholic cirrhosis than in cirrhosis of other aetiologies. Alcohol misuse may also cause damage of other organs and this should be specifically looked for (see Box 10.31, p. 247). Three types of alcoholic liver disease are recognised (Box 23.48), but in reality these overlap considerably, as do the pathological changes seen in the liver.

Alcoholic fatty liver disease (AFLD)

This usually presents with elevated transaminases in the absence of hepatomegaly. It has a good prognosis and steatosis usually disappears after 3 months of abstinence.

Alcoholic hepatitis

This presents with jaundice and hepatomegaly; complications of portal hypertension may also be present. It has a significantly worse prognosis than AFLD. About one-third of patients die in the acute episode, particularly those with hepatic encephalopathy or a prolonged prothrombin time. Cirrhosis often coexists; if not present, it is the likely outcome if drinking continues. Patients with acute alcoholic hepatitis often deteriorate during the first 1–3 weeks in hospital. Even if they abstain, it may take up to 6 months for jaundice to resolve. In patients presenting with jaundice who subsequently abstain, the 3- and 5-year survival is 70%. In contrast, those who continue to drink have 3- and 5-year survival rates of 60% and 34% respectively.

Alcoholic cirrhosis

Alcohol-induced cirrhosis often presents with a serious complication such as variceal haemorrhage or ascites, and only half of such patients will survive 5 years from presentation. However, most who survive the initial illness and who become abstinent will survive beyond 5 years.

Investigations

Investigations aim to establish alcohol misuse, exclude alternative or coexistent causes of liver disease, such as hepatitis C or haemochromatosis, and assess the severity of liver disease. The clinical history from patient, relatives and friends is most important in establishing alcohol misuse, duration and severity. Biological markers, particularly macrocytosis in the absence of anaemia, may suggest and support a history of alcohol misuse. A raised GGT is not specific for alcohol misuse and will be

23.47 Pathological features of alcoholic liver disease

- Neutrophil infiltration
- Mallory's hyaline
- Pericellular fibrosis
- Macrovesicular steatosis
- Fibrosis and cirrhosis
- Central hyaline sclerosis

elevated in the presence of hepatic steatosis and fibrosis. The level may not therefore return to normal with abstinence if chronic liver disease is present. Unexplained rib fractures, particularly bilateral, on a chest X-ray are also suggestive of alcohol misuse. The presence of jaundice suggests alcoholic hepatitis. Determining the extent of liver damage often requires a liver biopsy.

Prothrombin time and bilirubin are used to give a 'discriminant function' (DF), also known as the Maddrey score, which enables the clinician to assess prognosis in alcoholic hepatitis (PT = prothrombin time; serum bilirubin in $\mu\text{mol/L}$ is divided by 17 to convert to mg/dL):

$$\text{DF} = [4.6 \times \text{Increase in PT (sec)}] + \text{Bilirubin (mg/dL)}$$

A value over 32 implies severe liver disease with a poor prognosis.

A second scoring system, the Glasgow score, uses the age, white cell count and renal function in addition to PT and bilirubin to assess prognosis with a cutoff of 9 (Box 23.49).

Management

Cessation of alcohol consumption is the single most important treatment; without this, all other therapies are of limited value. Abstinence is even effective at preventing progression of liver disease and death when cirrhosis is present. Life-long abstinence is the best advice and is essential for those with more severe liver disease. Treatment of alcohol dependency is discussed on pages 246–247. In the acute presentation of alcoholic liver disease it is also important to identify and anticipate alcohol withdrawal and Wernicke's encephalopathy, which need treating in parallel with the liver disease (pp. 246 and 1199).

Treatment for complications of cirrhosis, such as variceal bleeding, encephalopathy and ascites, may also be needed.

The most important prognostic factor is the patient's ability to stop drinking alcohol. General health and life expectancy are improved when this occurs, irrespective of the form of alcoholic liver disease.

Nutrition

Good nutrition is very important, and enteral feeding via a fine-bore nasogastric tube may be needed in severely ill patients.

Corticosteroids

These are of value in patients with severe alcoholic hepatitis (Maddrey's discriminative score > 32) and increase

EBM 23.50 Corticosteroids in alcoholic hepatitis

'In severe alcoholic hepatitis, corticosteroids improve survival at 28 days from 65% to 85% (NNT₅ 5).'

• Mathurin P, et al. J Hepatol 2002; 36:480–487.

For further information:  www.aasld.org

survival (Box 23.50). A similar improvement in 28-day survival from 52% to 78% is seen when steroids are given to those with a Glasgow score of > 9 . Sepsis is the main side-effect of steroids, and existing sepsis and variceal haemorrhage are the main contraindications to their use. If the bilirubin has not fallen 7 days after starting steroids, the drugs are unlikely to reduce mortality and should be stopped.

Pentoxifylline

Pentoxifylline, which has a weak anti-TNF action, may be beneficial in severe alcoholic hepatitis. It appears to reduce the incidence of hepatorenal failure and its use is not complicated by sepsis (Box 23.51).

EBM 23.51 Pentoxifylline in alcoholic hepatitis

'In severe alcoholic hepatitis, oral pentoxifylline reduces inpatient mortality, particularly from hepatorenal failure, from 46% to 25% (NNT₅ 5).'

For further information:  www.aasld.org

Liver transplantation

The role of liver transplantation in the management of alcoholic liver disease remains controversial. In many centres, however, alcoholic liver disease is a common indication for liver transplantation. The challenge is to identify patients with an unacceptable risk of returning to harmful alcohol consumption. Many programmes require a 6-month period of abstinence from alcohol before a patient is considered for transplantation. Although this relates poorly to the incidence of alcohol relapse after transplantation, liver function may improve to the extent that transplantation is no longer necessary. The outcome of transplantation for alcoholic liver disease is good (if the patient remains abstinent) because minimal immunosuppression is often required and there is no risk of disease recurrence. Transplantation for alcoholic hepatitis has a poorer outcome than for complications of alcoholic cirrhosis.

NON-ALCOHOLIC FATTY LIVER DISEASE

Non-alcoholic fatty liver disease (NAFLD) is a disease of affluent societies which increases in prevalence in proportion to the rise in obesity. It has become the most common cause of chronic liver disease after hepatitis B, hepatitis

23.49 How to assess prognosis using the Glasgow alcoholic hepatitis score			
Score	1	2	3
Age	< 50	> 50	
WCC ($\times 10^9/\text{L}$)	< 15	> 15	> 2.0
Urea (mmol/L)	< 5	> 5	> 250
PT ratio	< 1.5	$1.5\text{--}2.0$	
Bilirubin ($\mu\text{mol/L}$)	< 125	$125\text{--}250$	
A score > 9 is associated with a 40% 28-day survival, compared to 80% for patients with a score < 9 .			
(PT = prothrombin time; WCC = white cell count)			

C and alcohol. It can be classified into simple fatty liver disease (or non-alcoholic fatty liver, NAFL) and non-alcoholic steatohepatitis (NASH). The former has a benign prognosis, but the latter is associated with fibrosis and progression to cirrhosis. Many consider NAFLD to be a liver complication of the metabolic syndrome (hypertriglyceridaemia, hypertension, diabetes mellitus, an elevated body mass index (BMI) > 25 and especially truncal obesity; see Box 21.4, p. 802).

NAFLD affects about 3% of the population in the USA. The prevalence is higher in those with diabetes and those with the metabolic syndrome. Rare causes of NAFLD include tamoxifen, amiodarone and exposure to certain petrochemicals. NAFLD has also been reported following weight-reducing jejunal bypass surgery. Many cases of cirrhosis that were previously labelled cryptogenic (i.e. cause unknown) are now thought to be due to NAFLD.

Pathophysiology

Most individuals with NAFLD have insulin resistance (see Box 21.4, p. 802) but not necessarily overt glucose intolerance. The current two-hit hypothesis (Fig. 23.32) explains why not everyone with fatty liver disease develops hepatic fibrosis. The 'first hit' results in steatosis (fatty liver), which is only complicated by inflammation if a 'second hit' occurs. Leptin (p. 108), which, as well as reducing appetite, is fibrogenic in vitro, is probably then needed to cause hepatic fibrosis. The components of the first hit include release of free fatty acids from central adipose tissue, which, along with adipokines, drain into the portal vein as well as causing insulin resistance. Together, these processes result in reduced hepatic fatty acid oxidation and increased fatty acid synthesis (p. 802 and Figure 21.2, p. 799).

Clinical features

Most patients present with asymptomatic abnormal LFTs, particularly elevation of the transaminases or isolated elevation of the GGT. Occasionally, the condition presents with a complication of cirrhosis such as variceal haemorrhage or hepatocellular carcinoma. In contrast to alcoholic liver disease, jaundice only occurs when cirrhosis is established. NAFLD is the most likely diagnosis in a patient with mild to moderately elevated serum transaminases, no history of alcohol abuse and a negative chronic liver disease screen.

Investigations

Liver function tests

Unfortunately, there is no single diagnostic blood test but, in contrast to alcoholic liver disease, the ALT is normally higher than the AST. Elevated ALP levels are seen in about 30% of cases. It is important to differentiate NAFL, which does not require follow-up, from NASH. Elevated serum transaminases greater than twice the upper limit of normal and the presence of the metabolic syndrome are useful predictors of NASH.

Ultrasound

Ultrasound cannot differentiate NAFL from NASH; in both cases the liver will appear bright on ultrasound.

Liver biopsy

Individuals with serum transaminases greater than twice the upper limit of normal and features of the metabolic

Fig. 23.32 Pathogenesis of non-alcoholic fatty liver disease: the 'two-hit' hypothesis. Fatty liver occurs as a result of increased fat import into hepatocytes and reduced fat export. Insulin resistance causes hepatic steatosis, which also perpetuates insulin resistance. Subsequent activation of TNF- α , oxidant stress through the production of reactive oxygen species, and production of endotoxin then result in inflammation and eventually fibrosis. Factors including leptin are probably needed for fibrosis. (FA = fatty acids; VLDL = very low-density lipoproteins)

syndrome should be offered a liver biopsy to determine whether inflammation and fibrosis are present. Histologically, fat deposition is usually macrovesicular (Fig. 23.33), in contrast to the microvesicular fat seen in acute fatty liver disease of pregnancy. NASH is characterised by fat, Mallory bodies, neutrophil infiltration and pericellular fibrosis. These features are indistinguishable histologically from alcoholic hepatitis, so a diagnosis of NASH relies on excluding alcohol misuse, the absence of jaundice, and the presence of risk factors such as obesity and diabetes. Fat often disappears by the time cirrhosis develops.

Fig. 23.33 Histology of non-alcoholic fatty liver disease. **A** Macroscopic steatosis (NAFL). Large fat droplets (F) fill hepatocytes but there is no inflammation. **B** Non-alcoholic steatohepatitis at higher power. Fat is associated with an inflammatory infiltrate of neutrophils (N) and dense pink Mallory's hyaline (MH).

Management

Current treatments are aimed at reducing BMI and insulin resistance. Metformin (p. 820) has been shown to improve LFTs and should be the first-line treatment in type 2 diabetes with NAFLD. Metformin can be used safely in patients with cirrhosis who have good liver function (Child–Pugh A). Thiazolidinediones such as pioglitazone (p. 821) also improve LFTs in NAFLD and early data suggest they may improve inflammation and fibrosis. Weight loss (pp. 118–121) will also reduce serum transaminase levels, improve liver fibrosis and reduce insulin resistance. Antioxidants such as vitamin E are not effective. There is no evidence that HMG-CoA reductase inhibitors (statins) are of value in the treatment of NAFLD but they are not contraindicated for treatment of coexistent hyperlipidaemia. The role of anti-obesity (bariatric) surgery in patients with morbid obesity and NAFLD has yet to be defined, but can result in improvement in liver fibrosis.

Once cirrhosis has occurred, survival is similar to that in hepatitis C cirrhosis with 5- and 10-year survival rates of 90% and 84% respectively. Hepatocellular carcinoma can complicate NAFLD cirrhosis. Although fewer than 5% of liver transplants are currently performed for NAFLD, this is likely to increase. Unfortunately, the condition may recur in the graft.

DRUGS, TOXINS AND THE LIVER

The liver is the primary site of drug metabolism. Liver disease may affect the capacity of the liver to metabolise drugs, and unexpected toxicity may occur when patients with liver disease are given drugs in normal doses (p. 28). Box 23.52 also shows drugs that should be avoided in patients with cirrhosis, as they can exacerbate known complications of cirrhosis.

Hepatotoxic drug reactions

Drug toxicity should be high in the differential diagnosis of acute liver failure, jaundice and abnormal liver biochemistry. Some typical patterns of drug toxicity are listed in Box 23.53; the most common picture is of a mixed cholestatic hepatitis. The presence of jaundice indicates more severe liver damage. Although acute liver failure

23.52 Drugs to be avoided in cirrhosis		
Drug	Problem	Toxicity
NSAIDs	Reduced renal blood flow Ulceration	Hepatorenal failure Bleeding varices
ACE inhibitors	Reduced renal blood flow	Hepatorenal failure
Codeine	Constipation	Hepatic encephalopathy
Narcotics	Constipation, drug accumulation	Hepatic encephalopathy
Anxiolytics	Drug accumulation	Hepatic encephalopathy

23.53 Examples of common causes of drug-induced hepatotoxicity	
Pattern	Drug
Cholestasis	Chlorpromazine High-dose oestrogens
Cholestatic hepatitis	NSAIDs Co-amoxiclav Statins
Acute hepatitis	Rifampicin Isoniazid
Non-alcoholic steatohepatitis	Amiodarone
Venous outflow obstruction	Busulfan Azathioprine
Fibrosis	Methotrexate

can occur, most drug reactions are self-limiting and chronic liver damage is rare. Abnormal LFTs often take weeks to normalise following a drug-induced hepatitis, and it may take months for them to normalise following a cholestatic hepatitis. Occasionally permanent bile duct loss (ductopenia) follows a cholestatic drug reaction, such as that due to co-amoxiclav, resulting in chronic cholestasis with persistent symptoms such as itching.

The key to diagnosing acute drug-induced liver disease is to take a detailed drug history (Box 23.54). A liver biopsy should be considered if there is suspicion of

23.54 The diagnosis of acute drug-induced liver disease

- Tabulate drugs taken
 - Prescribed
 - Self-administered
- Establish if reported hepatotoxicity in the literature
- Relate time drugs taken to onset of illness
 - 4 days–8 weeks (usual)
- Effect of stopping drugs on normalisation of liver biochemistry
 - Hepatic LFTs (2 months)
 - Cholestatic/mixed LFTs (6 months)
- Exclude other causes
 - Viral hepatitis
 - Biliary disease
- Consider liver biopsy

N.B. Challenge tests with drugs should be avoided.

pre-existing liver disease or if blood tests fail to improve when the suspect drug is withdrawn.

Types of liver injury

Different histological patterns of liver injury may occur.

Cholestasis

Pure cholestasis (selective interference with bile flow in the absence of liver injury) can occur with oestrogens; this was seen quite frequently when high concentrations of oestrogens (50 µg/day) were used as contraceptives. Both the current oral contraceptive pill and hormone replacement therapy can be safely used in chronic liver disease.

Chlorpromazine and antibiotics such as flucloxacillin are examples of drugs that cause cholestatic hepatitis, which is characterised by inflammation and canalicular injury. Co-amoxiclav is the most common antibiotic to cause abnormal LFTs but, unlike other antibiotics, it may not produce symptoms until 10–42 days after it is stopped. Anabolic steroids used by body-builders may also cause a cholestatic hepatitis. In some cases (e.g. NSAIDs and COX-2 inhibitors) there is overlap with acute hepatocellular injury.

Hepatocyte necrosis

Many drugs cause an acute hepatocellular necrosis with high serum transaminase concentrations; paracetamol (p. 209) is the best known. Inflammation is not always present but does accompany necrosis in liver injury due to diclofenac (an NSAID) and isoniazid (an anti-tuberculous drug). Granuloma may be seen in liver injury following the use of allopurinol. Acute hepatocellular necrosis has also been described following the use of several herbal remedies including germander, comfrey and jin bu huan. Recreational drugs, including cocaine and ecstasy, can also cause severe acute hepatitis.

Steatosis

Microvesicular hepatocyte fat deposition, due to direct effects on mitochondrial beta-oxidation, can follow exposure to tetracyclines and sodium valproate (see Box 23.66, p. 975). Macrovesicular hepatocyte fat deposition has been described with tamoxifen, and amiodarone

toxicity can produce a similar histological picture to NASH (p. 958).

Vascular/sinusoidal lesions

Drugs such as alkylating agents used in oncology can damage the vascular endothelium and lead to hepatic venous outflow obstruction. Chronic overdose of vitamin A can damage the sinusoids and trigger local fibrosis that can result in portal hypertension.

Hepatic fibrosis

Most drugs cause reversible liver injury and hepatic fibrosis is very uncommon. Methotrexate, however, as well as causing acute liver injury when it is started, can lead to cirrhosis when used in high doses over a long period of time. Risk factors for drug-induced hepatic fibrosis include pre-existing liver disease and a high alcohol intake.

INHERITED LIVER DISEASES

Haemochromatosis

Haemochromatosis is a condition in which the amount of total body iron is increased; the excess iron is deposited in, and causes damage to, several organs, including the liver. It may be primary or secondary to other diseases (Box 23.55).

Hereditary haemochromatosis

In hereditary haemochromatosis (HHC) iron is deposited throughout the body and total body iron may reach 20–60 g (normally 4 g). The important organs involved are the liver, pancreatic islets, endocrine glands and heart. In the liver, iron deposition occurs first in the periportal hepatocytes, extending later to all hepatocytes. The gradual development of fibrous septa leads to the formation of irregular nodules, and finally regeneration results in macronodular cirrhosis. An excess of liver iron can occur in alcoholic cirrhosis but this is mild by comparison with haemochromatosis.

Pathophysiology

The disease is caused by increased absorption of dietary iron and is inherited as an autosomal recessive trait.

23.55 Causes of haemochromatosis

Primary haemochromatosis

- Hereditary haemochromatosis
- Congenital acaeruloplasminaemia
- Congenital atransferrinaemia

Secondary iron overload

- Parenteral iron-loading (e.g. repeated blood transfusion)
- Iron-loading anaemia (thalassaemia, sideroblastic anaemia, pyruvate kinase deficiency)
- Liver disease

Complex iron overload

- Juvenile haemochromatosis
- Neonatal haemochromatosis
- Alcoholic liver disease
- Porphyria cutanea tarda
- African iron overload (Bantu siderosis)

Approximately 90% of patients are homozygous for a single-point mutation resulting in a cysteine to tyrosine substitution at position 282 (C282Y) in the HFE protein which has structural and functional similarity to the human leucocyte antigen (HLA) proteins. The mechanisms by which HFE regulates iron absorption are unclear. However, it is believed that HFE normally interacts with the transferrin receptor in the basolateral membrane of intestinal epithelial cells. In HHC, it is thought that the lack of functional HFE causes a defect in uptake of transferrin-associated iron, leading to up-regulation of enterocyte iron-specific divalent metal transporters and excessive iron absorption. A histidine to aspartic acid mutation at position 63 (H63D) in HFE causes a less severe form of haemochromatosis that is most commonly found in patients who are compound heterozygotes also carrying a C282Y mutated allele. Fewer than 50% of C282Y homozygotes will develop clinical features of haemochromatosis; therefore other factors must also be important. HHC may promote accelerated liver disease in patients with alcohol excess or hepatitis C infection. Iron loss in menstruation and pregnancy protects females from developing clinical manifestations of HHC, as 90% of patients are male.

Clinical features

Symptomatic disease usually presents in men over 40 years with features of liver disease (often with hepatomegaly), diabetes mellitus or heart failure. Fatigue and arthropathy are early symptoms. Lead-pigmentation due to excess melanin occurs, especially in exposed parts, axillae, groins and genitalia; hence the term 'bronzed diabetes'. Impotence, loss of libido, testicular atrophy and arthritis with chondrocalcinosis secondary to calcium pyrophosphate deposition are also common. Cardiac failure or cardiac dysrhythmia may occur due to iron deposition in the heart.

Investigations

Serum iron studies show a greatly increased ferritin, a raised plasma iron and saturated plasma iron-binding capacity. Transferrin saturation > 45% is suggestive of iron overload. Significant liver disease is unusual in patients with ferritin < 1000 µg/L. MRI has high specificity for iron overload, but poor sensitivity. Liver biopsy allows assessment of fibrosis and distribution of iron (hepatocyte iron characteristic of haemochromatosis). The Hepatic Iron Index (HII) provides quantification of liver iron (µmol of iron per g dry weight of liver/age in years). HII > 1.9 suggests genetic haemochromatosis (Fig. 23.34). Both the C282Y and H63D mutations can be identified by genetic testing.

Management

Treatment consists of weekly venesection of 500 mL blood (250 mg iron) until the serum iron is normal; this may take 2 years or more. The aim is to reduce ferritin to < 50 µg/L. Thereafter, venesection is continued as required to keep the serum ferritin normal. Liver and cardiac problems improve after iron removal, but joint pain is less predictable and can improve or worsen after iron removal. Diabetes mellitus does not resolve after venesection. Other therapy includes that for cirrhosis and diabetes mellitus. First-degree family members should be investigated, preferably by

Fig. 23.34 Liver histology: haemochromatosis. This Perl's stain shows accumulating iron within hepatocytes, which is stained blue. There is also accumulation of large fat globules in some hepatocytes (macrovesicular steatosis). Iron also accumulates in Kupffer cells and biliary epithelial cells.

genetic screening and also by checking the plasma ferritin and iron-binding saturation. Liver biopsy is only indicated in asymptomatic relatives if the LFTs are abnormal and/or the serum ferritin is greater than 1000 µg/L because these features are associated with significant fibrosis or cirrhosis. Asymptomatic disease should also be treated by venesection until the serum ferritin is normal.

Pre-cirrhotic patients with HHC have a normal life expectancy, and even cirrhotic patients have a good prognosis, compared with other forms of cirrhosis (three-quarters of patients are alive 5 years after diagnosis). This is probably because liver function is usually well preserved at diagnosis and improves with therapy. Screening for hepatocellular carcinoma (p. 968) is mandatory because this is the main cause of death, affecting about one-third of patients with cirrhosis irrespective of therapy. Venesection reduces but does not abolish the risk of hepatocellular carcinoma in the presence of cirrhosis.

Secondary haemochromatosis

Many conditions, including chronic haemolytic disorders, sideroblastic anaemia, other conditions requiring multiple blood transfusion (generally over 50 L), porphyria cutanea tarda, dietary iron overload and occasionally alcoholic cirrhosis, are associated with widespread secondary siderosis. The features are similar to primary haemochromatosis, but the history and clinical findings point to the true diagnosis. Some patients are heterozygotes for the HFE gene and this may contribute to the development of iron overload.

Wilson's disease

Wilson's disease (hepatolenticular degeneration) is a rare but important autosomal recessive disorder of copper metabolism that is caused by a variety of mutations in the *ATP7B* gene on chromosome 13. Total body copper is increased, with excess copper deposited in, and causing damage to, several organs.

Pathophysiology

Normally, dietary copper is absorbed from the stomach and proximal small intestine and is rapidly taken into the liver, where it is stored and incorporated into caeruloplasmin, which is secreted into the blood. The accumulation of excessive copper in the body is ultimately prevented by its excretion, the most important route being via the bile. In Wilson's disease, there is almost always a failure of synthesis of caeruloplasmin; however, some 5% of patients have a normal circulating caeruloplasmin concentration and this is not the primary pathogenic defect. The amount of copper in the body at birth is normal, but thereafter it increases steadily; the organs most affected are the liver, basal ganglia of the brain, eyes, kidneys and skeleton.

The *ATP7B* gene encodes a member of the copper-transporting P-type adenosine triphosphatase family, which functions to export copper from various cell types. At least 200 different mutations have been described. Although most of these are rare, their relative frequency varies in different populations. The histidine to glycine single-base mutation at position 1069 is most common in Polish and Austrian patients, but rare in India, other Asian countries and Sardinia. In contrast, approximately 60% of Sardinian patients have a 15 nucleotide deletion in the 5' untranslated region of the Wilson's gene. Most cases are compound heterozygotes with two different mutations in *ATP7B*. Attempts to correlate the genotype with the mode of presentation and clinical course have not shown any consistent patterns.

Clinical features

Symptoms usually arise between the ages of 5 and 45 years. Hepatic disease occurs predominantly in childhood and early adolescence, although it can present in adults in their fifties. Neurological damage causes basal ganglion syndromes and dementia which tends to present in later adolescence. These features can occur alone or simultaneously. Other manifestations include renal tubular damage and osteoporosis, but these are rarely presenting features.

Liver disease

Episodes of acute hepatitis, sometimes recurrent, can occur, especially in children, and may progress to acute fulminant liver failure. The latter is characterised by the liberation of free copper into the blood stream, causing massive haemolysis and renal tubulopathy. Chronic hepatitis can also develop insidiously and eventually present with established cirrhosis; liver failure and portal hypertension may supervene. Recurrent acute hepatitis of unknown cause, especially when accompanied by haemolysis, or chronic liver disease of unknown cause in a patient under 40 years old suggests Wilson's disease.

Neurological disease

Clinical features include a variety of extrapyramidal features, particularly tremor, choreoathetosis, dystonia, parkinsonism and dementia (p. 1203). Unusual clumsiness for age may be an early symptom.

Kayser–Fleischer rings

These are the most important single clinical clue to the diagnosis and can be seen in 60% of adults with Wilson's

disease (less often in children but almost always in neurological Wilson's disease), albeit sometimes only by slit-lamp examination. Kayser–Fleischer rings are characterised by greenish-brown discoloration of the corneal margin appearing first at the upper periphery (Fig. 23.35). They eventually disappear with treatment.

Investigations

A low serum caeruloplasmin is the best single laboratory clue to the diagnosis. However, advanced liver failure from any cause can reduce the serum caeruloplasmin, and occasionally it is normal in Wilson's disease. Other features of disordered copper metabolism should therefore be sought; these include a high free serum copper concentration, a high urine copper excretion of greater than 0.6 $\mu\text{mol}/24$ hrs (38 $\mu\text{g}/24$ hrs) and a very high hepatic copper content. Measuring 24-hour urinary copper excretion whilst giving D-penicillamine is a useful confirmatory test; more than 25 $\mu\text{mol}/24$ hrs is considered diagnostic of Wilson's disease.

Genetic testing may be useful in screening families once the abnormality has been identified in an affected individual.

Management

The copper-binding agent, penicillamine, is the drug of choice. The dose given must be sufficient to produce cupriuresis and most patients require 1.5 g/day (range 1–4 g). The dose can be reduced once the disease is in remission but treatment must continue for life, even through pregnancy. Care must be taken to ensure that reaccumulation of copper does not occur. Abrupt discontinuation of treatment must be avoided because this may precipitate acute liver failure. Toxic effects occur in one-third of patients and include rashes, protein-losing nephropathy, lupus-like syndrome and bone marrow depression. If these do occur, trientine dihydrochloride (1.2–2.4 g/day) and zinc (50 mg 8-hourly) are alternative effective therapies.

Liver transplantation is indicated for fulminant liver failure or for advanced cirrhosis with liver failure. The value of liver transplantation in severe neurological Wilson's disease is highly controversial.

The prognosis is excellent, provided treatment is started before there is irreversible damage. Siblings and children of patients with Wilson's disease must

Fig. 23.35 Kayser–Fleischer rings at the junction of the cornea and sclera (arrow) in a patient with Wilson's disease.

be investigated and treatment should be given to all affected individuals, even if they are asymptomatic.

Alpha₁-antitrypsin deficiency

Alpha₁-antitrypsin (α_1 -AT) is a serine protease inhibitor (Pi) produced by the liver. The mutated form of α_1 -AT (PiZ) cannot be secreted into the blood by liver cells because it is retained within the endoplasmic reticulum of the hepatocyte. Homozygous individuals (PiZZ) have low plasma α_1 -AT concentrations, although globules containing α_1 -AT are found in the liver, and they may develop hepatic and pulmonary disease. Liver manifestations include cholestatic jaundice in the neonatal period (neonatal hepatitis), which can resolve spontaneously, chronic hepatitis and cirrhosis in adults, and in the long term hepatocellular carcinoma.

There are no clinical features distinguishing liver disease due to α_1 -AT deficiency from liver disease due to other causes, and the diagnosis is made from the low plasma α_1 -AT concentration and genotyping for the presence of the mutation. Alpha₁-AT-containing globules can be demonstrated in the liver (Fig. 23.36) but this is not necessary to make the diagnosis. Occasionally, patients with liver disease and minor reductions of plasma α_1 -AT concentrations have α_1 -AT variants other than PiZZ, but the relationship of these to liver disease is uncertain.

No specific treatment is available; the concurrent risk of severe and early-onset emphysema means that all patients should be advised to abandon cigarette smoking.

Fig. 23.36 Liver histology in α_1 -antitrypsin deficiency. Accumulation of periodic acid-Schiff-positive granules (arrows) within individual hepatocytes is shown in this section from a patient with α_1 -AT deficiency.

Gilbert's syndrome

Gilbert's syndrome is by far the most common inherited disorder of bilirubin metabolism (see Box 23.10, p. 932). It is inherited as an autosomal dominant trait and is caused by a mutation in the promoter region of the UDP-glucuronyl transferase enzyme, which leads to reduced enzyme expression. This results in decreased conjugation of bilirubin, which accumulates as unconjugated bilirubin in the blood. The levels of unconjugated bilirubin increase during fasting, as fasting reduces levels of UDP-glucuronyl transferase.

Clinical features

There are no stigmata of chronic liver disease other than jaundice. Increased excretion of bilirubin and hence sterco-bilinogen leads to normal-coloured or dark stools, and increased urobilinogen excretion causes the urine to turn dark on standing as urobilin is formed. In the presence of haemolysis, pallor due to anaemia and splenomegaly due to excessive reticulo-endothelial activity are usually present.

Investigations

In Gilbert's syndrome the plasma bilirubin is usually less than 100 $\mu\text{mol/L}$ ($\sim 6 \text{ mg/dL}$) and the LFTs are otherwise normal. There is no bilirubinuria because the hyperbilirubinaemia is predominantly unconjugated. Other LFTs and hepatic histology are normal. The condition has an excellent prognosis, needs no treatment, and is clinically important only because it may be mistaken for more serious liver disease.

AUTOIMMUNE HEPATITIS

Autoimmune hepatitis is a liver disease of unknown aetiology characterised by a strong association with other autoimmune diseases (Box 23.56), high levels of serum immunoglobulins (hypergammaglobulinaemia) and autoantibodies in the serum. It occurs most often in women, particularly in the second and third decades of life, but may develop in either sex at any age.

Pathophysiology

Several subtypes of this disorder have been proposed which have differing immunological markers:

- *Classical (type I) autoimmune hepatitis* is characterised by a high frequency of other autoimmune disorders, such as Graves' disease. Type I autoimmune hepatitis is associated with HLA-DR3 and DR4, particularly HLA-DRB3*0101 and HLA-DRB1*0401. These patients have high titres of antinuclear and anti-smooth muscle antibodies, but none of these antibodies is cytotoxic. A suggested hypothesis for the development of type I autoimmune hepatitis is the aberrant expression on the hepatocyte of HLA antigen, influenced by viral, genetic and environmental factors.
- *Type II autoimmune hepatitis* is characterised by the presence of anti-LKM (liver-kidney microsomal) antibodies and lack of antinuclear and anti-smooth muscle antibodies. Anti-LKM antibodies recognise cytochrome P450-IID6, which is expressed on the hepatocyte membrane.
- *Type III autoimmune hepatitis* is characterised by elevated serum immunoglobulin levels; the

23.56 Conditions associated with autoimmune hepatitis

| • Thyrotoxicosis | • Nephrotic syndrome |
| • Myxoedema | |
| • Pleurisy | |

antibodies described above are absent, whilst antibodies against soluble liver antigen are present. The histopathological features of all forms of autoimmune hepatitis are similar.

Clinical features

The onset is usually insidious, with fatigue, anorexia and jaundice. In about one-quarter of patients the onset is acute, resembling viral hepatitis, but resolution does not occur. This acute presentation can lead to extensive liver necrosis and liver failure. Other features include fever, arthralgia, vitiligo and epistaxis. Amenorrhoea is the rule but general health may be good. Jaundice is mild to moderate or occasionally absent, but signs of chronic liver disease, especially spider naevi and hepatosplenomegaly, are usually present. Some patients have a 'Cushingoid' face with acne, hirsutism and pink cutaneous striae, especially on the thighs and abdomen.

Approximately two-thirds of patients have associated autoimmune disease such as Hashimoto's thyroiditis, renal tubular acidosis and rheumatoid arthritis.

Investigations

Serological tests for autoantibodies are often positive (Box 23.57), but low titres of these antibodies occur in some healthy people. Antinuclear antibodies also occur in connective tissue diseases and other autoimmune diseases, while anti-smooth muscle antibody has been reported in infectious mononucleosis and a variety of malignant diseases. Antimitochondrial antibodies (anti-LKM) occur particularly in children and adolescents. Elevated levels of serum IgG immunoglobulins are invariable and are an important diagnostic feature. If the diagnosis of autoimmune hepatitis is suspected, liver biopsy should be performed. It typically shows interface hepatitis, with or without cirrhosis.

Management

Treatment with corticosteroids is life-saving in autoimmune hepatitis, particularly during exacerbations of active and symptomatic disease. Initially, prednisolone 40 mg/day is given orally; the dose is then gradually reduced as the patient and LFTs improve. Maintenance therapy is required for at least 2 years after LFTs have returned to normal, and withdrawal of treatment should

EBM 23.58 Immunosuppression in autoimmune hepatitis

'In autoimmune hepatitis, treatment with prednisolone \pm azathioprine improves serum biochemistry and hepatic histology. It also improves survival at 10 years from 27% to 63% (NNT₆ 2.7).'

'In patients who have been in remission for more than 1 year, increasing the dose of azathioprine (from 1 to 2 mg/kg) and withdrawing prednisolone reduces steroid side-effects and does not increase the risk of relapse.'

- Kirk AP, et al. Gut 1980; 21:78–83.
- Johnson PJ, et al. N Engl J Med 1995; 333:958–963.

not be considered unless a liver biopsy is also normal. Most individuals require long-term immunosuppression. Azathioprine 1.0–1.5 mg/kg/day orally may allow the dose of prednisolone to be reduced (Box 23.58). Azathioprine can also be used as the sole maintenance immunosuppressive agent. Corticosteroids treat acute exacerbations but do not prevent cirrhosis; they are therefore less important in mild asymptomatic autoimmune hepatitis.

The disease is characterised by exacerbations and remissions, but most patients eventually develop cirrhosis and its complications. Hepatocellular carcinoma is uncommon. Approximately 50% of symptomatic patients will die of liver failure within 5 years if no treatment is given, but this falls to about 10% with therapy.

INTRAHEPATIC BILIARY DISEASES

Primary biliary cirrhosis

Primary biliary cirrhosis (PBC) is a chronic, progressive cholestatic liver disease of unknown cause which predominantly affects middle-aged women. The condition is strongly associated with the presence of antimitochondrial antibodies (AMA), which are diagnostic. It is characterised by a granulomatous inflammation of the portal tracts, leading to progressive damage and eventually loss of the small and middle-sized bile ducts. This in turn leads to fibrosis and cirrhosis of the liver. The condition typically presents with an insidious onset of itching and/or tiredness; it may also be found incidentally as the result of routine blood tests.

Epidemiology

The prevalence of PBC varies across the world. It is relatively common in northern Europe and North America (the prevalence in north-east England is 245/million), but is rare in Africa and Asia. There is a strong female to male predominance of 9:1; it is also more common amongst cigarette smokers. Clustering of cases has been reported, suggesting an infectious agent.

Pathophysiology

The cause of PBC is unknown but immune mechanisms are clearly involved. The condition is closely associated with other autoimmune non-hepatic diseases, such as thyroid disease, and there is a weak association with HLA-DR8. Antimitochondrial and antinuclear (nuclear pore antigens gp210) antibodies are found in the serum with elevations in serum immunoglobulin levels, particularly IgM; cellular immunity is impaired

23.57 Frequency of autoantibodies in chronic non-viral liver diseases and in healthy people

Disease	Antinuclear antibody (%)	Anti-smooth muscle antibody (%)	Antimitochondrial antibody*
Healthy controls	5	1.5	0.01
Autoimmune hepatitis	80	70	15
Primary biliary cirrhosis	25	35	95
Cryptogenic cirrhosis	40	30	15

*Patients with antimitochondrial antibody frequently have cholestatic LFTs and may have primary biliary cirrhosis (see text).

and abnormal cellular immune reactions have been described. Infectious agents, such as retroviruses and bacteria, including *E. coli* and mycobacteria, have been suggested as the trigger for the disease process, but this hypothesis remains unproven.

The primary pathological lesion is a chronic granulomatous inflammation which damages and destroys the interlobular bile ducts; progressive lymphocyte-mediated inflammatory damage causes fibrosis, which spreads from the portal tracts to the liver parenchyma and eventually leads to cirrhosis. A model of the natural history of the disease process is shown in Figure 23.37.

Clinical features

Non-specific symptoms, such as lethargy and arthralgia, are common and may precede diagnosis for years. Pruritus is the most common initial complaint, pointing to hepatobiliary disease, and may precede jaundice by months or years; jaundice is rarely a presenting feature. The itching is usually worse on the limbs. Although there may be right upper abdominal discomfort, fever and rigors do not occur. Bone pain or fractures can rarely result from osteomalacia (fat-soluble vitamin malabsorption) or, more commonly, from osteoporosis (hepatic osteodystrophy).

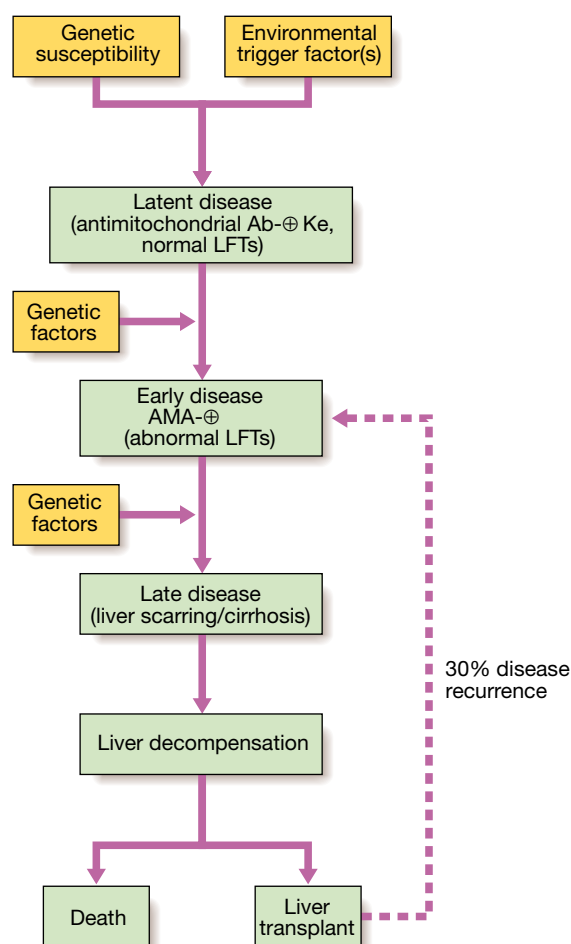

Fig. 23.37 Natural history of primary biliary cirrhosis.

Initially, patients are well nourished but considerable weight loss can occur as the disease progresses. Scratch marks may be found. Jaundice is only prominent late in the disease and can become intense. Xanthomatous deposits occur in a minority, especially around the eyes, in the hand creases and over the elbows, knees and buttocks. Hepatomegaly is virtually constant, and splenomegaly becomes increasingly common as portal hypertension develops. Liver failure may supervene.

Associated diseases

Autoimmune and connective tissue diseases occur with increased frequency in PBC, particularly the sicca syndrome (p. 1090), systemic sclerosis, coeliac disease (p. 879) and thyroid diseases. Hypothyroidism should always be considered in patients with fatigue.

Diagnosis and investigations

The LFTs show a pattern of cholestasis (p. 930). Hypercholesterolaemia is common and worsens as disease progresses; however, it is of no diagnostic value. The antimitochondrial antibody is present in over 95% of patients, and when it is absent the diagnosis should not be made without obtaining histological evidence and considering cholangiography (MRCP or ERCP) to exclude other biliary disease. Antinuclear and anti-smooth muscle antibodies are present in around 15% of patients (see Box 23.57); autoantibodies found in associated diseases may also be present. Ultrasound examination shows no sign of biliary obstruction. Liver biopsy is only necessary if there is diagnostic uncertainty. The histological features of PBC correlate poorly with the clinical features; portal hypertension can develop before the histological onset of cirrhosis.

Management

Asymptomatic patients require monitoring on a yearly basis to assess the onset of symptoms and associated disease. Immunosuppressants such as corticosteroids, azathioprine, penicillamine and ciclosporin have all been tried in PBC, but none is effective and all may have serious adverse effects. The hydrophilic bile acid, ursodeoxycholic acid (UDCA), improves bile flow, replaces toxic hydrophobic bile acids in the bile acid pool, and reduces apoptosis of the biliary epithelium. Clinically, UDCA improves LFTs, may slow down histological progression and has few side-effects (Box 23.59); it is therefore widely used in the treatment of PBC at a dose of 13–15 mg/kg/day.

Liver transplantation should be considered once liver failure has developed and may be indicated in patients with intractable pruritus. Prognostic models are available but serum bilirubin remains the most reliable marker of

EBM 23.59 Ursodeoxycholic acid (UDCA) in primary biliary cirrhosis (PBC)

'In PBC UDCA therapy (13–15 mg/kg/day) improves biochemical markers of cholestasis and jaundice. Some randomised trials have shown that UDCA treatment significantly slows disease progression, but whether it affects mortality or transplantation rates remains controversial.'

- Poupon RE, et al. *Gastroenterology* 1997; 113:884–890.
- Corpechot C, et al. *Hepatology* 2000; 32:1196–1199.
- Goullis J, et al. *Lancet* 1999; 354:1053–1060.

declining liver function. Transplantation is associated with an excellent 5-year survival of over 80%, although the disease will recur in over one-third of patients at 10 years.

Pruritus

This is the main symptom requiring treatment. The cause of itching is unknown but current research suggests that it is due to up-regulation of opioid receptors and increased levels of endogenous opioids. It is best treated with the anion-binding resin colestyramine, which probably acts by binding potential pruritogens in the intestine and increasing their excretion in the stool. A dose of 4–16 g/day orally is used. The powder is mixed in orange juice and the main dose (8 g) taken before and after breakfast when maximal duodenal bile acid concentrations occur. Colestyramine may bind other drugs in the gut (e.g. anticoagulants), which should therefore be taken 1 hour before the binding agent. Colestyramine is sometimes ineffective, especially in complete biliary obstruction. Alternative treatments include rifampicin 300 mg/day, naltrexone (an opioid antagonist) 25 mg/day initially increasing up to 300 mg/day, plasmapheresis and a liver support device (e.g. a molecular adsorbent recirculating system (MARS) machine).

Fatigue

Fatigue affects about one-third of patients with PBC. The cause is unknown but it may reflect intracerebral changes due to cholestasis. Unfortunately, once depression and hypothyroidism have been excluded, there is no treatment.

Malabsorption

Prolonged cholestasis is associated with steatorrhea and malabsorption of fat-soluble vitamins, which should be replaced as necessary. Coeliac disease should be excluded since its incidence is increased in PBC.

Bone disease

Osteopenia and osteoporosis are common, and normal post-menopausal bone loss is accelerated. Baseline bone density should be measured (p. 1118) and treatment started with replacement calcium and vitamin D₃. Bisphosphonates should be used if there is evidence of osteoporosis. Osteomalacia is rare.

Overlap syndromes

AMA-negative PBC ('autoimmune cholangitis')

A few patients demonstrate the clinical, biochemical and histological features of PBC but do not have detectable antimitochondrial antibodies in the serum. Serum transaminases, serum Ig levels and titres of antinuclear antibodies tend to be higher than in AMA-positive PBC. However, the clinical course mirrors classical PBC and these patients should be considered to have a variant of PBC.

PBC/autoimmune hepatitis overlap

A small minority of patients with AMA and cholestatic LFTs have elevated transaminases, high serum immunoglobulins and interface hepatitis on liver histology; in such patients a trial of corticosteroids may be beneficial.

Secondary biliary cirrhosis

This develops after prolonged large duct biliary obstruction due to gallstones, benign bile duct strictures or sclerosing cholangitis (see below). Carcinomas rarely cause secondary biliary cirrhosis because few patients survive long enough. The clinical features are of chronic cholestasis with episodes of ascending cholangitis or even liver abscess (p. 972). Cirrhosis, ascites and portal hypertension are late features. Relief of biliary obstruction may require endoscopic or surgical intervention. Cholangitis requires treatment with antibiotics, which can be given continuously if attacks recur frequently.

Primary sclerosing cholangitis

Primary sclerosing cholangitis is a cholestatic liver disease caused by diffuse inflammation and fibrosis; it can involve the entire biliary tree and leads to the gradual obliteration of intrahepatic and extrahepatic bile ducts, and ultimately biliary cirrhosis, portal hypertension and hepatic failure. The incidence is about 6.3/100 000 in Caucasians. Cholangiocarcinoma develops in about 10–30% of patients during the course of the disease.

Primary sclerosing cholangitis occurs mainly in young men (male:female ratio 2:1). Most patients present at age 25–40 years, although the condition may be diagnosed at any age and is an important cause of chronic liver disease in children. The generally accepted diagnostic criteria are:

- generalised beading and stenosis of the biliary system on cholangiography (Fig. 23.38)
- absence of choledocholithiasis (or history of bile duct surgery)

Fig. 23.38 A percutaneous cholangiogram in sclerosing cholangitis showing characteristic irregularity of the biliary tree.

- exclusion of bile duct cancer, usually by prolonged follow-up.

The term 'secondary sclerosing cholangitis' is used to describe the typical bile duct changes described above when a clear predisposing factor for duct fibrosis can be identified. The causes of secondary sclerosing cholangitis are shown in Box 23.60.

Pathophysiology

The cause of primary sclerosing cholangitis is unknown but there is a close association with inflammatory bowel disease, particularly ulcerative colitis (Box 23.61). About two-thirds of patients with primary sclerosing cholangitis have coexisting ulcerative colitis, and primary sclerosing cholangitis is the most common form of chronic liver disease in ulcerative colitis. Between 3% and 10% of patients with ulcerative colitis develop primary sclerosing cholangitis, particularly those with substantial or total colitis. The prevalence of primary sclerosing cholangitis is lower in patients with Crohn's colitis (about 1%). Patients with primary sclerosing cholangitis and ulcerative colitis are at greater risk of colorectal neoplasia than those with ulcerative colitis alone, and those who develop colorectal neoplasia are at greater risk of cholangiocarcinoma.

It is currently believed that primary sclerosing cholangitis is an immunologically mediated disease, triggered in genetically susceptible individuals by toxic or infectious agents, which may gain access to the biliary tract through a leaky diseased colon.

Immunogenic factors

A close link with HLA haplotype A1 B8 DR3 DRW52A has been identified. This haplotype is commonly found in association with other organ-specific autoimmune diseases (e.g. autoimmune hepatitis). The prevalence of HLA-DR2 and HLA-DR6 is greater in patients who are DR3-negative.

23.60 Causes of secondary sclerosing cholangitis

- Previous bile duct surgery with stricturing and cholangitis
- Bile duct stones causing cholangitis
- Intrahepatic infusion of 5-fluorodeoxyuridine
- Insertion of formalin into hepatic hydatid cysts
- Insertion of alcohol into hepatic tumours
- Parasitic infections (e.g. *Clonorchis*)
- Autoimmune pancreatitis/IgG4-associated cholangitis
- AIDS (probably infective as a result of cytomegalovirus or *Cryptosporidium*)

23.61 Diseases associated with primary sclerosing cholangitis

- Ulcerative colitis
- Crohn's colitis
- Chronic pancreatitis
- Retroperitoneal fibrosis
- Riedel's thyroiditis
- Retro-orbital tumours
- Immune deficiency states
- Sjögren's syndrome
- Angio-immunoplastic lymphadenopathy
- Histiocytosis X
- Autoimmune haemolytic anaemia
- Autoimmune pancreatitis/IgG4-associated cholangitis

The importance of immunological factors has been emphasised by reports showing humoral and cellular abnormalities in primary sclerosing cholangitis. Perinuclear antineutrophil cytoplasmic antibodies (ANCA) have been detected in the sera of about 60–80% of patients with primary sclerosing cholangitis with or without ulcerative colitis, and in about 30–40% of patients with ulcerative colitis alone. The antibody is not specific for primary sclerosing cholangitis and is found in other chronic liver diseases (e.g. 50% of patients with autoimmune hepatitis).

Clinical features

The diagnosis is often made incidentally when persistently raised serum ALP is discovered in an individual with ulcerative colitis. Common symptoms include fatigue, intermittent jaundice, weight loss, right upper quadrant abdominal pain and pruritus. Attacks of acute cholangitis are uncommon and usually follow biliary instrumentation. Physical examination is abnormal in about 50% of symptomatic patients; the most common findings are jaundice and hepatomegaly/splenomegaly. The condition may be associated with many other diseases (see Box 23.61).

Investigations

Biochemical screening usually reveals a cholestatic pattern of LFTs but ALP and bilirubin levels may vary widely in individual patients during the course of the disease. For example, ALP and bilirubin values increase during acute cholangitis, decrease after therapy, and sometimes fluctuate for no apparent reason. Modest elevations in serum transaminases are usually seen, whereas hypoalbuminaemia and clotting abnormalities are found only at a late stage. In addition to ANCA, low titres of serum antinuclear and anti-smooth muscle antibodies may be found in primary sclerosing cholangitis but have no diagnostic significance; serum anti-mitochondrial antibody is absent. IgM concentrations are increased in about 50% of symptomatic patients and elevations of IgG are found in about 30% of adults.

The key investigation is ERCP, which is usually diagnostic, revealing multiple irregular stricturing and dilatation (see Fig. 23.38). MRCP is a non-invasive method of imaging the biliary tree; it is being assessed and will probably become the standard method of diagnosis.

On liver biopsy the characteristic early features of primary sclerosing cholangitis are periductal 'onion-skin' fibrosis and inflammation, with portal oedema and bile ductular proliferation resulting in expansion of the portal tracts (Fig. 23.39). Later fibrosis spreads, leading inevitably to biliary cirrhosis; obliterative cholangitis leads to the so-called 'vanishing bile duct syndrome'.

Management

There is no cure for primary sclerosing cholangitis, but management of cholestasis and its complications and specific treatment of the disease process are indicated.

The course of primary sclerosing cholangitis is variable. In symptomatic patients, median survival from presentation to death or liver transplantation is about 12 years. About 75% of asymptomatic patients survive 15 years or more. Most patients die from liver failure, about 30% die from bile duct carcinoma, and the

Fig. 23.39 Primary sclerosing cholangitis. Note onion-skin scarring (arrows) surrounding a bile duct.

remainder die from colonic cancer or complications of colitis.

Management of cholestasis

Symptomatic patients often have pruritus, which is best managed initially with colestyramine; the dose should be increased until relief is obtained.

Management of complications

Broad-spectrum antibiotics (e.g. ciprofloxacin) should be given for acute attacks of cholangitis but have no proven value in preventing attacks. If cholangiography shows a well-defined obstruction to the extrahepatic bile ducts ('dominant stricture'), mechanical relief can be obtained by placement of a plastic stent or by balloon dilatation performed at ERCP. Fat-soluble vitamin replacement is necessary in jaundiced patients. Metabolic bone disease (usually osteoporosis) is a common complication that requires treatment (p. 1116).

Specific treatment

Ursodeoxycholic acid (UDCA) is a non-hepatotoxic hydrophilic bile acid that has been used widely for treatment of cholestasis; it reduces levels of cholestatic liver enzymes, but controlled trials in conventional doses have shown no effect on symptoms, histology or survival. Larger doses (20–25 mg/kg daily) have beneficial effects on liver histology and cholangiographic appearance. Immunosuppressive agents, including prednisolone, azathioprine, methotrexate and ciclosporin, have been tried; generally, results have been disappointing but combination therapy with UDCA may be beneficial.

Surgical treatment

Orthotopic transplantation is the only option in young patients with primary sclerosing cholangitis and advanced liver disease; 5-year survival is 80–90% in most centres. Unfortunately, the condition may recur in the graft. Cholangiocarcinoma is a contraindication to transplantation.

Cystic and fibropolycystic disease

Fibropolycystic diseases of the liver and biliary system constitute a heterogeneous group of rare disorders, some of which are inherited. They are not distinct entities and combined lesions occur.

Solitary hepatic cysts

Isolated hepatic cysts may be discovered by chance; rarely, they give rise to complications, including pain or jaundice from cyst enlargement, haemorrhage or infection. Portal hypertension and bleeding from varices are exceptional.

Diagnosis is best made by ultrasonography. Resection of a large cyst or groups of cysts is only required if symptoms are troublesome. The prognosis is excellent.

Adult hepatorenal polycystic disease

The kidneys are predominantly affected in this condition (Fig. 23.40), which is inherited as an autosomal dominant trait (p. 506). Hepatic cysts which do not communicate with the biliary system are present in over half of patients with renal cysts, and cysts can also be found in other organs. Cerebrovascular aneurysms may develop. Cysts restricted to the liver constitute a separate rare genetic disorder.

Caroli's syndrome

This is very rare and is characterised by segmental sacular dilations of the intrahepatic biliary tree. The whole liver is usually affected, and extrahepatic biliary dilatation occurs in about one-quarter of patients. Recurrent attacks of cholangitis (see Box 23.11, p. 932) occur and may cause hepatic abscesses. Complications include biliary stones and cholangiocarcinoma. Antibiotics are required for episodes of cholangitis. Occasionally, localised disease can be treated by segmental liver resection and liver transplantation may sometimes be required.

Congenital hepatic fibrosis

This is characterised by broad bands of fibrous tissue linking the portal tracts in the liver, abnormalities of the interlobular bile ducts, and sometimes a lack of portal venules. The renal tubules may show cystic dilatation (medullary sponge kidney, p. 507), and eventually renal cysts may develop. The condition can be inherited as an

Fig. 23.40 CT showing multiple cysts in the liver and kidneys in polycystic disease.

autosomal recessive trait. Liver involvement causes portal hypertension with splenomegaly and bleeding from oesophageal varices that usually presents in adolescence or in early adult life. The prognosis is good because liver function is preserved. Treatment may be required for variceal bleeding and occasionally cholangitis. Patients can present during childhood with renal failure if the kidneys are severely affected.

Choledochal cysts

This term applies to cysts anywhere in the biliary tree (Fig. 23.41). The great majority cause diffuse dilatation of the common bile duct (type I), but others take the form of biliary diverticula (type II), dilatation of the intraduodenal bile duct (type III) and multiple biliary cysts (type IV). The last type merges with Caroli's syndrome (see above). In the neonate they may present with jaundice or biliary peritonitis. Recurrent jaundice, abdominal pain and cholangitis may arise in the adult. Liver abscess and biliary cirrhosis may develop, and there is an increased incidence of cholangiocarcinoma. Excision of the cyst with hepatico-jejunostomy is the treatment of choice.

Cystic fibrosis

Cystic fibrosis (p. 678) is associated with a biliary cirrhosis in about 5% of individuals. Splenomegaly and an elevated ALP are characteristic. Complications do not normally arise until late adolescence or early adulthood, when bleeding due to variceal haemorrhage may occur. UDCA improves liver blood tests but it is not known whether the drug can prevent pro-

gression of liver disease. Deficiency of fat-soluble vitamins (A, D, E and K) may need to be treated in view of both biliary and pancreatic disease (pancreatic exocrine insufficiency occurs in 90% of individuals with cystic fibrosis).

Intrahepatic cholestasis

Mutations in the biliary transporter proteins on the hepatocyte canalicular membrane (FIC1—familial intrahepatic cholestasis 1), illustrated in Figure 23.7 (p. 925), have been shown to cause an inherited intrahepatic biliary disease in childhood characterised by raised ALP levels and progression to a biliary cirrhosis. It is also becoming increasingly clear that these proteins contribute to intrahepatic biliary disease in adulthood.

Benign recurrent intrahepatic cholestasis

This rare condition usually presents in adolescence and is characterised by recurrent episodes of cholestasis, lasting 1–6 months. It is now known to be mediated by mutations in the *ATP8B1* gene, which lies on chromosome 18 and encodes FIC1. The same gene is thought to be responsible for a cholestatic condition that causes cirrhosis in childhood.

Episodes start with pruritus, while painless jaundice develops later. LFTs show a cholestatic pattern. Liver biopsy shows cholestasis (bilirubin in hepatocytes) during an episode but is normal between episodes. Treatment is required to relieve pruritus and the long-term prognosis is good.

LIVER TUMOURS AND FOCAL LIVER LESIONS

Hepatocellular carcinoma

Hepatocellular carcinoma (HCC) is the most common primary liver tumour, and the sixth most common cause of cancer world-wide. The age-adjusted incidence rates vary from 28 per 100 000 in South-east Asia (reflecting the prevalence of hepatitis B) to 10 per 100 000 in southern Europe and 5 per 100 000 in northern Europe. The incidence in Europe and North America has risen recently; this is probably related to an increase in hepatitis C cirrhosis.

Hepatitis B vaccination has led to a fall in HCC in countries with a high prevalence of hepatitis B, such as Taiwan.

Chronic hepatitis B infection increases the risk of HCC 100-fold and is the major risk factor for HCC world-wide. The risk of HCC is 0.4% per year in the absence of cirrhosis and 2–6% in cirrhosis. The risk is four times higher in HBeAg-positive than in HBeAg-negative individuals.

Cirrhosis is present in 75–90% of individuals with HCC and is an important risk factor for the disease. The risk is between 1 and 5% in cirrhosis caused by hepatitis B and C. There is also an increased risk in cirrhosis due to haemochromatosis, alcohol, NASH and α_1 -antitrypsin deficiency. In northern Europe 90% of those with HCC have underlying cirrhosis, compared to 30% in Taiwan where hepatitis B is the main risk factor.

Fig. 23.41 Classification and frequency of choledochal cysts.

The risk is higher in men and rises with age. Women with PBC do not seem to be at an increased risk of HCC.

Macroscopically, the tumour usually appears as a single mass in the absence of cirrhosis, or as a single or multiple nodules in the presence of cirrhosis. It takes its blood supply from the hepatic artery and tends to spread by invasion into the portal vein and its radicals. Lymph node metastases are common, but lung and bone metastases are rare.

Well-differentiated tumours can resemble normal hepatocytes and can be difficult to distinguish from normal liver.

Clinical features

In patients with underlying cirrhosis there may be ascites, jaundice and variceal haemorrhage. Other symptoms include weight loss, anorexia and abdominal pain. Many tumours detected through screening programmes are asymptomatic. In patients without cirrhosis, tumours are often much larger at presentation (usually > 5 cm), in which case abdominal pain and weight loss are more common.

Examination may reveal hepatomegaly or a right hypochondrial mass. Tumour vascularity can lead to an abdominal bruit, and hepatic rupture with intra-abdominal bleeding may occur.

Investigations

Serum markers

Alpha-fetoprotein (AFP) is produced by 60% of HCCs. Levels increase with the size of the tumour and are often normal in small tumours detected by ultrasound screening. Serum AFP also rises in the presence of active hepatitis B and C viral replication; very high levels are seen in acute hepatic necrosis, such as that following paracetamol toxicity. AFP is used in conjunction with ultrasound in screening but, in view of low sensitivity and specificity, levels need to be interpreted with caution. Nevertheless, in the absence of a marked hepatic flare of disease, a progressively rising AFP, or AFP > 400 ng/mL (normal < 10 ng/mL) necessitates an aggressive search for HCC.

Imaging

Ultrasound scanning will detect focal liver lesions as small as 2–3 cm. The use of ultrasound contrast agents has increased sensitivity and specificity, but the technique is highly user-dependent. Ultrasound may also show evidence of portal vein involvement and features of coexistent cirrhosis. Helical CT, following intravenous contrast, identifies HCC by its classical hypervascular appearance (Fig. 23.42). Small lesions of less than 2 cm can be difficult to differentiate from hyperplastic nodules in cirrhosis. MRI can be used instead of helical CT. Hepatocellular cancers are characteristically hypo-intense on T1-weighted imaging and hyperintense on T2-weighted imaging. Imaging techniques tend to underestimate the multifocal nature of the tumour and combinations of ultrasound scanning and CT or MRI are often helpful. Angiography is now seldom performed and has been superseded by the above techniques.

Liver biopsy

Histological confirmation is advisable in patients with large tumours who do not have cirrhosis or hepatitis B, in order to confirm the diagnosis and exclude metastatic tumour. Biopsy should be avoided in patients who

Fig. 23.42 CT showing a large hepatocellular carcinoma (arrows).

may be eligible for transplantation or surgical resection because there is a small (< 2%) risk of tumour seeding along the needle tract.

Role of screening

Screening for HCC, by ultrasound scanning and AFP measurements at 3–6-month intervals, is indicated in high-risk patients, such as those with cirrhosis due to hepatitis B and C, haemochromatosis, alcohol and α_1 -AT deficiency. It may also be indicated in individuals with chronic hepatitis B (who carry an increased risk of HCC, even in the absence of cirrhosis). Although no randomised controlled studies of outcome have been undertaken, screening has been shown to identify smaller tumours, often less than 3 cm in size, which are more likely to be cured by surgical resection, local ablative therapy or transplantation (Box 23.62).

Management

This is different for patients with cirrhosis and those without (see Box 23.62). An algorithm for managing those with cirrhosis is shown in Figure 23.43; it is integral to the European and American Study of the Liver

EBM 23.62 Guidelines for screening and management of hepatocellular carcinoma

'Cirrhotic patients who would be suitable for curative therapy if diagnosed with hepatocellular carcinoma should be offered screening with 6-monthly ultrasound and AFP testing.'

'Curative therapies for hepatocellular carcinoma include liver transplantation, hepatic resection and ablative therapy. Treatment depends on the presence/absence of cirrhosis, underlying liver function, tumour size and tumour multicentricity.'

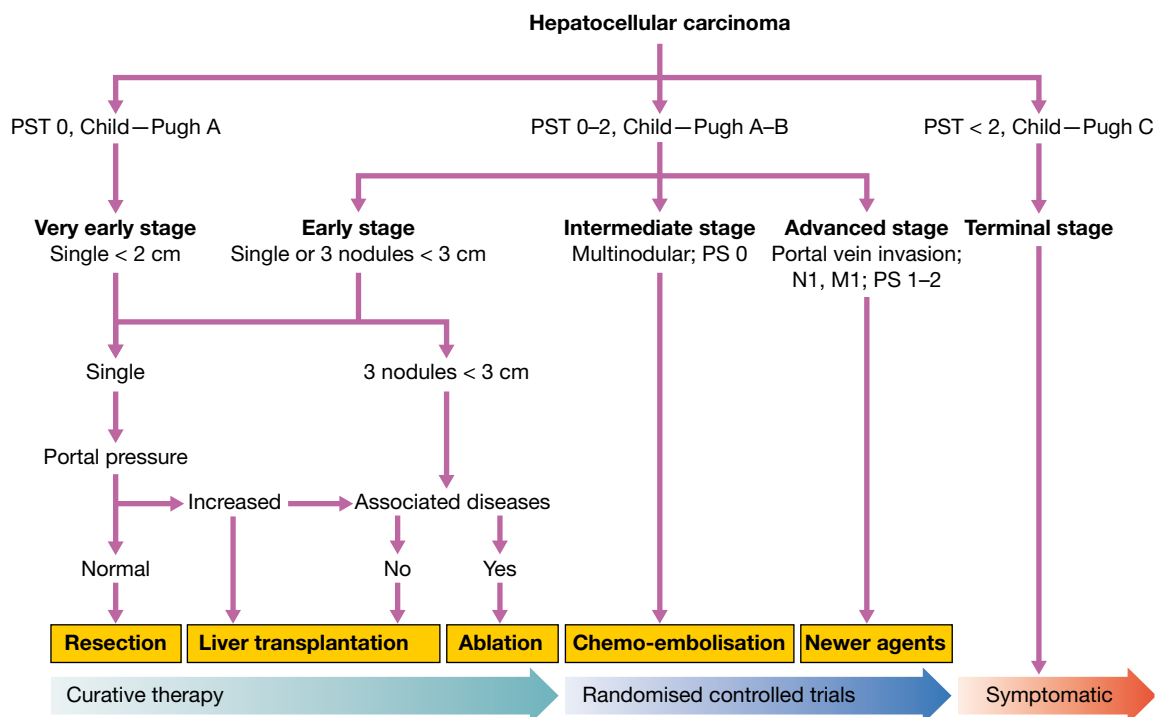

Fig. 23.43 Management of hepatocellular carcinoma (HCC) complicating cirrhosis. Performance status (PST; see Box 11.4, p. 263): 0 = fully active, no symptoms; > 2 = limited self-care, confined to bed or chair for 50% of waking hours. Child-Pugh score: see Box 23.29, p. 945. N1, M1: lymph node involvement and metastases (for TNM classification, see Box 11.1, p. 261).

guidelines. In the presence of cirrhosis, tumour size, multicentricity, extent of liver disease (Child–Pugh score) and performance status dictate appropriate therapy.

Prognosis depends on tumour size, the presence of vascular invasion, and liver function in those with cirrhosis. Screening has improved the outlook through early detection.

Hepatic resection

This is the treatment of choice for non-cirrhotic patients. The 5-year survival in this group is about 50%. However, there is a 50% recurrence rate at 5 years; this may be due to a second de novo tumour or recurrence of the original tumour. Few patients with cirrhosis are amenable to hepatic resection because of the high risk of hepatic failure; nevertheless, surgery is offered, particularly in the Far East, to some cirrhotic patients with small tumours and good liver function (Child–Pugh A with no portal hypertension).

Liver transplantation

Transplantation has the benefit of curing the cirrhosis and removing the risk of a second de novo tumour. The 5-year survival following liver transplantation is 75% for single tumours less than 5 cm in size or three tumours smaller than 3 cm. Unfortunately, the underlying liver disease, such as hepatitis B and C, may recur in the transplanted liver.

Percutaneous ablation

Percutaneous ethanol injection into the tumour under ultrasound guidance is efficacious (80% cure rate) for

tumours of 3 cm or smaller. Recurrence rates (50% at 3 years) are similar to those following surgical resection. Radiofrequency ablation, using a single electrode inserted into the tumour under radiological guidance, is an alternative means of ablation that takes longer to perform but appears to cause more complete tumour necrosis.

Transarterial chemo-embolisation (TACE)

Hepatocellular cancers are not radiosensitive and the response rate to chemotherapy with drugs such as doxorubicin is only around 30%. In contrast, hepatic artery embolisation with Gelfoam and doxorubicin is more effective, with survival rates of 60% in cirrhotic patients with unresectable HCC and good liver function (compared with 20% in untreated patients) at 2 years. Unfortunately, any survival benefit is lost at 4 years. TACE is contraindicated in decompensated cirrhosis and multifocal HCC.

Chemotherapy

A phase III trial has indicated an improvement in survival from 7.9 to 10.7 months in cirrhotic patients given intravenous sorafenib. The drug is a multikinase inhibitor with activity against Raf, VEGF and PDGF signalling, and is the first systemic therapy to prolong survival in this tumour.

Fibrolamellar hepatocellular carcinoma

This rare variant differs from the more common HCC in that it occurs in young adults, equally in males and females, in the absence of hepatitis B infection and

cirrhosis. The tumours are often large at presentation and the AFP is usually normal. Histology of the tumour reveals malignant hepatocytes that are surrounded by a dense fibrous stroma. The treatment of choice is surgical resection. This variant of HCC has a better prognosis following surgery than an equivalent-sized HCC, two-thirds of patients surviving beyond 5 years.

Other primary malignant tumours

These are rare but include haemangio-endothelial sarcomas.

Secondary malignant tumours

These are common and usually originate from carcinomas in the lung, breast, abdomen or pelvis. They may be single or multiple. Peritoneal dissemination frequently results in ascites.

Clinical features

The primary neoplasm is asymptomatic in about 50% of patients. There is usually liver enlargement and weight loss; jaundice may be present.

Investigations

A raised ALP activity is the most common biochemical abnormality, but LFTs may be normal. Ascitic fluid, if present, has a high protein content and may be blood-stained; cytology sometimes reveals malignant cells. Imaging (p. 928) usually shows up filling defects (Fig. 23.44); laparoscopy may reveal the tumour and facilitates liver biopsy.

Management

Hepatic resection can improve survival for slow-growing tumours such as colonic carcinomas. Patients with neuro-endocrine tumours, such as gastrinomas, insulinomas and glucagonomas, and those with lymphomas may benefit from surgery, hormonal treatment or chemotherapy. Unfortunately, palliative treatment to relieve pain is all that is available for most patients; this may include arterial embolisation of the tumour masses.

Fig. 23.44 CT showing multiple liver metastases (arrows).

Benign tumours

The increasing use of ultrasound scanning has led to more frequent identification of incidental benign focal liver lesions.

Haemangiomas

These are the most common benign liver tumours and are present in 1–20% of the population. Most are smaller than 5 cm and rarely cause symptoms (Fig. 23.45). The diagnosis is usually made by ultrasound, but CT may show a low-density lesion with delayed arterial filling. Surgery is only needed for very large symptomatic lesions, or where the diagnosis is in doubt.

Fig. 23.45 MRI showing a haemangioma (arrows) in the liver.

Hepatic adenomas

These are rare vascular tumours which may present as an abdominal mass, or with abdominal pain or intraperitoneal bleeding. They are more common in women and may be caused by oral contraceptives, androgens and anabolic steroids. Resection is indicated for the relief of symptoms. Hepatic adenomas can increase in size during pregnancy.

Focal nodular hyperplasia

Focal nodular hyperplasia (FNH) is common in women less than 40 years old. The lesions are usually asymptomatic but can be up to 10 cm in diameter; they can be differentiated from adenoma because of a focal central scar seen on CT or MRI. Histologically, they consist of nodular regeneration of hepatocytes but without fibrosis. They may be multiple but rarely need resection.

Liver abscess

Liver abscesses can be classified as pyogenic, hydatid or amoebic.

Pyogenic liver abscess

Pyogenic liver abscesses are uncommon but important because they are potentially curable, inevitably fatal if untreated, and readily overlooked.

The mortality of liver abscesses is 20–40%; failure to make the diagnosis is the most common cause of death. Older patients and those with multiple abscesses also have a higher mortality.

Pathophysiology

Infection can reach the liver in several ways (Box 23.63). Pyogenic abscesses are most common in older patients and usually result from ascending infection due to biliary obstruction (cholangitis) or contiguous spread from an empyema of the gallbladder. Abscesses complicating suppurative appendicitis used to be common in young adults but are now rare. Immunocompromised patients are particularly likely to develop liver abscesses. Single lesions are more common in the right liver; multiple abscesses are usually due to infection secondary to biliary obstruction. Abscesses vary greatly in size. *E. coli* and various streptococci, particularly *Strep. milleri*, are the most common organisms; anaerobes, including streptococci and *Bacteroides*, can often be found when infection has been transmitted from large bowel pathology via the portal vein, and multiple organisms are present in one-third of patients.

Clinical features

Patients are generally ill with fever, and sometimes rigors and weight loss. Abdominal pain is the most common symptom and is usually in the right upper quadrant, sometimes with radiation to the right shoulder. The pain may be pleuritic in nature. Hepatomegaly is found in more than 50% of patients, and tenderness can usually be elicited by gentle percussion over the organ. Mild jaundice may be present but is severe only when large abscesses cause biliary obstruction. Abnormalities are present at the base of the right lung in about one-quarter of patients. Atypical presentations are common and explain the frequency with which the diagnosis is made only at postmortem. This is a particular problem in patients with gradually developing illnesses or pyrexia of unknown origin without localising features. Necrotic colorectal metastases can be misdiagnosed as hepatic abscess.

Investigations

Liver imaging is the most revealing investigation and shows 90% or more of symptomatic abscesses. Needle aspiration under ultrasound guidance confirms the diagnosis and provides pus for culture. A leucocytosis is frequently found, plasma ALP activity is usually increased, and the serum albumin is often low. The chest X-ray may show a raised right diaphragm and lung collapse, or an effusion at the base of the right lung. Blood cultures are positive in 50–80%. Abscesses due to gut-derived organisms require active exclusion of significant colonic pathology, such as a colonoscopy to exclude colorectal carcinoma.

23.63 Causes of pyogenic liver abscesses

- Biliary obstruction (cholangitis)
- Haematogenous
 - Portal vein (mesenteric infections)
 - Hepatic artery (bacteraemia)
- Direct extension
- Trauma
 - Penetrating or non-penetrating
- Infection of liver tumour or cyst

Management

This includes prolonged antibiotic therapy and drainage of the abscess. Associated biliary obstruction and cholangitis require biliary drainage (preferably endoscopically). Pending the results of culture of blood and pus from the abscess, treatment should be commenced with a combination of antibiotics such as ampicillin, gentamicin and metronidazole. Aspiration or drainage with a catheter placed in the abscess under ultrasound guidance is required if the abscess is large or if it does not respond to antibiotics. Surgical drainage is rarely undertaken, although hepatic resection may be indicated for a chronic persistent abscess or 'pseudotumour'.

Hydatid cysts

Hydatid cysts are caused by *Echinococcus granulosus* infection (p. 375). They have an outer layer derived from the host, an intermediate laminated layer and an inner germinal layer. They can be single (Fig. 23.46) or multiple. Chronic cysts become calcified. The cysts may be asymptomatic but may present with abdominal pain or a mass. Peripheral blood eosinophilia is present in 20% of cases, whilst X-rays may show calcification of the rim of the abscess. CT reliably shows the cyst(s), and *Echinococcus* ELISA has 90% sensitivity for hepatic hydatid cysts. Rupture or secondary infection of cysts can occur, and a communication with the intrahepatic biliary tree can then result, with associated biliary obstruction.

All patients should be treated medically with albendazole or mebendazole prior to definitive therapy. In the absence of communications with the biliary tree, treatment consists of percutaneous aspiration of the cyst followed by the injection of 100% ethanol into the cysts and then re-aspiration of the cyst contents (PAIR). Where there is communication between the cyst and biliary system, surgical removal of the intact cyst is the preferred treatment.

Amoebic liver abscesses

Amoebic liver abscesses are caused by *Entamoeba histolytica* infection (p. 362). Up to 50% of cases do not have a previous history of intestinal disease. Although

Fig. 23.46 Hydatid cyst of the liver on CT (arrows).

amoebic liver abscesses are most often found in endemic areas, patients can present with no history of travel to these places. Abscesses are usually large, single and located in the right lobe; multiple abscesses may occur in advanced disease. Fever and abdominal pain or swelling are the most common symptoms. Diagnosis may depend on cyst aspiration revealing the classic anchovy sauce appearance of the cyst fluid. Analysis of serum for *Entamoeba* antibodies by immunoassay carries 99% sensitivity and > 90% specificity, and is more accurate than stool analysis in amoebic liver disease. Treatment is described on page 363.

VASCULAR LIVER DISEASES

Hepatic arterial disease

Hepatic arterial disease is rare and difficult to diagnose, but can cause serious liver damage. Hepatic artery occlusion may result from inadvertent injury during biliary surgery or may be caused by emboli, neoplasms, polyarteritis nodosa, blunt trauma or radiation. It usually causes severe upper abdominal pain with or without signs of circulatory shock. LFTs show raised transaminases (AST or ALT usually > 1000 U/L), as in other causes of acute liver damage. Patients usually survive if the liver and portal blood supply are otherwise normal.

Hepatic artery aneurysms are extrahepatic in three-quarters of cases and intrahepatic in one-quarter. Atheroma, vasculitis, bacterial endocarditis, and surgical or biopsy trauma are the main causes. These aneurysms usually cause bleeding into the biliary tree, peritoneum or intestine, and are best diagnosed by arteriography. Treatment is radiological or surgical. Any of the vasculitides can affect the hepatic artery, but this rarely causes symptoms.

Portal venous thrombosis

Portal venous thrombosis is rare but can occur in any condition predisposing to thrombosis. It may also complicate intra-abdominal inflammatory or neoplastic disease, and is a recognised cause of portal hypertension. Acute portal venous thrombosis causes abdominal pain and diarrhoea, and may lead to bowel infarction. This rare complication of infarction requires surgical management. Treatment is otherwise based on anticoagulation, although there are no randomised data on efficacy. An underlying thrombophilia needs to be excluded. Subacute thrombosis can be asymptomatic but may subsequently lead to extrahepatic portal hypertension (p. 945). Ascites is unusual in non-cirrhotic portal hypertension, unless the albumin is particularly low.

Hepatopulmonary syndrome

This is characterised by resistant hypoxaemia ($\text{PaO}_2 < 9.3 \text{ kPa}$ or 70 mmHg), intrapulmonary vascular dilatation and chronic liver disease with portal hypertension. Clinical features include digital clubbing, cyanosis, spider naevi and a characteristic reduction in arterial

oxygen saturation on standing. The hypoxia is due to intrapulmonary shunting through direct arteriovenous communications. It is believed that nitric oxide overproduction may be important in pathogenesis, as exhaled NO correlates with the severity of hypoxia. The hepatopulmonary syndrome can be treated by liver transplantation but, if severe ($\text{PaO}_2 < 6.7 \text{ kPa}$ or 50 mmHg), is associated with an increased operative risk.

Portopulmonary hypertension

This unusual complication of portal hypertension is similar to 'primary pulmonary hypertension' (p. 720); it is defined as pulmonary hypertension with increased pulmonary vascular resistance and a normal pulmonary artery wedge pressure in a patient with portal hypertension. It is caused by vasoconstriction and obliteration of the pulmonary arterial system, and leads to breathlessness and fatigue.

Hepatic venous outflow obstruction

Obstruction to hepatic venous blood flow can occur in the small central hepatic veins, the large hepatic veins, the inferior vena cava or the heart. The clinical features depend on the cause and on the speed with which obstruction develops, but congestive hepatomegaly and ascites are consistent features.

Budd–Chiari syndrome

Pathophysiology

This uncommon condition is caused by thrombosis of the larger hepatic veins and sometimes the inferior vena cava. Some patients have haematological disorders such as primary proliferative polycythaemia, paroxysmal nocturnal haemoglobinuria and antithrombin III, protein C or protein S deficiencies (Ch. 24). Pregnancy and oral contraceptive use, obstruction due to tumours (particularly carcinomas of the liver, kidneys or adrenals), congenital venous webs and occasionally inferior vena caval stenosis are the other main causes. The underlying cause cannot be found in about 50% of patients. Hepatic congestion affecting the centrilobular areas is the initial consequence; centrilobular fibrosis develops later and eventually cirrhosis supervenes in those who survive long enough.

Clinical features

Acute venous occlusion causes rapid development of upper abdominal pain, marked ascites and occasionally acute liver failure. More gradual occlusion causes gross ascites and often upper abdominal discomfort. Hepatomegaly, frequently with tenderness over the liver, is almost always present. Peripheral oedema occurs only when there is inferior vena cava obstruction. Features of cirrhosis and portal hypertension develop in those who survive the acute event.

Investigations

The LFTs vary considerably, depending on the presentation, and can show the features of acute hepatitis (p. 926). Ascitic fluid analysis typically shows a protein concentration above 25 g/L (exudate) in the early stages;

however, this often falls later in the disease. Doppler ultrasound examination may reveal obliteration of the hepatic veins and reversed flow or associated thrombosis in the portal vein. CT may show enlargement of the caudate lobe, as it often has a separate venous drainage system that is not involved in the disease. CT and MRI may also demonstrate occlusion of the hepatic veins and inferior vena cava. Liver biopsy demonstrates centrilobular congestion with fibrosis, depending on the duration of the illness. Venography is only needed if CT and MRI are unable to demonstrate the hepatic venous anatomy clearly.

Management

Predisposing causes should be treated as far as possible; where recent thrombosis is suspected, treatment with streptokinase followed by heparin and oral anticoagulation should be considered. Ascites is initially treated medically but often with limited success. Short hepatic venous strictures can be treated with angioplasty. In the case of more extensive hepatic vein occlusion, many patients can be managed successfully by insertion of a covered TIPSS followed by anticoagulation. Surgical shunts, such as portacaval shunts, are less commonly performed now that TIPSS is available. Occasionally, a web can be resected or an inferior vena caval stenosis dilated. Progressive liver failure is an indication for liver transplantation and life-long anticoagulation.

The prognosis without transplantation or shunting is poor, particularly following an acute presentation with liver failure. A 3-year survival of 50% is reported in those who survive the initial acute event. The 1- and 10-year survival following liver transplantation is 85% and 69% respectively, and this compares with a 5- and 10-year survival of 87% and 37% following surgical shunting.

Veno-occlusive disease

Veno-occlusive disease (VOD) is a rare condition characterised by widespread occlusion of the small central hepatic veins. Pyrrolizidine alkaloids in *Senecio* and *Heliotropium* plants used to make teas, cytotoxic drugs and hepatic irradiation are all recognised causes. VOD may develop in 10–20% of patients following bone marrow transplantation (usually within the first 20 days), and carries a 90% mortality in severe cases. Pathogenesis involves obliteration and fibrosis of terminal hepatic venules, due to deposition of red cells, haemosiderin-laden macrophages and coagulation factors. In this setting VOD is thought to relate to pre-conditioning therapy with irradiation and cytotoxic chemotherapy. The clinical features are similar to those of the Budd–Chiari syndrome (see above). Investigations show evidence of venous outflow obstruction histologically but, in contrast to Budd–Chiari, the large hepatic veins appear patent radiologically. Transjugular liver biopsy (with portal pressure measurements) may make the diagnosis. Traditionally, treatment has been supportive, but defibrotide shows promise (the drug binds to vascular endothelial cells, promoting fibrinolysis and suppressing coagulation).

Cardiac disease

Hepatic damage due primarily to congestion may develop in all forms of right heart failure (p. 543); the clinical features are usually dominated by the cardiac disease. Very rarely, long-standing cardiac failure and hepatic congestion cause cardiac cirrhosis.

Ischaemic hepatitis ('shock liver')

Acute heart failure sometimes causes a syndrome similar to acute hepatitis. This is usually mediated by a reduction in hepatic perfusion, and is termed 'shock liver'. Pre-existing right heart dysfunction is often present. Common causes include heart surgery, myocardial infarction, decompensation of any chronic myocardial disease, respiratory conditions associated with cor pulmonale and tamponade. The patient is generally very ill with an enlarged, tender liver, jaundice and LFTs showing very high serum transaminases (often over 2000 U/L). The correct diagnosis is made by recognising that the cardiac output is low, the jugular venous pressure is high and other signs of cardiac disease are present.

Ascites

Chronic congestive cardiac failure sometimes causes hepatomegaly and ascites disproportionate to the degree of peripheral oedema, and in the circumstances can mimic ascites due to liver disease. Constrictive pericarditis (p. 639) is easy to overlook as the heart size is normal, but the diagnosis can be confirmed by echocardiography.

Management

Treatment is that of the underlying heart disease.

Nodular regenerative hyperplasia of the liver

This is the most common cause of non-cirrhotic portal hypertension in developed countries; it is characterised by small hepatocyte nodules throughout the liver without fibrosis, which can result in sinusoidal compression. The condition is believed to be due to damage to small hepatic arterioles and portal venules. It occurs in older people and has been associated with many conditions, including connective tissue disease, haematological diseases and immunosuppressive drugs such as azathioprine used in transplant recipients. The condition is usually asymptomatic, but occasionally presents with portal hypertension or with an abdominal mass. The diagnosis is made by liver biopsy, which, in contrast to cirrhosis, shows nodule formation in the absence of fibrous septa. Liver function is good and the prognosis

23.64 Liver disease in old age

- **Alcoholic liver disease:** 10% of cases present over the age of 70 years, when disease is more likely to be severe and has a worse prognosis.
- **Hepatitis A:** causes more severe illness and runs a more protracted course.
- **Primary biliary cirrhosis:** one-third of cases are over 65 years and age is an adverse prognostic factor.
- **Liver abscess:** more than 50% of all cases in the UK are over 60 years.
- **Hepatocellular carcinoma:** approximately 50% of cases present over the age of 65 years in the UK.
- **Surgery:** older people are less likely to survive liver surgery (including transplantation) because comorbidity is more prevalent.

is very favourable. Management is based on treatment of the portal hypertension.

PREGNANCY AND THE LIVER

Intercurrent and pre-existing liver disease

When elevated serum transaminases are present, acute viral hepatitis and drug causes need to be excluded. Acute hepatitis A can occur during pregnancy but has no effect on the fetus. Chronic hepatitis B requires identification in pregnancy, because of long-term health implications for the mother and the effectiveness of perinatal vaccination (with or without pre-delivery maternal antiviral therapy) in reducing neonatal acquisition of chronic hepatitis B. Maternal transmission of hepatitis C occurs in 1% of cases, and there is no convincing evidence that the mode of delivery affects this. Hepatitis E is reported to progress to acute liver failure much more commonly in pregnancy, with a 20% maternal mortality. Pregnancy may be associated with both worsening and improvement of autoimmune liver disease (e.g. autoimmune hepatitis). Cirrhosis often leads to infertility, but full-term delivery can occur. Complications of portal hypertension may be a particular issue in the second and third trimesters.

Gallstones (p. 977) are more common during pregnancy, and may present with cholecystitis or biliary obstruction. The diagnosis can usually be made with ultrasound. In biliary obstruction due to gallstones, therapeutic ERCP can be safely performed, but lead protection for the fetus is essential and X-ray screening must be kept to an absolute minimum.

Pregnancy-associated liver disease

These conditions only occur during pregnancy, may recur in subsequent pregnancies and resolve after delivery of the baby. The causes of abnormal LFTs in pregnancy, which include pregnancy-associated liver disease, are shown in Box 23.65.

Intrahepatic cholestasis of pregnancy

This accounts for 20% of cases of jaundice in pregnancy; it usually occurs in the third trimester of pregnancy but can occur earlier. It is associated with intrauterine growth retardation and premature birth. There is a high prevalence in Chile. The condition characteristically presents with itching and cholestatic LFTs; however, the bilirubin may be normal and the liver biochemistry hepatic. Bile salts are elevated in the serum. Delivery leads to resolution, and pregnancy should not continue beyond term. UDCA effectively controls itching and probably prevents premature birth; it should be given at a daily dose of 15 mg/kg. Recurrence of cholestasis occurs in 60% of future pregnancies.

Acute fatty liver of pregnancy

This is more common in twin and first pregnancies; it occurs in 1 in 14 000 pregnancies in the USA. It typi-

23.65 Abnormal liver function tests in pregnancy

- **Liver function tests:** ALT levels and albumin normally fall in pregnancy. ALP levels can rise due to the contribution of placental ALP.
- **Pre-existing liver disease:** pregnancy is uncommon in cirrhosis due to infertility. Variceal bleeding can occur if varices present prior to conception, and ascites or polyhydramnios should be treated with amiloride rather than spironolactone. Penicillamine for Wilson's disease and azathioprine for autoimmune liver disease should be continued during pregnancy. Autoimmune liver disease can flare up post-partum.
- **Unrelated liver disease:** viral- and drug-induced hepatitis must be excluded in the presence of an elevated ALT. Immunoglobulin/vaccination given to the fetus at birth prevents transmission of hepatitis B to the fetus if the mother is infected. Gallstones are more common in pregnancy and post-partum, and are a cause of a raised ALP level. Biliary imaging with ultrasound and MRCP is safe. ERCP can be performed safely to remove stones with shielding of the fetus from radiation.
- **Pregnancy-related liver diseases:** occur predominantly in the third trimester and resolve post-partum. Maternal and fetal mortality and morbidity are prevented by early delivery.

cally presents between 31 and 38 weeks of pregnancy with vomiting and abdominal pain followed by jaundice. In severe cases this may be followed by lactic acidosis, a coagulopathy, encephalopathy and renal failure. Hypoglycaemia can also occur. The features are characteristic of a defect in beta-oxidation of fatty acids in the mitochondria that leads to the formation of small fat droplets in liver cells (known as microvesicular fatty liver). Some women are heterozygous for loss-of-function mutations in the long-chain 3-hydroxyacyl-CoA dehydrogenase (*LCHAD*) gene. Other causes of microvesicular steatosis due to defects in mitochondrial beta-oxidation of fatty acids that have a similar clinical presentation outside pregnancy are shown in Box 23.66. Differentiation from toxemia of pregnancy (which is more common) can be achieved by the finding of high serum uric acid levels and the absence of haemolysis. Overlap between acute fatty liver of pregnancy, HELLP (see below) and toxemia of pregnancy can occur. Early diagnosis, specialist care and delivery of the fetus have led to a fall in maternal and perinatal mortality to 1% and 7% respectively.

Toxaemia of pregnancy and HELLP

The HELLP syndrome (haemolysis, elevated liver enzymes and low platelets) is a variant of pre-eclampsia that tends to affect multiparous women. It usually presents at 27–36 weeks of pregnancy with hypertension, proteinuria and

fluid retention. Jaundice only occurs in 5% of cases. Blood tests may show low haemoglobin, with fragmented red cells, markedly elevated serum transaminases and raised D-dimers. The condition can be complicated by hepatic infarction and rupture. Maternal complications also include disseminated intravascular coagulation and placental abruption. Maternal mortality is 1% and perinatal mortality can be up to 30%. Delivery usually leads to prompt resolution, and disease recurs in < 5% of subsequent pregnancies.

LIVER TRANSPLANTATION

The outcome following liver transplantation has improved significantly over the last decade and this is now an effective treatment for end-stage liver disease. The number of procedures is limited by cadaveric donor availability, and in many parts of the world this has led to living donor transplant programmes. Despite this, 10% of those listed for liver transplantation will die while awaiting a donor liver. The main complications of liver transplantation relate to disease recurrence in the liver graft.

Indications and contraindications

Currently, around 9500 liver transplants are undertaken in Europe and the USA per year. About 10% are performed for acute liver failure, 6% for metabolic diseases, 71% for cirrhosis and 11% for hepatocellular carcinoma. Most patients are under 60 years of age, and only 10% are aged between 60 and 70 years. In North America the most common indication is hepatitis C cirrhosis, about 10–20% of transplants being for alcoholic cirrhosis (Fig. 23.47). Patients with alcoholic liver disease need to show a capacity for abstinence.

Liver transplantation in cirrhosis is considered when the anticipated mortality without transplantation exceeds 50% at 1 year (Box 23.67).

The main contraindications to transplantation are sepsis, extrahepatic malignancy, active alcohol or other substance misuse, and marked cardiorespiratory dysfunction.

Fig. 23.47 Indications for liver transplantation in the UK between 2001 and 2005.

23.67 Indications for liver transplant assessment for cirrhosis

Complications

- First episode of bacterial peritonitis
- Diuretic-resistant ascites
- Recurrent variceal haemorrhage
- Hepatocellular carcinoma < 5 cm
- Persistent hepatic encephalopathy

Poor liver function

- Bilirubin > 100 µmol/L (5.8 mg/dL) in primary biliary cirrhosis
- MELD score > 12
- Child–Pugh C

In many parts of the world the MELD score (see Box 23.31, p. 945) is used to identify and prioritise patients for transplantation. Patients are ABO- and size-matched, but not HLA-matched with donors.

Two types of transplant are increasingly used because of insufficient cadaveric donors:

- **Split liver transplantation.** A cadaveric donor liver can be split into two, with the larger right lobe used in an adult and the smaller left lobe used in a child. This practice has led to an increase in donor organs.
- **Living donor transplantation.** This is normally performed using the left lateral segment or the right lobe. The donor mortality is significant at 0.5%–1%. Pre-operative assessment includes looking at donor liver size and psychological status.

Complications

Early complications

Less immunosuppression is needed following liver transplantation than with kidney and heart/lung grafting. Initial immunosuppression is usually with tacrolimus or ciclosporin, prednisolone and azathioprine or mycophenolate. Some patients can eventually be maintained on a single agent.

- **Acute rejection.** This occurs in up to 60% of patients, usually within the first 6 weeks after transplantation, and normally responds to 3 days of high-dose methylprednisolone.
- **Surgical complications.** These include hepatic artery thrombosis, which may necessitate retransplantation. Anastomotic biliary strictures can also occur, and may respond to balloon dilatation or require surgical reconstruction. Portal vein thrombosis is rare.
- **Infections.** Bacterial infections such as pneumonia and wound infections can occur in the first few weeks after transplantation. Cytomegalovirus (primary infection or reactivation) is a common infection in the 3 months after transplantation and can cause hepatitis. Patients who have never had cytomegalovirus infection but who receive a liver from a donor who has been exposed are at greatest risk of infection, and are usually given prophylactic antiviral therapy such as valganciclovir. Tuberculous prophylaxis is given to recipients who have had previous exposure to tuberculosis for the first 6 months after transplantation to prevent reactivation.

Late complications

These include recurrence of the initial disease in the graft and complications due to the immunosuppres-

sive therapy, such as renal impairment from ciclosporin. Chronic vascular rejection is rare, occurring in only 5% of cases.

Prognosis

The outcome following transplantation for acute liver failure is worse than for chronic liver disease because most patients have multi-organ failure at the time of transplantation. The 1-year survival is 65% and falls only a little to 59% at 5 years. The 1-year survival for patients with cirrhosis is 80–90%, falling to 70–75% at 5 years.

GALLBLADDER AND EXTRAHEPATIC BILIARY DISEASE

Gallstones

Gallstone formation is the most common disorder of the biliary tree and it is unusual for the gallbladder to be diseased in the absence of gallstones. In developed countries gallstones are common and occur in 7% of males and 15% of females aged 18–65 years, with an overall prevalence of 11%. In those under 40 years there is a 3:1 female preponderance, whereas in the elderly the sex ratio is about equal. In developed countries the incidence of symptomatic gallstones appears to be increasing and they occur at an earlier age. Gallstones are less frequent in India, the Far East and Africa.

There has been much debate over the role of diet in cholesterol gallstone disease; an increase in dietary cholesterol, fat, total calories and refined carbohydrate or lack of dietary fibre has been implicated. At present, the best data support an association between simple refined sugar in the diet and gallstones. There is a negative association between a moderate alcohol intake (2–3 units daily) and gallstones.

Pathophysiology

Gallstones are conveniently classified into cholesterol or pigment stones, although the majority are of mixed composition. Cholesterol stones are most common in developed countries, whereas pigment stones are more frequent in developing countries. Gallstones contain varying quantities of calcium salts, including calcium bilirubinate, carbonate, phosphate and palmitate, which are radio-opaque.

Gallstone formation is multifactorial, and the factors involved are related to the type of gallstone (Boxes 23.68 and 23.69).

Cholesterol gallstones

Cholesterol is held in solution in bile by its association with bile acids and phospholipids in the form of micelles and vesicles. Biliary lipoproteins may also have a role in solubilising cholesterol. In gallstone disease the liver produces bile which contains an excess of cholesterol, because there is either a relative deficiency of bile salts or a relative excess of cholesterol. Bile, which is supersaturated with cholesterol, is termed 'lithogenic'. Disorders with the potential to induce the production of lithogenic bile are shown in Box 23.70. Factors initiating crystallisation of cholesterol in lithogenic bile

23.68 Risk factors and mechanisms for cholesterol gallstones

Risk factors	Haemolysis Age Hepatic cirrhosis Ileal resection/disease	Infected bile Stasis
*Major component.		

(nucleation factors) are also important; patients with cholesterol gallstones have gallbladder bile which forms cholesterol crystals more rapidly than equally saturated bile from patients who do not form gallstones. Factors favouring nucleation (mucus, calcium, fatty acids, other proteins) and antinucleating factors (apolipoproteins) have been described.

Pigment stones

Brown crumbly pigment stones are almost always the consequence of bacterial or parasitic infection in the biliary tree. They are common in the Far East, where infection of the biliary tree allows bacterial β -glucuronidase to hydrolyse conjugated bilirubin to its free form, which then precipitates as calcium bilirubinate. The mechanism of black pigment gallstone formation in developed countries is not satisfactorily explained. Haemolysis is important, as these stones occur in chronic haemolytic disease.

23.70 Pathogenic factors leading to the production of lithogenic bile

- Defective bile salt synthesis
- Excessive intestinal loss of bile salts
- Over-sensitive bile salt feedback
- Excessive cholesterol secretion
- Abnormal gallbladder function

Biliary sludge

The term 'biliary sludge' describes gelatinous bile that contains numerous microspheruliths of calcium bilirubinate granules and cholesterol crystals, as well as glycoproteins; it is an important precursor to the formation of gallstones in the majority of patients. Biliary sludge is frequently formed under normal conditions, but then either dissolves or is cleared by the gallbladder; only in about 15% of patients does it persist to form cholesterol stones. Fasting, parenteral nutrition and pregnancy are also associated with sludge formation.

Clinical features

The majority of gallstones are asymptomatic and only about 10% of those with gallstones develop clinical evidence of gallstone disease.

Symptomatic stones within the gallbladder (Box 23.71) manifest as either biliary pain ('biliary colic') or cholecystitis (see below). If a gallstone becomes acutely impacted in the cystic duct, the patient will experience pain. The term 'biliary colic' is a misnomer because the pain does not rhythmically increase and decrease in intensity like other forms of colic. Typically, the pain occurs suddenly and persists for about 2 hours; if it continues for more than 6 hours, a complication such as cholecystitis or pancreatitis may be present. Pain is usually felt in the epigastrium (70% of patients) or right upper quadrant (20% of patients), and radiates to the interscapular region or the tip of the right scapula, but other sites include the left upper quadrant and the lower chest. The pain can mimic intrathoracic disease, oesophagitis, myocardial infarction or dissecting aneurysm.

Combinations of fatty food intolerance, dyspepsia and flatulence not attributable to other causes have been referred to as 'gallstone dyspepsia'. These symptoms are not now recognised as being caused by gallstones and are best regarded as non-ulcer dyspepsia (p. 851).

Acute and chronic cholecystitis is described below.

A mucocele may develop if there is slow distension of the gallbladder from continuous secretion of mucus; if this material becomes infected, an empyema supervenes. Calcium may be secreted into the lumen of the hydropic gallbladder, causing 'limey' bile, and if calcium salts are precipitated in the gallbladder wall, the radiological appearance of 'porcelain' gallbladder results.

Gallstones in the gallbladder (cholecystolithiasis) migrate to the common bile duct (choledocholithiasis,

p. 980) in approximately 15% of patients and cause biliary colic. Rarely, fistulae develop between the gallbladder and the duodenum, colon or stomach. If this occurs, air will be seen in the biliary tree on plain abdominal X-rays. If a stone larger than 2.5 cm in diameter has migrated into the gut, it may impact either at the terminal ileum or occasionally in the duodenum or sigmoid colon. The resultant intestinal obstruction may be followed by 'gallstone ileus'. Gallstones impacted in the cystic duct may cause stricturing of the common hepatic duct and obstructive jaundice (Mirizzi's syndrome), which may be confused with a malignant bile duct stricture. The more common cause of jaundice due to gallstones is a stone passing from the cystic duct into the common bile duct (choledocholithiasis), which may also result in cholangitis or acute pancreatitis. It is usually very small stones that precipitate acute pancreatitis, due (it is thought) to oedema at the ampulla as the stone passes into the duodenum (no stone is seen within the bile duct in 80% of cases of presumed gallstone pancreatitis, suggesting stone passage). Previous stone passage is also the likely cause of most cases of benign papillary fibrosis, which is most commonly seen in patients with previous or present gallstone disease (it may present with jaundice, obstructive LFTs with biliary dilatation, post-cholecystectomy pain or acute pancreatitis).

Cancer of the gallbladder is uncommon (p. 981) but in over 95% of cases is associated with gallstones. The diagnosis is usually made as an incidental histological finding following cholecystectomy for gallstone disease.

Investigations

Ultrasound is the investigation of choice for diagnosing gallstones. Most stones are diagnosed by transabdominal ultrasound, which has a > 92% sensitivity and 99% specificity for gallbladder stones (see Fig. 23.8, p. 927). CT (Fig. 23.48) and MRCP are excellent modalities for detecting complications of gallstones (distal bile duct stone or gallbladder empyema), but are inferior to ultrasound in defining their presence in the gallbladder.

23.71 Clinical features and complications of gallstones	
Clinical features	
• Asymptomatic (80%)	• Acute cholecystitis
• Biliary colic	• Chronic cholecystitis
Complications	
• Empyema of the gallbladder	• Pressure on/inflammation of the common bile duct by a gallstone in the cystic duct (Mirizzi's syndrome)
• Porcelain gallbladder	• Cancer of the gallbladder
• Choledocholithiasis	
• Acute pancreatitis	
• Fistulae between the gallbladder and duodenum or colon	
• Gallstone ileus	

Fig. 23.48 CT showing a gallstone within the gallbladder (arrow).

Management

Asymptomatic gallstones found incidentally should not be treated because the majority will never cause symptoms. Symptomatic gallstones are best treated surgically by laparoscopic cholecystectomy. Non-surgical methods to dissolve gallstones or fragment gallbladder stones may be tried if surgery is not an option. Various techniques can be used to treat common bile duct stones (Box 23.72).

23.72 Treatment of gallstones

Gallbladder stones

- Cholecystectomy: open or laparoscopic
- Oral bile acids: chenodeoxycholic or ursodeoxycholic (low rate of stone dissolution)

Bile duct stones

- Lithotripsy (endoscopic or extracorporeal shock wave, ESWL)
- Endoscopic sphincterotomy and balloon trawl
- Surgical bile duct exploration

Medical dissolution of gallstones can be attempted by long-term oral administration of the bile acid UDCA. Medical treatment should be considered in those with radiolucent gallstones, a gallbladder that opacifies on oral cholecystography, stones smaller than 15 mm in diameter, moderate obesity and no or at most mild symptoms. Success can be expected in approximately 75% of patients who fulfil these criteria. An alternative is extracorporeal shock-wave lithotripsy (ESWL) but this is expensive and not widely available. Bile salt therapy is necessary following lithotripsy to dissolve the gallstone fragments within the gallbladder. Only 30% of patients with gallbladder disease are suitable for lithotripsy. All therapeutic regimens which retain the gallbladder have a 50% recurrence of stones after 5 years.

Cholecystitis

Acute cholecystitis

Pathophysiology

Acute cholecystitis is almost always associated with obstruction of the gallbladder neck or cystic duct by a gallstone. Occasionally, obstruction may be by mucus, parasitic worms or a bile tumour, or may follow endoscopic stent insertion. The pathogenesis is unclear, but the initial inflammation is possibly chemically induced. This leads to gallbladder mucosal damage which releases phospholipase, converting biliary lecithin to lysolecithin, a recognised mucosal toxin. At the time of surgery, approximately 50% of cultures of the gallbladder contents are sterile. Infection occurs eventually and in elderly patients or those with diabetes mellitus a severe infection with gas-forming organisms can cause emphysematous cholecystitis. Acalculous cholecystitis can occur in the intensive care setting and in association with parenteral nutrition, sickle cell disease and diabetes mellitus.

Clinical features

The cardinal feature is pain in the right upper quadrant but also in the epigastrium, the right shoulder tip or the interscapular region. Differentiation between biliary colic (p. 978) and acute cholecystitis may be difficult; features suggesting cholecystitis include severe and prolonged pain, fever and leucocytosis.

Examination shows right hypochondrial tenderness, rigidity worse on inspiration (Murphy's sign) and occasionally a gallbladder mass (30% of cases). Fever is present but rigors are unusual. Jaundice occurs in less than 10% of patients and is usually due to passage of stones into the common bile duct or to Mirizzi's syndrome. Gallbladder perforation occurs in 10–15% of cases, and gallbladder empyema may occur.

Investigations

Peripheral blood leucocytosis is common, except in the elderly patient in whom the signs of inflammation may be minimal. Minor increases of transaminases and amylase may be encountered. Amylase should be measured to detect acute pancreatitis (p. 888), which may be a potentially serious complication of gallstones. Only when the amylase is > 1000 U/L can pain be confidently attributed to acute pancreatitis, since moderately elevated levels of amylase can occur in many other causes of abdominal pain. Plain X-rays of the abdomen and chest may show radio-opaque gallstones, and rarely intrabiliary gas due to fistulation of a gallstone into the intestine; they are important in excluding lower lobe pneumonia and a perforated viscus. Ultrasonography detects gallstones and gallbladder thickening due to cholecystitis, but gallbladder empyema or perforation is best excluded with CT.

Management

Medical

This consists of bed rest, pain relief, antibiotics and maintenance of fluid balance. Moderate pain can be treated with NSAID but more severe pain should be treated with pethidine. A cephalosporin (such as cefuroxime) is the antibiotic of choice, but metronidazole is usually added in severely ill patients. Fluid balance is maintained by intravenous therapy, and nasogastric aspiration is only needed for persistent vomiting. Cholecystitis usually resolves with medical treatment, but the inflammation may progress to an empyema or perforation and peritonitis.

Surgical

Urgent surgery is the optimal treatment when cholecystitis progresses in spite of medical therapy and when complications such as empyema or perforation develop. Operation should be carried out within 5 days of the onset of symptoms. Delayed surgery after 2–3 months is no longer favoured. In patients in whom cholecystectomy may be difficult due to extensive inflammatory change, percutaneous gallbladder drainage can be performed, with subsequent cholecystectomy 4–6 weeks later. Recurrent biliary colic or cholecystitis is frequent if the gallbladder is not removed.

Chronic cholecystitis

Chronic inflammation of the gallbladder is almost invariably associated with gallstones. The usual symptoms are those of recurrent attacks of upper abdominal pain, often

at night and following a heavy meal. The clinical features are similar to those of acute calculous cholecystitis but milder. The patient may recover spontaneously or following analgesia and antibiotics. Patients are usually advised to undergo elective laparoscopic cholecystectomy.

Acute cholangitis

Acute cholangitis is caused by bacterial infection of bile ducts and occurs in patients with other biliary problems such as choledocholithiasis (see below), biliary strictures or tumours, or after ERCP. Jaundice, rigors and abdominal pain are the main presenting features. Treatment is with antibiotics, relief of biliary obstruction and removal (if possible) of the underlying cause.

Choledocholithiasis

Stones in the common bile duct (choledocholithiasis) occur in 10–15% of patients with gallstones (Fig. 23.49) which have usually migrated from the gallbladder. Primary bile duct stones are rare but can develop within the common bile duct many years after a cholecystectomy, and are sometimes related to biliary sludge arising from dysfunction of the sphincter of Oddi. In Far Eastern countries, where bile duct infection is common, primary common bile duct stones are thought to follow bacterial infection secondary to parasitic infections with *Clonorchis sinensis*, *Ascaris lumbricoides* or *Fasciola hepatica* (pp. 365 and 373). Common bile duct stones can cause partial or complete bile duct obstruction and may be complicated by cholangitis due to secondary bacterial infection, septicaemia, liver abscess and biliary stricture.

Fig. 23.49 ERCP showing common duct stones (arrows).

Clinical features

Choledocholithiasis may be asymptomatic, may be found incidentally by operative cholangiography at cholecystectomy, or may manifest as recurrent abdominal pain with or without jaundice. The pain is usually in the right upper quadrant, and fever, pruritus and dark urine may be present. Rigors may be a feature; jaundice is common and usually associated with pain. Physical examination may show the scar of a previous cholecystectomy; if the gallbladder is present, it is usually small, fibrotic and impalpable.

Investigations

The LFTs show a cholestatic pattern and there is bilirubinuria. If cholangitis is present, the patient usually has a leucocytosis. The most convenient method of demonstrating obstruction to the common bile duct is by trans-abdominal ultrasound; this shows dilated extrahepatic and intrahepatic bile ducts, together with gallbladder stones (Fig. 23.50), but does not always reveal the cause of the obstruction in the common bile duct as 50% of bile duct stones are missed on ultrasound, particularly those in the distal common bile duct. Endoscopic ultrasound is extremely accurate at identifying bile duct stones. MRCP is non-invasive, and is indicated when intervention is not necessarily mandatory (e.g. the patient with possible bile duct stones, but no jaundice or sepsis). ERCP can be used to diagnose obstruction and its cause, and to remove bile duct stones (see Fig. 23.49). If ERCP fails, PTC may be undertaken.

Management

Cholangitis should be treated with analgesia, intravenous fluids and broad-spectrum antibiotics such as cefuroxime and metronidazole. Blood cultures should be taken before the antibiotics are administered. Patients also require urgent decompression of the biliary tree and stone removal. ERCP with biliary sphincterotomy and

Fig. 23.50 Ultrasound showing dilated bile ducts (between arrows) in obstructive jaundice secondary to obstruction of the common bile duct.

stone extraction is the treatment of choice and is successful in about 90% of patients. Failure of stone extraction may relate to stone size or number, or difficult biliary access. Depending upon the clinical scenario, other approaches include percutaneous transhepatic drainage and combined ('rendez-vous') endoscopic procedures, ESWL and surgery.

Surgical treatment of choledocholithiasis is performed less frequently than ERCP because it carries higher morbidity and mortality. Before the common bile duct is explored, the diagnosis of choledocholithiasis should be confirmed by intraoperative cholangiography. If gallstones are found, the bile duct is explored, all stones are removed, stone clearance is checked by cholangiography or choledochoscopy, and a T-tube is inserted into the common bile duct. It is now possible to achieve these goals in specialist centres by laparoscopic means.

Recurrent pyogenic cholangitis

This disease occurs predominantly in South-east Asia. Biliary sludge, calcium bilirubinate concretions and stones accumulate in the intrahepatic bile ducts, with secondary bacterial infection. Patients present with recurrent attacks of upper abdominal pain, fever and cholestatic jaundice. Investigation of the biliary tree demonstrates that both the intrahepatic and the extrahepatic portions are filled with soft biliary mud. Eventually, the liver becomes scarred and liver abscesses and secondary biliary cirrhosis develop. The condition is difficult to manage, and requires drainage of the biliary tract with extraction of stones, antibiotics and, in certain patients, partial resection of damaged areas of the liver.

Tumours of the gallbladder and bile duct

Carcinoma of the gallbladder

This is an uncommon tumour, occurring more often in females and usually encountered above the age of 70 years. More than 90% are adenocarcinomas; the remainder are anaplastic or, rarely, squamous tumours. Gallstones are present in 70–80% of cases and are thought to be important in the aetiology of the tumour. Individuals with a calcified gallbladder ('porcelain gallbladder', p. 978) are at high risk of malignant change, and gallbladder polyps > 1 cm are associated with increased risk of malignancy.

The condition may be diagnosed incidentally and is found in 1–3% of gallbladders removed at cholecystectomy for gallstone disease. It may manifest as repeated attacks of biliary pain and later persistent jaundice and weight loss. A gallbladder mass may be palpable in the right hypochondrium. LFTs show cholestasis, and gallbladder calcification (porcelain gallbladder) may be found on X-ray. The tumour can be diagnosed by ultrasonography and staged by CT. The treatment is surgical excision, but local extension of the tumour beyond the wall of the gallbladder into the liver, lymph nodes and surrounding tissues is invariable and palliative management is usually all that can be offered. Survival is generally short, death typically occurring within 1 year.

Cholangiocarcinoma (CCA)

This uncommon tumour can arise anywhere in the biliary tree from the intrahepatic bile ducts (20–25% of

cases) and the confluence of the right and left hepatic ducts at the liver hilum (50–60%) to the distal common bile duct (20%). It accounts for only 1.5% of all cancers but the rate is increasing. The cause is unknown but the tumour is associated with gallstones, primary and secondary sclerosing cholangitis, Caroli's disease and choledochal cysts (see Fig. 23.41, p. 968). In the Far East, particularly northern Thailand, chronic liver fluke infection (*Clonorchis sinensis*) is a major risk factor for the development of CCA in men. Primary sclerosing cholangitis carries a lifetime risk of CCA of approximately 20%, although only 5% of CCAs relate to primary sclerosing cholangitis. Chronic biliary inflammation appears to be a common factor in the development of biliary dysplasia and cancer that is shared by all the predisposing causes.

Tumours typically invade the lymphatics and adjacent vessels, with a predilection for spread within perineural sheaths.

The presentation is with obstructive jaundice. About 50% of patients also have upper abdominal pain and weight loss. The diagnosis is made by a combination of CT and MRI but can be difficult to confirm in patients with sclerosing cholangitis. Serum levels of the tumour marker CA19-9 are elevated in up to 80% of cases, although this may occur in biliary obstruction of any cause. In the setting of biliary obstruction, ERCP may result in positive biliary cytology. CCAs can be treated surgically in about 20% of patients, which improves 5-year survival from less than 5% to 20–40%. Surgery involves excision of the extrahepatic biliary tree with or without a liver resection and a Roux loop reconstruction. However, most patients are treated by stents inserted across the biliary stricture caused by the tumour, using endoscopic or transhepatic techniques (Fig. 23.51). Combination chemotherapy is increasingly used and palliation with photodynamic therapy has provided encouraging results.

Carcinoma at the ampulla of Vater

Nearly 40% of all adenocarcinomas of the small intestine arise in relationship to the ampulla of Vater, and present with pain, anaemia, vomiting and weight loss. Jaundice may be intermittent or persistent. The diagnosis is made by duodenal endoscopy and biopsy of the tumour, but staging by CT/MRI is essential. Ampullary carcinoma must be differentiated from carcinoma of the head of the pancreas and a cholangiocarcinoma because these latter conditions both have a worse prognosis. Imaging may show a 'double duct sign' with stricturing of both the common bile duct and pancreatic duct at the ampulla indicated by a dilated common bile duct and pancreatic duct down to the level of the ampulla.

Curative surgical treatment can be undertaken by pancreaticoduodenectomy, and the 5-year survival may be as high as 50%. When resection is impossible, a palliative surgical bypass or stent insertion may be necessary.

Benign gallbladder tumours

These are uncommon, often asymptomatic and usually found incidentally at operation or postmortem. Cholesterol polyps, sometimes associated with cholesterosis, papillomas and adenomas, are the main types.

Fig. 23.51 Cholangiocarcinoma. **A** ERCP showing malignant biliary stricture (bottom arrow) and dilated intrahepatic bile ducts above (top arrow). **B** Post-ERCP stenting showing plastic endobiliary stent (arrow) which will draw bile from the dilated ducts above the stricture into the duodenum.

Miscellaneous biliary disorders

Post-cholecystectomy syndrome

Dyspeptic symptoms following cholecystectomy (post-cholecystectomy syndrome) occur in about 30% of patients, depending on how the condition is defined, how actively symptoms are sought and the original indication for cholecystectomy. The syndrome occurs most frequently in women, in patients who have had symptoms for more than 5 years before cholecystectomy, and in patients in whom the operation was undertaken for non-calculous gallbladder disease. An increase in bowel habit occurs in about 5–10% of patients after cholecystectomy, which often responds to colestyramine 4–8 g daily. Severe post-cholecystectomy syndrome occurs in only 2–5% of patients. The main causes are listed in Box 23.73.

The usual symptoms include right upper quadrant abdominal pain, flatulence, fatty food intolerance, and occasionally jaundice and cholangitis. The LFTs may be abnormal and sometimes show cholestasis. Ultrasonography is used to detect biliary obstruction, and ERCP or MRCP is used to seek common bile duct stones. If retained bile duct stones are excluded, sphincter of Oddi dysfunction should be considered (see below). Other investigations that may be required include upper gastrointestinal endoscopy, barium examination of the small intestine, pancreatic function tests, cholescintigraphy and a liver biopsy. The possibility of a functional illness should also be considered (p. 238).

23.73 Causes of post-cholecystectomy symptoms

Immediate post-surgical

- Bleeding
- Biliary peritonitis
- Abscess
- Bile duct trauma/transection
- Fistula

Biliary

- Common bile duct stones
- Benign stricture
- Tumour
- Cystic duct stump syndrome
- Disorders of the ampulla of Vater (e.g. benign papillary fibrosis; sphincter of Oddi dysfunction)

Extrabiliary

- Non-ulcer dyspepsia
- Peptic ulcer
- Pancreatic disease
- Gastro-oesophageal reflux
- Irritable bowel syndrome
- Functional abdominal pain

Sphincter of Oddi dysfunction

The sphincter of Oddi (SO) is a small smooth muscle sphincter situated at the junction of the bile duct and pancreatic duct in the duodenum. Sphincter of Oddi dysfunction (SOD) is characterised by an increase in contractility that produces a benign non-calculous obstruction to the flow of bile or pancreatic juice. This may cause pancreatobiliary pain, deranged LFTs or recurrent pancreatitis. A clinical classification system, based on clinical history, laboratory results and ERCP findings, is widely used (Boxes 23.74 and 23.75).

23.74 Classification of biliary sphincter of Oddi dysfunction

Biliary type I

- Biliary-type pain
- Abnormal liver enzymes (ALT/AST > twice normal on two or more occasions)
- Dilated common bile duct (> 12 mm diameter)
- Delayed drainage of ERCP contrast beyond 45 minutes

Biliary type II

- Biliary-type pain with one or two of the above criteria

Biliary type III

- Biliary-type pain with no other abnormalities

23.75 Classification of pancreatic sphincter of Oddi dysfunction

Pancreatic type I

- Pancreatic-type pain
- Twice normal amylase or lipase
- Pancreatic duct > 6 mm in the head or 5 mm in the body

Pancreatic type II

- Pancreatic-type pain with only one of the above criteria

Pancreatic type III

- Pancreatic-type pain with no other abnormalities

Clinical features

Patients with SOD, who are predominantly female, present with symptoms and signs suggestive of either biliary or pancreatic disease.

- *Patients with biliary-type SOD* experience recurrent episodic biliary-type pain. They have often had a cholecystectomy but the gallbladder may be intact.
- *Patients with pancreatic SOD* usually present with unexplained recurrent attacks of pancreatitis.

Investigations

The diagnosis is established by excluding gallstones and demonstrating a dilated or slowly draining bile duct. The gold standard for diagnosis is SO manometry. However, this is not widely available and is associated with a high rate of procedure-related pancreatitis.

Management

All biliary SOD patients with type I disease are treated with endoscopic sphincterotomy. The results are good but patients should be warned that there is a high risk of complications, particularly acute pancreatitis. Manometry should ideally be performed in all suspected SOD type II and III patients, and 'speculative' sphincterotomy should be avoided. In type III patients without documented evidence of sphincter hypertension (who should undergo sphincterotomy), medical therapy with nifedipine and/or low-dose amitriptyline may be tried. The role of botulinum toxin ('botox') injection into the sphincter to improve sphincter function remains unclear.

Pancreatic SOD can be treated with pancreatic stenting followed by pancreatic sphincterotomy, carried out in specialised units. Emerging evidence suggests that all

patients undergoing ERCP for suspected SOD should undergo prophylactic pancreatic stenting, because this significantly reduces the rate of procedure-related acute pancreatitis.

Cholesterolosis of the gallbladder

In this condition lipid deposits in the submucosa and epithelium appear as multiple yellow spots on the pink mucosa, giving rise to the description 'strawberry gallbladder'. The condition is usually asymptomatic but may occasionally present with right upper quadrant pain. Small, fixed filling defects may be visible on cholecystography or ultrasonography; the radiologist can usually differentiate between gallstones and cholesterolosis. The condition is usually diagnosed at cholecystectomy; if the diagnosis is made radiologically, cholecystectomy may be indicated, depending on symptoms.

Adenomyomatosis of the gallbladder

In this condition there is hyperplasia of the muscle and mucosa of the gallbladder. The projection of pouches of mucous membrane through weak points in the muscle coat produces Rokitsky-Aschoff sinuses. There is much disagreement over whether adenomyomatosis is a cause of right upper quadrant pain or other gastrointestinal symptoms. It may be diagnosed by oral cholecystography, when a halo or ring of opacified diverticula can be seen around the gallbladder. Other appearances include deformity of the body of the gallbladder or marked irregularity of the outline. Localised adenomyomatosis in the region of the gallbladder fundus causes the appearance of a 'Phrygian cap'. Most patients are treated by cholecystectomy but only after excluding other diseases in the upper gastrointestinal tract.

IgG4-associated cholangitis

This recently reported disease (as well as its nomenclature) is closely related to autoimmune pancreatitis (which is present in > 90% of the patients). IgG4-associated cholangitis (IAC) often presents with obstructive jaundice (due to either hilar stricturing/intrahepatic sclerosing cholangitis or a low bile duct stricture), and cholangiographic appearances suggest

23.76 Gallbladder disease in old age

- **Gallstones:** by the age of 70 years, prevalence is around 30% in women and 19% in men.
- **Acute cholecystitis:** tends to be severe, may have few localising signs, and is associated with a high frequency of empyema and perforation. If such complications supervene, mortality may reach 20%.
- **Cholecystectomy:** mortality after urgent cholecystectomy for acute uncomplicated cholecystitis is not significantly higher than in younger patients.
- **Endoscopic sphincterotomy and removal of common duct stones:** well tolerated by older patients and has a substantially lower mortality than surgical common bile duct exploration.
- **Cancer of the gallbladder:** a disease of old age, with a 1-year survival of 10%.

primary sclerosing cholangitis with or without hilar cholangiocarcinoma. The serum IgG4 is often raised, and liver biopsy shows a lymphoplasmacytic infiltrate, with IgG4-positive plasma cells. An important observation is that, compared to primary sclerosing cholangitis, IAC appears to respond well to steroid therapy.

Abnormalities detected in the blood are caused not only by primary diseases of the blood and lymphoreticular systems, but also by diseases affecting other systems of the body. The clinical assessment of patients with haematological abnormalities

must include a general history and examination, as well as a search for symptoms and signs of abnormalities of red cells, white cells, platelets, bleeding and clotting systems, lymph nodes and lymphoreticular tissues.

6 Lymphadenopathy

Lymphadenopathy can be caused by benign or malignant disease. The clinical points to clarify are shown in the box.

Lymphadenopathy	
History	
<ul style="list-style-type: none"> Speed of onset, rate of enlargement Painful or painless Associated symptoms: weight loss, night sweats, itch 	
Examination	
<ul style="list-style-type: none"> Sites: localised, generalised Size (cm) Character: hard, soft, rubbery Fixed, mobile Search area that node drains for abnormalities (e.g. tooth abscess) Other general examination (e.g. joints, rashes, finger clubbing) 	

8 Examination of the spleen

- Move hand up from right iliac fossa, towards left upper quadrant on expiration.

- Keep hand still and ask patient to take a deep breath through the mouth to feel spleen edge being displaced downwards.
- Place your left hand around patient's lower ribs and approach costal margin to pull spleen forward.
- To help palpate small spleens, roll patient on to the right side and examine as before.

Characteristics of the spleen	
<ul style="list-style-type: none"> Notch Superficial Dull to percussion Cannot get between ribs and spleen Moves well with respiration 	

Anaemia

The box shows the symptoms and signs that will help to indicate the clinical severity of anaemia. A full history and examination is needed to identify clues to the underlying cause.

Anaemia	
Non-specific symptoms	
<ul style="list-style-type: none"> Tiredness Lightheadedness Breathlessness Ankle-swelling Development/worsening of ischaemic symptoms e.g. angina or claudication 	
Non-specific signs	
<ul style="list-style-type: none"> Mucous membrane pallor Tachypnoea Raised jugular venous pressure Flow murmurs Ankle oedema Postural hypotension Tachycardia 	

Bleeding

Bleeding can be due to congenital or acquired abnormalities in components of the clotting system. The history and examination will help to clarify the severity and underlying cause of the bleeding problem.

Bleeding	
History	
<ul style="list-style-type: none"> Site of bleed Duration of bleed Precipitating causes, including previous surgery or trauma Family history Drug history Other medical conditions, e.g. liver disease 	
Examination	
There are two major patterns of bleeding:	
1. Mucosal bleeding Reduced number or function of platelets (e.g. bone marrow failure or aspirin) or von Willebrand factor (e.g. von Willebrand disease) <ul style="list-style-type: none"> Skin: petechiae, bruises, post-surgical bleeding Gum and mucous membrane bleeding Fundal haemorrhage 	
2. Coagulation factor deficiency (e.g. haemophilia or warfarin) <ul style="list-style-type: none"> Bleeding into joints (haemarthrosis) or muscles Bleeding into soft tissues Intracranial haemorrhage Post-surgical bleeding 	

Disorders of the blood cover a wide spectrum of illnesses, ranging from some of the most common disorders affecting mankind (anaemias), to relatively rare conditions such as leukaemias and congenital coagulation disorders. Although the latter are uncommon, advances in cellular and molecular biology have had major impacts on their diagnosis, treatment and prognosis. Haematological changes occur as a consequence of diseases affecting any system and give important information in the diagnosis and monitoring of many conditions.

FUNCTIONAL ANATOMY AND PHYSIOLOGY

Blood flows throughout the body in the vascular system, and consists of plasma and three cellular components:

- red cells, which transport oxygen from the lungs to the tissues
- white cells, which protect against infection
- platelets, which interact with blood vessels and clotting factors to maintain vascular integrity and prevent bleeding.

Haematopoiesis

Haematopoiesis describes the formation of blood cells, an active process that must maintain normal numbers of circulating cells and be able to respond rapidly to increased demands such as bleeding or infection. During development, haematopoiesis occurs in the liver and spleen and subsequently in red bone marrow in the medullary cavity of all bones. In childhood, red marrow is progressively replaced by fat (yellow marrow), so that in adults normal haematopoiesis is restricted to the vertebrae, pelvis, sternum, ribs, clavicles, skull, upper humeri and proximal femora. However, red mar-

row can expand in response to increased demands for blood cells.

Bone marrow contains a range of immature haematopoietic precursor cells and a storage pool of mature cells for release at times of increased demand. Haematopoietic cells interact closely with surrounding connective tissue stroma, made of reticular cells, macrophages, fat cells, blood vessels and nerve fibres (Fig. 24.1). In normal marrow, nests of red cell precursors cluster around a central macrophage, which provides iron and phagocytoses extruded nuclei. Megakaryocytes are large cells which produce and release platelets into vascular sinuses. White cell precursors are clustered next to the bone trabeculae; maturing cells migrate into the marrow spaces towards the vascular sinuses. Plasma cells are antibody-secreting mature B cells which normally represent < 5% of the marrow population and are scattered throughout the intertrabecular spaces.

Stem cells

All blood cells are derived from pluripotent stem cells. These comprise only 0.01% of the total marrow cells, but they can self-renew (i.e. make more stem cells) or differentiate to produce a hierarchy of lineage-committed stem cells. The resulting primitive progenitor cells cannot be identified morphologically, so they are named according to the types of cell (or colony) they form during cell culture experiments. CFU-GM (colony-forming unit-granulocyte, monocyte) is a stem cell that produces granulocytic and monocytic lines, CFU-E produces erythroid cells, and CFU-Meg produces megakaryocytes and ultimately platelets (Fig. 24.2).

A range of growth factors, produced in bone marrow stromal cells and elsewhere, controls the survival, proliferation, differentiation and function of stem cells and their progeny. Some, such as granulocyte macrophage-colony stimulating factor (GM-CSF), interleukin-3 (IL-3) and stem cell factor (SCF), act on a wide number of

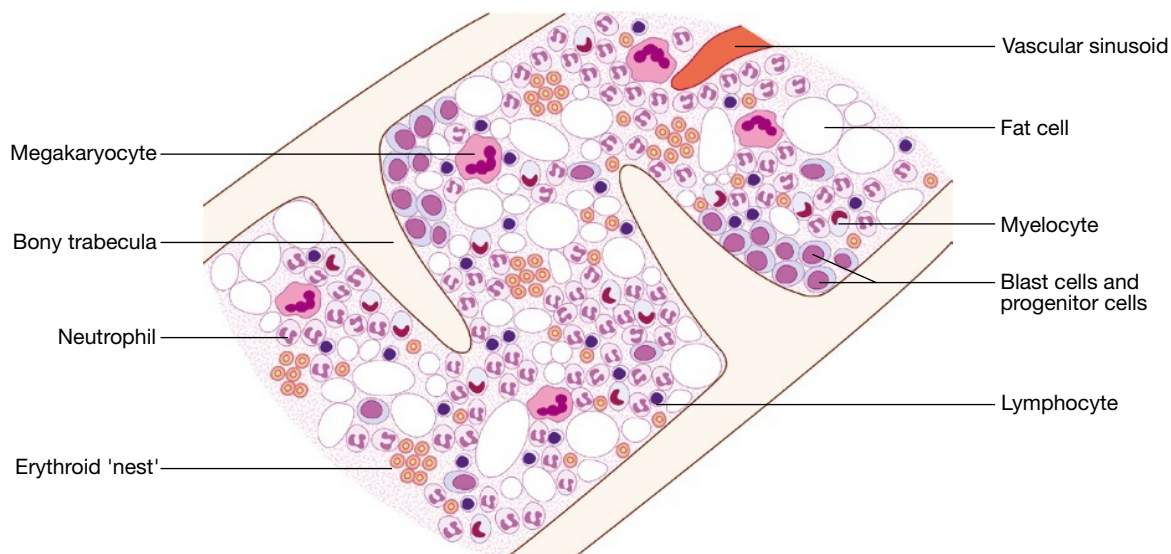

Fig. 24.1 Structural organisation of normal bone marrow.

24

Fig. 24.2 Stem cells and growth factors in haematopoietic cell development. (BFU-E = burst-forming unit–erythroid; CFU-E = colony-forming unit–erythroid; CFU-GM = colony-forming unit–granulocyte, monocyte; CFU-Meg = colony-forming unit–megakaryocyte; Epo = erythropoietin; G-CSF = granulocyte–colony-stimulating factor; GM-CSF = granulocyte macrophage–colony-stimulating factor; IL = interleukin; M-CSF = macrophage–colony-stimulating factor; SCF = stem cell factor; Tpo = thrombopoietin)

cell types at various stages of differentiation. Others, such as erythropoietin (Epo), granulocyte–colony stimulating factor (G-CSF) and thrombopoietin (Tpo), are lineage-specific. Many of these growth factors are now synthesised by recombinant DNA technology and used as treatments.

Recent evidence suggests that the bone marrow contains stem cells which can differentiate into non-haematological cells, such as nerve, skeletal muscle, cardiac muscle, liver and blood vessel endothelium. This is termed stem-cell plasticity and may have exciting clinical applications in the future (Ch. 3).

Fig. 24.3 Maturation pathway of red cells, granulocytes and platelets.

Blood cells and their functions

Red cells

Red cell precursors formed in the bone marrow from the erythroid (CFU-E) progenitor cells are called erythroblasts or normoblasts (Fig. 24.3). These divide and acquire haemoglobin which turns the cytoplasm pink; the nucleus condenses and is extruded from the cell. The first non-nucleated red cell is a reticulocyte which still contains ribosomal material in the cytoplasm, giving these large cells a faint blue tinge ('polychromasia'). Reticulocytes lose their ribosomal material and mature over 3 days, during which time they are released into the circulation. Increased numbers of circulating reticulocytes (reticulocytosis) reflect increased erythropoiesis. Proliferation and differentiation of red cell precursors is stimulated by erythropoietin, a polypeptide hormone produced by renal tubular cells in response to hypoxia. Failure of erythropoietin production in patients with renal failure (p. 482) causes anaemia, which can be treated with exogenous recombinant erythropoietin.

Mature red cells circulate for about 120 days. They are 8 μm biconcave discs lacking a nucleus but filled with haemoglobin, which delivers oxygen to the tissues from the lungs. In order to pass through the smallest capillaries the red cell membrane is adapted to be deformable, with a lipid bilayer to which a 'skeleton' of filamentous proteins is attached via special linkage proteins (Fig. 24.4). Inherited abnormalities of any of these proteins result in loss of membrane as cells pass through the spleen, and the formation of abnormally shaped red cells called spherocytes or elliptocytes (see Fig. 24.8D, p. 995).

Red cells are exposed to osmotic stress in the pulmonary and renal circulation; to maintain homeostasis, the membrane contains ion pumps which control intracellular levels of sodium, potassium, chloride and bicarbonate. In the absence of mitochondria, the energy for these functions is provided by anaerobic glycolysis and the pentose phosphate pathway in the cytosol. Membrane glycoproteins inserted into the lipid bilayer also form the antigens recognised by blood grouping (see Fig. 24.4). The ABO and Rhesus systems are the most commonly recognised (pp. 1008–1010), but over 400 blood group antigens have been described.

Haemoglobin

Haemoglobin is a protein specially adapted for oxygen transport. It is composed of four globin chains, each surrounding an iron-containing porphyrin pigment molecule termed haem. Globin chains are a combination of two alpha and two non-alpha chains; haemoglobin A ($\alpha\alpha/\beta\beta$) represents over 90% of adult haemoglobin, whereas haemoglobin F ($\alpha\alpha/\gamma\gamma$) is the predominant type in the fetus. Each haem molecule contains a ferrous ion (Fe^{2+}) to which oxygen reversibly binds; the affinity for oxygen increases as successive oxygen molecules bind. When oxygen is bound, the beta chains 'swing' closer together; they move apart as oxygen is lost. In the 'open' deoxygenated state, 2,3 diphosphoglycerate (DPG), a product of red cell metabolism, binds to the haemoglobin molecule and lowers its oxygen affinity. These complex interactions produce the sigmoid shape of the oxygen dissociation curve (Fig. 24.5). The position of this curve depends upon the concentrations of 2,3 DPG, H^+ ions and CO_2 ; increased levels shift the curve to the right and cause oxygen to be released more readily, e.g.

Fig. 24.4 Normal structure of red cell membrane. Red cell membrane flexibility is conferred by attachment of cytoskeletal proteins. Important transmembrane proteins include band 3 (an ion transport channel) and glycophorin (involved in cytoskeletal attachment and gas exchange, and a receptor for *Plasmodium falciparum* in malaria). Antigens on the red blood cell determine an individual's blood group. There are about 22 blood group systems (groups of carbohydrate or protein antigens controlled by a single gene or by multiple closely linked loci); the most important clinically are the ABO and Rhesus (Rh) systems (p. 1007). The ABO genetic locus has three main allelic forms: A, B and O. The A and B alleles encode glycosyltransferases that introduce N-acetylgalactosamine (open circle) and D-galactose (blue circle), respectively, on to antigenic carbohydrate molecules on the membrane surface. People with the O allele produce an O antigen which lacks either of these added sugar groups. Rh antigens are transmembrane proteins.

Fig. 24.5 The haemoglobin oxygen dissociation curve. Factors are listed which shift the curve to the right (more oxygen released from blood) and to the left (less oxygen released) at given PO_2 . (To convert kPa to mmHg, multiply by 7.5.)

when red cells reach hypoxic tissues. Haemoglobin F is unable to bind 2,3 DPG and has a left-shifted oxygen dissociation curve which, together with the low pH of fetal blood, ensures fetal oxygenation.

Genetic mutations affecting the haem-binding pockets of globin chains or the 'hinge' interactions between globin chains result in haemoglobinopathies or unstable haemoglobins. Alpha globin chains are produced by two genes on chromosome 16 and beta globin chains by a single gene on chromosome 11; imbalance in the production of globin chains produces the thalassaemias (p. 1029). Defects in haem synthesis cause the porphyrias (p. 456).

Destruction

Red cells at the end of their lifespan of approximately 120 days are phagocytosed by the reticulo-endothelial system. Amino acids from globin chains are recycled and iron is removed from haem for reuse in haemoglobin synthesis. The remnant haem structure is degraded to bilirubin and conjugated with glucuronic acid before being excreted in bile. In the small bowel, bilirubin is converted to stercobilin; most of this is excreted, but a small amount is reabsorbed and excreted by the kidney as urobilinogen. Increased red cell destruction due to haemolysis or ineffective haematopoiesis results in jaundice and increased urinary urobilinogen. Free intravascular haemoglobin is toxic and is normally bound by haptoglobins, which are plasma proteins produced by the liver.

White cells

White cells or leucocytes in the blood consist of granulocytes (neutrophils, eosinophils and basophils), monocytes and lymphocytes (see Fig. 24.12, p. 1000). Granulocytes and monocytes are formed from bone marrow CFU-GM progenitor cells. The first recognisable granulocyte in the marrow is the myeloblast, a large cell with a small amount of basophilic cytoplasm and a primitive nucleus with open chromatin and nucleoli. As the cells divide and mature, the nucleus segments and the cytoplasm acquires specific neutrophilic, eosinophilic or basophilic granules (see Fig. 24.3). This takes about 14 days. The cytokines G-CSF, GM-CSF and M-CSF are involved in the production of myeloid cells and G-CSF can be used clinically to hasten recovery of blood neutrophil counts after chemotherapy.

Myelocytes or metamyelocytes are normally only found in the marrow but may appear in the circulation in infection or toxic states. The appearance of more primitive myeloid precursors in the blood is often associated with the presence of nucleated red cells and is termed a 'leucoerythroblastic' picture; this indicates a serious disturbance of marrow function.

Neutrophils

Neutrophils, the most common white blood cells in the blood of adults, are 10–14 μm in diameter with a multi-lobular nucleus containing 2–5 segments and granules in their cytoplasm. Their main function is to recognise, ingest and destroy foreign particles and microorganisms (p. 70). A large storage pool of mature neutrophils exists in the bone marrow. Every day some 10^{11} neutrophils enter the circulation, where cells may be freely circulating or attached to endothelium in the marginating pool. These two pools are equal in size; factors such as exercise or catecholamines increase the number of cells flowing in the blood. Neutrophils spend 6–10 hours in the circulation before being removed, principally by the spleen. Alternatively, they pass into the tissues and either are consumed in the inflammatory process or undergo apoptotic cell death and phagocytosis by macrophages.

Eosinophils

Eosinophils represent 1–6% of the circulating white cells. They are a similar size to neutrophils but have a bilobed nucleus and prominent orange granules on Romanowsky staining. Eosinophils are phagocytic and their granules contain a peroxidase capable of generating reactive oxygen species and proteins involved in the intracellular killing of protozoa and helminths (p. 307). They are also involved in allergic reactions (e.g. atopic asthma, p. 662; see also p. 86).

Basophils

These cells are less common than eosinophils, representing less than 1% of circulating white cells. They contain dense black granules which obscure the nucleus. Mast cells resemble basophils but are only found in the tissues. These cells are involved in hypersensitivity reactions (p. 73).

Monocytes

Monocytes are the largest of the white cells, with a diameter of 12–20 μm and an irregular nucleus in abundant pale blue cytoplasm containing occasional cytoplasmic vacuoles. These cells circulate for a few hours and then migrate into the tissue where they become macrophages, Kupffer cells or antigen-presenting dendritic cells. The former phagocytose debris, apoptotic cells and microorganisms (see Box 4.1, p. 72).

Lymphocytes

Lymphocytes are derived from pluripotent haematopoietic stem cells in the bone marrow. There are two main types: T cells (which mediate cellular immunity) and B cells (which mediate humoral immunity) (pp. 75–76). Lymphoid cells which migrate to the thymus develop into T cells, whereas B cells develop in the bone marrow.

The majority of lymphocytes (approximately 80%) in the circulation are T cells. Lymphocytes are heterogeneous, the smallest cells being the size of red cells and

the largest being the size of neutrophils. Small lymphocytes are circular with scanty cytoplasm but the larger cells are more irregular with abundant blue cytoplasm. Lymphocyte subpopulations can be defined with specific functions and their lifespan can vary from a few days to many years.

Haemostasis

Blood must be maintained in a fluid state in order to function as a transport system, but must be able to solidify to form a clot following vascular injury to prevent excessive bleeding, a process known as haemostasis. Successful haemostasis is localised to the area of tissue damage and is followed by removal of the clot and tissue repair. This is achieved by complex interactions between the vascular endothelium, platelets,

coagulation factors, natural anticoagulants and fibrinolytic enzymes, as detailed in Figure 24.6. Dysfunction of any of these components may result in haemorrhage or thrombosis.

Platelets

Platelets are formed in the bone marrow from megakaryocytes. Megakaryocytic stem cells (CFU-Meg) divide to form megakaryoblasts, which undergo a process called 'endomitotic reduplication', in which there is division of the nucleus but not the cell. This creates mature megakaryocytes, large cells with several nuclei and cytoplasm containing platelet granules. Up to 3000 platelets then fragment off from each megakaryocyte into the circulation in the marrow sinusoids. The formation and maturation of megakaryocytes are stimulated by thrombopoietin produced in the liver. Platelets circulate for 8–10 days before they are destroyed in the reticulo-

Fig. 24.6 The stages of normal haemostasis.

A Stage 1 Pre-injury conditions encourage flow The vascular endothelium produces substances (including nitric oxide, prostacyclin and heparans) to prevent adhesion of platelets and white cells to the vessel wall. Platelets and coagulation factors circulate in a non-activated state.

B Stage 2 Early haemostatic response: platelets adhere; coagulation is activated. At the site of injury the endothelium is breached, exposing subendothelial collagen. Small amounts of tissue factor (TF) are released. Platelets bind to collagen via a specific receptor, glycoprotein Ia (GPIa), causing a change in platelet shape and its adhesion to the area of damage by the binding of other receptors (GPIb and GPIIb/IIIa) to von Willebrand factor and fibrinogen respectively. Coagulation is activated by the tissue factor (extrinsic) pathway, generating small amounts of thrombin.

C Stage 3 Fibrin clot formation: platelets become activated and aggregate; fibrin formation is supported by the platelet membrane; stable fibrin clot forms. The adherent platelets are activated by many pathways, including binding of ADP, collagen, thrombin and adrenaline (epinephrine) to surface receptors. The cyclo-oxygenase pathway converts arachidonic acid from the platelet membrane into thromboxane A_2 , which causes aggregation of platelets. Activation of the platelets results in release of the platelet granule contents, enhancing coagulation further (see Fig. 24.7). Thrombin plays a key role in the control of coagulation: the small amount generated via the TF pathway massively amplifies its own production; the 'intrinsic' pathway becomes activated and large amounts of thrombin are generated. Thrombin enhances clot formation by cleaving fibrinogen to produce fibrin. Fibrin monomers are cross-linked by factor XIII, which is also activated by thrombin. Having had a key role in clot formation and stabilisation, thrombin then starts to regulate clot formation in

endothelial system. Some 30% of peripheral platelets are normally pooled in the spleen and do not circulate.

Under normal conditions platelets are discoid, with a diameter of 2–4 μm (Fig. 24.7). The surface membrane invaginates to form a tubular network, the canalicular system, which provides a conduit for the discharge of the granule content following platelet activation. Drugs which inhibit platelet function and thrombosis include aspirin (cyclo-oxygenase inhibitor), clopidogrel (inhibits adenosine diphosphate (ADP)-mediated activation), dipyridamole (inhibits phosphodiesterase), and the IIb/IIIa inhibitors abciximab, tirofiban and eptifibatide (prevent fibrinogen binding) (p. 592).

Clotting factors

The coagulation system consists of a cascade of soluble inactive zymogen proteins designated by Roman

numerals. When proteolytically cleaved and activated, each is capable of activating one or more components of the cascade. Activated factors are designated by the suffix 'a'. Some of these reactions require phospholipid and calcium. Coagulation occurs by two pathways; it is initiated by the extrinsic (or tissue factor) pathway and amplified by the intrinsic pathway (see Fig. 24.6).

Clotting factors are synthesised by the liver, although factor V is also produced by platelets and endothelial cells. Factors II, VII, IX and X require post-translational carboxylation to allow them to participate in coagulation. The carboxylase enzyme responsible for this in the liver is vitamin K-dependent. Vitamin K is converted to an epoxide in this reaction and must be reduced to its active form by a reductase enzyme. This reductase is inhibited by warfarin, and this is the basis of the anticoagulant effect of coumarins (p. 1015). Congenital

two main ways: (a) activation of the protein C (PC) pathway (a natural anticoagulant), which reduces further coagulation; (b) activation of thrombin-activatable fibrinolysis inhibitor (TAFI), which inhibits fibrinolysis (see D and E).

D Stage 4 Limiting clot formation: natural anticoagulants reverse activation of coagulation factors. Once haemostasis has been secured, the propagation of clot is curtailed by anticoagulants. Antithrombin is a serine protease inhibitor synthesised by the liver, which destroys activated factors such as XIa, Xa and thrombin (IIa). Its major activity against thrombin and Xa is enhanced by heparin and fondaparinux, explaining their anticoagulant effect. Tissue factor pathway inhibitor (TFPI) binds to and inactivates VIIa and Xa. Activation of PC occurs following binding of thrombin to membrane-bound thrombomodulin; activated protein C (aPC) binds to its co-factor protein S (PS), and cleaves Va and VIIIa. PC and PS are vitamin K-dependent and are depleted by coumarin anticoagulants such as warfarin.

E Stage 5 Fibrinolysis: plasmin degrades fibrin to allow vessel recanalisation and tissue repair. The insoluble clot needs to be broken down for vessel recanalisation. Plasmin, the main fibrinolytic enzyme, is produced when plasminogen is activated, e.g. by tissue plasminogen activator (t-PA) or urokinase in the clot. Plasmin hydrolyses the fibrin clot, producing fibrin degradation products including the D-dimer. This process is highly regulated; the plasminogen activators are controlled by an inhibitor called plasminogen activator inhibitor (PAI), the activity of plasmin is inhibited by α_2 -antiplasmin and α_2 -macroglobulin, and fibrinolysis is further inhibited by the thrombin-activated TAFI.

Fig. 24.7 Normal platelet structure. (5-HT = 5-hydroxytryptamine, serotonin; ADP = adenosine diphosphate; ATP = adenosine triphosphate)

(e.g. haemophilia) and acquired (e.g. liver failure) causes of coagulation factor deficiency are associated with bleeding.

INVESTIGATION OF DISEASES OF THE BLOOD

The full blood count (FBC)

To obtain an FBC, anticoagulated blood is processed through automatic blood analysers which use a variety of technologies (particle-sizing, radiofrequency and laser instrumentation) to measure the haematological parameters. These include numbers of circulating cells and platelets, the proportion of whole blood volume occupied by red cells (the haematocrit, Hct), and the red cell indices which give information about the size of red cells (mean cell volume, MCV) and the amount of haemoglobin present in the red cells (mean cell haemoglobin, MCH). Modern blood analysers can differentiate types of white blood cell and give automated counts of neutrophils, lymphocytes, monocytes, eosinophils and basophils. It is important to appreciate, however, that a number of conditions can lead to spurious results (Box 24.1). The reference values for a number of common haematological parameters in adults are given in Chapter 28.

Blood film examination

Although the technical advances of modern full blood count analysers have resulted in fewer blood samples requiring manual examination, scrutiny of blood components prepared on a microscope slide (the 'blood film') can often yield invaluable information (Box 24.2 and Fig. 24.8). Analysers cannot identify abnormalities of red cell

24.1 Spurious FBC results from autoanalysers

Result	Explanation
Increased haemoglobin	Lipaemia, jaundice, very high white cell count
Reduced haemoglobin	Improper sample mixing, blood taken from vein into which an infusion is flowing
Increased red cell volume (MCV)	Cold agglutinins, non-ketotic hyperosmolarity
Increased white cell count	Nucleated red cells present
Reduced platelet count	Clot in sample, platelet clumping

shape and content (e.g. Howell-Jolly bodies, basophilic stippling, malaria parasites) or fully define abnormal white cells such as blasts.

Bone marrow examination

In adults bone marrow for examination is usually obtained from the posterior iliac crest. After a local anaesthetic, marrow may be sucked out from the medullary space, stained and examined under the microscope (bone marrow aspirate). In addition, a core of bone may be removed (trephine biopsy), fixed and decalcified before sections are cut for staining (Fig. 24.9). A bone marrow aspirate is used to assess the composition and morphology of haematopoietic cells or abnormal infiltrates. Further investigations may be performed, such as cell surface marker analysis (immunophenotyping), chromosome and molecular studies to assess malignant disease, or marrow culture for suspected tuberculosis. A trephine biopsy is superior for assessing marrow cellularity, marrow

24.2 How to interpret red cell appearances

Microcytosis (reduced average cell size, MCV < 76 fL) [A]

- Iron deficiency
- Sideroblastic anaemia
- Thalassaemia

Macrocytosis (increased average cell size, MCV > 100 fL) [B]

- Vitamin B₁₂ or folate deficiency
- Hypothyroidism
- Liver disease, alcohol
- Drugs (e.g. zidovudine)

Target cells (central area of haemoglobinisation) [C]

- Liver disease
- Post-splenectomy
- Thalassaemia
- Haemoglobin C disease

Spherocytes (dense cells, no area of central pallor) [D]

- Autoimmune haemolysis
- Hereditary spherocytosis
- Post-splenectomy

Red cell fragments (intravascular haemolysis) [E]

- Disseminated intravascular coagulation (DIC)
- Haemolytic uraemic syndrome (HUS)/thrombotic thrombocytopenic purpura (TTP)

Nucleated red blood cells (normoblasts) [F]

- Marrow infiltration
- Myelofibrosis
- Severe haemolysis
- Acute haemorrhage

Howell–Jolly bodies (small round nuclear remnants) [G]

- Hyposplenism
- Dyshaematopoiesis
- Post-splenectomy

Polychromasia (young red cells—reticulocytes present) [H]

- Haemolysis, acute
- Increased red cell turnover
- haemorrhage

Basophilic stippling (abnormal ribosomes appear as blue dots) [I]

- Dyshaematopoiesis
- Lead poisoning

Fig. 24.8 [A] Microcytosis. [B] Macrocytosis. [C] Target cells. [D] Spherocytes. [E] Red cell fragments. [F] Nucleated red blood cells. [G] Howell–Jolly bodies. [H] Polychromasia. [I] Basophilic stippling.

fibrosis, and infiltration by abnormal cells such as metastatic carcinoma. Bone marrow aspiration can usually be performed safely in a thrombocytopenic patient.

Investigation of coagulation

Bleeding disorders

In patients with clinical evidence of a bleeding disorder (p. 987), there are recommended screening tests (Box 24.3).

Coagulation tests measure the time to clot formation in vitro in a plasma sample after the clotting process is initiated by activators and calcium. The result of the test sample is compared with normal controls. The extrinsic pathway is assessed by the prothrombin time (PT) and the intrinsic pathway by the activated partial thromboplastin time (APTT), sometimes known as the partial thromboplastin time with kaolin, (PTTK). Clotting is

delayed by deficiencies of coagulation factors and the presence of inhibitors of coagulation, e.g. heparin. The approximate normal ranges and causes of abnormalities are shown in Box 24.3. If both the PT and APTT are prolonged, there is deficiency or inhibition of the final common pathway which includes factors X, V, prothrombin and fibrinogen, or global coagulation factor deficiency involving more than one factor. Further specific tests may be performed based on interpretation of the clinical scenario and results of these screening tests. A mixing test with normal plasma allows differentiation between a coagulation factor deficiency (the prolonged time corrects) and the presence of an inhibitor of coagulation (the prolonged time does not correct); the latter may be chemical (heparins) or an antibody (most often a lupus anticoagulant but occasionally a specific inhibitor of one of the coagulation factors, typically factor VIII). Von Willebrand disease may present with a normal APTT; further investigation of suspected cases is detailed on page 64.

Fig. 24.9 Bone marrow aspirate and trephine. **A** Trephine biopsy needle. **B** Macroscopic appearance of a trephine biopsy. **C** Microscopic appearance of stained section of trephine. **D** Bone marrow aspirate needle. **E** Stained macroscopic appearance of marrow aspirate: smear (left) and squash (right). **F** Microscopic appearance of stained marrow particles and trails of haematopoietic cells.

24.3 Coagulation screening tests		
Investigation	Normal range	Situations in which tests may be abnormal
Platelet count	150–400 × 10 ⁹ /L	Thrombocytopenia
Bleeding time	< 8 mins	Thrombocytopenia Abnormal platelet function von Willebrand disease Vascular and connective tissue abnormalities
Prothrombin time (PT)	9–12 secs	Deficiencies of factors II, V, VII or X Severe fibrinogen deficiency
Activated partial thromboplastin time (APTT)	26–36 secs	Deficiencies of factors II, V, VIII, IX, X, XI, XII Severe fibrinogen deficiency Unfractionated heparin therapy Antibodies against clotting factors Lupus anticoagulant
Fibrinogen concentration	1.5–4.0 g/L	Hypofibrinogenaemia, e.g. liver failure, disseminated intravascular coagulation
N.B. International normalised ratio (INR) is used only to monitor coumarin therapy and is not a coagulation screening test.		

Platelet function has historically been assessed by the bleeding time, using a standardised incision. However, many centres have abandoned this test as it is non-specific, being affected by the coagulation factor disorders shown in Box 24.3. Platelet function can be assessed in vitro by measuring aggregation in response to various agonists such as adrenaline (epinephrine), collagen, thrombin or ADP, or by measuring the constituents of the intracellular granules, e.g. ATP/ADP.

Coagulation screening tests are also performed in patients with suspected disseminated intravascular coagulation (DIC, p. 190) when clotting factors and platelets are consumed, resulting in thrombocytopenia and prolonged PT and APTT. In addition, there is evidence of active coagulation with consumption of fibrinogen and generation of fibrin degradation products (D-dimers). Note, however, that fibrinogen is an acute phase protein which may also be elevated in inflammatory disease (p. 81).

Monitoring anticoagulant therapy

The international normalised ratio (INR) is validated only to assess the therapeutic effect of coumarin anticoagulants, including warfarin. INR is the ratio of the patient's prothrombin time to that of a normal control, raised to the power of the international sensitivity index of the thromboplastin used in the test (ISI, derived by

comparison with an international reference standard material).

Monitoring of heparin therapy is on the whole only required with unfractionated heparins. Therapeutic anticoagulation prolongs the APTT relative to a control sample by a ratio of ~1.5–2.5. Low molecular weight heparins have such a predictable dose response that monitoring of the anticoagulant effect is not required, except in patients with renal impairment (GFR < 30 mL/min).

Thrombotic disorders

Measurement of plasma levels of D-dimers derived from fibrin degradation is useful in excluding the diagnosis of active thrombosis in some patients (see Fig. 24.15, p. 1006).

A variety of tests exist which may help to explain an underlying propensity to thrombosis, especially venous thromboembolism (Box 24.4). Examples of indications for testing are given in Box 24.5. In most patients, the results do not affect clinical management (p. 1049) but they may influence the duration and intensity of anticoagulation (e.g. antiphospholipid antibodies, p. 1050), justify family screening in inherited thrombophilias (p. 1049), or suggest additional management strategies to reduce thrombosis risk (e.g. in myeloproliferative disease and paroxysmal nocturnal haemoglobinuria; p. 1027). Anticoagulants can interfere with some of these assays; for example, warfarin reduces protein C and S levels and affects measurement of lupus anticoagulant, while heparin interferes with antithrombin and lupus anticoagulant assays.

24.4 Investigation of possible thrombophilia

Full blood count

Plasma levels

- Antithrombin
- Protein C
- Protein S (free)
- Antiphospholipid antibodies/lupus anticoagulant and anticardiolipin antibody

Thrombin/reptilase time (for dysfibrinogenemia)

Genetic testing

- Factor V Leiden
- Prothrombin G20210A
- JAK-2 mutation

Flow cytometry

- Screen for GPI-linked cell surface proteins (CD 14, 16, 55, 59), deficient in paroxysmal nocturnal haemoglobinuria

24.5 Indications for thrombophilia testing*

- Venous thrombosis < 45 years
- Recurrent venous thrombosis
- Family history of unprovoked or recurrent thrombosis
- Combined arterial and venous thrombosis
- Venous thrombosis at an unusual site
- Cerebral venous thrombosis
- Hepatic vein (Budd–Chiari syndrome)
- Portal vein, mesenteric vein

*Antiphospholipid antibodies should be sought where clinical criteria for antiphospholipid syndrome (APS) are fulfilled (p. 1050).

24.6 Haematological investigations in old age

- **Blood cell counts and film components:** not altered by ageing alone.
- **Ratio of bone marrow cells to marrow fat:** falls.
- **Neutrophils:** maintained throughout life, although leucocytes may be less readily mobilised by bacterial invasion in old age.
- **Lymphocytes:** functionally compromised by age due to a T cell-related defect in cell-mediated immunity.
- **Clotting factors:** no major changes, although mild congenital deficiencies may be first noticed in old age.
- **Erythrocyte sedimentation rate (ESR):** raised above the normal range, but usually in association with chronic or subacute disease. In truly healthy older people the ESR range is very similar to that in younger people.

PRESENTING PROBLEMS IN BLOOD DISEASE

Anaemia

Anaemia refers to a state in which the level of haemoglobin in the blood is below the normal range appropriate for age and sex. Other factors, including pregnancy and altitude, also affect haemoglobin levels and must be taken into account when considering whether an individual is anaemic. The clinical features of anaemia reflect diminished oxygen supply to the tissues (p. 987). A rapid onset of anaemia (e.g. due to blood loss) causes more profound symptoms than a gradually developing anaemia. Individuals with cardiorespiratory disease are more susceptible to symptoms of anaemia.

The clinical assessment and investigation of anaemia must not only assess its severity but also define the underlying cause (Box 24.7).

Clinical assessment

- *Iron deficiency anaemia* (p. 1017) is the most common type of anaemia world-wide. A thorough gastrointestinal history is important, looking in particular for symptoms of blood loss. Menorrhagia is a common cause of anaemia in pre-menopausal females, so women should always be asked about their periods.
- A *dietary history* should assess the intake of iron and folate which may become deficient in comparison to needs (e.g. in pregnancy or during periods of rapid growth; pp. 1020 and 114).

24.7 Causes of anaemia

Decreased or ineffective marrow production

- Lack of iron, vitamin B₁₂ or folate
- Hypoplasia
- Invasion by malignant cells
- Renal failure
- Anaemia of chronic disease

Peripheral causes

- Blood loss
- Haemolysis
- Hypersplenism

- *Past medical history* may reveal a disease which is known to be associated with anaemia, such as rheumatoid arthritis (the anaemia of chronic disease), or previous surgery (e.g. resection of the stomach or small bowel which may lead to malabsorption of iron and/or vitamin B₁₂).
- *Family history and ethnic background* may raise suspicion of haemolytic anaemias such as the haemoglobinopathies and hereditary spherocytosis. Pernicious anaemia may also be familial.
- *A drug history* may reveal the ingestion of drugs which cause blood loss (e.g. aspirin and anti-inflammatory drugs), haemolysis or aplasia.

On examination, as well as the general physical findings of anaemia shown on page 987, there may be specific findings related to the aetiology of the anaemia; for example, a patient may be found to have a right iliac fossa mass due to an underlying caecal carcinoma. Haemolytic anaemias can cause jaundice. Vitamin B₁₂ deficiency may be associated with neurological signs including peripheral neuropathy, dementia and signs of subacute combined degeneration of the cord (p. 1021). Sick-cell anaemia (p. 1028) may result in leg ulcers, stroke or features of pulmonary hypertension. Anaemia

may be multifactorial and the lack of specific symptoms and signs does not rule out silent pathology.

Investigations

Schemes for the investigation of anaemias are often based on the size of the red cells, which is most accurately indicated by the MCV in the FBC. Commonly, in the presence of anaemia:

- A normal MCV (normocytic anaemia) suggests either acute blood loss or the anaemia of chronic disease (ACD) (Fig. 24.10).
- A low MCV (microcytic anaemia) suggests iron deficiency or thalassaemia (see Fig. 24.10).
- A high MCV (macrocytic anaemia) suggests vitamin B₁₂ or folate deficiency or myelodysplasia (Fig. 24.11).

Specific types of anaemia and their management are described later in this chapter (pp. 1017–1027).

High haemoglobin

A haemoglobin level greater than the upper limit of normal (adult females 165 g/L or haematocrit > 0.48; adult males 180 g/L or haematocrit > 0.52) may be due

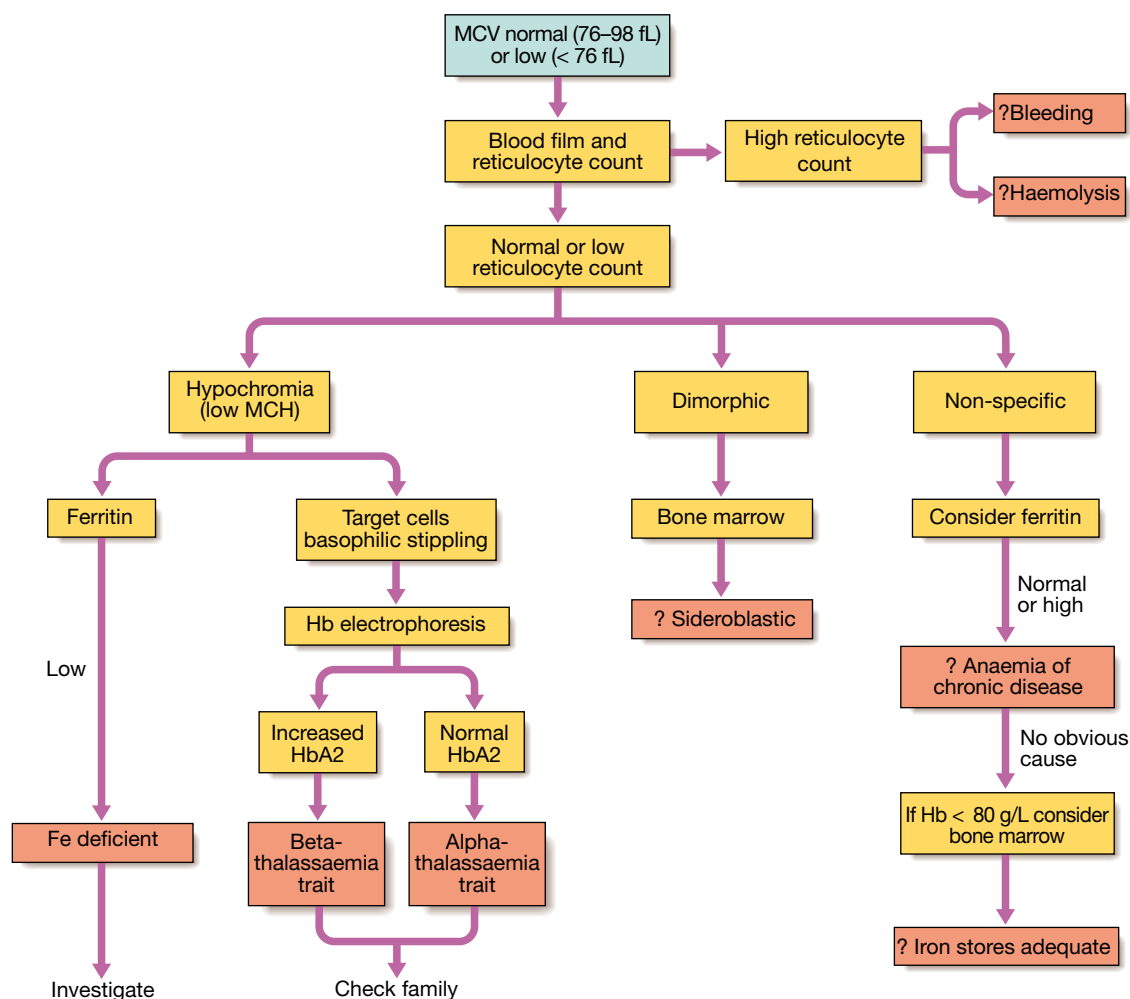

Fig. 24.10 Investigation of anaemia with normal or low MCV.

Fig. 24.11 Investigation of anaemia with high MCV. (LDH = lactate dehydrogenase)

to an increase in the number of red blood cells (true polycythaemia) or a reduction in the plasma volume (relative or apparent polycythaemia; Box 24.8). Circulating red cell mass is measured by radio-labelling an aliquot of the patient's red cells with ^{51}Cr , re-injecting the cells and measuring the dilution of the isotope. The plasma volume is measured by a similar dilution technique using albumin labelled with ^{125}I .

Causes of true polycythaemia are shown in Box 24.9. These involve increased erythropoiesis in the bone marrow, either due to a primary increase in marrow activity, in response to increased erythropoietin (Epo) levels in chronic hypoxaemia, or due to inappropriate secretion of Epo. Athletes who seek to benefit from increased oxygen-carrying capacity may be found guilty of doping offences as a result of their use of Epo.

Relative polycythaemia with a reduction in plasma volume is usually a consequence of dehydration, diuretic use or alcohol consumption.

Clinical assessment and investigations

A clinical history and examination will provide clues as to the aetiology of true polycythaemia. Those with PRV may have arterial thromboses, pruritus worse after a hot bath, hepatosplenomegaly and gout (due to high red cell turnover). The cardiovascular and respiratory systems should be assessed for evidence and causes of hypox-

24.9 Causes of true polycythaemia

	Aetiology	Examples
Primary	Myeloproliferative disorder	Polycythaemia rubra vera (PRV; primary proliferative polycythaemia)
Secondary	Increased Epo due to tissue hypoxia	High altitude Lung disease Cyanotic heart disease High-affinity haemoglobins
	Inappropriately increased Epo	Renal disease Hydronephrosis Cysts Carcinoma Other tumours Hepatoma Bronchogenic carcinoma Uterine fibroids Pheochromocytoma Cerebellar haemangioblastoma Exogenous administration (e.g. endurance athletes)

aemia. In PRV a mutation in *JAK-2* is found in over 97% of cases (p. 1044). If no other cause is identified, further investigations to exclude inappropriate erythropoietin secretion should be performed.

24.8 Classification of polycythaemia

	Red cell mass	Plasma volume
True polycythaemia	Increased	Normal
Relative polycythaemia	Normal	Decreased

Leucopenia (low white cell count)

A reduction in the total numbers of circulating white cells is called leucopenia. This may be due to a reduction in all types of white cell or in individual cell types

24.10 How to interpret white blood cell results

Neutrophils **A**

Neutrophilia

- Infection: bacterial, fungal
- Trauma: surgery, burns
- Infarction: myocardial infarct, pulmonary embolus, sickle-cell crisis
- Inflammation: gout, rheumatoid arthritis, ulcerative colitis, Crohn's disease
- Malignancy: solid tumours, Hodgkin lymphoma
- Myeloproliferative disease: polycythaemia, chronic myeloid leukaemia
- Physiological: exercise, pregnancy

Neutropenia

- Infection: viral, bacterial (e.g. *Salmonella*), protozoal (e.g. malaria)
- Drugs: see Box 24.11
- Autoimmune: connective tissue disease
- Alcohol
- Bone marrow infiltration: leukaemia, myelodysplasia
- Congenital: Kostmann's syndrome

Eosinophils **B**

Eosinophilia

- Allergy: hay fever, asthma, eczema
- Infection: parasitic
- Drug hypersensitivity: e.g. gold, sulphonamides
- Skin disease
- Connective tissue disease: polyarteritis nodosa
- Malignancy: solid tumours, lymphomas
- Primary bone marrow disorders: myeloproliferative disorders, hypereosinophilia syndrome (HES), acute myeloid leukaemia

Basophils **C**

Basophilia

- Myeloproliferative disease: polycythaemia, chronic myeloid leukaemia
- Inflammation: acute hypersensitivity, ulcerative colitis, Crohn's disease
- Iron deficiency

Monocytes **D**

Monocytosis

- Infection: bacterial (e.g. tuberculosis)
- Inflammation: connective tissue disease, ulcerative colitis, Crohn's disease
- Malignancy: solid tumours

Lymphocytes **E**

Lymphocytosis

- Infection: viral, bacterial (e.g. *Bordetella pertussis*)
- Lymphoproliferative disease: chronic lymphocytic leukaemia, lymphoma
- Post-splenectomy

Lymphopenia

- Inflammation: connective tissue disease
- Lymphoma
- Renal failure
- Sarcoidosis
- Drugs: corticosteroids, cytotoxics
- Congenital: severe combined immunodeficiency

Fig. 24.12 **A** Neutrophil. **B** Eosinophil. **C** Basophil. **D** Monocyte. **E** Lymphocyte.

(usually neutrophils or lymphocytes). Leucopenia may occur in isolation or as part of a reduction in all three haematological lineages (pancytopenia; p. 1004).

Neutropenia

A reduction in neutrophil count (usually less than $1.5 \times 10^9/L$, but dependent on age and race) is called neutropenia. The main causes are listed in Box 24.10. Drug-induced neutropenia is not uncommon (Box 24.11). Clinical manifestations range from no symptoms to overwhelming sepsis. The risk of bacterial infection is related to the degree of neutropenia, with counts lower than $0.5 \times 10^9/L$ considered to be critically low. Fever is the first and often only manifestation of infection. A sore throat, perianal pain or skin inflammation may be present. The lack of neutrophils allows the patient to become septicaemic and shocked within hours if immediate antibiotic therapy is not commenced. The management of such patients is discussed on page 1033.

Lymphopenia

This occurs when the absolute lymphocyte count is less than $1 \times 10^9/L$. The causes are shown in Box 24.10. Although minor deficiencies may be asymptomatic, deficiencies in cell-mediated immunity may cause infections (with organisms such as fungi, viruses and mycobacteria) and a propensity to lymphoid and other malignancies (particularly those associated with viral infections such as Epstein-Barr virus (EBV), human papillomavirus (HPV) and human herpes virus 8 (HHV-8)).

Leucocytosis (high white cell count)

An increase in the total numbers of circulating white cells is called leucocytosis. This is usually due to an increase in a specific type of cell (see Box 24.10). It is important to realise that an increase in a single type of white cell (e.g. eosinophils or monocytes) may not

24.11 Drugs which can induce neutropenia

Group	Examples
Analgesics/anti-inflammatory agents	Gold, penicillamine, naproxen
Antithyroid drugs	Carbimazole, propylthiouracil
Anti-arrhythmics	Quinidine, procainamide
Antihypertensives	Captopril, enalapril, nifedipine
Antidepressants/psychotropics	Amitriptyline, dosulepin, mianserin
Antimalarials	Pyrimethamine, dapsone, sulfadoxine, chloroquine
Anticonvulsants	Phenytoin, sodium valproate, carbamazepine
Antibiotics	Sulphonamides, penicillins, cephalosporins
Miscellaneous	Cimetidine, ranitidine, chlorpropamide, zidovudine

increase the total white cell count (WCC) above the upper limit of normal and will only be apparent if the 'differential' of the white count is examined.

Neutrophilia

An increase in the number of circulating neutrophils is called a neutrophilia or a neutrophil leucocytosis. It can result from an increased production of cells from the bone marrow or redistribution from the marginated pool. The normal neutrophil count depends upon age, race and certain physiological parameters. During pregnancy, not only is there an increase in neutrophils but also earlier forms such as metamyelocytes can be found in the blood. The causes of a neutrophilia are shown in Box 24.10.

Eosinophilia

A high eosinophil count $> 0.5 \times 10^9/L$ is usually secondary to infection (especially parasites; p. 307), allergy (e.g. eczema, asthma, reactions to drugs; p. 86), immunological disorders (e.g. polyarteritis, sarcoidosis) or malignancy (e.g. lymphomas) (see Box 24.10). Usually, such eosinophilia is short-lived.

In the rarer primary disorders, there is a persistently raised, often clonal, eosinophilia: for example, in myeloproliferative disorders, subtypes of acute myeloid leukaemia and idiopathic hypereosinophilic syndrome (HES). Recently, specific mutations in receptor tyrosine kinase genes have been found in some primary eosinophilias (e.g. causing rearrangements of platelet-derived growth factor receptors α and β or c-kit), which allow diagnosis and, in some cases, specific therapy with tyrosine kinase inhibitors such as imatinib.

Eosinophil infiltration can damage many organs (e.g. heart, lungs, gastrointestinal tract, skin, musculoskeletal system); therefore evaluation of eosinophilia includes not only the identification of any underlying cause and its appropriate treatment, but also assessment of any related organ damage.

Lymphocytosis

A lymphocytosis is an increase in circulating lymphocytes above that expected for the patient's age. In adults this is $> 3.5 \times 10^9/L$. Infants and children have higher counts; age-related normal ranges should be consulted. Causes are shown in Box 24.10; the most common is viral infection.

Lymphadenopathy

Enlarged lymph glands may be an important indicator of haematological disease but they are not uncommon in reaction to infection or inflammation (Box 24.12). The sites of lymph node groups, and symptoms and signs that may help elucidate the underlying cause are shown on page 987. Nodes which enlarge in response to local infection or inflammation ('reactive nodes') usually expand rapidly and are painful, whereas those due to haematological disease are more frequently painless. Localised lymphadenopathy should elicit a search for a source of inflammation in the appropriate drainage area:

- the scalp, ear, mouth, face or teeth for neck nodes
- the breast for axillary nodes
- the perineum or external genitalia for inguinal nodes.

Generalised lymphadenopathy may be secondary to infection, connective tissue disease or extensive skin disease, but is more likely to signify underlying haematological malignancy. Weight loss and drenching night sweats which may require a change of night clothes are associated with haematological malignancies, particularly lymphoma.

Initial investigations in lymphadenopathy include an FBC (to detect neutrophilia in infection or evidence of haematological disease), an ESR and a chest X-ray (to detect mediastinal lymphadenopathy). If the findings suggest malignancy, a formal cutting needle or excision biopsy of a representative node is indicated to obtain a histological diagnosis.

24.12 Causes of lymphadenopathy

Infective

- Bacterial: streptococcal, tuberculosis, brucellosis
- Viral: Epstein-Barr virus (EBV), human immunodeficiency virus (HIV)
- Protozoal: toxoplasmosis
- Fungal: histoplasmosis, coccidioidomycosis

Neoplastic

- Primary: lymphomas, leukaemias
- Secondary: lung, breast, thyroid, stomach

Connective tissue disorders

- Rheumatoid arthritis
- Systemic lupus erythematosus (SLE)

Sarcoidosis

Amyloidosis

Drugs

- Phenytoin

Splenomegaly

The spleen may be enlarged due to involvement by lymphoproliferative disease, the resumption of extra-medullary haematopoiesis in myeloproliferative disease, enhanced reticulo-endothelial activity in autoimmune haemolysis, expansion of the lymphoid tissue in response to infections or vascular congestion as a result of portal hypertension (Box 24.13). Hepatosplenomegaly is suggestive of lympho- or myeloproliferative disease, liver disease or infiltration (e.g. with amyloid). Associated lymphadenopathy is suggestive of lymphoproliferative disease. An enlarged spleen may cause abdominal discomfort, accompanied by back pain and abdominal bloating due to stomach compression. Splenic infarction may occur and produces severe abdominal pain radiating to the left shoulder tip, associated with a splenic rub on auscultation. Rarely, spontaneous or traumatic rupture and bleeding may occur.

Investigation will focus on the suspected cause. Imaging of the spleen by ultrasound or computed tomography (CT) will detect variations in density in the spleen which may be a feature of lymphoproliferative disease; it also allows imaging of the liver and abdominal lymph nodes. Biopsy of enlarged abdominal or superficial lymph nodes may provide the diagnosis. A chest X-ray or CT of the thorax will detect mediastinal lymphadenopathy. An FBC may show pancytopenia secondary to hypersplenism, when the enlarged spleen has become overactive, destroying blood cells prematurely. If other abnormalities are present, such as abnormal lymphocytes or a leuco-erythroblastic blood film, a bone marrow examination is indicated. Screening for infectious or liver disease (pp. 307 and 926) may be appropriate. If all investigations are unhelpful, splenectomy may be diagnostic.

Bleeding

Normal bleeding is seen following surgery and trauma. Pathological bleeding occurs when structurally abnormal vessels rupture or when a vessel is breached in the presence of a defect in haemostasis. This may be due to a deficiency or dysfunction of platelets, the coagulation factors, or occasionally to excessive fibrinolysis, which is most commonly observed following therapeutic thrombolysis (p. 594).

Clinical assessment

'Screening' blood tests (see Box 24.3, p. 996) do not reliably detect all causes of pathological bleeding (e.g. von Willebrand disease, scurvy and the causes of purpura in Box 24.14) and should not be used indiscriminately. A careful clinical evaluation is the key to diagnosis of bleeding disorders (see pp. 1044–1049).

It is important to consider the following points:

- *Site of bleeding.* Bleeding into muscle and joints, along with retroperitoneal and intracranial haemorrhage, indicates a likely defect in coagulation factors. Purpura, prolonged bleeding from superficial cuts, epistaxis, gastrointestinal haemorrhage or menorrhagia is more likely to be due to thrombocytopenia, a platelet function disorder or von Willebrand disease. Recurrent

24.13 Causes of splenomegaly

Congestive

Intrahepatic portal hypertension

- Cirrhosis
- Hepatic vein occlusion

Extrahepatic portal hypertension

- Thrombosis
- Stenosis or malformation of the portal or splenic vein

Cardiac

- Chronic congestive cardiac failure
- Constrictive pericarditis

Infective

Bacterial

- Endocarditis
- Septicaemia
- Tuberculosis
- Brucellosis
- Salmonella

Viral

- Hepatitis
- Epstein–Barr
- Cytomegalovirus

Protozoal

- Malaria*
- Leishmaniasis (kala-azar)*
- Trypanosomiasis

Fungal

- Histoplasmosis

Inflammatory/granulomatous disorders

- Felty's syndrome in rheumatoid arthritis
- Systemic lupus erythematosus
- Sarcoidosis

Haematological

Red cell disorders

- Megaloblastic anaemia
- Haemoglobinopathies

Autoimmune haemolytic anaemias

Myeloproliferative disorders

- Chronic myeloid leukaemia*
- Myelofibrosis*
- Polycythaemia rubra vera
- Essential thrombocythaemia

Neoplastic

- Leukaemias, including chronic myeloid leukaemia*
- Lymphomas

Other malignancies

- Metastatic cancer—rare

Lysosomal storage diseases

- Gaucher's disease
- Niemann–Pick disease

Miscellaneous

- Cysts, amyloid, thyrotoxicosis

*Causes of massive splenomegaly.

bleeds at a single site suggest a local structural abnormality.

- *Duration of history.* It may be possible to assess whether the disorder is congenital or acquired.
- *Precipitating causes.* Bleeding arising spontaneously indicates a more severe defect than bleeding that occurs only after trauma.

24.14 Causes of non-thrombocytopenic purpura

- Senile purpura
- Factitious purpura
- Henoch-Schönlein purpura (pp. 501 and 1114)
- Vasculitis (p. 1112)
- Paraproteinaemias
- Purpura fulminans

- **Surgery.** Ask about all operations. Dental extractions, tonsillectomy and circumcision are particularly stressful tests of the haemostatic system. Immediate post-surgical bleeding suggests defective platelet plug formation and primary haemostasis, while delayed haemorrhage is more suggestive of a coagulation defect. However, in post-surgical patients, persistent bleeding from a single site is more likely to indicate surgical bleeding than a bleeding disorder.
- **Family history.** While a positive family history may be present in patients with inherited disorders, the absence of affected relatives does not exclude a hereditary bleeding diathesis; about one-third of cases of haemophilia arise in individuals without a family history and deficiencies of factor VII, X and XIII are recessively inherited. Recessive disorders are more common in cultures where there is consanguineous marriage.
- **Drugs.** Use of antithrombotic, anticoagulant and fibrinolytic drugs must be elicited. Drug interactions with warfarin and drug-induced thrombocytopenia should be considered. Some 'herbal' remedies may result in a bleeding diathesis.

Superficial clinical examination may reveal different patterns of skin bleeding. Petechial purpura is minor bleeding into the dermis that is flat and non-blanching (Fig. 24.13). Petechiae are typically found in patients with thrombocytopenia or platelet dysfunction. Palpable purpura occurs in vasculitis. Ecchymosis, or bruising, is more extensive bleeding into deeper layers of the skin. The lesions are initially dark red or purple but become yellow as haemoglobin is degraded. Retroperitoneal bleeding presents with a flank haematoma. Telangiectasia of lips and tongue points to hereditary haemorrhagic telangiectasia (p. 1045). Joints should be examined for evidence of haemarthroses. A full exam-

Fig. 24.13 Petechial purpura.

ination is important, as it may give clues to an underlying associated systemic illness such as a haematological or other malignancy, liver disease, renal failure, connective tissue disease and possible causes of splenomegaly.

Investigations

Screening investigations and their interpretation are described on pages 995–997. If the patient has a history strongly suggestive of a bleeding disorder and all the preliminary screening tests give normal results, further investigations, such as measurement of von Willebrand factor and assessment of platelet function, should be performed (p. 1048).

Thrombocytopenia (low platelet count)

A reduced platelet count may arise by one of two mechanisms:

Box 24.15 Causes of thrombocytopenia

Decreased production

Marrow hypoplasia

- Childhood bone marrow failure syndromes, e.g. Fanconi's anaemia, dyskeratosis congenita, amegakaryocytic thrombocytopenia
- Idiopathic aplastic anaemia
- Drug-induced: cytotoxics, antimetabolites
- Transfusion-associated graft-versus-host disease

Marrow infiltration

- Leukaemia
- Myeloma
- Carcinoma (rare)
- Myelofibrosis
- Osteopetrosis
- Lysosomal storage disorders, e.g. Gaucher's disease

Haematinic deficiency

- Vitamin B₁₂ and/or folate deficiency

Familial (macro-)thrombocytopathies

- Myosin heavy chain abnormalities, e.g. Alport's syndrome, Fechner's syndrome
- Bernard Soulier disease
- Montreal platelet syndrome
- Wiskott-Aldrich syndrome (small platelets)

Increased consumption of platelets

Immune mechanisms

- Idiopathic thrombocytopenic purpura (ITP)*
- Post-transfusion purpura
- Neonatal alloimmune thrombocytopenia
- Drug-associated, especially quinine

Coagulation activation

- Disseminated intravascular coagulation (DIC) (see Box 24.70, p. 1050)

Mechanical pooling

- Hypersplenism

Thrombotic microangiopathies

- Haemolytic uraemic syndrome
- Liver disease
- Thrombotic thrombocytopenic purpura

Others

- Gestational thrombocytopenia
- Type 2B von Willebrand disease

*Associated conditions include collagen vascular diseases (particularly SLE), B cell malignancy, HIV infection, antiphospholipid syndrome

- decreased or abnormal production (bone marrow failure and hereditary thrombocytopathies)
- increased consumption following release into the circulation (immune-mediated, disseminated intravascular coagulation (DIC) or sequestration).

Spontaneous bleeding does not usually occur until the platelet count falls below $20 \times 10^9/L$, unless their function is also compromised. Purpura and spontaneous bruising are characteristic but there may also be oral, nasal, gastrointestinal or genitourinary bleeding. Severe thrombocytopenia ($<10 \times 10^9/L$) may result in retinal haemorrhage and potentially fatal intracranial bleeding.

Investigations are directed at the possible causes listed in Box 24.15. A blood film is the single most useful initial investigation. Examination of the bone marrow may reveal increased megakaryocytes in consumptive causes of thrombocytopenia, or the underlying cause of bone marrow failure in leukaemia, hypoplastic anaemia or myelodysplasia.

Treatment (if required) depends on the underlying cause. Platelet transfusion is rarely required and is usually confined to patients with bone marrow failure and platelet counts $<10 \times 10^9/L$, or to clinical situations with actual or predicted serious haemorrhage.

Thrombocytosis (high platelet count)

The most common reason for a raised platelet count is that it is reactive to another process such as infection, connective tissue disease, malignancy, iron deficiency, acute haemolysis or gastrointestinal bleeding (Box 24.16). The presenting clinical features are usually those of the underlying disorder and haemostasis is rarely affected. Reactive thrombocytosis is distinguished from the myeloproliferative disorders by the presence of uniform small platelets and lack of splenomegaly. The key to diagnosis is the clinical history and examination, combined with observation of the platelet count over time.

The platelets are a product of an abnormally expanding clone of cells in the myeloproliferative disorders, chronic myeloid leukaemia and some forms of myelodysplasia. Patients with PRV, essential thrombocythaemia and occasionally myelofibrosis may present with thrombosis or rarely bleeding. Stroke and transient ischaemic attacks, amaurosis fugax, or digital ischaemia or gangrene are also features. In addition, patients with myeloproliferative disorders present with features such

as itching after exposure to water (aquagenic pruritus), splenomegaly and systemic upset.

Pancytopenia

Pancytopenia refers to the combination of anaemia, leucopenia and thrombocytopenia. It may be due to reduced production of blood cells as a consequence of bone marrow suppression or infiltration, or there may be peripheral destruction or splenic pooling of mature cells. Causes are shown in Box 24.17. A bone marrow aspirate and trephine are usually required to establish the diagnosis.

24.17 Causes of pancytopenia

Bone marrow failure

- Hypoplastic/aplastic anaemia (p. 1043): inherited, idiopathic, viral, drugs

Bone marrow infiltration

- Acute leukaemia
- Myeloma
- Lymphoma
- Carcinoma
- Haemophagocytic syndrome
- Myelodysplastic syndromes

Ineffective haematopoiesis

- Megaloblastic anaemia
- Acquired immunodeficiency syndrome (AIDS)

Peripheral pooling/destruction

- Hypersplenism: portal hypertension, Felty's syndrome, malaria, myelofibrosis
- Systemic lupus erythematosus (SLE)

Infection

Infection is a major complication of haematological disorders. The type of infection relates to the immunological deficit caused by the disease itself, or its treatment with chemotherapy and/or immunotherapy (pp. 1000 and 298).

Venous thrombosis

While the most common presentation of venous thromboembolic disease (VTE) is with deep vein thrombosis (DVT) of the leg and/or pulmonary embolism (PE; see also p. 717), similar principles apply to rarer manifestations such as jugular vein thrombosis, upper limb DVT, cerebral sinus thrombosis (p. 1191) and intra-abdominal venous thrombosis (e.g. Budd–Chiari syndrome; p. 973).

DVT has an annual incidence of approximately 1:1000 in Western populations and the case mortality is 1–3%. It is increasingly common with ageing, and many of the deaths are related to coexisting medical conditions. Risk factors for DVT and PE are often present (Box 24.18). Figure 24.14 illustrates some of the causes and consequences of VTE disease.

24.16 Causes of a raised platelet count

Reactive thrombocytosis

- Chronic inflammatory disorders
- Malignant disease
- Tissue damage
- Haemolytic anaemias
- Post-splenectomy
- Post-haemorrhage

Clonal thrombocytosis

- Primary thrombocythaemia
- Polycythaemia rubra vera (PRV)
- Myelofibrosis
- Chronic myeloid leukaemia
- Myelodysplastic syndromes (refractory anaemia with sideroblasts (RARS) with thrombocytosis, 5q⁻ syndrome)

Fig. 24.14 Causes and consequences of venous thromboembolic disease.

Clinical assessment

Lower limb DVT characteristically starts in the distal veins, causing pain, swelling, an increase in temperature and dilatation of the superficial veins. Often, however, there are only minimal symptoms and signs. It is typically unilateral but may be bilateral when clot extends proximally into the inferior vena cava. Bilateral DVT is more commonly seen in patients with underlying malignancy or anomalies of the inferior vena cava. The differential diagnosis of unilateral leg swelling includes a spontaneous or traumatic calf muscle tear or a ruptured Baker's cyst, both characterised by sudden onset and by localised tenderness. Baker's cysts usually occur in patients with rheumatoid arthritis. Infective cellulitis is usually distinguished by marked skin erythema and heat which is localised within a well-demarcated area of the leg and may be associated with an obvious source of entry of infection (e.g. an insect bite or leg ulcer).

Risk factors for DVT should be considered (see Box 24.18), and examination should include assessment for malignancy. Symptoms and signs of PE should be sought (p. 717), particularly in those with proximal thrombosis; asymptomatic PE is thought to be present in approximately 30% of patients with lower limb DVT.

Clinical criteria can be used to rank patients according to their likelihood of DVT using the Wells scoring system (Box 24.19).

Investigations

Figure 24.15 gives an algorithm for investigation of suspected DVT based on initial Wells score (see Box 24.19). In patients with a low pre-test probability of DVT, D-dimer levels can be measured; if these are normal, further investigation for DVT is unnecessary. In those with moderate or high probability of DVT or with elevated D-dimer levels, objective diagnosis of DVT should be obtained using appropriate imaging.

24.18 Factors predisposing to venous thrombosis

Patient factors	
<ul style="list-style-type: none"> Increasing age Obesity Varicose veins Previous DVT Family history, especially of unprovoked VTE at a young age Pregnancy/puerperium 	<ul style="list-style-type: none"> Oestrogen-containing oral contraceptives and hormone replacement therapy Immobility, e.g. long-distance travel (> 4 hours) Intravenous drug use involving the femoral vein
Surgical conditions	
<ul style="list-style-type: none"> Major surgery, especially if > 30 mins' duration Abdominal or pelvic surgery, especially for cancer 	<ul style="list-style-type: none"> Major lower limb orthopaedic surgery, e.g. joint replacement and hip fracture surgery
Medical conditions	
<ul style="list-style-type: none"> Myocardial infarction/heart failure Inflammatory bowel disease Malignancy Nephrotic syndrome 	<ul style="list-style-type: none"> Pneumonia Neurological conditions associated with immobility, e.g. stroke, paraplegia, Guillain-Barré syndrome
Haematological disorders	
<ul style="list-style-type: none"> Polycythaemia rubra vera Essential thrombocythaemia Deficiency of anticoagulants: antithrombin, protein C, protein S Paroxysmal nocturnal haemoglobinuria 	<ul style="list-style-type: none"> Gain-of-function prothrombotic mutations: factor V Leiden, prothrombin gene <i>G20210A</i> Myelofibrosis
Antiphospholipid syndrome

Compression ultrasound is the imaging modality of choice in most centres. It has a sensitivity for proximal DVT (clot involving the popliteal vein or above) of 99.5%. Sensitivity and specificity are lower for diagnosing calf vein thrombosis. Contrast venography is

24.19 Predicting the pre-test probability of deep vein thrombosis

Clinical characteristic	Score
Active cancer (patient receiving treatment for cancer within the previous 6 months or currently receiving palliative treatment)	1
Paralysis, paresis or recent plaster immobilisation of the lower extremities	1
Recently bedridden for 3 days or more, or major surgery within the previous 4 weeks	1
Localised tenderness along the distribution of the deep venous system	1
Entire leg swollen	1
Calf swelling at least 3 cm larger than that on the asymptomatic side (measured 10 cm below the tibial tuberosity)	1
Pitting oedema confined to the symptomatic leg	1
Collateral superficial veins (non-varicose)	1
Alternative diagnosis at least as likely as DVT	-2
Clinical probability	Total score
DVT low probability	< 1
DVT moderate probability	1-2
DVT high probability	> 2

an alternative that is now rarely used. In patients with suspected PE, further investigation is described on pages 717-719.

Predisposing factors, particularly pelvic malignancy and those listed in Box 24.18, should be considered and investigation pursued as appropriate. In occasional patients, further investigation for an underlying thrombophilic condition may be considered (see Boxes 24.4 and 24.5, p. 997).

Management

The management of leg DVT includes elevation and analgesia. Thrombolysis may be considered for limb-threatening DVT, but the mainstay of treatment is anticoagulation with low molecular weight heparin (LMWH) followed by a coumarin anticoagulant, such as warfarin, to achieve a target INR of 2.5 (range 2-3; pp. 996 and 1014).

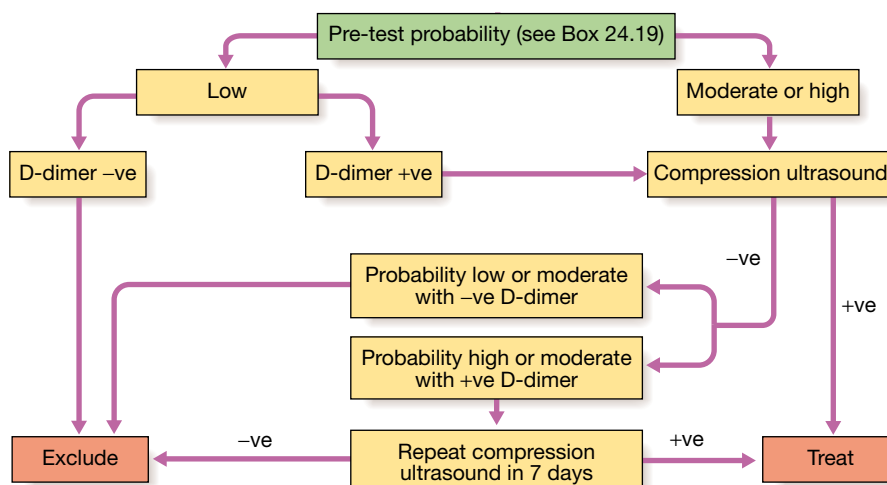

Fig. 24.15 Investigation of suspected DVT. Pre-test probability is calculated in Box 24.19.

EBM 24.20 Treatment of venous thromboembolism

'In patients with active cancer, treatment of DVT with LMWH for 6 months is superior in preventing recurrence of thrombosis to short-term LMWH followed by warfarin.'

• Lee AY, et al. *N Engl J Med* 2003; 349(2):146–153.

Treatment of acute VTE with heparin should continue for a minimum of 5 days. If a coumarin is being introduced, the heparin should continue until the INR has been in the target range for 2 days. Patients who have had a DVT and have a strong contraindication to anticoagulation, and those who, despite therapeutic anticoagulation, continue to have new pulmonary emboli, should have an inferior vena cava filter inserted to prevent life-threatening PE.

The optimal duration of anticoagulation is between 6 weeks and 6 months. Patients who have thrombosis in the presence of a temporary risk factor which is then removed can usually be treated for shorter periods (e.g. 3 months) than those who sustain unprovoked thrombosis. In patients with active cancer and VTE, there is evidence that LMWH should be continued for 6 months rather than being replaced by a coumarin (Box 24.20). Evidence indicates that periods of anticoagulation of more than 6 months do not alter the rate of recurrence following discontinuation of therapy.

Recurrence of DVT is about 2–3% per annum in patients who have a medical temporary risk factor at presentation and about 10% per annum in those with apparently unprovoked DVT. This plateaus at around 30–40% recurrence at 5 years. Post-thrombotic syndrome is due to damage of venous valves by the thrombus. It results in persistent leg swelling, heaviness and discoloration. The most severe complication of this syndrome is ulceration around the medial malleolus.

BLOOD PRODUCTS AND TRANSFUSION

Blood is a tissue; transfusion from an unrelated donor to a recipient is a form of allogeneic transplant and inevitably carries some risk, including adverse immunological interactions between the host and graft (p. 93) and transmission of infectious agents. Although there are many compelling clinical indications for blood component transfusion, there are also many clinical circumstances in which transfusion is conventional but the evidence for its effectiveness is very limited. In these settings, allogeneic transfusion may be avoided by following protocols that recommend use of low haemoglobin thresholds for red cell transfusion (Box 24.21), perioperative blood salvage, antifibrinolytic drugs or recombinant coagulation proteins.

Blood products

Blood components are prepared from blood collected from individual human donors and include whole blood, red cells, platelets, plasma or cryoprecipitate (see Box 24.23 overleaf).

Plasma derivatives are licensed pharmaceutical products produced on a factory scale from large volumes

EBM 24.21 Red cell transfusion in critically ill patients

'In patients in intensive care, mortality and morbidity are similar or better in patients in whom Hb is maintained at 70–90 g/L than in those who received approximately twice as many red cell units to maintain Hb at 100–200 g/L.'

• Scottish Intercollegiate Guidelines Network (SIGN) guideline 54: Perioperative blood transfusion for elective surgery; revised 2004.

For further information:  www.transfusionguidelines.org.uk
 www.sign.ac.uk

of human plasma obtained from many individuals and treated to remove virus contamination. Examples include the following:

- *Coagulation factors.* Concentrates of factors VIII and IX were used for the treatment of conditions such as haemophilia A, haemophilia B and von Willebrand disease. Coagulation factors made by recombinant DNA technology are now preferred due to perceived lack of infection risk.
- *Immunoglobulins.* Intravenous immunoglobulin (IVIgG) is administered as regular replacement therapy to reduce infective complications in patients with antibody deficiencies. A short high-dose course of IVIgG may also be effective in some immunological disorders, including immune thrombocytopenia (p. 1045) and Guillain-Barré syndrome (p. 1229). However, IVIgG can cause acute renal failure, especially in the elderly, and acute reactions. It must be infused strictly according to the manufacturer's product information. Anti-zoster immunoglobulin has a role in the prophylaxis of varicella zoster (p. 313). Anti-Rhesus D immunoglobulin is used in pregnancy to prevent haemolytic disease of the newborn (see Box 24.25).
- *Human albumin.* This is available in two strengths. The 5% solution can be used as a colloid resuscitation fluid, but it is no more effective and is more expensive than crystalloid solutions (Box 24.22). Human albumin 20% solution is used in the management of hypoproteinaemic oedema with nephrotic syndrome (p. 479), and ascites in chronic liver disease (p. 936). It is hyperoncotic and expands plasma volume by more than the amount infused.
- Blood components and their use are summarised in Box 24.23.

Blood donation

A safe supply of blood products depends on a well-organised system with regular donation by healthy individuals who have no excess risk of infections transmissible

EBM 24.22 Fluid resuscitation in critically ill patients

'In patients with trauma, burns or following surgery there is no evidence that resuscitation with albumin or other colloid solutions reduces the risk of death compared to resuscitation with crystalloid solutions.'

• Perel P, Roberts I. (Cochrane Review). *Cochrane Library*, issue 4, 2007. Oxford: Update Software.

24.23 Blood components and their use

	Major haemorrhage	Other indications
Red cell concentrate¹ Most of the plasma is removed and replaced with a solution of glucose and adenine in saline to maintain viability of red cells ABO compatibility with recipient essential	Replace acute blood loss: increase circulating red cell mass to relieve clinical features caused by insufficient oxygen delivery	Severe anaemia If no cardiovascular disease, transfuse to maintain Hb at 70–90 g/L If known or likely to have cardiovascular disease, maintain Hb 90–100 g/L
Platelet concentrate One adult dose is made from 4–5 donations of whole blood, or from a single platelet apheresis ABO compatibility with recipient preferable	Maintain platelet count $> 50 \times 10^9/L$, or in multiple or CNS trauma $> 100 \times 10^9/L$ Each adult dose has $\sim 2.5\text{--}3 \times 10^{11}$ platelets, which raises platelet count by $\sim 50 \times 10^9/L$ unless there is consumptive coagulopathy, e.g. disseminated intravascular coagulation (DIC)	Thrombocytopenia , e.g. in acute leukaemia Maintain platelet count $> 10 \times 10^9/L$ if not bleeding Maintain platelet count $> 20 \times 10^9/L$ if bleeding or at risk (sepsis, concurrent use of antibiotics, abnormal clotting) Increase platelet count $> 50 \times 10^9/L$ for minor invasive procedure (e.g. lumbar puncture, gastroscopy and biopsy, insertion of indwelling lines, liver biopsy, laparotomy) Increase platelet count $> 100 \times 10^9/L$ for operations in critical sites such as brain or eyes
Fresh frozen plasma (FFP)² 150–300 mL plasma from one donation of whole blood ABO compatibility with recipient recommended	Dilutional coagulopathy with a prothrombin time prolonged $> 50\%$ is likely after replacement of 1–1.5 blood volumes with red cell concentrate Initial dose of FFP 15 mL/kg Further doses only if bleeding continues and guided by PT and APTT	Replacement of coagulation factor deficiency If no virally inactivated or recombinant product is available Thrombotic thrombocytopenic purpura (TTP) Plasma exchange (or plasma infusion in HIV-related TTP) is frequently effective
Cryoprecipitate² Fibrinogen and coagulation factor concentrated from plasma by controlled thawing 10–20 mL pack contains fibrinogen 150–300 mg, factor VIII 80–120 U, von Willebrand factor 80–120 U In UK supplied as pools of 5 units	May be indicated if fibrinogen $< 1\text{ g/L}$ due to dilution and DIC Pooled units containing 3–6 g fibrinogen in 200–500 mL raise fibrinogen by $\sim 1\text{ g/L}$	von Willebrand disease and haemophilia If virus-inactivated or recombinant products are not available

¹Whole blood is an alternative to red cell concentrate. ABO compatibility with recipient essential.
²Use only if an alternative virus-inactivated plasma is unavailable: Pooled plasma can be treated with solvent and detergent or single units treated with methylene blue.

in blood (Fig. 24.16). Blood donations are obtained by either venesection of a unit of whole blood or collection of a specific component, such as platelets, by apheresis. During apheresis the donor's blood is drawn via a closed system into a machine which separates the components by centrifugation and collects the desired fraction into a bag, returning the rest of the blood to the donor. Each donation must be tested for hepatitis B (HBV), hepatitis C (HCV), HIV and human T lymphotropic (HTLV) virus nucleic acid and/or antibodies. Platelet concentrates may be tested for bacterial contamination. The need for other microbiological tests depends on local epidemiology. For example, testing for *Trypanosoma cruzi* (Chagas disease; p. 354) is required in areas of South America and the USA where infection is prevalent; tests for West Nile virus have been required in the USA since this agent became prevalent; plasma donated in the UK is not used at present for producing pooled plasma derivatives in view of concerns about transmission of variant Creutzfeldt–Jakob disease (vCJD; p. 1214).

Adverse effects of transfusion

Death directly attributable to transfusion is rare, at < 0.5 per 100 000 transfusions. However, relatively minor symptoms of transfusion reactions (fever, itch or urticaria) occur during about 1% of transfusions, usually in patients who have had repeated transfusions. Any symptoms or signs that arise during a transfusion must be taken seriously, as they may be the first warnings of a serious reaction. Figure 24.18 (p. 1012) outlines the symptoms and signs, management and investigation of acute reactions to blood products.

Red cell incompatibility

Red blood cell membranes contain numerous cell surface molecules which are potentially antigenic (see Fig. 24.4, p. 990). The ABO and Rh(D) antigens are the most important in routine transfusion and antenatal practice.

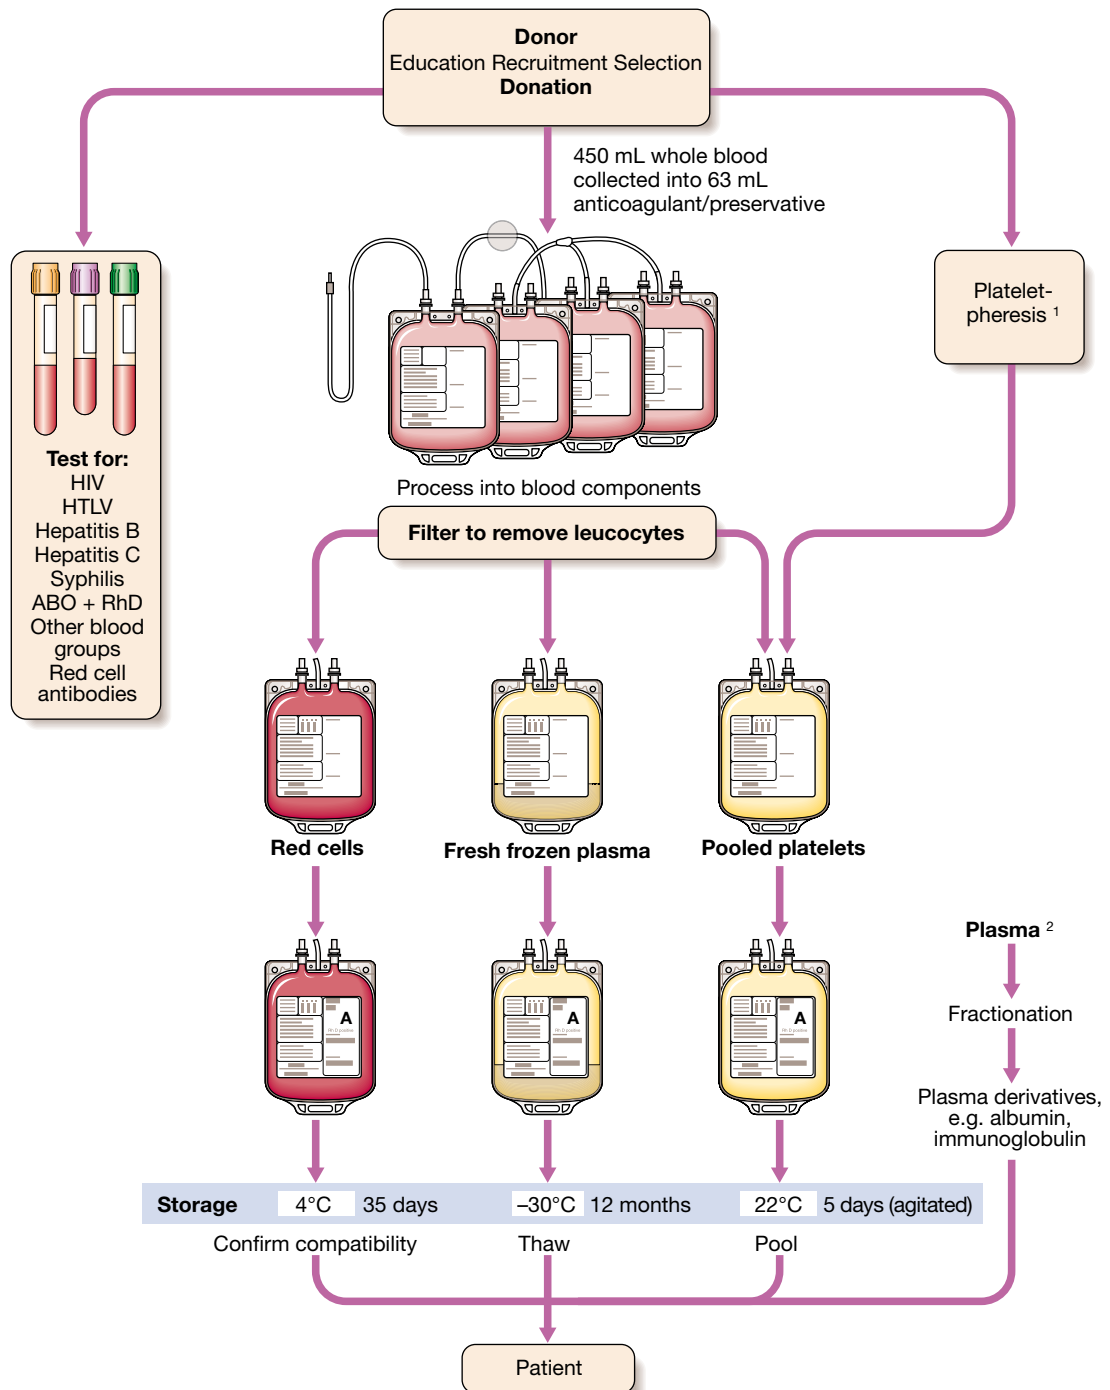

Fig. 24.16 Blood donation, processing and storage. ¹Platelet-pheresis involves circulating the donor's blood through a cell separator to remove platelets before returning other blood components to the donor. ²In the UK, plasma for fractionation is imported as a precautionary measure against vCJD.

ABO blood groups

The frequency of the ABO antigens varies among different populations. The ABO blood group antigens are oligosaccharide chains that project from the red cell surface. These chains are attached to proteins and lipids that lie in the red cell membrane. The ABO gene encodes a glycosyltransferase that catalyses the final step in the synthesis of the chain which has three common alleles: A, B and O. The O allele encodes an inactive enzyme,

leaving the ABO antigen precursor (called the H antigen) unmodified. The A and B alleles encode enzymes that differ by four amino acids and hence attach different sugars to the end of the chain. Individuals are tolerant to their own ABO antigens, but do not suppress B cell clones producing antibodies against ABO antigens that they do not carry themselves (Box 24.24). They are therefore capable of mounting a humoral immune response to these 'foreign' antigens.

24.24 ABO blood group antigens and antibodies			
ABO blood group	Red cell A or B antigens	Antibodies in plasma	UK frequency (%)
O	None	Anti-A and anti-B	46
A	A	Anti-B	42
B	B	Anti-A	9
AB	A and B	None	3

ABO-incompatible red cell transfusion

If red cells of an incompatible ABO group are transfused (especially if a group O recipient is transfused with group A, B or AB red cells), the recipient's IgM anti-A, anti-B or anti-AB binds to the transfused red cells. This activates the full complement pathway (p. 73), creating pores in the red cell membrane and destroying the transfused red cells in the circulation (intravascular haemolysis). The anaphylatoxins C3a and C5a, released by complement activation, liberate cytokines such as tumour necrosis factor (TNF), interleukin 1 (IL-1) and IL-8, and stimulate degranulation of mast cells with release of vasoactive mediators. All these substances may lead to inflammation, increased vascular permeability and hypotension, which may in turn cause shock and renal failure. Inflammatory mediators can also cause platelet aggregation, lung peribronchial oedema and smooth muscle contraction. About 20–30% of ABO-incompatible transfusions cause some degree of morbidity, and 5–10% cause or contribute to a patient's death. The main reason for this relatively low morbidity is the lack of potency of ABO antibodies in group A or B subjects; even if the recipient is group O, those who are very young or very old usually have weaker antibodies that do not lead to the activation of large amounts of complement.

The Rhesus D blood group and haemolytic disease of the newborn

About 15% of Caucasians are Rhesus-negative: that is, they lack the Rhesus D (RhD) red cell surface antigen (see Fig. 24.4, p. 990). In other populations (e.g. in Chinese and Bengalis), only 1–5% may be Rhesus-negative. RhD-negative individuals do not normally produce substantial amounts of anti-RhD antibodies. However, if RhD-positive red cells enter the circulation of an RhD-negative individual, then IgG antibodies are produced. This can occur during pregnancy if the mother is exposed to fetal cells via fetomaternal haemorrhage, or following transfusion. If a woman is so sensitised, during a subsequent pregnancy anti-RhD antibodies can cross the placenta; if the fetus is RhD-positive, haemolysis with severe fetal anaemia and hyperbilirubinaemia can result. This can cause severe neurological damage or death due to haemolytic disease of the newborn (HDN). Therefore, an RhD-negative female who may subsequently become pregnant should never be transfused with RhD-positive blood.

In RhD-negative women, administration of anti-RhD immunoglobulin (anti-D) perinatally can block the immune response to RhD antigen on fetal cells and is the only effective product for preventing the development of Rhesus antibodies (Box 24.25).

HDN can also be caused by other alloantibodies against red cell antigens, usually after previous transfu-

24.25 Rhesus D blood groups in pregnancy

- **Haemolytic disease of the newborn (HDN):** occurs when the mother has anti-red cell IgG antibodies that cross the placenta and haemolyse fetal red cells.
- **Screening for HDN in pregnancy:** at the time of booking (12–16 weeks) every pregnant woman should have a blood sample sent for determination of ABO and RhD group and testing for red cell allo-antibodies that may be directed against paternal blood group antigens.
- **Anti-D immunoglobulin prophylaxis in a mother who is RhD-negative:** following delivery of an RhD-positive baby, the mother is given anti-D within 72 hours; a maternal sample is checked for remaining fetal red cells and extra anti-D given if indicated. Anti-D is also given after other antenatal events (e.g. early bleeding). Doses vary according to national recommendations.

cies or transfusions. These antigens include RhC, Rhc, RhE, Rhe, and the Kidd, Kell and Duffy antigen systems.

Other immunological complications of transfusion

Rare but serious complications include transfusion-associated lung injury (TRALI) and transfusion-associated graft-versus-host disease (TA GVHD). The latter occurs when there is sharing of a human leucocyte antigen (HLA) haplotype between donor and recipient which allows transfused lymphocytes to engraft, proliferate and recognise the recipient as foreign, resulting in acute GVHD (p. 1014). Prevention is by gamma irradiation of blood components to prevent lymphocyte proliferation. Patients at risk of TA GVHD who must receive irradiated blood components include those with congenital T cell immunodeficiencies or Hodgkin lymphoma, recipients of stem-cell transplants or of blood from a family member, neonates and patients taking T lymphocyte-suppressing drugs such as fludarabine.

Infections transmitted by transfusion

Over the past 30 years, the viruses that cause HBV, AIDS and HCV have been identified and effective tests introduced to detect and exclude infected blood units. Where blood is from 'safe' donors and correctly tested, the current risk of a donation being infectious is very small. By 2002–3 in the UK, the estimated chances that a unit of blood might transmit one of the viruses for which blood is tested, was 0.25 per million units for HIV, 0.02 for HCV and 1.62 for HBV. However, some patients who received transfusions before these tests were available have suffered very serious consequences from these infections; this is a reminder to avoid non-essential transfusions since it is impossible to exclude the possibility that some new or currently unrecognised transfusion-transmissible infection may emerge. Licensed plasma derivatives that have been virus-inactivated do not transmit HIV, HTLV, HBV, HCV, cytomegalovirus or other lipid-enveloped viruses.

vCJD is a human prion disease linked to bovine spongiform encephalitis (BSE; p. 1214). The risk of a recipient acquiring the agent of vCJD from a transfusion is

uncertain, but of 16 surviving recipients of blood from donors who later developed the disease, 3 have died with clinical vCJD and 1 of unrelated causes who had postmortem immunohistological signs of infection.

Bacterial contamination of a blood component—usually platelets—is extremely rare (2 reports in the UK in 2005 and in 2006) but can cause very severe and often lethal transfusion reactions.

Safe transfusion procedures

The proposed transfusion and any alternatives should be discussed with the patient or, if that is not possible, with a relative, and this should be documented. Some patients, e.g. Jehovah's Witnesses, may refuse transfusion and require specialised management to survive profound anaemia following blood loss.

Pre-transfusion testing

To ensure that red cells supplied for transfusion are compatible with the intended recipient, the transfusion laboratory will perform either a 'group and screen' procedure or a 'cross-match'.

In the group and screen procedure, the red cells from the patient's blood sample are tested to determine the ABO and RhD type, and the patient's serum is also tested against an array of red cells expressing the most important antigens to detect any red cell antibodies. Any antibody detected can be identified by further testing, so that red cell units that lack the corresponding antigen

can be selected. The patient's sample can be held in the laboratory for up to a week, so that the hospital blood bank can quickly prepare compatible blood without the need for a further patient sample. In the so-called 'electronic cross-match' blood can be issued for suitable patients on the basis of blood group information held in the laboratory's computer.

Conventional cross-matching consists of the group and antibody screen, followed by direct confirmation of the compatibility of individual units of red cell with the patient's serum. Full cross-matching takes about 45 minutes if no red cell antibodies are present, but may require hours if a patient has multiple antibodies.

Bedside procedures for safe transfusion

Errors leading to patients receiving the wrong blood are an important avoidable cause of mortality and morbidity. Most incompatible transfusions result from failure to adhere to standard procedures for taking correctly labelled blood samples from the patient and ensuring that the correct pack of blood component is transfused into the intended patient. In the UK in 2003/4, there were 787 reports of transfusion of an incorrect blood component (12 per 100 000 units transfused). Every hospital where blood is transfused should have a written transfusion policy that is used by all staff who order, check or administer blood products (Fig. 24.17).

Management of suspected transfusion reactions is described in Figure 24.18.

Taking blood for pre-transfusion testing

Positively identify the patient at the bedside
Label the sample tube and complete the request form clearly and accurately after identifying the patient
Do not write forms and labels in advance

Administering blood

Positively identify the patient at the bedside
Ensure that the identification of each blood pack matches the patient's identification
Check that the ABO and RhD groups of each pack are compatible with the patient's
Check each pack for evidence of damage
If in doubt, do not use and return to the blood bank
Complete the forms that document the transfusion of each pack

Record-keeping

Record in the patient's notes the reason for transfusion, the product given, dose, any adverse effects and the clinical response

Observations

Transfusions should only be given when the patient can be observed
Blood pressure, pulse and temperature should be monitored before and 15 minutes after starting each pack
In conscious patients, further observations are only needed if the patient has symptoms or signs of a reaction
In unconscious patients, check pulse and temperature at intervals during transfusion
Signs of abnormal bleeding during the transfusion could be due to disseminated intravascular coagulation resulting from an acute haemolytic reaction

Check the compatibility label on the pack against the patient's wristband

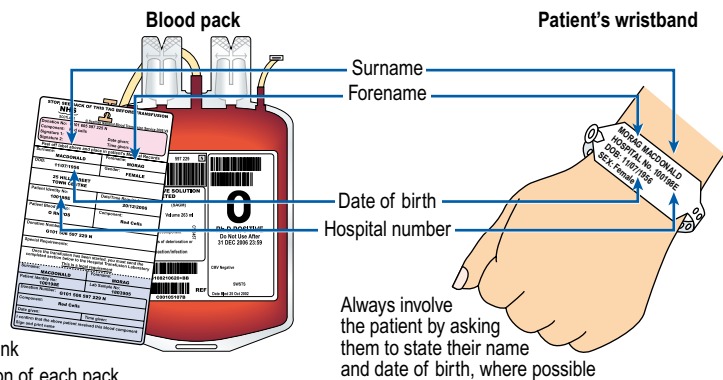

Fig. 24.17 Bedside procedures for safe blood transfusion. The patient's safety depends on adherence to standard procedures for taking samples for compatibility testing, administering blood, record-keeping and observations.

Fig. 24.18 Investigation and management of reactions to blood products.

BONE MARROW AND PERIPHERAL BLOOD STEM CELL TRANSPLANTATION

Blood and marrow transplantation (BMT) refers to the transplantation of haematopoietic stem cells and has offered the only hope of 'cure' in a variety of haematological and non-haematological disorders (Box 24.26). As standard treatment improves, the indications for BMT are being refined and extended, although its use remains most common in haematological malignancies. The type of BMT is defined according to the donor and source of stem cells:

- In *allogeneic* BMT the stem cells come from a *donor*—either related (usually an HLA-identical sibling) or from a closely HLA-matched volunteer unrelated donor (VUD).
- In an *autologous* transplant the stem cells are harvested from the *patient* and stored in the vapour phase of liquid nitrogen until required. Stem cells can be harvested from the bone marrow or from the blood.

Allogeneic BMT

Healthy marrow or blood stem cells from a donor are infused intravenously into the recipient, who has been suitably 'conditioned'. The conditioning treatment (chemotherapy with or without radiotherapy) destroys malignant cells and immunosuppresses the recipient, as well as ablating the recipient's haematopoietic tissues. The injected donor cells 'home' to the marrow, engraft and produce enough erythrocytes, granulocytes and platelets for the patient's needs after about 3–4 weeks. During this period of aplasia patients are at risk of infection and bleeding, and require intensive supportive care as described on page 1033. It may take several years to regain normal immunological function and patients remain at risk from opportunistic infections, in particular in the first year.

An advantage of receiving allogeneic donor stem cells is that the donor's immunological system can recognise residual malignant recipient cells and destroy them. This immunological 'graft versus disease' effect is a powerful tool against many haematological tumours and can be boosted post-transplantation by the infusion of T cells taken from the donor, so-called donor lymphocyte infusion (DLI).

Haematological indications for allogeneic transplantation are shown in Box 24.27. There is considerable morbidity and mortality associated with BMT. The best results are obtained in patients with minimal residual

24.26 General indications for allogeneic BMT

- Neoplastic disorders affecting stem cell compartments (e.g. leukaemias)
- Failure of haematopoiesis (e.g. aplastic anaemia)
- Major inherited defects in blood cell production (e.g. thalassaemia, immunodeficiency diseases)
- Inborn errors of metabolism with missing enzymes or cell lines

24.27 Haematological indications for bone marrow transplantation

Allogeneic transplant

- Acute myeloid leukaemia (AML) high-risk CR1, CR2
- Adult acute lymphoblastic leukaemia (ALL) CR1, CR2
- Chronic myeloid leukaemia (CML) resistant to imatinib
- Myelodysplastic syndrome
- Severe aplastic anaemia
- Myelofibrosis
- Severe immune deficiency syndromes

Autologous transplant

- AML CR2
- Myeloma
- Poor-risk Hodgkin lymphoma
- High-grade non-Hodgkin lymphoma second response
- Mantle cell lymphoma

disease, and in those under 20 years of age who have an HLA-identical sibling donor. Older patients can be transplanted, but results become progressively worse with age and an upper age limit of 55 years is usually applied.

Complications

These are outlined in Boxes 24.28 and 24.29. The risks and outcomes of transplantation depend upon several patient- and disease-related factors. In general, 25% die from procedure-related complications such as graft-versus-host disease (see below), and there remains a significant risk of relapse in haematological malignancy. The

24.28 Complications of allogeneic bone marrow transplantation

- Mucositis
- Infection
- Bleeding
- Cataract formation
- Pneumonitis
- Infertility
- Chronic graft-versus-host disease
- Acute graft-versus-host disease
- Secondary malignant disease

24.29 Infection during recovery from bone marrow transplantation

Infection	Time after BMT	Management
Herpes simplex (p. 321)	0–4 weeks	Aciclovir
Bacterial, fungal	0–4 weeks	As for acute leukaemia (p. 1031)
Cytomegalovirus (CMV; p. 317)	7–21 weeks	Hyperimmune immunoglobulin and ganciclovir for documented infections
Varicella zoster (p. 313)	After 13 weeks	Aciclovir i.v.
Pneumocystis jirovecii (p. 395)	8–26 weeks	Co-trimoxazole
Interstitial pneumonitis (non-infective)	6–18 weeks	No specific therapy Prednisolone may be tried

long-term survival for patients undergoing allogeneic BMT in acute leukaemia is around 50%.

Graft-versus-host disease (GVHD)

GVHD is due to the cytotoxic activity of donor T lymphocytes which become sensitised to their new host, regarding it as foreign. This may cause either an acute or a chronic form of GVHD.

Acute GVHD occurs in the first 100 days after transplant in about one-third of patients. It can affect the skin, causing rashes, the liver, causing jaundice, and the gut, causing diarrhoea, and may vary from mild to lethal. Prevention includes HLA-matching of the donor, immunosuppressant drugs, including methotrexate and ciclosporin, and antithymocyte globulin. The more severe forms are very difficult to control and, despite high-dose corticosteroids, may result in death.

Chronic GVHD may follow acute GVHD or arise independently; it occurs later than acute GVHD. It often resembles a connective tissue disorder, although in mild cases a rash may be the only manifestation. Chronic GVHD is usually treated with corticosteroids and prolonged immunosuppression with, for example, ciclosporin. Associated with chronic GVHD is the graft-versus-leukaemia effect, which results in a lower relapse rate.

Reduced-intensity BMT

This concept has been developed in an attempt to reduce the mortality of allografting. Rather than use very intensive conditioning which causes morbidity from organ damage, relatively low doses of drugs such as fludarabine and cyclophosphamide are used simply to immunosuppress the recipient and allow donor stem cells to engraft. The emerging donor immune system then eliminates malignant cells via the 'graft versus disease' effect, which may be boosted by the elective use of donor T cell infusions post-transplant. This approach is less toxic and allows BMT to be offered to an older group of patients. However, relapse and infections post-transplant remain a concern and the role of this type of transplant is still under investigation.

Autologous BMT

This procedure can also be used in haematological malignancies. The patient's own stem cells from blood or marrow are first harvested and frozen. After conditioning therapy, the autologous stem cells are reinfused in order to rescue the patient from the marrow damage and aplasia caused by chemotherapy. Autologous BMT may be used for disorders which do not primarily involve the haematopoietic tissues, or in patients in whom very good remissions have been achieved. The preferred source of stem cells for autologous transplants is peripheral blood. These stem cells engraft more quickly, marrow recovery occurring within 2–3 weeks. There is no risk of GVHD and no immunosuppression is required. Thus autologous stem cell transplantation carries a lower procedure-related mortality rate than allogeneic BMT at around 5%, but there is a higher rate of recurrence of malignancy. The issue of whether the stem cells should be treated (purged) in an attempt to remove any residual leukaemia cells is controversial.

ANTICOAGULANT AND ANTITHROMBOTIC THERAPY

There are numerous indications for anticoagulant and antithrombotic medications (Box 24.30). The guiding principles are outlined here, but management in specific indications is discussed elsewhere in the book. Broadly speaking, antiplatelet medications are of greater efficacy in the prevention of arterial thrombosis and of less value in the prevention of venous thromboembolism. Thus, anti-platelet agents such as aspirin and clopidogrel are the drugs of choice in acute coronary events, and in ischaemic cerebrovascular disease, while warfarin and other anticoagulants are favoured in venous thromboembolism. In some extremely prothrombotic situations, such as coronary artery stenting, a combination of anticoagulant and anti-platelet drugs is used.

A wide range of anticoagulant and antithrombotic drugs are used in clinical practice. These drugs and their modes of action are given in Box 24.31. The ultimate aim is to produce antithrombotics for oral anticoagulation which can be given at fixed doses with predictable effects and no need for monitoring. A variety of drugs are presently undergoing clinical trials in the prevention and treatment of thrombosis. Initial studies show that dabigatran and rivaroxaban are effective in preventing venous thromboembolism following high-risk orthopaedic surgery.

24.30 Indications for anticoagulation

Heparin

- Prevention and treatment of VTE
- Percutaneous coronary intervention
- Post thrombolysis for myocardial infarction
- Unstable angina pectoris
- Non-Q wave myocardial infarction
- Acute peripheral arterial occlusion
- Cardiopulmonary bypass
- Haemodialysis and haemofiltration

Coumarins (warfarin etc.)

- | | | |
|---|---|---------------------|
| <ul style="list-style-type: none"> • Prevention and treatment of VTE • Arterial embolism • Atrial fibrillation with specific stroke risk factors (p. 562) • Mobile mural thrombus post-myocardial infarction • Extensive anterior myocardial infarction • Dilated cardiomyopathy • Cardioversion • Ischaemic stroke in antiphospholipid syndrome • Mitral stenosis and mitral regurgitation with atrial fibrillation | } | Therapeutic INR 2.5 |
| <ul style="list-style-type: none"> • Recurrent venous thrombosis whilst on warfarin • Mechanical prosthetic cardiac valves | } | INR 3.5 |

(INR = International normalised ratio)

24.31 Modes of action of anticoagulant and antithrombotic drugs

Drug	Mode of action
Antiplatelet drugs	
Aspirin	Cyclo-oxygenase (COX) inhibition
Clopidogrel	Adenosine diphosphate (ADP) receptor inhibition
Abciximab	Glycoprotein IIb/IIIa inhibition
Tirofiban	Glycoprotein IIb/IIIa inhibition
Eptifibatide	Glycoprotein IIb/IIIa inhibition
Dipyridamole	Phosphodiesterase inhibition
Oral anticoagulants	
Warfarin/coumarins	Vitamin K antagonism
Dabigatran	Direct thrombin inhibition
Rivaroxaban	Direct Xa inhibition
Apixaban	Direct Xa inhibition
Intravenous anticoagulants	
Heparin	Antithrombin-dependent inhibition of thrombin and Xa
Fondaparinux/idaraparinux	Antithrombin-dependent inhibition of Xa
Lepirudin	Direct thrombin inhibition
Argatroban	Direct thrombin inhibition
Bivalirudin	Direct thrombin inhibition

Heparins

Unfractionated heparin (UFH) and low molecular weight heparins (LMWH) both act by binding to a specific pentasaccharide on antithrombin which potentiates its natural anticoagulant activity (see Fig. 24.6, pp. 992–993). Increased cleavage of activated proteases, particularly factor Xa and thrombin (IIa), accounts for the anticoagulant effect. LMWHs preferentially augment antithrombin activity against factor Xa. For the licensed indications, LMWHs are at least as efficacious as UFH but have several advantages.

- LMWHs are nearly 100% bioavailable and therefore produce reliable dose-dependent anticoagulation.
- LMWHs do not require monitoring of their anticoagulant effect (except possibly in patients with very low body weight and with GFR < 30 mL/min).
- LMWHs have a half-life of around 4 hours when given subcutaneously, compared with 1 hour for UFH. This permits once-daily dosing by the subcutaneous route, rather than the therapeutic continuous intravenous infusion or prophylactic twice-daily subcutaneous administration required for UFH.
- While rates of bleeding are similar between products, the risk of osteoporosis and heparin-induced thrombocytopenia is much lower for LMWH.
- However, UFH is more completely reversed by protamine sulphate in the event of bleeding and at the end of cardiopulmonary bypass, for which UFH remains the drug of choice.

LMWHs are widely used for the prevention and treatment of VTE, the management of acute coronary syndromes and for most other scenarios listed in Box 24.30. In some situations, UFH is still favoured by some clinicians, though there is little evidence that it is advantageous except when rapid reversibility is required. UFH

is useful in patients with a high risk of bleeding, e.g. who have peptic ulceration or may require surgery. It is also favoured in treatment of life-threatening thromboembolism, e.g. major PE with significant hypoxaemia, hypotension and right-sided heart strain. In this situation UFH is started with a loading dose of 5000 U i.v., followed by a continuous infusion of 20 U/kg/hr initially. The level of anticoagulation should be assessed by the APTT after 6 hours and, if satisfactory, twice daily thereafter. It is usual to aim for a patient time which is 1.5–2.5 times the control time of the test.

Heparin-induced thrombocytopenia (HIT)

HIT is a rare complication of heparin therapy, caused by induction of anti-heparin/PF4 antibodies which bind to and activate platelets via an Fc receptor. This results in platelet activation and a prothrombotic state, with a paradoxical thrombocytopenia. HIT is more common in surgical than medical patients (especially cardiac and orthopaedic patients), with use of UFH rather than LMWH, and with higher doses of heparin.

Clinical features

Patients present, typically 5–14 days after starting heparin treatment, with a fall in platelet count of > 30% from baseline. The count may still be in the normal range. They may be asymptomatic, or develop venous or arterial thrombosis and skin lesions, including overt skin necrosis. Affected patients may complain of pain or itch at injection sites and of systemic symptoms such as shivering following heparin injections. Patients who have received heparin in the preceding 100 days and who have preformed antibodies may develop acute systemic symptoms and an abrupt fall in platelet count in the first 24 hours after re-exposure.

Investigations

The pre-test probability of the diagnosis is assessed using the 4Ts scoring system. This assigns a score based on:

- the thrombocytopenia
- the timing of the fall in platelet count
- the presence of new thrombosis
- the likelihood of another cause for the thrombocytopenia.

Individuals at low risk need no further test; those with intermediate and high likelihood scores should have the diagnosis confirmed or refuted using an anti-PF4 enzyme-linked immunosorbent assay (ELISA).

Management

Heparin should be discontinued as soon as HIT is diagnosed and an alternative anticoagulant which does not cross-react with the antibody substituted. Lepirudin (a hirudin analogue) and danaparoid (a heparin analogue) are licensed for use in the UK. In asymptomatic patients with HIT who do not receive an alternative anticoagulant, around 50% will sustain a thrombosis in the subsequent 30 days. Patients with established thrombosis have a poor prognosis.

Coumarins (e.g. warfarin)

Although several coumarin anticoagulants are used around the world, warfarin is the most common.

Coumarins inhibit the vitamin K-dependent post-translational carboxylation of factors II, VII, IX and X in the liver. This results in anticoagulation due to an effective deficiency of these factors. This is monitored by the INR, a standardised test based on measurement of the prothrombin time (p. 996). Recommended target INR values for specific indications are given in Box 24.30.

Warfarin anticoagulation typically takes more than 3 days to become established, even using initial loading doses. Patients who require rapid initiation of therapy may receive higher initiation doses of warfarin. A typical regime is to give 10mg warfarin on the first and second days, with 5mg on the third day; subsequent doses are titrated against the INR. Patients with risk factors requiring prophylactic anticoagulation (e.g. atrial fibrillation) can have warfarin introduced slowly using lower doses. Low-dose regimens are associated with a lower risk of the patient developing a supratherapeutic INR, and hence a lower bleeding risk. The duration of warfarin therapy depends on the clinical indication, and while treatment of DVT or preparation for cardioversion requires a limited duration, anticoagulation to prevent cardioembolic stroke in atrial fibrillation or from heart valve disease is long-term.

The major problems with warfarin are:

- it has a narrow therapeutic window
- its metabolism is affected by many factors.

Drug interactions are common through protein binding and metabolism by the cytochrome P-450 system. Naturally occurring polymorphisms in the *CYP2C9* and the *VKORC1* genes account for many of the observed differences in dose requirements between races. Dietary intake of vitamin K also affects dose requirements.

Major bleeding is the most common serious side-effect of warfarin and occurs in about 1.0% of patients each year. Fatal haemorrhage, which is most commonly intracranial, occurs in about 0.25% per annum. There are

scoring systems which predict the annual bleeding risk and these can be used to help compare the risks and benefits of warfarin for an individual patient (Box .32). There are also some specific contraindications to anticoagulation (see Box 24.32). Management of warfarin includes strategies for over-anticoagulation and for bleeding.

- If the INR is above the therapeutic level, warfarin should be withheld or the dose reduced. If the patient is not bleeding, it may be appropriate to give a small dose of vitamin K either orally or intravenously (1–2.5 mg), especially if the INR is > 8.
- In the event of bleeding, withhold further warfarin. Minor bleeding can be treated with 1–2.5 mg of vitamin K intravenously. Major haemorrhage should be treated as an emergency with vitamin K 5–10 mg slowly i.v., combined with coagulation factor replacement. This should optimally be a prothrombin complex concentrate (30–50 U/kg) which contains factors II, VII, IX and X; if that is not available, fresh frozen plasma (15–30 mL/kg) should be given.

Prophylaxis of venous thrombosis

All patients admitted to hospital should be assessed for their risk of developing VTE. Both medical and surgical patients are at increased risk. A summary of the risk categories is given in Box 24.33. Early mobilisation of all patients is important to prevent DVT. Patients at medium or high risk require additional antithrombotic measures;

24.32 Assessing risks of anticoagulation

Contraindications

- Recent surgery, especially to eye or central nervous system
- Pre-existing haemorrhagic state, e.g. liver disease, haemophilia, thrombocytopenia
- Pre-existing structural lesions, e.g. peptic ulcer
- Recent cerebral haemorrhage
- Uncontrolled hypertension
- Cognitive impairment
- Frequent falls in old age

Bleeding risk score

- Age > 65 years (1 point)
- Previous gastrointestinal bleed (1 point)
- Previous stroke (1 point)
- Medical illness (1 point)
 - Recent myocardial infarction
 - Renal failure
 - Anaemia
 - Diabetes mellitus

Score: annual rate of major haemorrhage

- 0 = 3%
- 1–2 = 12%
- 3–4 = 30–48%

24.33 Antithrombotic prophylaxis

Patients in the following categories should be considered for specific antithrombotic prophylaxis:

Moderate risk of DVT

Major surgery

- In patients > 40 years or with other risk factor for VTE

Major medical illness, e.g.

- Heart failure
- Myocardial infarction with complications
- Sepsis
- Active malignancy
- Inflammatory bowel disease
- Nephrotic syndrome
- Stroke and other conditions leading to lower limb paralysis

High risk of DVT

- Major abdominal or pelvic surgery for malignancy or with history of DVT or known thrombophilia (Box 24.4, p. 997)
- Major hip or knee surgery
- Neurosurgery

Methods of VTE prophylaxis

Mechanical

- Intermittent pneumatic compression
- Mechanical foot pumps
- Graduated compression stockings

Pharmacological

- Low molecular weight heparins
- Unfractionated heparin
- Fondaparinux
- Dabigatran
- Rivaroxaban
- Warfarin
- Aspirin

these may be pharmacological or mechanical. There is increasing evidence in high-risk groups, such as patients who have had major lower limb orthopaedic surgery, for protracted thrombocytophylaxis extending out to 30 days after the procedure. Particular care should be taken with the use of pharmacological prophylaxis in patients with a high risk of bleeding or with specific risks of haemorrhage related to the site of surgery or the use of spinal or epidural anaesthesia.

ANAEMIAS

Around 30% of the total world population is anaemic and half of these, some 600 million people, have iron deficiency. The classification of anaemia by the size of the red cells (MCV) indicates the likely cause (see Figs 24.10 and 24.11, pp. 998–999).

Red cells in the bone marrow must acquire a minimum level of haemoglobin before being released into the blood stream (Fig. 24.19). Whilst in the marrow compartment, red cell precursors undergo cell division driven by erythropoietin. If red cells cannot acquire haemoglobin at a normal rate, they will undergo more divisions than normal and will have a low MCV when finally released into the blood. The MCV is low because component parts of the haemoglobin molecule are not fully available: that is, iron in iron deficiency, globin chains in thalassaemia, haem ring in congenital sideroblastic anaemia and, occasionally, poor iron utilisation in the anaemia of chronic disease.

In megaloblastic anaemia the biochemical consequence of vitamin B₁₂ or folate deficiency is an inability to synthesise new bases to make DNA. A similar defect of cell division is seen in the presence of cytotoxic drugs or haematological disease in the marrow such as myelodysplasia. In these states, cells haemoglobinise normally but undergo fewer cell divisions, resulting in circulating red cells with a raised MCV. The red cell membrane is composed of a lipid bilayer which will freely exchange with the plasma pool of lipid. Conditions such as liver disease, hypothyroidism, hyperlipidaemia and pregnancy are associated with raised lipids and may also cause a raised MCV. Reticulocytes are larger than mature red cells, so when the reticulocyte count is raised—for example, in haemolysis—this may also increase the MCV.

Iron deficiency anaemia

This occurs when iron losses or physiological requirements exceed absorption.

Blood loss

The most common explanation in men and post-menopausal women is gastrointestinal blood loss (p. 852). This may result from occult gastric or colorectal malignancy, gastritis, peptic ulceration, inflammatory bowel disease, diverticulitis, polyps and angiodysplastic lesions. World-wide, hookworm and schistosomiasis are the most common causes of gut blood loss (pp. 364

Fig. 24.19 Factors which influence the size of red cells in anaemia. ↓ MCV is < 76 fL; ↑ MCV is > 100 fL.

and 370). Gastrointestinal blood loss may be exacerbated by the chronic use of aspirin or non-steroidal anti-inflammatory drugs (NSAIDs), which cause intestinal erosions and impair platelet function. In women of child-bearing age, menstrual blood loss, pregnancy and breastfeeding contribute to iron deficiency by depleting iron stores; in developed countries one-third of premenopausal women have low iron stores but only 3% display iron-deficient haematopoiesis. Very rarely, chronic haemoptysis or haematuria may cause iron deficiency.

Malabsorption

A dietary assessment should be made in all patients to ascertain their iron intake (p. 114). Gastric acid is required to release iron from food and helps to keep iron in the soluble ferrous state (Fig. 24.20). Hypochlorhydria in the elderly or that due to drugs such as proton pump inhibitors may contribute to the lack of iron availability from the diet, as may previous gastric surgery. Iron is absorbed actively in the upper small intestine and hence can be affected by coeliac disease (p. 879).

Physiological demands

At times of rapid growth, such as infancy and puberty, iron demands increase and may outstrip absorption. In pregnancy, iron is diverted to the fetus, the placenta and

the increased maternal red cell mass, and is lost with bleeding at parturition (Box 24.34).

Investigations

Confirmation of iron deficiency

Plasma ferritin is a measure of iron stores in tissues and is the best single test to confirm iron deficiency (Box 24.35). It is a very specific test; a subnormal level is due to iron deficiency, hypothyroidism or vitamin C deficiency. Levels can be raised by liver disease and in an acute phase response; in these conditions a ferritin level of up to 100 µg/L may still be compatible with low bone marrow iron stores.

Plasma iron and total iron binding capacity (TIBC) are measures of iron availability; hence they are affected by many factors besides iron stores. Plasma iron has a marked diurnal and day-to-day variation and becomes very low during an acute phase response but is raised in liver disease and haemolysis. Levels of transferrin, the binding protein for iron, are lowered by malnutrition, liver disease, an acute phase response and nephrotic syndrome, but raised by pregnancy or the oral contraceptive pill. A transferrin saturation (i.e. iron/TIBC × 100) of less than 16% is consistent with iron deficiency but is less specific than a ferritin measurement.

Fig. 24.20 The regulation of iron absorption, uptake and distribution in the body. The transport of iron is regulated in a similar fashion to enterocytes in other iron-transporting cells such as macrophages.

24.34 Haematological physiology in pregnancy

- **Full blood count:** increased plasma volume (40%) lowers normal Hb (reference range reduced to $> 105 \text{ g/L}$ at 28 weeks). The MCV may increase by 5 fL. A progressive neutrophilia occurs. Gestational thrombocytopenia (rarely $< 60 \times 10^9/\text{L}$) is a benign phenomenon.
- **Depletion of iron stores:** iron deficiency is a common cause of anaemia in pregnancy and, if present, should be treated with oral iron supplement.
- **Vitamin B₁₂:** serum levels are physiologically low in pregnancy but deficiency is uncommon.
- **Folate:** tissue stores may become depleted, and folate supplementation is recommended in all pregnancies (see Box 5.20, p. 113).
- **Coagulation factors:** from the second trimester, procoagulant factors increase approximately three-fold, particularly fibrinogen, von Willebrand factor and factor VIII. This causes activated protein C resistance and a shortened APTT, and contributes to a prothrombotic state.
- **Anticoagulants:** levels of protein C increase from the second trimester while levels of free protein S fall as C4b binding protein increases.

24.35 Investigations to differentiate anaemia of chronic disease from iron deficiency anaemia

	Ferritin	Iron	TIBC	Transferrin saturation	Soluble transferrin receptor
Iron deficiency anaemia	↓	↓	↑	↓	↑
Anaemia of chronic disease	↑/Normal	↓	↓	↓	↓/Normal

(TIBC = total iron binding capacity)

All proliferating cells express membrane transferrin receptors to acquire iron; a small amount of this receptor is shed into blood, where it can be detected in a free soluble form. At times of poor iron stores, cells up-regulate transferrin receptor expression and the levels of soluble plasma transferrin receptor increase. This can now be measured by immunoassay and used to distinguish storage iron depletion in the presence of an acute phase response or liver disease when a raised level indicates iron deficiency. In difficult cases it may still be necessary to examine a bone marrow aspirate for iron stores.

Investigation of the cause

This will depend upon the age and sex of the patient, as well as the history and clinical findings. In men and in post-menopausal women with a normal diet, the upper and lower gastrointestinal tract should be investigated by endoscopy or barium studies. Serum anti-endomysial antibodies and possibly a duodenal biopsy are indicated (p. 894) to detect coeliac disease in iron-deficient patients who have features of malabsorption or recurrent deficiency in the absence of other expla-

nations, or who are young men with normal diet or young women with normal menstruation and diet. In the tropics, stool and urine should be examined for parasites (p. 307).

Management

Unless the patient has angina, heart failure or evidence of cerebral hypoxia, transfusion is not necessary and oral iron supplementation is appropriate. Ferrous sulphate 200mg 8-hourly (195mg of elemental iron per day) is more than adequate and should be continued for 3–6 months to replete iron stores. The occasional patient is intolerant of ferrous sulphate, with dyspepsia and altered bowel habit. In this case a reduction in dose to 200mg 12-hourly or a switch to ferrous gluconate 300mg 12-hourly (70mg of elemental iron per day) should be made. Delayed-release preparations are not useful, since they release iron beyond the upper small intestine where it cannot be absorbed.

The haemoglobin should rise by 10g/L every 7–10 days and a reticulocyte response will be evident within a week. A failure to respond adequately may be due to non-compliance, continued blood loss, malabsorption or an incorrect diagnosis. The occasional patient with malabsorption or chronic gut disease may need parenteral iron therapy with single or multiple doses of intravenous iron dextran or iron sucrose. Doses required can be calculated based on the patient's starting Hb and body weight. Observation for anaphylaxis following an initial test dose is recommended.

Anaemia of chronic disease (ACD)

This is a common type of anaemia, particularly in hospital populations. It occurs in the setting of chronic infection, chronic inflammation or neoplasia. The anaemia is not related to bleeding, haemolysis or marrow infiltration, is mild, with Hb in the range of 85–115 g/L, and is usually associated with a normal MCV (normocytic, normochromic), though this may be reduced in long-standing inflammation. The serum iron is low but iron stores are normal or increased, as indicated by the ferritin or stainable marrow iron.

Pathogenesis

It has recently become clear that the key regulatory protein that accounts for the findings characteristic of ACD is hepcidin, which is produced by the liver (see Fig. 24.20). High levels of production are encouraged by pro-inflammatory cytokines, especially IL-6. Hepcidin binds to ferroportin on the membrane of iron exporting cells, such as small intestinal enterocytes and macrophages, internalising the ferroportin and thereby inhibiting the export of iron from these cells into the blood (and hence to the main target cells and proteins of iron). The iron remains trapped inside the cells in the form of ferritin, levels of which are therefore normal or high in the face of significant anaemia. Inhibition or blockade of hepcidin is a likely target for potential treatment of this form of anaemia.

Diagnosis and management

It is often difficult to distinguish ACD associated with a low MCV from iron deficiency. Box 24.35 summarises

the investigations and results. Examination of the marrow may ultimately be required to assess iron stores directly. A trial of oral iron can be given in difficult situations. A positive response occurs in true iron deficiency but not in ACD. Measures which reduce the severity of the underlying disorder generally help to improve the ACD.

Megaloblastic anaemia

This results from a deficiency of vitamin B₁₂ or folic acid, or from disturbances in folic acid metabolism. Folate is an important substrate of, and vitamin B₁₂ a co-factor for, the generation of the essential amino acid methionine from homocysteine. This reaction produces tetrahydrofolate, which is converted to thymidine monophosphate for incorporation into DNA. Deficiency of either vitamin B₁₂ or folate will therefore produce high plasma levels of homocysteine and impaired DNA synthesis.

The end result is cells with arrested nuclear maturation but normal cytoplasmic development: so-called nucleocytoplasmic asynchrony. All proliferating cells will exhibit megaloblastosis; hence changes are evident in the buccal mucosa, tongue, small intestine, cervix, vagina and uterus. The high proliferation rate of bone marrow results in striking changes in the haematopoietic system in megaloblastic anaemia. Cells become arrested in development and die within the marrow; this ineffective erythropoiesis results in an expanded hypercellular marrow. The megaloblastic changes are most evident in the early nucleated red cell precursors, and haemolysis within the marrow results in a raised bilirubin and lactate dehydrogenase (LDH), but without the reticulocytosis characteristic of other forms of haemolysis (p. 1022). Iron stores are usually raised. The mature red cells are large and oval, and sometimes contain nuclear remnants. Nuclear changes are seen in the immature granulocyte precursors and a characteristic appearance is that of 'giant' metamyelocytes with a large 'sausage-shaped' nucleus. The mature neutrophils show hypersegmentation of their nuclei, with cells having six or more nuclear lobes. If severe, a pancytopenia may be present in the peripheral blood.

Vitamin B₁₂ deficiency, but not folate deficiency, is associated with neurological disease in up to 40% of cases. The main pathological finding is focal demyelination affecting the spinal cord, peripheral nerves, optic nerves and cerebrum. The most common manifestations are sensory, with peripheral paraesthesiae and ataxia of gait. The clinical and diagnostic features of megaloblastic anaemia are summarised in Boxes 24.36 and 24.37, and the neurological findings of B₁₂ deficiency in Box 24.38.

Vitamin B₁₂

Vitamin B₁₂ absorption

The average daily diet contains 5–30 µg of vitamin B₁₂ mainly in meat, fish, eggs and milk—well in excess of the 1 µg daily requirement. In the stomach, gastric enzymes release vitamin B₁₂ from food and at gastric pH it binds to a carrier protein termed R protein. The gastric parietal cells produce intrinsic factor, a vitamin B₁₂-binding protein which optimally binds vitamin B₁₂

24.36 Clinical features of megaloblastic anaemia

Symptoms

- Malaise (90%)
- Breathlessness (50%)
- Paraesthesiae (80%)
- Sore mouth (20%)
- Weight loss
- Altered skin pigmentation
- Grey hair
- Impotence
- Poor memory
- Depression
- Personality change
- Hallucinations
- Visual disturbance

Signs

- Smooth tongue
- Angular cheilosis
- Vitiligo
- Skin pigmentation
- Heart failure
- Pyrexia

24.37 Investigations in megaloblastic anaemia

Investigation	Result
Haemoglobin	Often reduced, may be very low
MCV	Usually raised, commonly > 120 fL
Erythrocyte count	Low for degree of anaemia
Blood film	Oval macrocytosis, poikilocytosis, red cell fragmentation, neutrophil hypersegmentation
Reticulocyte count	Low for degree of anaemia
Leucocyte count	Low or normal
Platelet count	Low or normal
Bone marrow	Increased cellularity, megaloblastic changes in erythroid series, giant metamyelocytes, dysplastic megakaryocytes, increased iron in stores, pathological non-ring sideroblasts
Serum ferritin	Elevated
Plasma lactate dehydrogenase (LDH)	Elevated, often markedly

24.38 Neurological findings in B₁₂ deficiency

Peripheral nerves

- Glove and stocking paraesthesiae
- Loss of ankle reflexes

Spinal cord

- Subacute combined degeneration of the cord
 - Posterior columns—diminished vibration sensation and proprioception
 - Corticospinal tracts—upper motor neuron signs

Cerebrum

- Dementia
- Optic atrophy

Autonomic neuropathy

at pH 8. As gastric emptying occurs, pancreatic secretion raises the pH and vitamin B₁₂ released from the diet switches from the R protein to intrinsic factor. Bile also contains vitamin B₁₂ which is available for reabsorption in the intestine. The vitamin B₁₂ intrinsic factor complex binds to specific receptors in the terminal ileum and vitamin B₁₂ is actively transported by the enterocytes to plasma, where it binds to transcobalamin II, a transport protein produced by the liver, which carries it to the tissues for utilisation. The liver stores enough vitamin B₁₂ for 3 years and this, together with the enterohepatic circulation, means that vitamin B₁₂ deficiency takes years to become manifest, even if all dietary intake is stopped.

Blood levels of vitamin B₁₂ provide a reasonable indication of tissue stores and are usually diagnostic of deficiency. Levels of cobalamins fall in normal pregnancy. Each laboratory must validate its own normal range but levels below 150 ng/L are common and in the last trimester 5–10% of women have levels below 100 ng/L. Paraproteins can interfere with vitamin B₁₂ assays and so myeloma may be associated with a spuriously low vitamin B₁₂.

Causes of vitamin B₁₂ deficiency

Dietary deficiency

This only occurs in strict vegans but the onset of clinical features can occur at any age between 10 and 80 years. Less strict vegetarians often have slightly low vitamin B₁₂ levels but are not tissue vitamin B₁₂-deficient.

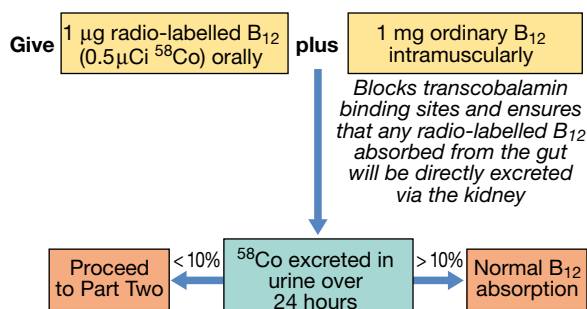

Gastric factors

Release of vitamin B₁₂ from the food requires normal gastric acid and enzyme secretion, and this is impaired by hypochlorhydria in elderly patients or following gastric surgery. Total gastrectomy invariably results in vitamin B₁₂ deficiency within 5 years, often combined with iron deficiency; these patients need life-long 3-monthly vitamin B₁₂ injections. After partial gastrectomy vitamin B₁₂ deficiency only develops in 10–20% of patients by 5 years; an annual injection of vitamin B₁₂ should prevent deficiency in this group.

Pernicious anaemia

This is an autoimmune disorder in which the gastric mucosa is atrophic, with loss of parietal cells causing intrinsic factor deficiency. In the absence of intrinsic factor, less than 1% of dietary vitamin B₁₂ is absorbed. Pernicious anaemia has an incidence of 25/100 000 population over the age of 40 years in developed countries, but an average age of onset of 60 years. It is more common in individuals with other autoimmune disease (Hashimoto's thyroiditis, Graves' disease, vitiligo, hypoparathyroidism or Addison's disease; Ch. 20) or a family history of these or pernicious anaemia. The finding of anti-intrinsic factor antibodies in the context of B₁₂ deficiency is diagnostic of pernicious anaemia without further investigation. Antiparietal cell antibodies are present in over 90% of cases but are also present in 20% of normal females over the age of 60 years; a negative result makes pernicious anaemia less likely but a positive result is not diagnostic. Patients with low B₁₂ levels and negative anti-intrinsic factor antibodies should have a Schilling test performed to determine whether there is B₁₂ malabsorption, and if so, where it is occurring (Fig. 24.21).

Part One

Part Two (if excretion ↓ in Part One)

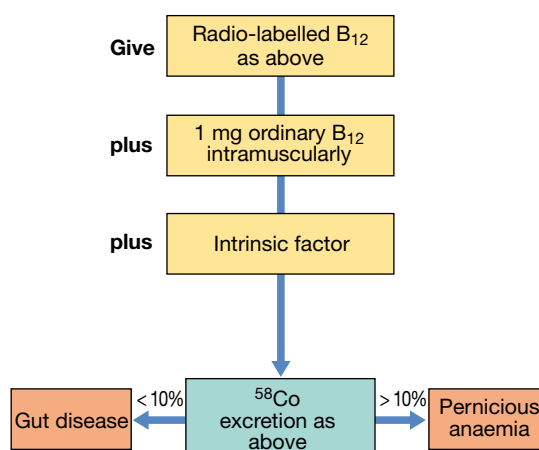

Fig. 24.21 The two-part Schilling test in the diagnosis of the cause of vitamin B₁₂ deficiency.

Small bowel factors

One-third of patients with pancreatic exocrine insufficiency fail to transfer dietary vitamin B₁₂ from R protein to intrinsic factor. This usually results in slightly low vitamin B₁₂ values but no tissue evidence of vitamin B₁₂ deficiency.

Motility disorders or hypogammaglobulinaemia can result in bacterial overgrowth and the ensuing competition for free vitamin B₁₂ can lead to deficiency. This is corrected to some extent by appropriate antibiotics.

A small number of people heavily infected with the fish tapeworm (p. 373) develop vitamin B₁₂ deficiency.

Inflammatory disease of the terminal ileum, such as Crohn's disease, may impair the interaction of the vitamin B₁₂-intrinsic factor complex with its receptor, as will surgery on part of the bowel. Both may result in vitamin B₁₂ malabsorption.

It is possible to distinguish pernicious anaemia from intestinal problems with a two-part Schilling test (see Fig. 24.21). The patient must be vitamin B₁₂-replete, have normal renal function and be able to comply with a 24-hour urine collection. This latter criterion is important, as up to 25% of tests are invalidated by an incomplete urine collection. It is important to note that this is not a test of gut function, but simply distinguishes pernicious anaemia from the other causes of vitamin B₁₂ deficiency.

Folate

Folate absorption

Folates are produced by plants and bacteria; hence dietary leafy vegetables (spinach, broccoli, lettuce), fruits (bananas, melons) and animal protein (liver, kidney) are a rich source. An average Western diet contains more than the minimum daily intake of 50 µg but excess cooking for longer than 15 minutes destroys folates. Most dietary folate is present as polyglutamates; these are converted to monoglutamate in the upper small bowel and actively transported into plasma. Plasma folate is loosely bound to plasma proteins such as albumin and there is an enterohepatic circulation. Total body stores of folate are small and deficiency can occur in a matter of weeks.

Folate deficiency

The causes and diagnostic features of folate deficiency are shown in Boxes 24.39 and 24.40. The edentulous elderly or psychiatric patient is particularly susceptible to dietary deficiency and this is exacerbated in the presence of gut disease or malignancy. Pregnancy-induced folate deficiency is the most common cause of megaloblastosis world-wide and is more likely in the context of twin pregnancies, multiparity and hyperemesis gravidarum. Serum folate is very sensitive to dietary intake; a single meal can normalise it in a patient with true folate deficiency, whereas anorexia, alcohol and anticonvulsant therapy can reduce it in the absence of megaloblastosis. For this reason red cell folate levels are a more accurate indicator of folate stores and tissue folate deficiency.

24.39 Causes of folate deficiency

Diet	
<ul style="list-style-type: none"> Poor intake of vegetables

Corroborative findings	
<ul style="list-style-type: none"> Macrocytic dysplastic blood picture Megaloblastic marrow 	

Management of megaloblastic anaemia

If a patient with a severe megaloblastic anaemia is very ill and treatment must be started before vitamin B₁₂ and red cell folate results are available, treatment should always include both folic acid and vitamin B₁₂. The use of folic acid alone in the presence of vitamin B₁₂ deficiency may result in worsening of neurological deficits.

Rarely, if severe angina or heart failure is present, transfusion can be used in megaloblastic anaemia. The cardiovascular system is adapted to the chronic anaemia present in megaloblastosis, and the volume load imposed by transfusion may result in decompensation and severe cardiac failure. In such circumstances, exchange transfusion or slow administration of 1 unit each day with diuretic cover may be given cautiously.

Vitamin B₁₂ deficiency

Vitamin B₁₂ deficiency is treated with hydroxycobalamin 1000 µg i.m. in five doses 2 or 3 days apart, followed by maintenance therapy of 1000 µg every 3 months for life. The reticulocyte count will peak by the 5th–10th day after therapy and may be as high as 50%. The haemoglobin will rise by 10 g/L every week. The response of the marrow is associated with a fall in plasma potassium levels and rapid depletion of iron stores. If an initial response is not maintained and the blood film is dimorphic (i.e. shows a mixture of microcytic and macrocytic cells), the patient may need additional iron therapy. A sensory neuropathy may take 6–12 months to correct; long-standing neurological damage may not improve.

Folate deficiency

Oral folic acid 5 mg daily for 3 weeks will treat acute deficiency and 5 mg once weekly is adequate maintenance therapy. Prophylactic folic acid in pregnancy prevents megaloblastosis in women at risk, and reduces the risk of fetal neural tube defects (p. 113). Prophylactic supplementation is also given in chronic haematological disease associated with reduced red cell lifespan (e.g. autoimmune haemolytic anaemia or haemoglobinopathies). There is some evidence that supraphysiological supplementation (400 µg/day) can reduce the risk of coronary and cerebrovascular disease by reducing plasma homocysteine levels. This has led the US Food and Drug Administration to introduce fortification of bread, flour and rice with folic acid.

Haemolytic anaemia

The normal red cell lifespan of 120 days may be shortened by a variety of abnormalities. The bone marrow may increase its output of red cells six- to eight-fold by increasing the proportion of red cells produced, expanding the volume of active marrow and releasing reticulocytes prematurely. If the rate of destruction exceeds this increased production rate, then anaemia will develop.

Investigation and differential diagnosis of haemolysis are outlined in Figure 24.22. Red cell destruction overloads pathways for haemoglobin breakdown, causing a modest rise in unconjugated bilirubin in the blood and mild jaundice. Increased reabsorption of urobilinogen

Fig. 24.22 Laboratory features and classification of the causes of haemolysis. (LDH = lactate dehydrogenase; DAT = direct antiglobulin test)

from the gut results in an increase in urinary urobilinogen (pp. 930 and 990). Red cell destruction releases LDH into the serum. The bone marrow compensation results in a reticulocytosis, and nucleated red cell precursors may also appear in the blood. Activation of the bone marrow can result in a neutrophilia and immature granulocytes appearing in the blood to cause a leuco-erythroblastic blood film. The appearances of the red cells may give an indication of the likely cause of the haemolysis (see Box 24.2, p. 995).

- Spherocytes are small, dark red cells which suggest autoimmune haemolysis or hereditary spherocytosis.
- Sickle cells suggest haemoglobinopathy.
- Red cell fragments indicate microangiopathic haemolysis.

The compensatory erythroid hyperplasia may give rise to folate deficiency, when the blood findings will be complicated by the presence of megaloblastosis. Measurement of red cell folate is unreliable in the presence of haemolysis and serum folate will be elevated.

Intravascular haemolysis

When rapid red cell destruction occurs, free haemoglobin is released into the plasma. Free haemoglobin is toxic to cells and binding proteins have evolved to minimise this risk. Haptoglobin is an α_2 -globulin produced by the liver which binds free haemoglobin, resulting in a fall in levels of haptoglobin. Once haptoglobins are saturated, free haemoglobin is oxidised to form methaemoglobin which binds to albumin, in turn forming methaemalbumin which can be detected spectrophotometrically in the Schumm's test. Methaemoglobin is degraded and any free haem is bound to a second binding protein termed haemopexin. If all the protective mechanisms are overloaded, free haemoglobin may appear in the urine. When fulminant, this gives rise to black urine, as in severe *falciparum* malaria infection (p. 348). In smaller amounts, renal tubular cells absorb the haemoglobin, degrade it and store the iron as haemosiderin. When the tubular cells are subsequently sloughed into the urine, they give

rise to haemosiderinuria, which is always indicative of intravascular haemolysis.

Extravascular haemolysis

Physiological red cell destruction occurs in the fixed reticulo-endothelial cells in the liver or spleen, so avoiding free haemoglobin in the plasma. In most haemolytic states, haemolysis is predominantly extravascular.

To confirm the haemolysis, patients' red cells can be labelled with $^{51}\text{Chromium}$. When re-injected, they can be used to determine red cell survival; when combined with body surface radioactivity counting this test may indicate whether the liver or the spleen is the main source of red cell destruction. However, this is seldom performed in clinical practice.

Causes of haemolytic anaemia

These can be classified as congenital or acquired.

- *Inherited* red cell abnormalities resulting in chronic haemolytic anaemia may arise from pathologies of the red cell membrane (hereditary spherocytosis or elliptocytosis), of the haemoglobin (haemoglobinopathies) or of protective enzymes which prevent cellular oxidative damage, such as glucose-6-phosphate dehydrogenase (G6PD).
- *Acquired* causes include auto- and allo-antibody-mediated destruction of red blood cells and other mechanical, toxic and infective causes, as detailed below.

Red cell membrane defects

The structure of the red cell membrane is shown in Figure 24.4 (p. 990). The basic structure is a cytoskeleton 'stapled' on to the lipid bilayer by special protein complexes. This structure ensures great deformability and elasticity; the red cell diameter is $8\mu\text{m}$ but the narrowest capillaries in the circulation are in the spleen, measuring just $2\mu\text{m}$ in diameter. When the normal red cell structure is disturbed, usually by a quantitative or functional deficiency of one or more proteins in the cytoskeleton, cells lose their elasticity. Each time such cells pass through the spleen, they lose membrane relative to their cell volume. This results in an increase in mean cell haemoglobin concentration (MCHC), abnormal cell shape (see Box 24.2, p. 995) and reduced red cell survival due to extravascular haemolysis.

Hereditary spherocytosis

This is usually inherited as an autosomal dominant condition, although 25% of cases have no family history and represent new mutations. The incidence is approximately 1:5000 in developed countries but this may be an underestimate, since the disease may present de novo in patients aged over 65 years and is often discovered as a chance finding on a blood count. The most common abnormalities are deficiencies of beta spectrin or ankyrin (see Fig. 24.4, p. 990). The severity of spontaneous haemolysis varies. Most cases are associated with an asymptomatic compensated chronic haemolytic state with spherocytes present on the blood film, a reticulocytosis and mild hyperbilirubinaemia. Pigment gallstones are present in up to 50% of patients and may cause symptomatic cholecystitis. Occasional cases are associated with more severe haemolysis; these may be due to coincidental polymorphisms in alpha spectrin or

co-inheritance of a second defect involving a different protein.

The clinical course may be complicated by crises:

- A *haemolytic crisis* occurs when the severity of haemolysis increases; this is rare, and usually associated with infection.
- A *megaloblastic crisis* follows the development of folate deficiency; this may occur as a first presentation of the disease in pregnancy.
- An *aplastic crisis* occurs in association with erythrovirus infection (p. 311). Erythrovirus causes a common exanthem in children, but if individuals with chronic haemolysis become infected, the virus directly invades red cell precursors and temporarily switches off red cell production. Patients present with severe anaemia and a low reticulocyte count.

Investigations

The patient and other family members should be screened for features of compensated haemolysis (see Fig. 24.22). This may be all that is required to confirm the diagnosis. Haemoglobin levels are variable, depending on the degree of compensation. The blood film will show spherocytes but the direct Coombs test (see Fig. 24.23 below) is negative, excluding immune haemolysis. An osmotic fragility test may show increased sensitivity to lysis in hypotonic saline solutions but is limited by lack of sensitivity and specificity. More specific flow cytometric tests, detecting binding of eosin-5-maleimide to red cells, are recommended in borderline cases.

Management

Folic acid prophylaxis, 5mg once weekly, should be given for life. Consideration may be given to splenectomy, which improves but does not normalise red cell survival. Potential indications include moderate to severe haemolysis with complications (anaemia and gallstones), although splenectomy should be delayed until after 6 years of age in view of the risk of sepsis. Guidelines for the management of patients after splenectomy are presented in Box 24.41.

24.41 Management of the splenectomised patient

- Vaccinate with pneumococcal, *Haemophilus influenzae* type B, meningococcal group C and influenza vaccines at least 2–3 weeks before elective splenectomy. Vaccination should be given after emergency surgery, but may be less effective
- Pneumococcal re-immunisation should be given at least 5-yearly and influenza annually. Vaccination status must be documented
- Life-long prophylactic penicillin V 500 mg 12-hourly is recommended. In penicillin-allergic patients, consider erythromycin
- A card or bracelet should be carried by splenectomised patients to alert health professionals to the risk of overwhelming sepsis
- In septicaemia, splenectomised patients should be resuscitated and given intravenous antibiotics to cover pneumococcus, *Haemophilus* and meningococcus
- The risk of malaria is increased
- Animal bites should be promptly treated with local disinfection and antibiotics, to prevent serious soft tissue infection and septicaemia

Acute, severe haemolytic crises require transfusion support, but blood must be cross-matched carefully and transfused slowly as haemolytic transfusion reactions may occur (p. 1012).

Hereditary elliptocytosis

This term refers to a heterogeneous group of disorders that produce an increase in elliptocytic red cells on the blood film and a variable degree of haemolysis. This is due to a functional abnormality of one or more anchor proteins in the red cell membrane, e.g. alpha spectrin or protein 4.1. Inheritance may be autosomal dominant or recessive. It is less common than hereditary spherocytosis in Western countries, with an incidence of 1/10 000, but is more common in equatorial Africa and parts of South-east Asia. The clinical course is variable and depends upon the degree of membrane dysfunction caused by the inherited molecular defect(s); most cases present as an asymptomatic blood film abnormality, but occasional cases result in neonatal haemolysis or a chronic compensated haemolytic state. Management of the latter is the same as for hereditary spherocytosis.

A characteristic variant of hereditary elliptocytosis occurs in South-east Asia, particularly Malaysia and Papua New Guinea, with stomatocytes and ovalocytes in the blood. This has a prevalence of up to 30% in some communities because it offers relative protection from malaria and thus has sustained a high gene frequency. The differential diagnosis includes iron deficiency, thalassaemia, myelofibrosis, myelodysplasia and pyruvate kinase deficiency.

Red cell enzymopathies

The mature red cell must produce energy via ATP to maintain a normal internal environment and cell volume whilst protecting itself from the oxidative stress presented by oxygen carriage. Anaerobic glycolysis via the Embden-Meyerhof pathway generates ATP, and the hexose monophosphate shunt produces NADPH and glutathione to protect against oxidative stress. The impact of functional or quantitative defects in the enzymes in these pathways depends upon the importance of the steps affected and the presence of alternative pathways. In general, defects in the hexose monophosphate shunt pathway result in periodic haemolysis induced by oxidative stress, whilst those in the Embden-Meyerhof pathway result in shortened red cell survival and chronic haemolysis.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency

This enzyme is pivotal in the hexose monophosphate shunt pathway. Deficiencies result in the most common human enzymopathy, affecting 10% of the world's population, with a geographical distribution which parallels the malaria belt because heterozygotes are protected from malarial parasitisation. The enzyme is a heteromeric structure made of catalytic subunits which are encoded by a gene on the X chromosome. The deficiency therefore affects males and rare homozygotic females (p. 50), but it is carried by females. Carrier heterozygous females are usually only affected in the neonatal period or in the presence of extreme lyonisation, producing selective inactivation of one of the X chromosomes.

There are over 400 subtypes of G6PD described. The most common types associated with normal activity

	24.42 Glucose-6-phosphate dehydrogenase deficiency
Clinical features	
<ul style="list-style-type: none"> Acute drug-induced haemolysis to (e.g.) <ul style="list-style-type: none"> Analgesics: aspirin, phenacetin Antimalarials: primaquine, quinine, chloroquine, pyrimethamine Antibiotics: sulphonamides, nitrofurantoin, ciprofloxacin Miscellaneous: quinidine, probenecid, vitamin K, dapsone Chronic compensated haemolysis Infection or acute illness Neonatal jaundice: may be a feature of the B⁻ enzyme Favism, i.e. acute haemolysis after ingestion of the broad bean <i>Vicia faba</i>

G6PD level	
<ul style="list-style-type: none"> Can be indirectly assessed by screening methods which usually depend upon the decreased ability to reduce dyes Direct assessment of G6PD is made in those with low screening values Care must be taken close to an acute haemolytic episode because reticulocytes may have higher enzyme levels and give rise to a false normal result 	

are the B⁺ enzyme present in most Caucasians and 70% of Afro-Caribbeans, and the A⁺ variant present in 20% of Afro-Caribbeans. The two common variants associated with reduced activity are the A⁻ variety in approximately 10% of Afro-Caribbeans, and the Mediterranean or B⁻ variety in Caucasians. In East and West Africa, up to 20% of males and 4% of females (homozygotes) are affected and have enzyme levels of approximately 15% of normal. The deficiency in Caucasian and Oriental populations is more severe, with enzyme levels as low as 1%.

Clinical features and investigation findings are shown in Box 24.42.

Management aims to stop any precipitant drugs and treat any underlying infection. Acute transfusion support may be life-saving.

Pyruvate kinase deficiency

This is the second most common red cell enzyme defect. It results in deficiency of ATP production and a chronic haemolytic anaemia. It is inherited as an autosomal recessive trait. The extent of anaemia is variable; the blood film shows characteristic 'prickle cells' which resemble holly leaves. Enzyme activity is only 5–20% of normal. Transfusion support may be necessary.

Pyrimidine 5' nucleotidase deficiency

This enzyme catalyses the dephosphorylation of nucleoside monophosphates and is important during the

degradation of RNA in reticulocytes. It is inherited as an autosomal recessive trait and is as common as pyruvate kinase deficiency in Mediterranean, African and Jewish populations. The accumulation of excess ribonucleoprotein results in coarse basophilic stippling (see Box 24.2, p. 998) associated with a chronic haemolytic state. The enzyme is very sensitive to inhibition by lead and this is the reason why basophilic stippling is a feature of lead poisoning.

Autoimmune haemolytic anaemia

This results from increased red cell destruction due to red cell autoantibodies. The antibodies may be IgG or M, or more rarely IgE or A. If an antibody avidly fixes complement, it will cause intravascular haemolysis, but if complement activation is weak, the haemolysis will be extravascular. Antibody-coated red cells lose membrane to macrophages in the spleen and hence spherocytes are present in the blood. The optimum temperature at which the antibody is active (thermal specificity) is used to classify immune haemolysis:

- Warm antibodies** bind best at 37°C and account for 80% of cases. The majority are IgG and often react against Rhesus antigens.
- Cold antibodies** bind best at 4°C but can bind up to 37°C in some cases. They are usually IgM and bind complement. They account for the other 20% of cases.

Warm autoimmune haemolysis

The incidence of warm autoimmune haemolysis is approximately 1/100 000 population per annum; it occurs at all ages but is more common in middle age and in females. No underlying cause is identified in up to 50% of cases. The remainder are secondary to a wide variety of other conditions:

- lymphoid neoplasms: lymphoma, chronic lymphocytic leukaemia, myeloma
- solid tumours: lung, colon, kidney, ovary, thymoma
- connective tissue disease: SLE, rheumatoid arthritis
- drugs: methyldopa, mefenamic acid, penicillin, quinidine
- miscellaneous: ulcerative colitis, HIV.

Investigations

There is evidence of haemolysis and spherocytes on the blood film. The diagnosis is confirmed by the direct Coombs or antiglobulin test (Fig. 24.23). The patient's red cells are mixed with Coombs reagent, which contains antibodies against human IgG/M/complement. If the red cells have been coated by antibody in vivo, the Coombs reagent will induce their agglutination and this can be detected visually. The relevant antibody can be eluted from the red cell surface and tested against a panel of typed red cells to determine against which red cell antigen it is directed. The most common specificity is Rhesus and most often anti-e; this is helpful when choosing blood to cross-match. The direct Coombs test can be negative in the presence of brisk haemolysis. A positive test requires about 200 antibody molecules to attach to each red cell; with a very avid complement-fixing antibody, haemolysis may occur at lower levels of antibody-binding. The standard Coombs reagent will miss IgA or IgE antibodies.

A Direct antiglobulin test (DAT) (Coombs test)

Detects the presence of antibody bound to the red cell surface, e.g.

1. Autoimmune haemolytic anaemia
2. Haemolytic disease of newborn (HDN)
3. Transfusion reactions

**Key****B Indirect antiglobulin test (IAT) (indirect Coombs test)**

Detects antibodies in the plasma, e.g.

1. Antibody screen in pre-transfusion testing
2. Screening in pregnancy for antibodies that may cause haemolytic disease of the newborn

Fig. 24.23 Direct and indirect antiglobulin tests.

Management

If the haemolysis is secondary to an underlying cause, this must be treated and any offending drugs stopped.

It is usual to treat patients initially with prednisolone 1 mg/kg orally. A response is seen in 70–80% of cases but may take up to 3 weeks; a rise in haemoglobin will be matched by a fall in bilirubin, LDH and reticulocyte levels. Once the haemoglobin has normalised and the reticulocytosis resolved, the corticosteroid dose can be reduced slowly over about 10 weeks. Corticosteroids work by decreasing macrophage destruction of antibody-coated red cells and reducing antibody production.

Transfusionsupportmayberequiredforlife-threatening problems, such as the development of heart failure or rapid unabated falls in Hb. The least incompatible blood should be used but this may still give rise to transfusion reactions or the development of alloantibodies.

If the haemolysis fails to respond to corticosteroids or can only be stabilised by large doses, then splenectomy should be considered. This removes a main site of red cell destruction and antibody production, with a good response in 50–60% of cases. The operation can be performed laparoscopically with reduced morbidity. If splenectomy is not appropriate, alternative immunosuppressive therapy with azathioprine or cyclophosphamide may be considered. This is least suitable for young patients, in whom long-term immunosuppression carries a risk of secondary neoplasms. The anti-CD20 (B cell) monoclonal antibody, rituximab, has shown some success in difficult cases.

Cold agglutinin disease

This is due to antibodies, usually IgM, which bind to the red cells at 4°C and cause them to agglutinate. It may cause

intravascular haemolysis if complement fixation occurs. This can be chronic when the antibody is monoclonal, or acute or transient when the antibody is polyclonal.

Chronic cold agglutinin disease

This affects elderly patients and may be associated with an underlying low-grade B cell lymphoma. It causes a low-grade intravascular haemolysis with cold, painful and often blue fingers, toes, ears or nose (so-called acrocyanosis). The latter is due to red cell agglutination in the small vessels in these colder exposed areas. The blood film shows red cell agglutination and the MCV may be spuriously raised because the automated analysers count aggregates as single cells. The monoclonal IgM usually has specificity against the I or, more rarely, i red cell antigen and is present in a very high titre. Treatment is directed at any underlying lymphoma but if the disease is idiopathic, then patients must keep extremities warm, especially in winter. Some patients respond to corticosteroid therapy and blood transfusion may be considered, but the cross-match sample must be placed in a transport flask at a temperature of 37°C and blood administered via a blood-warmer.

Other causes of cold agglutination

Cold agglutination can occur in association with *Mycoplasma pneumoniae* or with infectious mononucleosis. Paroxysmal cold haemoglobinuria is a very rare cause seen in children in association with congenital syphilis. An IgG antibody binds to red cells in the peripheral circulation but lysis occurs in the central circulation when complement fixation takes place. This antibody is termed the Donath-Landsteiner antibody and has specificity against the P antigen on the red cells.

Alloimmune haemolytic anaemia

Alloimmune haemolytic anaemia is due to an antibody against non-self red cells. It has two main causes:

- an unmatched transfusion of red cells (a haemolytic transfusion reaction, p. 1012)
- maternal sensitisation to paternal antigens on fetal cells (haemolytic disease of the newborn, p. 1010).

Non-immune haemolytic anaemia

Physical trauma

Physical disruption of red cells may occur in a number of conditions and is characterised by the presence of red cell fragments on the blood film and markers of intravascular haemolysis:

- *Mechanical heart valves*. High flow through incompetent valves or periprosthetic leaks through the suture ring holding a valve in place result in shear stress damage.
- *March haemoglobinuria*. Vigorous exercise, such as prolonged marching or marathon running, can cause red cell damage in the capillaries in the feet.
- *Thermal injury*. Severe burns cause thermal damage to red cells characterised by fragmentation and the presence of microspherocytes in the blood.
- *Microangiopathic haemolytic anaemia*. Fibrin deposition in capillaries can cause severe red cell disruption. It may occur in a wide variety of conditions: disseminated carcinomatosis, malignant or pregnancy-induced hypertension, haemolytic uraemic syndrome (p. 498), thrombotic thrombocytopenic purpura (p. 1051) and disseminated intravascular coagulation (p. 1050).

Infection

Plasmodium falciparum malaria (p. 348) may be associated with intravascular haemolysis; when severe, this is termed blackwater fever due to the associated haemoglobinuria. *Clostridium perfringens* septicaemia (p. 301), usually in the context of ascending cholangitis, may cause severe intravascular haemolysis with marked spherocytosis due to bacterial production of a lecithinase which destroys the red cell membrane.

Chemicals or drugs

Dapsone and sulfasalazine cause haemolysis by oxidative denaturation of haemoglobin. Denatured haemoglobin forms Heinz bodies in the red cells, visible on supravital staining with brilliant cresyl blue. Arsenic gas, copper, chlorates, nitrites and nitrobenzene derivatives may all cause haemolysis.

Paroxysmal nocturnal haemoglobinuria (PNH)

This rare acquired non-malignant clonal expansion of haematopoietic stem cells deficient in GPI-anchor protein results in intravascular haemolysis and anaemia because of increased sensitivity of red cells to lysis by complement. Episodes of intravascular haemolysis result in haemoglobinuria, most noticeable in early morning urine which has a characteristic red-brown colour. The disease is associated with an increased risk of venous thrombosis in unusual sites such as the liver or abdomen. PNH is also associated with hypoplastic bone marrow failure, aplastic anaemia and myelodysplastic syndrome (pp. 1043 and 1036). Management is supportive with transfusion and treatment of thrombosis. Recently the anti-complement C5 monoclonal antibody eculizumab was shown to be effective in reducing haemolysis.

HAEMOGLOBINOPATHIES

These diseases are caused by dysfunction of the genes encoding the globin chains of the haemoglobin molecule. Normal haemoglobin is comprised of two alpha and two non-alpha globin chains. Alpha globin chains are produced throughout life, so severe mutations may cause intrauterine death. Production of non-alpha chains varies with age; fetal haemoglobin (HbF- $\alpha\alpha/\gamma\gamma$) has two gamma chains, while the predominant adult haemoglobin (HbA- $\alpha\alpha/\beta\beta$) has two beta chains. Thus, disorders affecting the beta chains do not present until after 6 months of age. A constant small amount of haemoglobin A₂ (HbA₂- $\alpha\alpha/\delta\delta$, usually < 2%) is made from birth.

The geographical distribution of the common haemoglobinopathies is shown in Figure 24.24. The

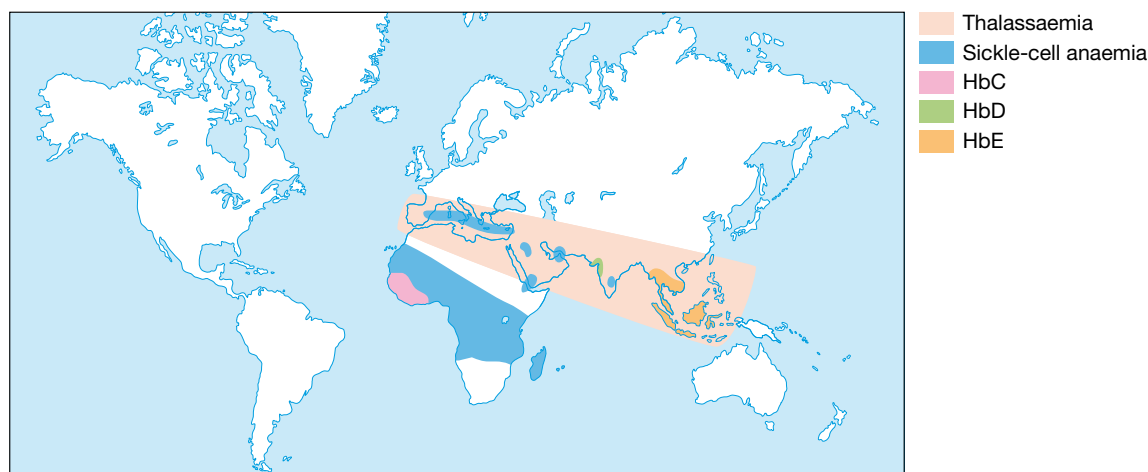

Fig. 24.24 The geographical distribution of the haemoglobinopathies.

haemoglobinopathies can be classified into qualitative or quantitative abnormalities.

Qualitative abnormalities—abnormal haemoglobins

In qualitative abnormalities (called the abnormal haemoglobins), there is a functionally important alteration in the amino acid structure of the polypeptide chains of the globin chains. Several hundred such variants are known; they were originally designated by letters of the alphabet, e.g. S, C, D or E, but are now described by names usually taken from the town or district in which they were first described. The best-known example is haemoglobin S, found in sickle-cell anaemia. Mutations around the haem-binding pocket cause the haem ring to fall out of the structure and produce an unstable haemoglobin. These substitutions often change the charge of the globin chains, producing different electrophoretic mobility, and this forms the basis for the diagnostic use of haemoglobin electrophoresis to identify haemoglobinopathies.

Quantitative abnormalities—thalassaemias

In quantitative abnormalities (the thalassaemias) there are mutations causing a reduced rate of production of one or other of the globin chains, altering the ratio of alpha to non-alpha chains. In alpha-thalassaemia excess beta chains are present, whilst in beta-thalassaemia excess alpha chains are present. The excess chains precipitate, causing red cell membrane damage and reduced red cell survival.

Sickle-cell anaemia

Sickle-cell disease results from a single glutamic acid to valine substitution at position 6 of the beta globin polypeptide chain. It is inherited as an autosomal recessive trait (p. 50). Homozygotes only produce abnormal beta chains that make haemoglobin S (HbS, termed SS), and this results in the clinical syndrome of sickle-cell disease. Heterozygotes produce a mixture of normal and abnormal beta chains that make normal HbA and HbS (termed AS), and this results in the clinically asymptomatic sickle-cell trait.

Epidemiology

The heterozygote frequency is over 20% in tropical Africa (see Fig. 24.24). In black American populations, sickle-cell trait has a frequency of 8%. Individuals with sickle-cell trait are relatively resistant to the lethal effects of *falciparum* malaria in early childhood; the high prevalence in equatorial Africa can be explained by the selective survival advantage it confers in areas where *falciparum* malaria is endemic. However, homozygous patients with sickle-cell anaemia do not have correspondingly greater resistance to *falciparum* malaria.

Pathogenesis

When haemoglobin S is deoxygenated, the molecules of haemoglobin polymerise to form pseudocrystalline structures known as 'tactoids'. These distort the red cell membrane and produce characteristic sickle-shaped cells (Fig. 24.25). The polymerisation is reversible when reoxygenation occurs. The distortion of the red cell membrane, however, may become permanent and the red cell 'irreversibly sickled'. The greater the concentration of sickle-cell haemoglobin in the individual cell, the

more easily tactoids are formed, but this process may be enhanced or retarded by the presence of other haemoglobins. Thus, the abnormal haemoglobin C variant participates in the polymerisation more readily than haemoglobin A, whereas haemoglobin F strongly inhibits polymerisation.

Clinical features

Sickling is precipitated by hypoxia, acidosis, dehydration and infection. Irreversibly sickled cells have a shortened survival and plug vessels in the microcirculation. This results in a number of acute syndromes, termed 'crises', and chronic organ damage, as shown in Figure 24.25:

- **Vaso-occlusive crisis.** Plugging of small vessels in the bone produces acute severe bone pain. This affects areas of active marrow: the hands and feet in children (so-called dactylitis) or the femora, humeri, ribs, pelvis and vertebrae in adults. Patients usually have a systemic response with tachycardia, sweating and a fever. This is the most common crisis.
- **Sickle chest syndrome.** This may follow on from a vaso-occlusive crisis and is the most common cause of death in adult sickle disease. Bone marrow infarction results in fat emboli to the lungs which cause further sickling and infarction, leading to ventilatory failure if not treated.
- **Sequestration crisis.** Thrombosis of the venous outflow from an organ causes loss of function and acute painful enlargement. In children the spleen is the most common site. Massive splenic enlargement may result in severe anaemia, circulatory collapse and death. Recurrent sickling in the spleen in childhood results in infarction and adults may have no functional spleen. In adults the liver may undergo sequestration with severe pain due to capsular stretching.
- **Aplastic crisis.** Infection of adult sicklers with human erythrovirus 19 results in a severe but self-limiting red cell aplasia. This produces a very low haemoglobin which may cause heart failure. Unlike in all other sickle crises, the reticulocyte count is low.

Investigations

Patients with sickle-cell disease have a compensated anaemia, usually around 60–80 g/L. The blood film shows sickle cells, target cells and features of hyposplenism. A reticulocytosis is present. The presence of HbS can be demonstrated by exposing red cells to a reducing agent such as sodium dithionite; HbA gives a clear solution, whereas HbS polymerises to produce a turbid solution. This forms the basis of emergency screening tests before surgery in appropriate ethnic groups but cannot distinguish between sickle-cell trait and disease. The definitive diagnosis requires haemoglobin electrophoresis to demonstrate the absence of HbA, 2–20% HbF and the predominance of HbS. Both parents of the affected individual will have sickle-cell trait.

Management

All patients with sickle-cell disease should receive prophylaxis with daily folic acid, and penicillin V to protect against pneumococcal infection which may be lethal in the presence of hyposplenism. These patients should be

Fig. 24.25 Clinical manifestations of sickle-cell disease.

vaccinated against pneumococcus and, where vaccine is available, *Haemophilus influenzae* B and hepatitis B.

Vaso-occlusive crises are managed by aggressive rehydration, oxygen therapy, adequate analgesia (which often requires opiates) and antibiotics. Transfusion should be with fully genotyped blood wherever possible. Simple top-up transfusion may be used in a sequestration or aplastic crisis. A regular transfusion programme to suppress HbS production and maintain the HbS level below 30% may be indicated in patients with recurrent severe complications such as cerebrovascular accidents in children or chest syndromes in adults. Exchange transfusion, in which a patient is simultaneously venesected and transfused to replace HbS with HbA, may be used in life-threatening crises or to prepare patients for surgery.

A high HbF level inhibits polymerisation of HbS and reduces sickling. Patients with sickle-cell disease and high HbF levels have a mild clinical course with few crises. Some agents are able to increase synthesis of HbF and this has been used to reduce the frequency of severe crises. The oral cytotoxic agent hydroxycarbamide has been shown to have clinical benefit with acceptable side-effects in children and adults who have recurrent severe crises.

Relatively few allogeneic stem-cell transplants from HLA-matched siblings have been performed but this procedure appears to be potentially curative (p. 1013).

Prognosis

In Africa few children with sickle-cell anaemia survive to adult life without medical attention. Even with standard medical care, approximately 15% die by the age of 20 years and 50% by the age of 40 years.

Other abnormal haemoglobins

Another beta chain haemoglobinopathy, haemoglobin C (HbC) disease, is clinically silent but associated with microcytosis and target cells on the blood film. Compound heterozygotes inheriting one HbS gene and one HbC gene from their parents have haemoglobin SC disease, which behaves like a mild form of sickle-cell disease. It is associated with a reduced frequency of crises but is not uncommonly associated with complications in pregnancy and retinal vein thrombosis.

The thalassaemias

Thalassaemia is an inherited impairment of haemoglobin production, in which there is partial or complete failure to synthesise a specific type of globin chain. In alpha-thalassaemia, disruption of one or both alleles on chromosome 16 may occur, with production of some or no alpha globin chains. In beta-thalassaemia, defective production usually results from disabling point

mutations causing no (β^0) or reduced (β^-) beta chain production.

Beta-thalassaemia

Failure to synthesise beta chains (beta-thalassaemia) is the most common type of thalassaemia, most prevalent in the Mediterranean area. Heterozygotes have thalassaemia minor, a condition in which there is usually mild anaemia and little or no clinical disability, which may be detected only when iron therapy for a mild microcytic anaemia fails. Homozygotes (thalassaemia major) either are unable to synthesise haemoglobin A or at best produce very little; after the first 4–6 months of life they develop profound hypochromic anaemia. The diagnostic features are summarised in Box 24.43. Intermediate grades of severity occur.

Management and prevention

See Box 24.44. Cure is now a possibility for selected children, with allogeneic bone marrow transplantation (p. 1013).

It is possible to identify a fetus with homozygous beta-thalassaemia by obtaining chorionic villous material for DNA analysis sufficiently early in pregnancy to allow termination. This examination is only appropriate if both parents are known to be carriers (beta-thalassaemia minor) and will accept a termination.

24.43 Diagnostic features of beta-thalassaemia

Beta-thalassaemia major (homozygotes)

- Profound hypochromic anaemia
- Evidence of severe red cell dysplasia
- Erythroblastosis
- Absence or gross reduction of the amount of haemoglobin A
- Raised levels of haemoglobin F
- Evidence that both parents have thalassaemia minor

Beta-thalassaemia minor (heterozygotes)

- Mild anaemia
- Microcytic hypochromic erythrocytes (not iron-deficient)
- Some target cells
- Punctate basophilia
- Raised haemoglobin A₂ fraction
- Evidence that one parent has thalassaemia minor

24.44 Treatment of beta-thalassaemia major

Problem	Management
Erythropoietic failure	Allogeneic bone marrow transplantation from human leucocyte antigen (HLA)-compatible sibling Transfusion to maintain Hb > 100 g/L Folic acid 5 mg daily
Iron overload	Iron therapy forbidden Iron chelation therapy
Splenomegaly causing mechanical problems, excessive transfusion needs	Splenectomy

Alpha-thalassaemia

Reduced or absent alpha chain synthesis is common in Southeast Asia. There are two alpha gene loci on chromosome 16 and therefore each individual carries four alpha gene alleles.

- If one is deleted, there is no clinical effect.
- If two are deleted, there may be a mild hypochromic anaemia.
- If three are deleted, the patient has haemoglobin H disease.
- If all four are deleted, the baby is stillborn (hydrops fetalis).

Haemoglobin H is a beta-chain tetramer, formed from the excess of beta chains, which is functionally useless, so that patients rely on their low levels of HbA for oxygen transport. Treatment of haemoglobin H disease is similar to that of beta-thalassaemia of intermediate severity, involving folic acid supplementation, transfusion if required and avoidance of iron therapy.

24.45 Anaemia in old age

- **Mean haemoglobin:** falls with age in both sexes, but remains well within the normal range. When a low haemoglobin does occur, it is generally due to disease.
- **Anaemia can never be considered 'normal' in old age.**
- **Symptoms:** may be subtle and insidious. Cardiovascular features such as dyspnoea and oedema, and cerebral features such as dizziness and apathy, tend to predominate.
- **Ferritin:** if less than 45 µg/L in older people, is highly predictive of iron deficiency.
- **Serum iron and transferrin:** fall with age because of the prevalence of other disorders, and are not reliable indicators of deficiency.
- **Most common cause of iron deficiency:** gastrointestinal blood loss.
- **Most common cause of vitamin B₁₂ deficiency:** pernicious anaemia, as the prevalence of chronic atrophic gastritis rises in old age.
- **Neuropsychiatric symptoms associated with vitamin B₁₂ deficiency:** well established association but a causal relationship has not been clearly shown. Dementia associated with vitamin B₁₂ deficiency in the absence of haematological abnormalities is rare.
- **Anaemia of chronic disease:** frequent in old age because of the rising prevalence of diseases that inhibit iron transport.

HAEMATOLOGICAL MALIGNANCIES

Haematological malignancies arise when the processes controlling proliferation or apoptosis are corrupted in blood cells. If mature differentiated cells are involved, the cells will have a low growth fraction and produce indolent neoplasms, such as the low-grade lymphomas or chronic leukaemias, when patients have an expected survival of many years. In contrast, if more primitive stem cells are involved, the cells can have the highest growth fractions of all human neoplasms, producing rapidly progressive life-threatening illnesses such as the acute leukaemias or high-grade lymphomas. Involvement of pluripotent stem cells produces the most aggressive acute leukaemias. In general, haematological neoplasms

are diseases of elderly patients, the exceptions being acute lymphoblastic leukaemia which predominantly affects children, and Hodgkin lymphoma which affects people aged 20–40 years.

Leukaemias

Leukaemias are malignant disorders of the haematopoietic stem cell compartment, characteristically associated with increased numbers of white cells in the bone marrow and/or peripheral blood. The course of leukaemia may vary from a few days or weeks to many years, depending on the type.

Epidemiology and aetiology

The incidence of leukaemia of all types in the population is approximately 10/100 000 per annum, of which just under half are cases of acute leukaemia. Males are affected more frequently than females, the ratio being about 3:2 in acute leukaemia, 2:1 in chronic lymphocytic leukaemia and 1.3:1 in chronic myeloid leukaemia. Geographical variation in incidence does occur, the most striking being the rarity of chronic lymphocytic leukaemia in the Chinese and related races. Acute leukaemia occurs at all ages. Acute lymphoblastic leukaemia shows a peak of incidence in children aged 1–5 years. All forms of acute myeloid leukaemia have their lowest incidence in young adult life and there is a striking rise over the age of 50. Chronic leukaemias occur mainly in middle and old age.

The cause of the leukaemia is unknown in the majority of patients. Several risk factors, however, are known (Box 24.46).

Terminology and classification

Leukaemias are traditionally classified into four main groups:

- acute lymphoblastic leukaemia (ALL)
- acute myeloid leukaemia (AML)

24.46 Risk factors for leukaemia

Ionising radiation

- After atomic bombing of Japanese cities (myeloid leukaemia)
- Radiotherapy for ankylosing spondylitis
- Diagnostic X-rays of the fetus in pregnancy

Cytotoxic drugs

- Especially alkylating agents (myeloid leukaemia, usually after a latent period of several years)
- Industrial exposure to benzene

Retroviruses

- One rare form of T-cell leukaemia/lymphoma appears to be associated with a retrovirus similar to the viruses causing leukaemia in cats and cattle

Genetic

- Identical twin of patients with leukaemia
- Down's syndrome and certain other genetic disorders

Immunological

- Immune deficiency states (e.g. hypogammaglobulinaemia)

- chronic lymphocytic leukaemia (CLL)
- chronic myeloid leukaemia (CML).

In acute leukaemia there is proliferation of primitive stem cells leading to an accumulation of blasts, predominantly in the bone marrow, which causes bone marrow failure. In chronic leukaemia the malignant clone is able to differentiate, resulting in an accumulation of more mature cells. Lymphocytic and lymphoblastic cells are those derived from the lymphoid stem cell (B cells and T cells). Myeloid refers to the other lineages, i.e. precursors of red cells, granulocytes, monocytes and platelets (see Fig. 24.2, p. 989).

The diagnosis of leukaemia is usually suspected from an abnormal blood count, often a raised white count, and is confirmed by examination of the bone marrow. This includes the morphology of the abnormal cells, analysis of cell surface markers (immunophenotyping), clone-specific chromosome abnormalities and molecular changes. These results are incorporated in the World Health Organization (WHO) classification of tumours of haematopoietic and lymphoid tissues; the subclassification of acute leukaemias is shown in Box 24.47. The features in the bone marrow not only provide an accurate diagnosis but also give valuable prognostic information, allowing therapy to be tailored to the patient's disease.

Acute leukaemia

There is a failure of cell maturation in acute leukaemia. Proliferation of cells which do not mature leads to an accumulation of useless cells which take up more and more marrow space at the expense of the normal haematopoietic elements. Eventually, this proliferation spills into the blood. Acute myeloid leukaemia (AML) is about four times more common than acute lymphoblastic leukaemia (ALL) in adults. In children the proportions are reversed, the lymphoblastic variety being more common. The clinical features are usually those of bone marrow failure (anaemia, bleeding or infection—pp. 997, 1002 and 1004).

24.47 WHO classification of acute leukaemia

Acute myeloid leukaemia (AML) with recurrent genetic abnormalities

- AML with t(8;21) gene product AML/ETO
- AML with eosinophilia inv(16) or t(16;16), gene product CBFβ/MYH11
- Acute promyelocytic leukaemia t(15;17), gene product PML/RARA
- AML with 11q23 abnormalities (MLL)

Acute myeloid leukaemia with multilineage dysplasia

- e.g. Following a myelodysplastic syndrome

Acute myeloid leukaemia and myelodysplastic syndromes, therapy-related

- e.g. Alkylating agent or topoisomerase II inhibitor

Acute myeloid leukaemia not otherwise specified

- e.g. AML with or without differentiation, acute myelomonocytic leukaemia, erythroleukaemia, megakaryoblastic leukaemia, myeloid sarcoma

Acute lymphoblastic leukaemia (ALL)

- Precursor B ALL
- Precursor T ALL

Investigations

Blood examination usually shows anaemia with a normal or raised MCV. The leucocyte count may vary from as low as $1 \times 10^9/L$ to as high as $500 \times 10^9/L$ or more. In the majority of patients the count is below $100 \times 10^9/L$. Severe thrombocytopenia is usual but not invariable. The appearance of blast cells in the blood film is usually diagnostic. Sometimes the blast cell count may be very low in the peripheral blood and a bone marrow examination is necessary to confirm the diagnosis.

The bone marrow is usually hypercellular, with replacement of normal elements by leukaemic blast cells in varying degrees (but more than 20% of the cells)(Fig. 24.26). The presence of Auer rods in the cytoplasm of blast cells indicates a myeloblastic type of leukaemia. Illustrations of immunophenotyping and chromosome analysis are shown in Figure 24.27.

Management

The general strategy for acute leukaemia is shown in Figure 24.28. The first decision must be whether or not to give specific treatment. This is generally aggressive, has a number of side-effects, and may not be appropriate for the very elderly or patients with other serious disorders

Fig. 24.26 Acute myeloid leukaemia. Bone marrow aspirate showing infiltration with large blast cells which display nuclear folding and prominent nucleoli.

Fig. 24.28 Treatment strategy in acute leukaemia.

(Chs 7 and 11). In these patients supportive treatment can effect considerable improvement in well-being.

Specific therapy

If a decision to embark on specific therapy has been taken, the patient should be prepared as recommended in Box 24.48. It is unwise to attempt aggressive management of acute leukaemia unless adequate services are available for the provision of supportive therapy.

The aim of treatment is to destroy the leukaemic clone of cells without destroying the residual normal stem cell compartment from which repopulation of

Fig. 24.27 Investigation of acute lymphoblastic leukaemia (ALL). **A** Flow cytometric analysis of blasts labelled with the fluorescent antibodies anti-CD19 (y axis) and anti-CD10 (x axis). ALL blasts are positive for both CD19 and CD10 (arrow). **B** Chromosome analysis (karyotype) of blasts showing additional chromosomes X, 4, 6, 7, 14, 18 and 21.

24.48 Preparation for specific therapy in acute leukaemia

- Existing infections identified and treated (e.g. urinary tract infection, oral candidiasis, dental, gingival and skin infections)
- Anaemia corrected with red cell concentrate transfusion
- Thrombocytopenic bleeding controlled with platelet transfusions
- If possible, central venous catheter (e.g. Hickman line) inserted to facilitate access to the circulation for delivery of chemotherapy
- Therapeutic regimen carefully explained to the patient and informed consent obtained

the haematopoietic tissues will occur. There are three phases:

- **Remission induction.** In this phase, the bulk of the tumour is destroyed by combination chemotherapy. The patient goes through a period of severe bone marrow hypoplasia, requiring intensive support and inpatient care from a specially trained multidisciplinary team.
- **Remission consolidation.** If remission has been achieved, residual disease is attacked by therapy during the consolidation phase. This consists of a number of courses of chemotherapy, again resulting in periods of marrow hypoplasia. In poor-prognosis leukaemia this may include bone marrow transplantation.
- **Remission maintenance.** If the patient is still in remission after the consolidation phase for ALL, a period of maintenance therapy is given, consisting of a repeating cycle of drug administration. This may extend for up to 3 years if relapse does not occur and is usually given on an outpatient basis.

In patients with ALL it is necessary to give prophylactic treatment to the central nervous system, as this is a sanctuary site where standard therapy does not penetrate. This usually consists of a combination of cranial irradiation, intrathecal chemotherapy and high-dose methotrexate, which crosses the blood-brain barrier.

Thereafter, specific therapy is discontinued and the patient observed.

The detail of the schedules for these treatments can be found in specialist texts. The drugs most commonly employed are listed in Box 24.49. Generally, if a patient

fails to go into remission with induction treatment, alternative drug combinations may be tried but the outlook is poor unless remission can be achieved. Disease which relapses during treatment or soon after the end of treatment carries a poor prognosis and is difficult to treat. The longer after the end of treatment that relapse occurs, the more likely it is that further treatment will be effective.

In some patients, alternative chemotherapy, not designed to achieve remission, may be used to curb excessive leucocyte proliferation. Drugs used for this purpose include hydroxycarbamide and mercaptopurine. The aim is to reduce the leucocyte count without inducing bone marrow failure.

Supportive therapy

Aggressive and potentially curative therapy which involves periods of severe bone marrow failure would not be possible without adequate and skilled supportive care. The following problems commonly arise.

Anaemia. Anaemia is treated with red cell concentrate transfusions.

Bleeding. Thrombocytopenic bleeding requires platelet transfusions, unless the bleeding is trivial. Prophylactic platelet transfusion should be given to maintain the platelet count above $10 \times 10^9/L$. Coagulation abnormalities occur and need accurate diagnosis and treatment as appropriate (p. 1049).

Infection. Fever ($> 38^\circ C$) lasting over 1 hour in a neutropenic patient indicates possible septicaemia. Parenteral broad-spectrum antibiotic therapy is essential. Empirical therapy is given with a combination of an aminoglycoside (e.g. gentamicin) and a broad-spectrum penicillin (e.g. piperacillin/tazobactam). This combination is synergistic and bactericidal and should be continued for at least 3 days after the fever has resolved. The organisms most commonly associated with severe neutropenia are Gram-positive bacteria, such as *Staphylococcus aureus* and *Staph. epidermidis*, which are present on the skin and gain entry via cannulae and central lines. Gram-negative infections often originate from the gastrointestinal tract, which is affected by chemotherapy-induced mucositis; organisms such as *Escherichia coli*, *Pseudomonas* and *Klebsiella* spp. are more likely to cause rapid clinical deterioration and must be covered with the initial empirical therapy. Gram-positive infection may require vancomycin therapy.

Patients with ALL are susceptible to infection with *Pneumocystis jirovecii* (p. 395), which causes a severe pneumonia. Prophylaxis with co-trimoxazole is given during chemotherapy. Diagnosis can be difficult and may require either bronchoalveolar lavage or open lung biopsy. Treatment is with high-dose co-trimoxazole, initially intravenously, changing to oral treatment as soon as possible.

Oral and pharyngeal monilial infection is common. Fluconazole is effective for the treatment of established local infection. Prophylaxis against systemic fungal infections with either fluconazole or itraconazole is usual practice during intensive chemotherapy.

For systemic fungal infection with *Candida* or aspergillosis, intravenous amphotericin is required for at least 3 weeks, but is nephrotoxic and hepatotoxic. Lipid formulations of amphotericin have a lower incidence of renal toxicity and allow high-dose therapy for aspergillosis. New antifungal agents such as caspofungin and voriconazole are also available (p. 157).

24.49 Drugs commonly used in the treatment of acute leukaemia

Phase	ALL	AML
Induction	Vincristine (i.v.) Prednisolone (oral) L-asparaginase (i.m.) Daunorubicin (i.v.) Methotrexate (intrathecal)	Daunorubicin (i.v.) Cytarabine (i.v.) Etoposide (i.v. and oral)
Consolidation	Daunorubicin (i.v.) Cytarabine (i.v.) Etoposide (i.v.) Methotrexate (i.v.)	Cytarabine (i.v.) Amsacrine (i.v.) Mitoxantrone (i.v.)
Maintenance	Prednisolone (oral) Vincristine (i.v.) Mercaptopurine (oral) Methotrexate (oral)	

Herpes simplex infection (p. 321) occurs frequently around the lips and nose during ablative therapy for acute leukaemia, and is treated with aciclovir. This may also be prescribed prophylactically to patients with a history of cold sores or elevated antibody titres to herpes simplex. Herpes zoster manifesting as chicken pox or, after reactivation, as shingles (p. 314) should be treated in the early stage with high-dose aciclovir, as it can be fatal in immunocompromised patients.

The value of isolation facilities, such as laminar flow rooms, is debatable but may contribute to staff awareness of careful reverse barrier nursing practice. The isolation is often psychologically stressful for the patient.

Metabolic problems. Frequent monitoring of fluid balance and renal, hepatic and haemostatic function is necessary. Patients are often severely anorexic as a consequence of the side-effects of therapy; they may find drinking difficult and hence require intravenous fluids and electrolytes. Renal toxicity occurs with some antibiotics (e.g. aminoglycosides) and antifungal agents (amphotericin). Cellular breakdown during induction therapy (tumour lysis syndrome) releases intracellular ions and nucleic acid breakdown products, causing hyperkalaemia, hyperuricaemia, hyperphosphataemia and hypocalcaemia. This may cause renal failure. Allopurinol and intravenous hydration are given to try to prevent this. In patients at high risk of tumour lysis syndrome prophylactic rasburicase (a recombinant urate oxidase enzyme) can be used. Occasionally, dialysis may be required.

Psychological problems. Psychological support is a key aspect of care. Patients should be kept informed, and their questions answered and fears allayed as far as possible. An optimistic attitude from the staff is vital. Delusions, hallucinations and paranoia are not uncommon during periods of severe bone marrow failure and septicaemic episodes, and should be met with patience and understanding.

Bone marrow transplantation

This is described on pages 1013–1014. Indications for BMT are shown in Box 24.27 (p. 1013). In patients with high-risk acute leukaemia, allogeneic BMT can improve 5-year survival from 20% to around 50%.

24.50 Outcome in adult acute leukaemia

Disease/risk	Risk factors	5-year overall survival
AML		
Good risk	Promyelocytic leukaemia t(15;17) t(8;21) inv 16 or t(16;16)	76%
Poor risk	Cytogenetic abnormalities –5, –7, del 5q, abn(3q), complex (≥ 5)	21%
Intermediate risk	AML with none of the above	48%
ALL		
Poor risk	Philadelphia chromosome High white count > 100 × 10 ⁹ /L Abnormal short arm of chromosome 11 t(1;19)	20%
Standard	ALL with none of the above	37%

Prognosis

Without treatment, the median survival of patients with acute leukaemia is about 5 weeks. This may be extended to a number of months with supportive treatment. Patients who achieve remission with specific therapy have a better outlook. Around 80% of adult patients under 60 years of age with ALL or AML achieve remission, although remission rates are lower for older patients. However, the relapse rate continues to be high. Box 24.50 shows the survival in ALL and AML and the influence of prognostic features.

Advances in treatment have led to steady improvement in survival from leukaemia. Advances include the introduction of drugs such as ATRA (all transretinoic acid) in acute promyelocytic leukaemia, which has greatly reduced induction deaths from bleeding in this good-risk leukaemia. Current trials aim to improve survival, especially in standard and poor-risk disease, with strategies that include allogeneic BMT.

Chronic myeloid leukaemia (CML)

Chronic myeloid leukaemia is a myeloproliferative stem-cell disorder resulting in proliferation of all haematopoietic lineages but manifesting predominantly in the granulocytic series. Maturation of cells proceeds fairly normally. The disease occurs chiefly between the ages of 30 and 80 years, with a peak incidence at 55 years. It is rare, with an annual incidence in the UK of 1.8/100 000, and accounts for 20% of all leukaemias. The disease is found in all races.

Approximately 95% of patients with CML have a chromosome abnormality known as the Philadelphia (Ph) chromosome. This is a shortened chromosome 22 resulting from a reciprocal translocation of material with chromosome 9. The break on chromosome 22 occurs in the breakpoint cluster region (BCR). The fragment from chromosome 9 that joins the BCR carries the *abl* oncogene, which forms a chimeric gene with the remains of the BCR. This *BCR ABL* chimeric gene codes for a 210 kDa protein with tyrosine kinase activity, which plays a causative role in the disease as an oncogene (p. 56), influencing cellular proliferation, differentiation and survival. In some patients in whom conventional chromosomal analysis does not detect a Ph chromosome, the *BCR ABL* gene product is detectable by molecular techniques.

Natural history

The disease has three phases:

- A *chronic phase*, in which the disease is responsive to treatment and is easily controlled, typically lasting 3–5 years. With the introduction of imatinib therapy this phase has been prolonged to longer than 5 years in many patients.
- An *accelerated phase* (not always seen), in which disease control becomes more difficult.
- *Blast crisis*, in which the disease transforms into an acute leukaemia, either myeloid (70%) or lymphoblastic (30%), which is relatively refractory to treatment. This is the cause of death in the majority of patients; therefore survival is dictated by the timing of blast crisis, which cannot be predicted. Prior to imatinib therapy (see below) approximately 10% of patients per year would transform. In those treated with imatinib for up to 5 years, only between 0.5–2.5% have transformed each year.

24.51 Symptoms at presentation of chronic myeloid leukaemia	
Symptom	Present (%)
Tiredness	37
Weight loss	26
Breathlessness	21
Abdominal pain and discomfort	21
Lethargy	13
Anorexia	12
Sweating	11
Abdominal fullness	10
Bruising	7
Vague ill health	7

Patients who are Ph chromosome-negative and *BCR ABL*-negative tend to be older, mostly male, with lower platelet counts and higher absolute monocyte counts, and respond poorly to treatment, with a median survival of less than 1 year.

Clinical features

The common symptoms at presentation are shown in Box 24.51; about 25% of patients are asymptomatic at diagnosis. Splenomegaly is present in 90%; in about 10% the enlargement is massive, extending to over 15cm below the costal margin. A friction rub may be heard in cases of splenic infarction. Hepatomegaly occurs in about 50%. Lymphadenopathy is unusual.

Investigations

FBC results are variable between patients. There is usually a normocytic, normochromic anaemia. The leucocyte count can vary from 10 to $600 \times 10^9/L$. In about one-third of patients there is a very high platelet count, sometimes as high as $2000 \times 10^9/L$. In the blood film the full range of granulocyte precursors from myeloblasts to mature neutrophils is seen but the predominant cells are neutrophils and myelocytes (see Fig. 24.3, p. 989). Myeloblasts usually constitute less than 10% of all white cells. There is often an absolute increase in eosinophils and basophils, and nucleated red cells are common. If the disease progresses through an accelerated phase, the percentage of more primitive cells increases. Blast transformation is characterised by a dramatic increase in the number of circulating blasts. In patients with thrombocytosis, very high platelet counts may persist during treatment, in both chronic and accelerated phases, but usually drop dramatically at blast transformation. Basophilia tends to increase as the disease progresses.

Bone marrow should be obtained to confirm the diagnosis and phase of disease by morphology, chromosome analysis to demonstrate the presence of the Ph chromosome, and RNA analysis to demonstrate the presence of the *BCR ABL* gene product. Blood LDH levels are elevated and the uric acid level may be high due to increased cell breakdown.

Management

Chronic phase

Imatinib specifically inhibits *BCR ABL* tyrosine kinase activity and reduces the uncontrolled proliferation of white cells. It is recommended as first-line therapy in chronic phase CML, producing complete cytogenetic

EBM 24.52 Imatinib and chronic myeloid leukaemia

'As first-line therapy in CML, imatinib is better tolerated and induces a cytogenetic response in ~87% of cases at 18 months, compared with ~35% response to interferon + cytarabine.'

• O'Brien SG for the IRIS Investigators. *N Engl J Med* 2003; 348:994–1004.

response (disappearance of the Ph chromosome) in 76% at 18 months of therapy (Box 24.52). Patients are monitored by repeated bone marrow examination until in a complete cytogenetic response, and then by 3-monthly real-time quantitative polymerase chain reaction (PCR) for *BCR ABL* mRNA transcripts in blood. For those failing to respond or progress on imatinib, options include second-generation tyrosine kinase inhibitors such as dasatinib or nilotinib, allogeneic bone marrow transplantation (p. 1013) or classical cytotoxic drugs such as hydroxycarbamide (hydroxyurea) or interferon. Hydroxycarbamide was previously used widely for initial control of disease, and is still useful in this context or in palliative situations. It does not diminish the frequency of the Ph chromosome or affect the onset of blast cell transformation. Interferon- α was considered first-line treatment before imatinib was developed. It was given alone or with the chemotherapy agent Ara-C, and controlled CML chronic phase in about 70% of patients.

Accelerated phase and blast crisis

Management is more difficult. For patients presenting in accelerated phase, imatinib is indicated if the patient has not already received it. Hydroxycarbamide can be an effective single agent and low-dose cytarabine can also be tried. When blast transformation occurs, the type of blast cell should be determined. Response to appropriate acute leukaemia treatment (see Box 24.49) is better if disease is lymphoblastic than if myeloblastic. Given the very poor response in myeloblastic transformation, there is a strong case for supportive therapy only, particularly in older patients.

Patients progressing to advanced-phase disease on imatinib may respond to a second-generation tyrosine kinase inhibitor and may be considered for allogeneic BMT (p. 1013).

Chronic lymphocytic leukaemia (CLL)

This is the most common variety of leukaemia, accounting for 30% of cases. The male:female ratio is 2:1 and the median age at presentation is 65–70 years. In this disease B lymphocytes, which would normally respond to antigens by transformation and antibody formation, fail to do so. An ever-increasing mass of immuno-incompetent cells accumulates, to the detriment of immune function and normal bone marrow haematopoiesis.

Clinical features

The onset is very insidious. Indeed, in around 70% of patients the diagnosis is made incidentally on a routine FBC. Presenting problems may be anaemia, infections, painless lymphadenopathy, and systemic symptoms such as night sweats or weight loss. However, these more often occur later in the progress of the disease.

Investigations

The diagnosis is based on the peripheral blood findings of a mature lymphocytosis ($>5 \times 10^9/L$) with characteristic morphology and cell surface markers. Immunophenotyping reveals the lymphocytes to be monoclonal B cells expressing the B cell antigens CD19 and CD23, with either kappa or lambda immunoglobulin light chains and, characteristically, an aberrant T cell antigen, CD5.

Other useful investigations in CLL include a reticulocyte count and a direct Coombs test as autoimmune haemolytic anaemia may occur (p. 1025). Serum immunoglobulin levels should be estimated to establish the degree of immunosuppression, which is common and progressive. Bone marrow examination by aspirate and trephine is not essential for the diagnosis of CLL, but may be helpful in difficult cases, for prognosis (patients with diffuse marrow involvement have a poorer prognosis) and to monitor response to therapy. The main prognostic factor is stage of disease (Box 24.53); however, newer markers such as CD38 expression, mutations of IgV_H genes, and cytogenetic abnormalities of chromosome 11 or 17 may also suggest a poorer prognosis.

24.53 Staging of chronic lymphocytic leukaemia	
Clinical stage A (60% patients)	<ul style="list-style-type: none"> No anaemia or thrombocytopenia and fewer than three areas of lymphoid enlargement
Clinical stage B (30% patients)	<ul style="list-style-type: none"> No anaemia or thrombocytopenia, with three or more involved areas of lymphoid enlargement
Clinical stage C (10% patients)	<ul style="list-style-type: none"> Anaemia and/or thrombocytopenia, regardless of the number of areas of lymphoid enlargement

Management

No specific treatment is required for most clinical stage A patients unless progression occurs. Life expectancy is usually normal in older patients. The patient should be offered clear information about CLL, and be reassured about the 'benign' nature of the disease, as the diagnosis of leukaemia inevitably causes anxiety.

Treatment is only required if there is evidence of bone marrow failure, massive or progressive lymphadenopathy or splenomegaly, systemic symptoms such as weight loss or night sweats, a rapidly increasing lymphocyte count or autoimmune haemolytic anaemia or thrombocytopenia. Initial therapy for those requiring treatment (stages B and C) may consist of oral chemotherapy with the alkylating agent chlorambucil. This will reduce the abnormal lymphocyte mass and produce symptomatic improvement in most patients. More recently, the purine analogue fludarabine, in combination with the alkylating agent cyclophosphamide, has increased remission rates and disease-free survival, although there is an increased risk of infection. Bone marrow failure or autoimmune cytopenias may respond to corticosteroid treatment.

Supportive care is increasingly required in progressive disease, e.g. transfusions for symptomatic anaemia or thrombocytopenia, prompt treatment of infections

and, for some patients with hypogammaglobulinaemia, immunoglobulin replacement. Radiotherapy may be used for lymph nodes causing discomfort or local obstruction, and for symptomatic splenomegaly. Splenectomy may be required to improve low blood counts due to autoimmune destruction or to hypersplenism, and can relieve massive splenomegaly.

Prognosis

The overall median survival for patients with CLL is about 6 years. The majority of clinical stage A patients have a normal life expectancy but stage C patients have a median survival of between 2 and 3 years. Approximately 50% of patients die from infection and 30% of causes unrelated to CLL. Rarely, CLL transforms to an aggressive high-grade lymphoma, called Richter's transformation.

Prolymphocytic leukaemia

This is a variant of chronic lymphatic leukaemia found mainly in males over the age of 60 years; 25% of cases are of the T cell variety. There is massive splenomegaly with little lymphadenopathy and a very high leucocyte count, often in excess of $400 \times 10^9/L$; the characteristic cell is a large lymphocyte with a prominent nucleolus. Treatment is generally unsuccessful and the prognosis very poor. Leukapheresis, splenectomy and chemotherapy may be tried.

Hairy cell leukaemia

This is a rare chronic lymphoproliferative B cell disorder. The male:female ratio is 6:1 and the median age at diagnosis is 50 years. Presenting symptoms are those of general ill health and recurrent infections. Splenomegaly occurs in 90% but lymph node enlargement is unusual.

Severe neutropenia, monocytopenia and the characteristic hairy cells in the blood and bone marrow are typical. These cells usually have a B lymphocyte immunotype but they also characteristically express CD25 and CD103. A useful test is the demonstration that the acid phosphatase staining reaction in the cells is resistant to the action of tartrate.

Over recent years a number of treatments, including cladribine and deoxycoformycin, have been shown to produce long-lasting remissions.

Myelodysplastic syndrome (MDS)

This syndrome consists of a group of clonal haematopoietic disorders which represent steps in the progression to the development of leukaemia. It presents with consequences of bone marrow failure (anaemia, recurrent infections or bleeding), usually in older people (median age at diagnosis is 69 years). The overall incidence is 4/100 000 in the population, rising to more than 30/100 000 in the over-seventies. The blood film is characterised by cytopenias and abnormal-looking (dysplastic) blood cells, including macrocytic red cells and hypogranular neutrophils with nuclear hyper- or hyposegmentation. The bone marrow is hypercellular with dysplastic changes in all three cell lines. Blast cells may be increased but do not reach the 20% level which indicates acute leukaemia. Chromosome analysis frequently reveals abnormalities, particularly of chromosome 5 or 7. The WHO classification of MDS is shown in Box 24.54.

i 24.54 WHO classification of myelodysplastic syndromes	
Disease	Bone marrow findings
Refractory anaemia (RA)	Blasts < 5% Erythroid dysplasia only
Refractory anaemia with sideroblasts (RARS)	Blasts < 5% Ringed sideroblasts > 15%
Refractory cytopenias with multilineage dysplasia (RCMD)	Blasts < 5% 2–3 lineage dysplasia
Refractory anaemia with excess blasts (RAEB)	Blasts 5–20% 2–3 lineage dysplasia
Myelodysplastic syndrome with 5q–	Myelodysplastic syndrome associated with a del (5q) cytogenetic abnormality Blasts < 5% Often normal or increased blood platelet count
Myelodysplastic syndrome unclassified	None of the above or inadequate material

Management

For the majority of patients the disease is incurable, and supportive care with red cell and platelet transfusions is the mainstay of treatment. A trial of erythropoietin and granulocyte-colony-stimulating factor (G-CSF) is recommended in some patients with early disease to improve haemoglobin and white cell counts. Allogeneic bone marrow transplantation may afford a cure in younger patients. Transplantation should be preceded by intensive chemotherapy in those with more advanced disease.

Prognosis

Inevitably, MDS progresses to acute myeloid leukaemia, although the time to progression varies (from months to years) with the subtype of MDS, being slowest in refractory anaemia and most rapid in refractory anaemia with excess of blasts. Poor prognostic factors include blasts > 10% in the marrow, certain cytogenetic abnormalities and more than one cytopenia in the blood.

Lymphomas

These neoplasms arise from lymphoid tissues, and are diagnosed from the pathological findings on biopsy as Hodgkin or non-Hodgkin lymphoma. The majority are of B cell origin. Non-Hodgkin lymphomas are classified as low- or high-grade tumours on the basis of their proliferation rate.

- *High-grade tumours* divide rapidly, are typically present for a matter of weeks before diagnosis and may be life-threatening.
- *Low-grade tumours* divide slowly, may be present for many months before diagnosis and typically behave in an indolent fashion.

Hodgkin lymphoma (HL)

The histological hallmark of HL is the presence of Reed–Sternberg cells, large malignant lymphoid cells of B cell origin (Fig. 24.29). They are often only present in small

Fig. 24.29 Hodgkin lymphoma. In the centre of this lymph node biopsy is a large typical Reed–Sternberg cell with two nuclei containing a prominent eosinophilic nucleolus.

numbers but are surrounded by large numbers of reactive non-malignant T cells, plasma cells and eosinophils.

The epidemiology of HL is shown in Box 24.55 and its histological WHO classification in Box 24.56.

Nodular lymphocyte-predominant HL is slow-growing, localised and rarely fatal. Classical HL is divided into four histological subtypes from the appearance of the Reed–Sternberg cells and surrounding reactive cells. The nodular sclerosing type is more common in young patients and in women. Mixed cellularity is more common in the

24.56 WHO pathological classification of Hodgkin lymphoma (HL)		
Type	Histology classification	Proportion of HL
Nodular lymphocyte-predominant HL		5%
Classical HL	Nodular sclerosing	70%
	Mixed cellularity	20%
	Lymphocyte-rich	5%
	Lymphocyte-depleted	Rare

elderly. Lymphocyte-rich HL usually presents in men. Lymphocyte-depleted HL is rare and probably represents large-cell or anaplastic non-Hodgkin lymphoma.

Clinical features

There is painless rubbery lymphadenopathy, usually in the neck or supraclavicular fossae; the lymph nodes may fluctuate in size. Young patients with nodular sclerosing disease may have large mediastinal masses which are surprisingly asymptomatic but may cause dry cough and some breathlessness. Isolated subdiaphragmatic nodes occur in fewer than 10% at diagnosis. Hepatosplenomegaly may be present but does not always indicate disease in those organs. Spread is contiguous from one node to the next and extranodal disease, such as bone, brain or skin involvement, is rare.

24.57 Clinical stages of Hodgkin lymphoma (Ann Arbor classification)	
Stage	Definition
I	Involvement of a single lymph node region (I) or extralymphatic* site (I _e)
II	Involvement of two or more lymph node regions (II) or an extralymphatic site and lymph node regions on the same side of (above or below) the diaphragm (II _e)
III	Involvement of lymph node regions on both sides of the diaphragm with (III _e) or without (III) localised extralymphatic involvement or involvement of the spleen (III _s) or both (III _{se})
IV	Diffuse involvement of one or more extralymphatic tissues, e.g. liver or bone marrow
Each stage is subclassified:	
A	No systemic symptoms
B	Weight loss, drenching sweats
*The lymphatic structures are defined as the lymph nodes, spleen, thymus, Waldeyer's ring, appendix and Peyer's patches.	

Investigations

Treatment of HL depends upon the stage at presentation; therefore investigations aim not only to diagnose lymphoma but also to determine the extent of disease (Box 24.57).

- **FBC** may be normal. If a normochromic, normocytic anaemia or lymphopenia is present, this is a poor prognostic factor. An eosinophilia or a neutrophilia may be present.
- **ESR** may be raised.
- **Renal function tests** are required to ensure function is normal prior to treatment.
- **Liver function** may be abnormal in the absence of disease or may reflect hepatic infiltration. An obstructive pattern may be caused by nodes at the porta hepatis.
- **LDH measurements** showing raised levels are an adverse prognostic factor.
- **Chest X-ray** may show a mediastinal mass.
- **CT scan** of chest, abdomen and pelvis permits staging. Bulky disease (> 10 cm in a single node mass) is an adverse prognostic feature.
- **Lymph node biopsy** may be undertaken surgically or by percutaneous needle biopsy under radiological guidance (Fig. 24.30).

Fig. 24.30 CT-guided percutaneous needle biopsy of retroperitoneal nodes involved by lymphoma.

Management

Historically, radiotherapy to lymph nodes alone has been used to treat localised stage IA or stage IIA disease effectively with no adverse prognostic features. Careful planning of radiotherapy is required to limit the doses delivered to normal tissues. Fertility is usually preserved after radiotherapy. Young women receiving breast irradiation during the treatment of chest disease have an increased risk of breast cancer and should participate in a screening programme. Patients continuing to smoke after lung irradiation are at particular risk of lung cancer.

Recent data have, however, shown that patients with early-stage disease have better outcomes if chemotherapy is included in their treatment. The majority of HL patients are now treated with chemotherapy and adjunctive radiotherapy. The ABVD regimen (doxorubicin, vinblastine, bleomycin and dacarbazine) is widely used in the UK. Standard therapy of early-stage patients usually includes additional treatment with radiotherapy to the involved lymph nodes after four courses of ABVD. Treatment response is assessed clinically and by repeat CT and newer scanning modalities such as positron emission tomography (PET). ABVD chemotherapy can cause cardiac and pulmonary toxicity, due to doxorubicin and bleomycin, respectively. The incidence of infertility and secondary myelodysplasia/AML is low with this regime.

Patients with advanced-stage disease are most commonly managed with chemotherapy alone. Standard treatment in the UK is 6–8 cycles of ABVD, followed by an assessment of response. As with early disease, achieving PET-negative remission predicts a better long-term remission rate. Overall, the long-term disease control/cure rates are lower with advanced disease.

Patients with disease which is resistant to therapy may be considered for autologous bone marrow transplantation (BMT) (p. 1014).

Prognosis

Over 90% of patients with early-stage HL achieve complete remission when treated with chemotherapy followed by involved field radiotherapy, and the great majority are cured. The major challenge is how to reduce treatment intensity, and hence long-term toxicity, without reducing the excellent cure rates in this group.

24.58 The Hasenclever prognostic index for advanced Hodgkin lymphoma

Score 1 for each of the following risk factors present at diagnosis:

- Age > 45 years
- Male gender
- Serum albumin < 40 g/L
- Hb < 105 g/L
- Stage IV disease
- WBC > $15 \times 10^9/L$
- Lymphopenia < $0.6 \times 10^9/L$

Score	5-year rate of freedom from progression (%)	5-year rate of overall survival (%)
0–1	79	90
≥ 2	60	74
≥ 3	55	70
≥ 4	47	59

Between 50 and 70% of those with advanced-stage HL can be cured. The Hasenclever index (Box 24.58) can be helpful in assigning approximate chances of cure when discussing treatment plans with patients. Patients who fail to respond to initial chemotherapy have a poor prognosis but some may achieve long-term survival after autologous BMT. Patients relapsing within a year of initial chemotherapy have a good salvage rate with autologous BMT. Patients relapsing after 1 year may obtain long-term survival with further chemotherapy alone.

Non-Hodgkin lymphoma (NHL)

NHL represents a monoclonal proliferation of lymphoid cells of B cell (70%) or T cell (30%) origin. The incidence of these tumours increases with age, to 62.8/million population per annum at age 75 years, and the overall rate is increasing at about 3% per year.

The epidemiology of NHL is shown in Box 24.59. It has been difficult to establish a reproducible and clinically useful histological classification. The current WHO classification stratifies according to cell lineage. Clinically, the most important factor is grade, which is a reflection of proliferation rate. High-grade NHL has high proliferation rates, rapidly produces symptoms, is fatal if untreated, but is potentially curable. Low-grade NHL has low proliferation rates, may be asymptomatic for many months before presentation, runs an indolent course, but is not curable by conventional therapy. Of all cases of NHL, 85% are either high-grade diffuse large B-cell NHL or low-grade follicular NHL (Fig. 24.31). Other

24.59 Epidemiology and aetiology of non-Hodgkin lymphoma

Incidence

- 12 new cases/100 000 people/year

Sex ratio

- Slight male excess

Age

- Median age 65–70 years

Aetiology

- No single causative abnormality described
- Lymphoma is a late manifestation of HIV infection (p. 401)
- Specific lymphoma types are associated with EBV, human herpes virus 8 (HHV8) and human T-cell lymphotropic virus (HTLV) infection
- Gastric lymphoma can be associated with *Helicobacter pylori* infection
- Some lymphomas are associated with specific chromosome lesions; the t(14:18) translocation in follicular lymphoma results in the dysregulated expression of the BCL-2 gene product, which inhibits apoptotic cell death
- Lymphoma occurs in congenital immunodeficiency states and in immunosuppressed patients after organ transplantation

forms of NHL, including mantle cell lymphoma and MALT lymphomas, are less common.

Clinical features

Unlike Hodgkin lymphoma, NHL is often widely disseminated at presentation, including in extranodal sites. Patients present with lymph node enlargement which may be associated with systemic upset: weight loss, sweats, fever and itching. Hepatosplenomegaly may be present. Extranodal involvement is more common in T cell disease and involves the bone marrow, gut, thyroid, lung, skin, testis, brain and, more rarely, bone. Bone marrow involvement is more common in low-grade (50–60%) than high-grade (10%) disease. Compression syndromes may occur, including gut obstruction, ascites, superior vena caval obstruction and spinal cord compression.

The same staging system (see Box 24.57) is used for both HL and NHL, but NHL is more likely to be stage III or IV at presentation.

A

B

Fig. 24.31 Histology of non-Hodgkin lymphoma. **A** (Low-grade) follicular or nodular pattern. **B** (High-grade) diffuse pattern.

Investigations

These are as for HL, but in addition the following should be performed:

- *Routine bone marrow aspiration and trephine.*
- *Immunophenotyping of surface antigens to distinguish T and B cell tumours.* This may be done on blood, marrow or nodal material.
- *Immunoglobulin determination.* Some lymphomas are associated with IgG or IgM paraproteins, which serve as markers for treatment response.
- *Measurement of uric acid levels.* Some very aggressive high-grade NHLs are associated with very high urate levels, which can precipitate renal failure when treatment is started.
- *HIV testing.* This may be appropriate if risk factors are present (p. 385).

Management

Low-grade NHL

Asymptomatic patients may not require therapy. Indications for treatment include marked systemic symptoms, lymphadenopathy causing discomfort or disfigurement, bone marrow failure or compression syndromes. The options are:

- *Radiotherapy.* This can be used for localised stage I disease, which is rare.
- *Chemotherapy.* Most patients will respond to oral therapy with chlorambucil, which is well tolerated but not curative. More intensive intravenous chemotherapy in younger patients produces better quality of life but no survival benefit.
- *Monoclonal antibody therapy.* Humanised monoclonal antibodies can be used to target surface antigens on tumour cells, and induce tumour cell apoptosis directly. The anti-CD20 antibody rituximab has been shown to induce durable clinical responses in up to 60% of patients when given alone, and acts synergistically when given with chemotherapy. Rituximab in combination with cyclophosphamide, vincristine and prednisolone (R-CVP) is recommended as first-line therapy.
- *Transplantation.* Particular interest centres on the role of high-dose chemotherapy and bone marrow transplantation in patients with relapsed disease. Such high-dose therapy improves disease-free survival but longer follow-up is awaited before conclusions can be drawn about cure.

High-grade NHL

Patients with high-grade NHL need treatment at initial presentation:

- *Chemotherapy.* The majority (> 90%) are treated with intravenous combination chemotherapy, typically with the CHOP regimen (cyclophosphamide, doxorubicin, vincristine and prednisolone).
- *Radiotherapy.* A few stage I patients without bulky disease may be suitable for radiotherapy. Radiotherapy is also indicated for a residual localised site of bulk disease after chemotherapy, and for spinal cord and other compression syndromes.
- *Monoclonal antibody therapy.* When combined with CHOP chemotherapy, rituximab (R) increases the complete response rates and improves overall survival. R-CHOP is currently recommended as first-

EBM 24.60 Autologous bone marrow transplantation in non-Hodgkin lymphoma

'The addition of autologous bone marrow transplantation to conventional salvage chemotherapy improves survival from 32% to 54% in relapsed high-grade NHL.'

• Philip T, et al. *N Engl J Med* 1995; 333:1540–1545.

For further information:  www.lymphoma.org.uk

line therapy for those with stage II or greater diffuse large-cell lymphoma.

- *Bone marrow transplantation.* Autologous BMT benefits patients with relapsed chemosensitive disease (Box 24.60).

Prognosis

Low-grade NHL runs an indolent remitting and relapsing course, with an overall median survival of 10 years. Transformation to a high-grade NHL is associated with poor survival.

In high-grade NHL, some 80% of patients overall respond initially to therapy but only 35% will have disease-free survival at 5 years. The prognosis for patients with NHL is further refined according to the international prognostic index (IPI). For high-grade NHL, 5-year survival ranges from 75% in those with low-risk scores (age < 60 years, stage I or II, one or fewer extranodal sites, normal LDH and good performance status) to 25% in those with high-risk scores (increasing age, advanced stage, concomitant disease and a raised LDH).

Relapse is associated with a poor response to further chemotherapy (< 10% 5-year survival), but in patients under 65 years, bone marrow transplantation improves survival.

Paraproteinaemias

A gammopathy refers to over-production of one or more classes of immunoglobulin. It may be polyclonal in association with acute or chronic inflammation, such as infection, sarcoidosis, autoimmune disorders or some malignancies. Alternatively, a monoclonal increase in a single immunoglobulin class may occur in association with normal or reduced levels of the other immunoglobulins. Such monoclonal proteins (also called M-proteins, paraproteins or monoclonal gammopathies) occur as a feature of myeloma, lymphoma and amyloidosis, in connective tissue disease such as rheumatoid arthritis or polymyalgia rheumatica, in infection such as HIV, and in solid tumours. In addition, they may be present with no underlying disease. Gammopathies are detected by plasma immunoelectrophoresis.

Monoclonal gammopathy of uncertain significance (MGUS)

In this condition (also known as benign monoclonal gammopathy or monoclonal gammopathy unclassified (MGU)), a paraprotein is present in the blood but with no other features of myeloma, Waldenström macroglobulinaemia (see below), lymphoma or related disease. It is a common condition associated with increasing age; a paraprotein can be found in 1% of the population aged over 50 years, increasing to 5% over 80 years.

Clinical features and investigations

Patients are usually asymptomatic, and the paraprotein is found on blood testing for other reasons. The routine blood count and biochemistry are normal, the paraprotein is usually present in small amounts with no associated immune paresis, and there are no lytic bone lesions. The bone marrow may have increased plasma cells but these usually constitute less than 10% of nucleated cells.

Prognosis

After follow-up of 20 years, only one-quarter will progress to myeloma or a related disorder. There is no way of predicting progression in an individual patient, and if investigations remain stable, annual monitoring is all that is required.

Waldenström macroglobulinaemia

This is a low-grade lymphoplasmacytoid lymphoma associated with an IgM paraprotein, causing clinical features of hyperviscosity syndrome. It is a rare tumour occurring in the elderly and affects a slight excess of males.

Patients classically present with features of hyperviscosity, such as nosebleeds, bruising, confusion and visual disturbance. However, presentation may be with anaemia, systemic symptoms, splenomegaly or lymphadenopathy. Patients are found on investigation to have an IgM paraprotein associated with a raised plasma viscosity. The bone marrow has a characteristic appearance, with infiltration of lymphoid cells and prominent mast cells.

Management

Severe hyperviscosity and anaemia may necessitate plasmapheresis to remove IgM and make blood transfusion possible. Treatment with alkylating agents, such as chlorambucil, is effective but rather slow; fludarabine may be more effective in this disease. The monoclonal anti-CD20 antibody rituximab can also be effective. The median survival is 5 years.

Multiple myeloma

This is a malignant proliferation of plasma cells. Normal plasma cells are derived from B cells and produce immunoglobulins which contain heavy and light chains. Normal immunoglobulins are polyclonal, which means that a variety of heavy chains are produced and each may be of kappa or lambda light chain type (p. 75). In myeloma, plasma cells produce immunoglobulin of a single heavy and light chain, a monoclonal protein commonly referred to as a paraprotein. In some cases only light chain is produced and this appears in the urine as Bence Jones proteinuria. The frequency of different paraprotein types in myeloma is shown in Box 24.61.

24.61 Classification of multiple myeloma

Type of paraprotein	Relative frequency (%)
IgG	55
IgA	21
Light chain only	22
Others (D, E, non-secretory)	2

Although a small number of malignant plasma cells are present in the circulation, the majority are present in the bone marrow. The malignant plasma cells produce cytokines which stimulate osteoclasts and result in net bone reabsorption. The resulting lytic lesions cause bone pain, fractures and hypercalcaemia. Marrow involvement can result in anaemia or pancytopenia.

Clinical features and investigations

The incidence of myeloma is 4/100 000 new cases per annum, with a male:female ratio of 2:1. The median age of diagnosis is 60–70 years and the disease is more common in Afro-Caribbeans. The clinical features are demonstrated in Figure 24.32.

Diagnosis of myeloma requires two of the following criteria:

- increased malignant plasma cells in the bone marrow
- serum and/or urinary paraprotein
- skeletal lytic lesions.

Bone marrow aspiration, plasma and urinary electrophoresis, and a skeletal survey are thus required. Other investigations are listed in Box 24.62. Normal immunoglobulin levels, i.e. the absence of immunoparesis, should cast doubt on the diagnosis. Paraproteinaemia can cause an elevated ESR (p. 82), but this is a non-specific test; only approximately 5% of patients with a persistently elevated ESR above 100 mm/hr have underlying myeloma.

Management

If patients are asymptomatic, treatment may not be required.

24.62 Rationale for investigations in multiple myeloma

Question	Investigations
Presence of lytic lesions, bone fractures?	X-rays (skeletal survey) ¹ Alkaline phosphatase ¹
Spinal cord compression?	MRI spine ²
Presence of urine or plasma paraprotein?	Blood and urine protein electrophoresis
Type of paraprotein?	Blood and urine immunoelectrophoresis
Amount of paraprotein?	Quantification of paraprotein
Degree of immune paresis?	Plasma immunoglobulins
Presence of plasma cells in bone marrow?	Bone marrow aspiration and trephine
Degree of bone marrow failure?	Full blood count
Renal function?	Urea and electrolytes, creatinine, urate
Presence of hypercalcaemia?	Blood calcium and albumin
Degree of haemostasis?	Coagulation screen
Poor prognostic factors at diagnosis?	β_2 microglobulin > 5.5 mg/L, albumin < 35 g/L

¹In the absence of fractures, the plasma alkaline phosphatase and isotope bone scan will be normal despite the lytic lesions.

²All investigations shown above are routine in myeloma, except the MRI spine, which is reserved for those with clinical indications.

Fig. 24.32 Manifestations of multiple myeloma.

Immediate support

- High fluid intake to treat renal impairment and hypercalcaemia (p. 764).
- Analgesia for bone pain.
- Bisphosphonates for hypercalcaemia and to delay other skeletal related events (p. 1119).
- Allopurinol to prevent urate nephropathy.
- Plasmapheresis, as necessary, for hyperviscosity.

Chemotherapy ± bone marrow transplantation

Myeloma therapy has improved with the addition of thalidomide to first-line treatments. In older patients, thalidomide combined with the alkylating agent melphalan and prednisolone has increased the median overall survival to 51 months. Thalidomide has both anti-angiogenic effects against tumour blood vessels and immunomodulatory effects. It can cause somnolence, constipation and a peripheral neuropathy. It is vital that females of child-bearing age use adequate contraception, as thalidomide is teratogenic. Treatment is administered until paraprotein levels have stopped falling. This is termed 'plateau phase' and can last for weeks or years.

In younger, fitter patients standard treatment includes first-line chemotherapy to maximum response and then an autologous stem-cell transplantation, which improves quality of life and prolongs survival (Box

24.63) but does not cure myeloma. The role of allogeneic transplantation (p. 1013) remains under evaluation. Studies are in progress on the role of reduced-intensity allografting after autologous transplantation in younger patients.

When myeloma progresses, treatment is given to induce a further plateau phase. In the UK at present, the proteasome inhibitor bortezomib is recommended. Successive relapses respond less well to treatment and the interval between them tends to be shorter.

Radiotherapy

This is effective for localised bone pain not responding to simple analgesia and for pathological fractures. It is also useful for the emergency treatment of spinal cord compression complicating extradural plasmacytomas.

EBM 24.63 Autologous bone marrow transplantation in multiple myeloma

'The addition of autologous bone marrow transplantation to conventional intravenous chemotherapy improves survival from 42 to 54 months.'

- Child JA, et al. N Engl J Med 2003; 348:1875–1883.

For further information:  www.ukmf.org.uk

Bisphosphonates

Long-term bisphosphonate therapy reduces bone pain and skeletal events. These drugs protect bone (p. 1119) and may cause apoptosis of malignant plasma cells. Osteonecrosis of the jaw may be associated with long-term use; therefore regular dental review is advisable.

Prognosis

Poor prognostic features include high β_2 -microglobulin, low albumin, low haemoglobin or high calcium at presentation. Although new treatments have increased overall survival, fewer than 5% of patients survive longer than 10 years with standard treatment. The recent advances in therapy with thalidomide and bortezomib and the development of other new drugs, such as the thalidomide derivative lenalidomide, may improve this in future.

24.64 Haematological malignancy in old age

- **Median age:** approximately 70 years for most haematological malignancies.
- **Poor-risk biological features:** adverse cytogenetics or the presence of a multidrug resistance phenotype are more frequent.
- **Prognosis:** increasing age is an independent adverse variable in acute leukaemia and aggressive lymphoma.
- **Chemotherapy:** may be less well tolerated. Older people are more likely to have antecedent cardiac, pulmonary or metabolic problems, tolerate systemic infection less well and metabolise cytotoxic drugs differently.
- **Cure rates:** similar to those in younger patients, in those who do tolerate treatment.
- **Decision to treat:** should be based on the individual's biological status, the level of social support available, and the patient's wishes and those of the immediate family, but not on chronological age.

APLASTIC ANAEMIA

Primary idiopathic acquired aplastic anaemia

This is a rare disorder in Europe and North America, with 2–4 new cases per million population per annum; the disease is much more common in certain other parts of the world: for example, east Asia. The basic problem is failure of the pluripotent stem cells, producing hypoplasia of the bone marrow with a pancytopenia in the blood. The diagnosis rests on exclusion of other causes of secondary aplastic anaemia (see below) and rare congenital causes such as Fanconi's anaemia.

Clinical features and investigations

Patients present with symptoms of bone marrow failure, usually anaemia or bleeding, and less commonly infections. An FBC demonstrates pancytopenia, low reticulocytes and often macrocytosis. Bone marrow aspiration and trephine reveal hypocellularity.

Management

All patients will require blood product support and aggressive management of infection. The prognosis of

severe aplastic anaemia managed with supportive therapy only is poor and more than 50% of patients die, usually in the first year. The curative treatment for patients under 30 years of age with severe idiopathic aplastic anaemia is allogeneic bone marrow transplantation if there is an available donor (p. 1013). Those with a compatible sibling donor should proceed to transplantation as soon as possible; they have a 75–90% chance of long-term cure. In older patients, immunosuppressive therapy with ciclosporin and antithymocyte globulin gives 5-year survival rates of 75%. Such patients may relapse or other clonal disorders of haematopoiesis may evolve, such as paroxysmal nocturnal haemoglobinuria (p. 1027), myelodysplastic syndrome (p. 1036) and even acute myeloid leukaemia (p. 1031). They must be followed up long-term.

Secondary aplastic anaemia

Causes of this condition are listed in Box 24.65. It is not practical to list all the drugs which have been suspected of causing aplasia. It is important to check the reported side-effects of all drugs taken over the preceding months. In some instances the cytopenia is more selective and affects only one cell line, most often the neutrophils. Frequently, this is an incidental finding with no ill health. It probably has an immune basis but this is difficult to prove.

The clinical features and methods of diagnosis are the same as for primary idiopathic aplastic anaemia. An underlying cause should be treated or removed but otherwise management is as for the idiopathic form.

24.65 Causes of acquired aplastic anaemia

- **Drugs**
 - Cytotoxic drugs
 - Antibiotics—chloramphenicol, sulphonamides
 - Antirheumatic agents—penicillamine, gold, phenylbutazone, indometacin
 - Antithyroid drugs
 - Anticonvulsants
 - Immunosuppressives—azathioprine
- **Chemicals**
 - Benzene toluene solvent misuse—glue-sniffing
 - Insecticides—chlorinated hydrocarbons (DDT), organophosphates and carbamates (p. 218)
- **Radiation**
- **Viral hepatitis**
- **Pregnancy**
- **Paroxysmal nocturnal haemoglobinuria**

MYELOPROLIFERATIVE DISORDERS

These make up a group of chronic conditions characterised by clonal proliferation of marrow erythroid precursors (polycythaemia rubra vera, PRV), megakaryocytes (essential thrombocythaemia and myelofibrosis) or myeloid cells (chronic myeloid leukaemia; p. 1034). Although the majority of patients are classifiable as having one of these disorders, some have overlapping features and there is often progression from one

to another, e.g. PRV to myelofibrosis. The recent discovery of the molecular basis of these disorders will lead to changes in classification and treatment; a mutation in the gene on chromosome 9 encoding the signal transduction molecule *JAK-2* has been found in 97% of PRV cases and 50% of those with essential thrombocythaemia and myelofibrosis.

Myelofibrosis

In myelofibrosis the marrow is initially hypercellular, with an excess of abnormal megakaryocytes which release growth factors, e.g. platelet-derived growth factor, to the marrow microenvironment, resulting in a reactive proliferation of fibroblasts. As the disease progresses, the marrow becomes fibrosed.

Most patients present over the age of 50 years with lassitude, weight loss and night sweats. The spleen can be massively enlarged due to extramedullary haematopoiesis (blood cell formation outside the bone marrow), and painful splenic infarcts may occur.

The characteristic blood picture is a leucoerythroblastic anaemia, with circulating immature red blood cells (increased reticulocytes and nucleated red blood cells) and granulocyte precursors (myelocytes). The red cells are shaped like teardrops (teardrop poikilocytes), and giant platelets may be seen in the blood. The white count varies from low to moderately high, and the platelet count may be high, normal or low. Urate levels may be high due to increased cell breakdown, and folate deficiency is common. The marrow is often difficult to aspirate and a trephine biopsy shows an excess of megakaryocytes, increased reticulin and fibrous tissue replacement. The presence of a *JAK-2* mutation supports the diagnosis.

Management and prognosis

Median survival is 4 years from diagnosis, but ranges from 1 year to over 20 years. Treatment is directed at control of symptoms, e.g. red cell transfusions for anaemia. Folic acid should be given to prevent deficiency. Cytotoxic therapy with hydroxycarbamide may help control spleen size, the white cell count or systemic symptoms. Splenectomy may be required for a grossly enlarged spleen or symptomatic pancytopenia secondary to splenic pooling of cells and hypersplenism. Bone marrow transplantation may be considered for younger patients.

Essential thrombocythaemia

Malignant proliferation of megakaryocytes results in a raised level of circulating platelets that are often dysfunctional. Prior to making a diagnosis of essential thrombocythaemia, reactive causes of increased platelets must be excluded (p. 1004). The presence of a *JAK-2* mutation supports the diagnosis. Patients present at a median age of 60 years with vascular occlusion or bleeding events, or with an asymptomatic isolated raised platelet count. In most individuals the condition is chronic, with the platelet count gradually increasing. A very small percentage may transform to acute leukaemia and others to myelofibrosis.

Low-risk patients (age < 40 years, platelet count < $1000 \times 10^9/L$ and no bleeding or thrombosis) may not require treatment to reduce the platelet count. For those with a platelet count > $1000 \times 10^9/L$, with symptoms, or with other risk factors for thrombosis such as diabetes or hypertension, treatment to control platelets should

be given. Agents include oral hydroxycarbamide or anagrelide, an inhibitor of megakaryocyte maturation. Intravenous radioactive phosphorus (^{32}P) may be useful in old age. Aspirin therapy is recommended for all patients to reduce the risk of thrombosis and is particularly useful for those with digital ischaemia.

Polycythaemia rubra vera (PRV)

PRV occurs mainly in patients over the age of 40 years and presents either as an incidental finding of a high haemoglobin, or with symptoms of hyperviscosity, such as lassitude, loss of concentration, headaches, dizziness, blackouts, pruritus and epistaxis. Some patients present with manifestations of peripheral arterial disease or a cerebrovascular accident. Venous thromboembolism may also occur. Peptic ulceration is common, sometimes complicated by bleeding. Patients are often plethoric and the majority have a palpable spleen at diagnosis.

Investigation of polycythaemia is discussed on page 998. The diagnosis of PRV now rests upon the demonstration of a high haematocrit and the presence of the *JAK-2* mutation. In the occasional *JAK-2*-negative cases, a raised red cell mass and absence of causes of a secondary erythrocytosis must be established. The spleen is enlarged, neutrophil and platelet counts are frequently raised, an abnormal karyotype may be found in the marrow, and in vitro culture of the marrow can be used to demonstrate autonomous growth in the absence of added growth factors.

Management and prognosis

Aspirin reduces the risk of thrombosis. Venesection gives prompt relief of hyperviscosity symptoms. Between 400 and 500 mL of blood (less if the patient is elderly) are removed and the venesection is repeated every 5–7 days until the haematocrit is reduced to below 45%. Less frequent but regular venesection will maintain this level until the haemoglobin remains reduced because of iron deficiency.

Suppression of marrow proliferation with hydroxycarbamide or α -interferon may reduce the risk of vascular occlusion, control spleen size and reduce transformation to myelofibrosis. Radioactive phosphorus (5 mCi of ^{32}P i.v.) is reserved for older patients, as it increases the risk of transformation to acute leukaemia by 6- to 10-fold.

Median survival after diagnosis in treated patients exceeds 10 years. Some patients survive more than 20 years; however, cerebrovascular or coronary events occur in up to 60% of patients. The disease may convert to another myeloproliferative disorder, with about 15% developing myelofibrosis. Acute leukaemia develops principally in those patients who have been treated with radioactive phosphorus.

BLEEDING DISORDERS

Disorders of primary haemostasis

The initial formation of the platelet plug (see Fig. 24.6A, p. 993; also known as 'primary haemostasis') may fail in thrombocytopenia (p. 1003), von Willebrand disease (p. 1048), and also in platelet function disorders and diseases affecting the vessel wall.

Vessel wall abnormalities

Vessel wall abnormalities may be:

- congenital, such as hereditary haemorrhagic telangiectasia
- acquired, as in a vasculitis (p. 1112) or scurvy.

Hereditary haemorrhagic telangiectasia (HHT)

HHT is a dominantly inherited condition caused by mutations in the genes encoding endoglin and activin receptor-like kinase, which are endothelial cell receptors for transforming growth factor-beta (TGF- β), a potent angiogenic cytokine. Telangiectasia and small aneurysms are found on the fingertips, face and tongue, and in the nasal passages, lung and gastrointestinal tract. A significant proportion of these patients develop larger pulmonary arteriovenous malformations (PAVMs) that cause arterial hypoxaemia due to a right-to-left shunt. These predispose to paradoxical embolism, resulting in stroke or cerebral abscess. All patients with HHT should be screened for PAVMs; if these are found, ablation by percutaneous embolisation should be considered.

Patients present either with recurrent bleeds, particularly epistaxis, or with iron deficiency due to occult gastrointestinal bleeding. Treatment can be difficult because of the multiple bleeding points but regular iron therapy often allows the marrow to compensate for blood loss. Local cautery or laser therapy may prevent single lesions from bleeding. A variety of medical therapies have been tried but none has been found to be universally effective.

Ehlers–Danlos disease

Vascular Ehlers–Danlos syndrome (type 4) is a rare autosomal dominant disorder (1 in 100 000) caused by a defect in type 3 collagen which results in fragile blood vessels and organ membranes, leading to bleeding and organ rupture. Classical joint hypermobility (p. 1128) is often limited in this form of the disease but skin changes and facial appearance are typical. The diagnosis should be considered when there is a history of bleeding but normal laboratory tests.

Scurvy

Vitamin C deficiency affects the normal synthesis of collagen and results in a bleeding disorder characterised by perifollicular and petechial haemorrhage, bruising and subperiosteal bleeding. The key to diagnosis is the dietary history (p. 128).

Platelet functional disorders

Bleeding may result from thrombocytopenia (see Box 24.15, p. 1003) or from congenital or acquired abnormalities of platelet function. The most common acquired disorders are iatrogenic, resulting from the use of aspirin, clopidogrel, dipyridamole and the IIb/IIIa inhibitors to prevent arterial thrombosis (see Box 24.31, p. 1015). Inherited platelet function abnormalities are relatively rare. Congenital abnormalities may be due to deficiency of the membrane glycoproteins, e.g. Glanzmann's thrombasthenia (IIb/IIIa) or Bernard–Soulier disease (Ib), or due to the presence of defective platelet granules, e.g. a deficiency of dense (delta) granules (see Fig. 24.6A, p. 992) giving rise to storage pool disorders. The congenital macrothrombocytopathies, which are due to mutations in the

myosin heavy chain gene *MYH-9*, are characterised by large platelets, inclusion bodies in the neutrophils (Döhle bodies) and a variety of other features, including sensorineural deafness and renal abnormalities.

Apart from Glanzmann's thrombasthenia, these conditions are mild disorders with bleeding typically occurring after trauma or surgery but rarely spontaneously. Glanzmann's is an autosomal recessive condition associated with a variable but often severe bleeding disorder. These conditions are usually managed by local mechanical measures, but antifibrinolytics such as tranexamic acid may be useful and in severe bleeding platelet transfusion may be required. Recombinant VIIa is licensed for the treatment of resistant bleeding in Glanzmann's thrombasthenia.

Thrombocytopenia

Thrombocytopenia occurs in many disease processes, listed in Box 24.15 (p. 1003), many of which are discussed elsewhere in this chapter.

Idiopathic thrombocytopenic purpura (ITP)

ITP is mediated by autoantibodies, most often directed against the platelet membrane glycoprotein IIb/IIIa, which sensitise the platelet, resulting in premature removal from the circulation by cells of the reticulo-endothelial system. It is not a single disorder; some cases occur in isolation while others are associated with underlying immune dysregulation in conditions such as connective tissue diseases, HIV infection, B cell malignancies, pregnancy and certain drug therapies. However, the clinical presentation and pathogenesis are similar, whatever the cause of ITP.

Clinical features and investigations

The presentation depends on the degree of thrombocytopenia. Spontaneous bleeding typically occurs only when the platelet count is $< 20 \times 10^9/L$. At higher counts the patient may complain of easy bruising or sometimes epistaxis or menorrhagia. Many cases with counts of $> 50 \times 10^9/L$ are discovered by chance.

In adults ITP more commonly affects females and has an insidious onset. Unlike ITP in children, it is unusual for there to be a history of a preceding viral infection. Symptoms or signs of a connective tissue disease may be apparent at presentation or emerge several years later. Patients aged over 65 years should have a bone marrow examination to look for an accompanying B cell malignancy and appropriate autoantibody testing performed if a diagnosis of connective tissue disease is likely. HIV testing should be considered. The peripheral blood film is normal, apart from a greatly reduced platelet number, whilst the bone marrow reveals an obvious increase in megakaryocytes.

Management

Many patients with stable compensated ITP and a platelet count $> 30 \times 10^9/L$ do not require treatment to raise the platelet count, except at times of increased bleeding risk such as surgery and biopsy. First-line therapy for patients with spontaneous bleeding is with prednisolone 1 mg/kg daily to suppress antibody production and inhibit phagocytosis of platelets by reticuloendothelial cells. Administration of intravenous immunoglobulin (IVIg) can raise the platelet count by blocking antibody receptors on reticuloendothelial cells, and is combined

with corticosteroid therapy if there is severe haemostatic failure or a slow response to steroids alone. A similar effect can be obtained by administering intravenous anti-D which will bind red cells and saturate antibody receptors in RhD-positive individuals who have a spleen. Persistent or potentially life-threatening bleeding should be treated with platelet transfusion in addition to the other therapies.

The condition may become chronic, with remissions and relapses. Relapses should be treated by re-introducing corticosteroids. If a patient has two relapses, or primary refractory disease, splenectomy is considered with the precautions shown in Box 24.41 (p. 1024). Splenectomy produces complete remission in about 70% of patients and improvement in a further 20–25%, so that following splenectomy only 5–10% of patients require further medical therapy. If significant bleeding persists despite splenectomy, low-dose corticosteroid therapy, immunosuppressive therapy such as rituximab, ciclosporin and tacrolimus should be considered.

Coagulation disorders

Normal coagulation is explained in Figure 24.6 (p. 992). Coagulation factor deficiency may be congenital or acquired and may affect one or several of the coagulation factors (Box 24.66). Inherited disorders are almost uniformly related to decreased synthesis, as a result of mutation in the gene encoding a key protein in coagula-

tion. Von Willebrand disease is the most common inherited bleeding disorder. Haemophilia A and B are the most common single coagulation factor deficiencies, but deficiencies of all the other coagulation factors are seen. Acquired disorders may be due to under-production (e.g. in liver failure), increased consumption (e.g. in disseminated intravascular coagulation) or inhibition of function (such as heparin therapy or immune inhibitors of coagulation, e.g. acquired haemophilia A).

Haemophilia A

Factor VIII deficiency resulting in haemophilia A affects 1/10 000 individuals. It is the most common congenital coagulation factor deficiency. Factor VIII is primarily synthesised by the liver and endothelial cells, and has a half-life of about 12 hours. It is protected from proteolysis in the circulation by binding to von Willebrand factor (vWF).

Genetics

The factor VIII gene is located on the X chromosome. Severe haemophilia is associated with large deletions in the gene, while single-base changes more often result in moderate or mild disease (Box 24.67). As the factor VIII gene is on the X chromosome, haemophilia A is a sex-linked disorder (p. 50). Thus all daughters of haemophiliacs are obligate carriers and they, in turn, have a 1 in 4 chance of each pregnancy resulting in the birth of an affected male baby, a normal male baby, a carrier female or a normal female. Antenatal diagnosis by chorionic villous sampling is possible in families with a known mutation.

Haemophilia 'breeds true' within a family; all members have the same factor VIII gene mutation and a similarly severe or mild phenotype. Female carriers of haemophilia may have reduced factor VIII levels because of random inactivation of their normal X chromosome in the developing fetus (lyonisation). This can result in a mild bleeding disorder; thus all known or suspected carriers of haemophilia should have their factor VIII level measured.

Clinical features

The extent and patterns of bleeding are closely related to residual factor VIII levels. Patients with severe haemophilia (< 1% of normal factor VIII levels) present with spontaneous bleeding into skin, muscle and joints. Retroperitoneal and intracranial bleeding is also a feature. Babies with severe haemophilia have an increased

24.66 Causes of coagulopathy

Congenital

X-linked

- Haemophilia A and B

Autosomal

- Von Willebrand disease
- Factor II, V, VII, X, XI and XIII deficiencies
- Combined II, VII, IX and X deficiency
- Combined V and VIII deficiency
- Hypofibrinogenaemia
- Dysfibrinogenaemia

Acquired

Underproduction

- Liver failure

Increased consumption

- Coagulation activation
 - Disseminated intravascular coagulation (DIC)
- Immune-mediated
 - Acquired haemophilia and von Willebrand syndrome
- Others
 - Acquired factor X deficiency (in amyloid)
 - Acquired von Willebrand syndrome in Wilms tumour

Drug-induced

- Inhibition of function
 - Heparins
 - Lepirudin
 - Fondaparinux
 - Rivaroxaban
 - Dabigatran
- Inhibition of synthesis
 - Warfarin

24.67 Severity of haemophilia (ISTH criteria)

Degree of severity	Factor VIII or IX level	Clinical presentation
Severe	< 0.01 U/mL	Spontaneous haemarthroses and muscle haematomas
Moderate	0.01–0.05 U/mL	Mild trauma or surgery causes bleeding
Mild	> 0.05 < 0.4 U/mL	Major injury or surgery results in excess bleeding

(ISTH = International Society on Thrombosis and Haemostasis)

risk of intracranial haemorrhage and, although there is insufficient evidence to recommend routine caesarean section for these births, it is appropriate to avoid head trauma and to perform imaging of the newborn within the first 24 hours of life. Individuals with moderate and mild haemophilia (factor VIII levels 1–40%) present with the same pattern of bleeding, but usually after trauma or surgery when bleeding is greater than would be expected from the severity of the insult.

The major morbidity of recurrent bleeding in severe haemophilia is musculoskeletal. Bleeding is typically into large joints, especially knees, elbows, ankles and hips. Muscle haematomas are also characteristic, most commonly in the calf and psoas muscles. If early treatment is not given to arrest bleeding, a hot, swollen and very painful joint or muscle haematoma develops. Recurrent bleeding into joints leads to synovial hypertrophy, destruction of the cartilage and secondary osteoarthritis (Fig. 24.33). Complications of muscle haematomas depend on their location. A large psoas bleed may extend to compress the femoral nerve; calf haematomas may increase pressure within the inflexible fascial sheath causing a compartment syndrome with

ischaemia, necrosis, fibrosis, and subsequent contraction and shortening of the Achilles tendon.

Management

In severe haemophilia A, bleeding episodes should be treated by raising the factor VIII level, usually by intravenous infusion of factor VIII concentrate. Factor VIII concentrates are freeze-dried and stable at 4°C and can therefore be stored in domestic refrigerators, allowing patients to treat themselves at home at the earliest indication of bleeding. Factor VIII concentrate prepared from blood donor plasma is now screened for HBV, HCV and HIV, and undergoes two separate viral inactivation processes during manufacture; these preparations have a good safety record. However, factor VIII concentrates prepared by recombinant technology are now widely available and, although more expensive, are perceived as being safer than those derived from human plasma. In addition to raising factor VIII concentrations, resting of the bleeding site by either bed rest or a splint reduces continuing haemorrhage. Once bleeding has settled, the patient should be mobilised and physiotherapy used to restore strength to the surrounding muscles. All non-immune potential recipients of pooled blood products should be offered hepatitis A and B immunisation.

The vasopressin receptor agonist DDAVP (p. 793) raises the vWF and factor VIII levels by 3–4-fold, which is useful in arresting bleeding in patients with mild or moderate haemophilia A. The dose required for this purpose is high, typically 0.3 µg/kg given intravenously or subcutaneously. Alternatively, the same effect can be achieved by intranasal administration of 300 µg. Following repeated administration of DDAVP, patients need to be monitored for evidence of water retention which can result in significant hyponatraemia (p. 793).

In addition to treatment 'on demand' for bleeding, factor VIII can be administered 2 or 3 times per week as 'prophylaxis' to prevent bleeding in severe haemophilia. This is most appropriate in children, but its widespread use is limited by the high cost of factor VIII preparations.

Complications of coagulation factor therapy

Before 1986, coagulation factor concentrates from human plasma were not virally inactivated with heat or chemicals, and many patients became infected with HIV and the hepatitis viruses HBV and HCV. In exposed patients with severe haemophilia, infection with HCV is almost universal, 80–90% have evidence of HBV exposure, and 60% became HIV-positive. Management of these is described in Chapters 23 and 14. Since 1986, viral inactivation of these blood products has eradicated the risk of viral infection.

Concern that the infectious agent which causes vCJD (p. 1214) might be transmissible by blood and blood products has been confirmed in recipients of red cell transfusion, and in at least one recipient of factor VIII. Pooled plasma products, including factor VIII concentrate, are now manufactured from plasma collected in countries with a low incidence of bovine spongiform encephalopathy.

Another serious complication of factor VIII infusion is the development of anti-factor VIII antibodies, which arise in about 20% of severe haemophiliacs. Such antibodies rapidly neutralise therapeutic infusions, making

Fig. 24.33 Chronic haemophilic arthropathy of the left knee. **[A]** Repeated bleeds have led to broadening of the femoral epicondyles. Unilateral atrophy of the quadriceps (A) is easily seen. **[B]** X-ray confirms broadening of femoral epicondyles. There is no cartilage present, as evidenced by the close proximity of the femur and tibia (B); sclerosis (C), osteophyte (D) and bony cysts (E) are present.

treatment relatively ineffective. Infusions of activated clotting factors, e.g. VIIa or FEIBA, may stop bleeding.

Haemophilia B (Christmas disease)

Aberrations of the factor IX gene, which is also present on the X chromosome, result in a reduction of the plasma factor IX level, giving rise to haemophilia B. This disorder is clinically indistinguishable from haemophilia A but is less common. The frequency of bleeding episodes is related to the severity of the deficiency of the plasma factor IX level. Treatment is with a factor IX concentrate, used in much the same way as factor VIII for haemophilia A. Although factor IX concentrates shared the problems of virus transmission seen with factor VIII, they do not commonly induce inhibitor antibodies (< 1% patients); when this does occur, however, it may be heralded by the development of a severe allergic-type reaction.

von Willebrand disease

Von Willebrand disease is a common but usually mild bleeding disorder caused by impaired function of von Willebrand factor (vWF). vWF is a protein synthesised by endothelial cells and megakaryocytes, which is involved in both platelet function and coagulation. vWF normally forms a multimeric structure which is essential for its interaction with subendothelial collagen and platelets (see Fig. 24.7, p. 994). vWF acts as a carrier protein for factor VIII, to which it is non-covalently bound; deficiency of vWF lowers the plasma factor VIII level. vWF also forms bridges between platelets and subendothelial components (e.g. collagen; see Fig. 24.6, p. 992), allowing platelets to adhere to damaged vessel walls; deficiency of vWF therefore leads to impaired platelet plug formation. Blood group antigens (A and B) are expressed on vWF. This reduces its susceptibility to proteolysis; as a result, people with blood group O have lower circulating vWF levels than individuals with non-O groups. This needs to be borne in mind when making a diagnosis of von Willebrand disease.

Most patients with von Willebrand disease have type 1 vWD which is characterised by a quantitative decrease in a normal functional protein. Patients with type 2 disorders inherit vWF molecules which are functionally abnormal. The type of abnormality depends on the site of the mutation in the vWD gene; patients with mutations in platelet binding have type 2A disease, those with mutations in the platelet glycoprotein 1b binding site have type 2B, those with mutations in the factor VIII binding site have type 2N disease, and those with other abnormalities in platelet binding have type 2M. The patterns of laboratory abnormality accompanying these types is described in Box 24.68. The gene for vWF is located on chromosome 12 and the disease is usually inherited as an autosomal dominant, except in cases of type 2N when it is recessive. Rare patients carrying two defective copies of the vWF gene ('compound heterozygosity') develop a clinically severe form with almost undetectable levels of vWF.

Clinical features

Patients present with haemorrhagic manifestations similar to those in individuals with reduced platelet function. Superficial bruising, epistaxis, menorrhagia and gastrointestinal haemorrhage are common. Bleeding episodes are usually much less common than in severe

24.68 Classification of von Willebrand disease

Type	Defect	Inheritance	Investigations
1	Partial quantitative	AD	Parallel decrease in vWF: Ag and VIII:c
2A	Qualitative	AD	Absent HWM of vWF Ratio of vWF activity to antigen < 0.7
2B	Qualitative	AD	Reduced HWM of vWF Enhanced platelet agglutination (RIPA)
2M	Qualitative	AD	Normal multimers of vWF Abnormal platelets interactions
2N	Qualitative	AR	Defective binding of vWF to VIII
3	Severe quantitative	AD or CH	Very low vWF activity and VIII:c Absent multimers

(AD = autosomal dominant; AR = autosomal recessive; CH = compound heterozygote; HWM = high-weight multimers of vWF; RIPA = ristocetin-induced platelet agglutination; VIII: c = coagulation factor VIII activity in functional assay vWF = von Willebrand factor; vWF: Ag = vWF antigen measured by ELISA)

haemophilia and excessive haemorrhage may only be observed after trauma or surgery. Within a single family the disease has variable penetrance, so that some members may have quite severe and frequent bleeds, whereas others are relatively asymptomatic.

Investigations

The disorder is characterised by reduced activity of vWF and factor VIII, and a prolongation of the bleeding time. The disease can be classified using a combination of assays which include functional and antigenic measures of vWF, multimeric analysis of the protein, and specific tests of function to determine binding to platelet glycoprotein 1b (RIPA) and factor VIII (see Box 24.68).

Management

Many episodes of mild haemorrhage can be successfully treated by local means or with DDAVP, which raises the vWF level, resulting in a secondary increase in factor VIII. Tranexamic acid may be useful in mucosal bleeding. For more serious or persistent bleeds, haemostasis can be achieved with selected factor VIII concentrates which contain considerable quantities of vWF in addition to factor VIII. Young children and patients with severe arterial disease should not receive DDAVP, and patients with type 2B disease develop thrombocytopenia which may be troublesome following DDAVP. Bleeding in type 3 patients responds to nothing apart from concentrates.

Rare inherited bleeding disorders

Deficiencies of factor VII, X and XIII occur as autosomal recessive disorders. They are rare but are associated with severe bleeding. Typical features include haemorrhage from the umbilical stump and intracranial haemorrhage.

Factor XIII deficiency is typically associated with female infertility.

Factor XI deficiency may occur in heterozygous or homozygous individuals. Bleeding is very variable and is not accurately predicted by coagulation factor levels. In general, severe bleeding is confined to patients with levels below 15% of normal.

Acquired bleeding disorders

Disseminated intravascular coagulation (DIC) is an important cause of bleeding which begins with exaggerated coagulation. It is discussed under thrombotic disease on page 1050.

Liver disease

In severe parenchymal liver disease (Ch. 23), bleeding may arise from many different causes. Pathological sources of potential major bleeding, such as oesophageal varices or peptic ulcer, are more likely. There is reduced hepatic synthesis, e.g. of factors V, VII, VIII, IX, X, XI, prothrombin and fibrinogen. Clearance of plasminogen activator is reduced. Thrombocytopenia may occur secondary to hypersplenism in portal hypertension. In cholestatic jaundice there is reduced vitamin K absorption, leading to deficiency of factors II, VII, IX and X. Treatment with plasma products or platelet transfusion should be reserved for acute bleeds or to cover interventional procedures such as liver biopsy. Vitamin K deficiency can be readily corrected with parenteral administration of vitamin K.

Renal failure

The severity of the haemorrhagic state in renal failure is proportional to the plasma urea concentration (p. 482). Bleeding manifestations are those of platelet dysfunction, with gastrointestinal haemorrhage being particularly common. The causes are multifactorial, including anaemia, mild thrombocytopenia and the accumulation of low molecular weight waste products, normally excreted by the kidney, which inhibit platelet function. Treatment is by dialysis to reduce the urea concentration. Rarely, in severe or persistent bleeding, platelet concentrate infusions and red cell transfusions are indicated. Increasing the concentration of vWF, either by cryoprecipitate or by DDAVP, may promote haemostasis.

THROMBOTIC DISORDERS

Venous thromboembolic disease (VTE) and its treatment have many clinical manifestations. The approach to patients with the most common presentation, deep venous thrombosis of the leg, is described on pages 1004–1006. Pulmonary embolism is discussed on page 717. Anticoagulant therapy is discussed on pages 1014–1016.

Predisposing factors for VTE are listed in Box 24.18 (p. 1006). In a small proportion of cases, there is an underlying haematological disorder predisposing to venous thrombosis, detected using the screening tests described in Boxes 24.4 and 24.5 (p. 997). These disorders include myeloproliferative disorders and paroxysmal nocturnal haemoglobinuria, which are discussed above (pp. 1027 and 1043–1044). They also include inherited acquired conditions, described below.

Inherited abnormalities of coagulation

Several inherited conditions predispose to VTE, with several points in common which are worth noting:

- None of them is strongly associated with arterial thrombosis.
- All are associated with a slightly increased incidence of adverse outcome of pregnancy, including recurrent early fetal loss, but there are no data to indicate that any specific intervention changes that outcome.
- Apart from in antithrombin deficiency and homozygous factor V Leiden, most carriers of these genes will never have an episode of VTE; if they do, it will be associated with the presence of an additional temporary risk factor.
- There is little evidence that detection of these abnormalities predicts recurrence of VTE.
- None of these conditions per se requires treatment with anticoagulants. Patients with thrombosis should receive LMWH followed by a coumarin, as discussed on page 1006. Patients who are deemed to be at high risk of thrombosis, e.g. those with antithrombin deficiency in pregnancy, should receive treatment or prophylactic doses of heparin (p. 1006) to cover the period of risk only.

Antithrombin deficiency

Antithrombin (AT) is a serine protease inhibitor (SERPIN) which inactivates factors IIa, IXa, Xa and XIa. Heparins, fondaparinux and idraparinux achieve their therapeutic effect by potentiating the activity of AT. Familial deficiency of AT is inherited as an autosomal dominant; homozygosity for mutant alleles is not compatible with life. Around 70% of affected individuals will have an episode of VTE before the age of 60 years and the relative risk for thrombosis compared with the background population is 10–20. Pregnancy is a high-risk period for VTE and this requires fairly aggressive management with doses of LMWH which are greater than the usual prophylactic doses (≥ 100 U/kg/day). AT concentrate (either plasma-derived or recombinant) is available; this is required for cardiopulmonary bypass and may be used as an adjunct to heparin in surgical prophylaxis.

Protein C and S deficiencies

Protein C and S are vitamin K-dependent natural anticoagulants involved in switching off coagulation factor activation and thrombin generation (see Fig. 24.6E, p. 993). Inherited deficiency of either protein C or S results in a prothrombotic state with a five-fold relative risk of VTE compared with the background population.

Factor V Leiden

Factor V Leiden results from a gain of function single-base pair mutation which prevents the cleavage and hence inactivation of activated factor Va. This results in a relative risk of venous thrombosis of 5 in heterozygotes and ≥ 50 in rare homozygotes. The mutation is found in about 5% of Northern Europeans, 2% of Hispanics, 1.2% of African-Americans, 0.5% of Asian-Americans and 1.25% of Native Americans, and is rare in Chinese and Malay people.

Prothrombin G20210A

This gain-of-function mutation in the non-coding 3' end of the prothrombin gene is associated with an increased plasma level of prothrombin. It is present in about 2% of Northern Europeans but is rare in native populations of Korea, China, India and Africa. In the heterozygous state it is associated with a 2–3-fold increase in risk of VTE compared with background population.

Antiphospholipid syndrome (APS)

APS is a clinicopathological entity in which a constellation of clinical conditions, alone or in combination, is found in association with a persistently positive test for an antiphospholipid antibody. The antiphospholipid antibodies are heterogeneous and typically are directed against proteins which bind to phospholipids (Box 24.69). Although causal roles for these antibodies have been proposed, the mechanisms underlying the clinical features of APS are not clear. In clinical practice, two types of test are used, which detect:

- antibodies which bind to negatively charged phospholipid on an ELISA plate (called an anticardiolipin antibody test)
- those which interfere with phospholipid-dependent coagulation tests like the APTT or the dilute Russell viper venom time (DRVVT; called a lupus anticoagulant test).

The term antiphospholipid antibody encompasses both a lupus anticoagulant and an anticardiolipin antibody; individuals may be positive for one or both of these activities.

Clinical features and management

APS may present in isolation (primary APS) or in association with one of the conditions shown in Box 24.69, most typically SLE (secondary APS). Most patients present with a single manifestation and APS is now most frequently diagnosed in women with adverse outcomes of pregnancy. It is extremely important to make the diagnosis in patients with APS, whatever the manifesta-

tion, because it affects the prognosis and management of arterial thrombosis, VTE and pregnancy.

Arterial thrombosis, typically stroke, associated with APS should be treated with warfarin as opposed to aspirin. APS-associated VTE is one of the situations where the predicted recurrence rate is high enough to indicate long-term anticoagulation after a first event. In women with APS it is likely that intervention with heparin and possibly aspirin increases the chance of a successful pregnancy outcome.

Disseminated intravascular coagulation (DIC)

DIC may complicate a range of illnesses (Box 24.70). It is characterised by systemic activation of the pathways involved in coagulation and its regulation. This may result in the generation of intravascular fibrin clots causing organ failure, with simultaneous coagulation factor and platelet consumption causing bleeding. The systemic coagulation activation is induced either through cytokine pathways which are activated as part of a systemic inflammatory response, or by the release of procoagulant substances such as tissue factor. In addition, suboptimal function of the natural anticoagulant pathways and dysregulated fibrinolysis contribute to DIC. There is consumption of platelets, coagulation factors (notably factors V and VIII) and fibrinogen. The

24.70 Disseminated intravascular coagulation

Underlying conditions

- Infection/sepsis
- Trauma
- Obstetric, e.g. amniotic fluid embolism, placental abruption, pre-eclampsia
- Severe liver failure
- Malignancy, e.g. solid tumours and leukaemias
- Tissue destruction, e.g. pancreatitis, burns
- Vascular abnormalities, e.g. vascular aneurysms, liver haemangiomas
- Toxic/immunological, e.g. ABO incompatibility, snake bites, recreational drugs

ISTH scoring system for diagnosis of DIC

Presence of an associated disorder	Essential
Platelets	<p>> 100 = 0</p> <p>< 100 = 1</p> <p>< 50 = 2</p>
Elevated fibrin degradation products	<p>No increase = 0</p> <p>Moderate = 2</p> <p>Strong = 3</p>
Prolonged prothrombin time	<p>< 3 s = 0</p> <p>> 3 s but < 6 s = 1</p> <p>> 6 s = 2</p>
Fibrinogen	<p>> 1 g/L = 0</p> <p>< 1 g/L = 1</p>

Total score:

- ≥ 5 = Compatible with overt DIC
- < 5 = Repeat monitoring over 1–2 days

(ISTH = International Society for Thrombosis and Haemostasis)

24.69 Antiphospholipid syndrome (APS)

Clinical manifestations

- Adverse pregnancy outcome
- Recurrent first trimester abortion (≥ 3)
- Unexplained death of morphologically normal fetus after 10 weeks' gestation
- Severe early pre-eclampsia
- Venous thromboembolism
- Arterial thromboembolism
- Livedo reticularis, catastrophic APS, transverse myelitis, skin necrosis, chorea

Conditions associated with secondary APS

- SLE
- Rheumatoid arthritis
- Systemic sclerosis
- Behçet's syndrome
- Temporal arteritis
- Sjögren's syndrome

Targets for antiphospholipid antibodies

- β_2 -glycoprotein 1
- Protein C
- Annexin V
- Prothrombin (may result in haemorrhagic presentation)

lysis of fibrin clot results in production of fibrin degradation products (FDP), including D-dimers.

Investigations

DIC should be suspected when any of the conditions listed in Box 24.70 are met. Measurement of coagulation times (APTT and PT; p. 997), along with fibrinogen, platelet count and FDPs, helps in the assessment and aids clinical decision-making with regard to both bleeding and thrombotic complications.

Management

Therapy is primarily aimed at the underlying cause. These patients will often require intensive care to deal with concomitant issues, such as acidosis, dehydration, renal failure and hypoxia. Blood component therapy, such as fresh frozen plasma, cryoprecipitate and platelets, should be given if the patient is bleeding or to cover interventions with high bleeding risk, but should not be given routinely based on coagulation tests and platelet counts alone. Prophylactic doses of heparin should be given, unless there is a clear contraindication. Established thrombosis should be treated cautiously with therapeutic doses of unfractionated heparin, unless clearly contraindicated. Some patients with sepsis-associated DIC benefit from treatment with activated protein C concentrate. Patients with DIC should not in general be treated with antifibrinolytic therapy, e.g. tranexamic acid.

Thrombotic thrombocytopenic purpura

Like DIC and also heparin-induced thrombocytopenia (p. 1015), this is a disorder in which thrombosis is accompanied by paradoxical thrombocytopenia. Thrombotic thrombocytopenic purpura is characterised by a pentad of findings, although few patients have all five components:

- thrombocytopenia
- microangiopathic haemolytic anaemia
- neurological sequelae
- fever
- renal impairment.

It is an acute autoimmune disorder mediated by antibodies against ADAMTS-13 (A disintegrin and metalloproteinase with a thrombospondin type-1 motif).

This enzyme normally cleaves vWF multimers to produce normal functional units and its deficiency results in large vWF multimers which cross-link platelets. The features are of microvascular occlusion by platelet thrombi affecting key organs, principally brain and kidneys. It is a rare disorder (1 in 750 000 per annum) which may occur alone or in association with drugs (ticlopidine, ciclosporin), HIV, shiga toxins and malignancy. It should be treated by emergency plasma exchange. Corticosteroids, aspirin and rituximab also have a role in management. Untreated mortality rates are 90% in the first 10 days, and even with appropriate therapy the mortality rate is 20–30% at 6 months.

24.71 Haemostasis and thrombosis in old age

- **Thrombocytopenia:** not uncommon because of the rising prevalence of disorders in which it may be a secondary feature, and also because of the greater use of drugs which can cause it.
- **'Senile' purpura:** presumed to be due to an age-associated loss of subcutaneous fat and the collagenous support of small blood vessels, making them more prone to damage from minor trauma.
- **Thrombosis:** more frequent in old age. This may be due to stasis, to which older people are prone; some studies show increased platelet aggregation with age, and others age-associated hyperactivity of the haemostatic system which could create a prothrombotic state.

Detailed regional examination involves 'look' (at rest and during movement), 'feel' and 'move'

A. Inspection at rest

(See figure above for examples)

- Skin changes
- Swelling
- Wasting of muscle
- Attitude
- Deformity

B. Inspection during movement

- Restriction
 - Limited to one plane–periarticular lesion
 - Affecting most or all movements–joint problem
- Increased range
 - Hypermobility, instability
- Pain on usage
 - Stress pain = increasing pain towards extremes of movement
 - Universal stress pain (in most/all directions)
 - synovitis
 - Selective stress pain (one plane only)
 - periarticular lesion

C. Palpation with movement

- Tenderness
 - Joint line–intra-articular/joint problem
 - Periarticular–periarticular lesion
- Increased warmth
 - Inflammation (e.g. synovitis, bursitis)
- Swelling
 - Fluid (fluctuant)
 - Soft tissue (soft, non-fluctuant)
 - Bone (hard)
- Crepitus
 - Coarse, easily felt, may be readily audible–joint damage
 - Fine, localised, heard with stethoscope–tendon sheath, bursa
- Stability
- Resisted active movements
 - Reproduce pain from muscle, tendon, enthesis
- Stress tests
 - Reproduce pain from ligament or tendon sheath

Important MSK symptoms	
Pain	
<ul style="list-style-type: none"> Usage pain: worse on use, relieved by rest (mechanical strain, damage) Rest pain: worse after rest, improved by movement (inflammation) Night or 'bone' pain: mostly at night, poorly related to movement (bone origin) 	
Stiffness	
<ul style="list-style-type: none"> Subjective feeling of inability to move freely Duration and severity of early morning and inactivity stiffness that can be 'worn off' suggest degree of inflammation 	
Weakness	
<ul style="list-style-type: none"> Consider primary or secondary muscle abnormality 	
Swelling	
<ul style="list-style-type: none"> Fluid Soft tissue Bone 	
Deformity	
<ul style="list-style-type: none"> Joint Bone 	
Non-specific symptoms of systemic illness	
<ul style="list-style-type: none"> Weight loss \pm reduction in appetite Fatigability, poor concentration Sweats and chills, particularly at night Feeling ill, low, irritable 	

Regional examination differences between joint and periarticular lesions		
Sign	Joint	Periarticular
Tenderness	Over joint line	Away from joint line
Restricted movement	Active and passive movement affected equally	Active more restricted than passive
Resisted active	Not painful	May reproduce muscle, tendon, ligament or enthesis pain
Stress pain	Present in all tight-pack positions (several directions)	Present in direction of use of ligament, tendon or enthesis (mainly one direction)
Swelling	Capsular pattern	Localised, periarticular
Crepitus	Coarse or fine	Fine

Features that differentiate joint inflammation ('synovitis') from joint damage		
Feature	Synovitis	Joint damage
Stiffness (early morning, inactivity)	+++	\pm
Increased warmth	+	—
Stress pain	+	—
Soft tissue swelling	+	—
Effusion	+++	\pm
Crepitus	—	+++
Deformity	—	+
Instability	—	+

Example of 'stress pain' at the wrist.

Pain worsens as the wrist moves towards the 'tight-pack' positions (flexion and extension) because of increased intracapsular pressure from inflammatory swelling and effusion. In the mid 'loose-pack' position, when the capsule is at its slackest, there is no pain. Stress pain is the earliest and most sensitive sign of synovitis, occurring before visible swelling or reduction of movement. With joint damage, pain is more evenly spread throughout the range.

Example of resisted active movement.

Attempted external rotation reproduces upper arm pain resulting from an infraspinatus/teres minor rotator cuff lesion.

Example of a stress test. Passive ulnar flexion reproduces pain from de Quervain's tenosynovitis.

Disorders of the musculoskeletal (MSK) system are prevalent throughout the world, affecting all ages and ethnic groups. In the UK, up to 1 in 4 new consultations in general practice are for MSK symptoms. The principal manifestations are pain and impairment of locomotor function.

Most MSK conditions predominate in women and show a strong association with age; 40% of those over 65 have a significant MSK disorder. They are the single most common cause of physical disability in older people and account for one-third of physical disability at all ages.

Non-inflammatory conditions are far more prevalent than inflammatory disease (Box 25.1). Most regional MSK pain arises from muscles, tendons and periarticular structures. Osteoarthritis (OA) is the most common joint disorder, with knee involvement a major cause of disability. Osteoporosis is the most prevalent bone disorder and in developed countries about 30% of women and 12% of men sustain a fracture related to osteoporosis during their lifetime.

FUNCTIONAL ANATOMY AND PHYSIOLOGY

The MSK system is responsible for body movements, provides a structural framework to protect internal organs and acts as a reservoir for storage of calcium and phosphate in the regulation of mineral homeostasis. Individual components are depicted in Figure 25.1.

Bone

Bones are of two main types based on their embryonic development. Flat bones, such as the skull, develop by intramembranous ossification, in which embryonic fibroblasts differentiate directly into bone within condensations of mesenchymal tissue during early fetal life. Long bones, such as the femur and radius, develop by endochondral ossification from a cartilage template. During development, the cartilage is invaded by vascular tissue containing osteoprogenitor cells and is gradually

replaced by bone from centres of ossification situated in the middle and at the ends of the bone. A thin remnant of cartilage called the growth plate or epiphysis remains at each end of long bones, and chondrocyte proliferation here is responsible for skeletal growth during childhood and adolescence. During puberty, the rise in levels of sex hormones halts cell division in the growth plate. The cartilage remnant then disappears as the epiphysis fuses and longitudinal bone growth ceases.

The normal skeleton has two types of bone (see Fig. 25.1). Cortical bone is formed from Haversian systems, comprising concentric lamellae of bone tissue surrounding a central canal that contains blood vessels. Cortical bone is dense and forms a hard envelope around the long bones. Trabecular or cancellous bone fills the centre of the bone and consists of an interconnecting meshwork of trabeculae, separated by spaces filled with bone marrow.

There are three main cell types in bone:

- **Osteoclasts:** multinucleated cells of haemopoietic origin, responsible for bone resorption
- **Osteoblasts:** mononuclear cells of mesenchymal origin, responsible for bone formation
- **Osteocytes:** these differentiate from osteoblasts during bone formation and become embedded in bone matrix. Osteocytes play a critical role in regulating phosphate metabolism by producing the hormone FGF23 (Fig. 25.2) and are thought to be responsible for sensing and responding to mechanical loading of the skeleton.

Bone matrix and mineral

The most abundant protein of bone is type I collagen, which is formed from two $\alpha 1$ peptide chains and one $\alpha 2$ chain wound together in a triple helix. Type I collagen is proteolytically processed inside the cell before being laid down in the extracellular space, releasing propeptide fragments that can be used as biochemical markers of bone formation (p. 1064). Subsequently, the collagen fibrils become 'cross-linked' to one another by pyridinium molecules, a process which enhances bone strength. When bone is broken down by osteoclasts, the cross-links are released, providing biochemical markers of bone resorption (p. 1064). Bone is normally laid down in an orderly fashion, but when bone turnover is high, as in Paget's disease or severe hyperparathyroidism, it is laid down in a chaotic pattern, giving rise to 'woven bone' which is mechanically weak. Bone matrix also contains growth factors, other structural proteins and proteoglycans, thought to be involved in helping bone cells attach to bone matrix and in regulating bone cell activity. The other major component of bone is mineral, comprised of calcium and phosphate crystals deposited between the collagen fibrils in the form of hydroxyapatite $[\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2]$. Mineralisation is essential for bone's rigidity and strength, but over-mineralisation can increase brittleness which contributes to bone fragility in diseases like osteogenesis imperfecta (p. 1126).

Bone remodelling

Bone remodelling is responsible for renewal and repair of the skeleton during adult life (see Fig. 25.2). It starts with attraction of osteoclast precursors in peripheral blood to the target site, probably by local release of chemotactic

i 25.1 Relative prevalence of musculoskeletal disorders

	Prevalence	Female: male	Age association
'Non-inflammatory' conditions			
Neck and back pain	20%	=	–
Osteoarthritis			
Knee	10%	F > M	++
Hip	4%	=	+
Osteoporosis	15%	F > M	++
Regional 'soft tissue' pain	10%	F > M	++
Fibromyalgia	3%	F > M	++
'Inflammatory' conditions			
Rheumatoid arthritis	1.5%	F > M	+
Gout	1.5%	M > F	–
Seronegative spondyloarthritis	0.8%	=	–
Polymyalgia rheumatica	0.04%	F > M	++
Connective tissue diseases (mainly lupus)	0.02%	F > M	–

Fig. 25.1 Structure of major musculoskeletal tissues.

factors from areas of microdamage. The osteoclast precursors differentiate into mature osteoclasts in response to RANK ligand (RANKL), which is expressed by bone marrow stromal cells. RANKL activates the RANK receptor, which is expressed on osteoclasts and precursors. This is blocked by osteoprotegerin (OPG), a decoy receptor for RANKL that inhibits osteoclast formation. Mature osteoclasts attach to the bone surface by a tight sealing zone, and secrete hydrochloric acid and proteolytic enzymes such as cathepsin K into the space underneath. The acid dissolves the mineral and cathepsin K degrades collagen. When resorption is complete, osteoclasts undergo programmed cell death, and bone formation begins with the attraction of osteoblast precursors to the resorption site. These differentiate into mature osteoblasts, which deposit new bone matrix in the resorption lacuna, until the hole is filled. Some osteoblasts become trapped in bone matrix and differentiate into osteocytes. These act as biomechanical sensors and produce several molecules that influence bone remodelling and phosphate metabolism. Bone formation is stimulated by Wnt proteins which bind to and activate lipoprotein-related receptor protein 5 (LRP5), expressed on osteoblasts. This process is inhibited by other molecules such as sclerostin (SOST) (see Fig. 25.2). Initially, the newly formed bone matrix (osteoid) is uncalcified but subsequently becomes mineralised to form mature bone. Alkaline phosphatase (ALP), produced by osteoblasts, plays an important role

in bone mineralisation by degrading pyrophosphate, an inhibitor of mineralisation. Bone remodelling is regulated by circulating hormones, such as parathyroid hormone (PTH) and oestrogen, and locally produced factors such as cytokines (Box 25.2). Many systemic hormones exert

i 25.2 Regulators of bone remodelling

Factor	Bone resorption	Bone formation
Parathyroid hormone (PTH)	↑	↑
RANKL	↑	↔
Osteoprotegerin (OPG)	↑	↔
Wnt/LRP5	↓	↑
Sclerostin (SOST)	↔	↓
Interleukin-1 (IL-1)	↑	↓
Tumour necrosis factor- α (TNF- α)	↑	↓
Thyroid hormone	↑	↔
Glucocorticoids	↑	↓↓
Oestrogen/testosterone	↓	↑
Mechanical loading	↓	↑

Fig. 25.2 The bone remodelling cycle. (CatK = cathepsin K; LRP5 = lipoprotein receptor protein 5; OPG = osteoprotegerin; RANK = receptor activator of nuclear factor κ B; RANKL = RANK ligand; SOST = sclerostin)

effects on bone turnover by affecting local expression of RANK, RANKL, OPG, sclerostin (SOST) and molecules in the Wnt/LRP5 pathway (see Fig. 25.2).

Joints

Bones are linked by joints. There are three main subtypes: fibrous, fibrocartilaginous and synovial (Box 25.3).

Fibrous and fibrocartilaginous joints

These comprise a simple bridge of fibrous or fibrocartilaginous tissue joining two bones together where there is little requirement for movement. The intervertebral disc is a special type of fibrocartilaginous joint in which an amorphous area, the nucleus pulposus, lies in the centre of the fibrocartilaginous bridge. The nucleus has a high

water content and acts as a cushion to improve the disc's shock-absorbing properties.

Synovial joints

These are complex structures containing several cell types and are found where a wide range of movement is required.

Articular cartilage

This avascular tissue covers the bone ends in synovial joints. Cartilage cells (chondrocytes) are responsible for synthesis and turnover of cartilage, which consists of a mesh of type II collagen fibrils that extend through a hydrated 'gel' of proteoglycan molecules. The most important proteoglycan is aggrecan, which consists of a core protein to which several glycosaminoglycan (GAG) side-chains are attached (Fig. 25.3). The GAGs are polysaccharides that consist of long chains of disaccharide repeats comprising one normal sugar and an amino sugar. The most abundant GAGs in aggrecan are chondroitin sulphate and keratan sulphate. Hyaluronan is another important GAG which binds to aggrecan molecules to form very large complexes with a total molecular weight more than 100 million. Aggrecan has a strong negative charge and avidly binds water molecules to assume a shape that occupies the maximum possible volume available. The expansive force of the hydrated aggrecan, combined with the restrictive strength of the collagen mesh, gives articular cartilage excellent shock-absorbing properties.

25.3 Types of joint		
Type	Range of movement	Examples
Fibrous	Minimal	Skull sutures
Fibrocartilaginous	Limited	Symphysis pubis Costochondral junctions Intervertebral discs Sacroiliac joints
Synovial	Large	Most limb joints Temporomandibular Costovertebral

Fig. 25.3 Ultrastructure of articular cartilage.

With ageing, the concentration of chondroitin sulphate decreases, whereas that of keratan sulphate increases, resulting in reduced water content and shock-absorbing properties. These changes differ from those found in OA (p. 1083), where there is abnormal chondrocyte division, loss of proteoglycan from matrix and an increase in water content. Cartilage matrix is constantly turning over and in health there is a perfect balance between synthesis and degradation. Degradation is mediated by enzymes such as aggrecanase and matrix metalloproteinases that degrade the proteins, and glycosidases that degrade GAGs. Pro-inflammatory cytokines such as interleukin-1 (IL-1) and tumour necrosis factor (TNF), which are released during joint inflammation, stimulate production of aggrecanase and metalloproteinases that promote cartilage degradation.

Synovial fluid

The surfaces of articular cartilage are separated by a space filled with synovial fluid, a viscous liquid that lubricates the joint. Synovial fluid is an ultrafiltrate of plasma into which synovial cells secrete hyaluronan and proteoglycans.

Intra-articular discs

Some joints contain fibrocartilaginous discs within the joint space (e.g. the menisci of the knee) that act as shock absorbers. These are avascular and remain viable by diffusion of oxygen and nutrients from the synovial fluid.

The synovial membrane, joint capsule and bursae

The bones of synovial joints are connected by the joint capsule, a fibrous structure richly supplied with blood vessels, nerves and lymphatics which encases the joint. Ligaments are discrete, regional thickenings of the capsule that act to stabilise joints. The inner surface of the joint capsule is the synovial membrane, comprising an outer layer of blood vessels and loose connective tissue, and an inner layer 1–4 cells thick consisting of two main cell types. Type A synoviocytes are phagocytic cells derived from the monocyte/macrophage lineage and are responsible for removing particulate matter from the joint cavity; type B synoviocytes are fibroblast-like cells that secrete synovial fluid. Most inflammatory and degenerative joint diseases associate with thickening of the synovial membrane and infiltration by lymphocytes, polymorphs and macrophages.

Bursae are hollow sacs lined with synovium and contain a small amount of synovial fluid. They help tendons and muscles move smoothly in relation to bones and other articular structures.

Skeletal muscle

Skeletal muscles are responsible for body movements and respiration. Muscle consists of bundles of cells (myocytes) embedded in fine connective tissue containing nerves and blood vessels. Myocytes are large, elongated, multinucleated cells formed by fusion of mononuclear precursors (myoblasts) in early embryonic life. The nuclei lie peripherally and the centre of the cell contains actin and myosin molecules which interdigitate with one another to form the myofibrils that are responsible for muscle contraction. The molecular mechanisms of skeletal muscle contraction are the same as for cardiac muscle (p. 526). Myocytes contain many mitochondria which provide the large amounts of adenosine triphosphate (ATP) necessary for muscle contraction, and are rich in the protein myoglobin which acts as a reservoir for oxygen during contraction.

Individual myofibrils are organised into bundles (fasciculi) that are bound together by a thin layer of connective tissue (the perimysium). The surface of the muscle is surrounded by a thicker layer of connective tissue, the epimysium, which merges with the perimysium to form the muscle tendon. Tendons are tough, fibrous structures that attach muscles to the point of insertion on the bone surface that is called the enthesis.

INVESTIGATION OF MUSCULOSKELETAL DISEASE

For most MSK conditions, clinical enquiry and examination alone give sufficient information for diagnosis and management. Investigations may be helpful in confirming the diagnosis, assessing disease activity or indicating prognosis.

Synovial fluid analysis

This is the pivotal investigation when septic arthritis, crystal-associated arthritis or intra-articular bleeding is suspected, and should be performed in all patients with acute monoarthritis, especially with overlying erythema.

Synovial fluid (SF) can be obtained by aspiration from most peripheral joints and only a small volume is required for diagnostic purposes. Normal SF is present in small volume, contains few cells, is clear and either colourless or pale yellow, and has high viscosity. With joint inflammation, the volume increases, the cell count and the proportion of neutrophils rise (causing turbidity), and the viscosity reduces (due to enzymatic degradation of hyaluronan and aggrecan). However, there is considerable overlap between arthropathies, and these features alone have little diagnostic value. High concentrations of crystals, mainly urate or cholesterol, can make SF appear white.

Non-uniform blood-staining of SF is common, usually reflecting needle trauma to the synovium. Uniform blood-staining (haemarthrosis) often accompanies florid synovitis but may also result from a bleeding diathesis,

Fig. 25.4 Compensated polarised light microscopy of synovial fluids ($\times 400$). **A** Monosodium urate crystals showing bright birefringence (negative sign) and needle-shaped morphology. **B** Calcium pyrophosphate crystals showing weak birefringence (positive sign), scant numbers and a predominantly rhomboid morphology. These are clearly more difficult to detect than urate crystals.

trauma or pigmented villonodular synovitis. A lipid layer floating above blood-stained fluid is diagnostic of intra-articular fracture and is caused by release of bone marrow fat into the joint.

If sepsis is suspected, SF should be sent for urgent Gram stain and culture in a sterile container. If gonococcus or uncommon organisms are suspected, especially in immunocompromised patients, the microbiologist should be asked to ensure optimal cultures and that molecular techniques of antigen detection are used, if appropriate.

Crystals are identified by compensated polarised light microscopy of fresh unrefrigerated SF (to avoid crystal dissolution and post-aspiration crystallisation). Urate crystals are long and needle-shaped and show a strong light intensity and negative birefringence (Fig. 25.4A). Calcium pyrophosphate crystals are smaller, rhomboid in shape and usually less numerous than urate, and have weak intensity and positive birefringence (Fig. 25.4B).

Imaging

Plain radiography

X-rays can show anatomical changes that reflect important pathological processes (Box 25.4). Although most changes have low specificity, combinations of features

25.4 Abnormalities seen on plain X-ray

Soft tissue swelling

- e.g. Altered skin contours, displaced fat planes and intracapsular fat pads (fat appears dark on X-ray)

Bone density

- Decreased (osteopenia) or increased (osteosclerosis)
- Localised or generalised change

Bone enlargement and deformity

- e.g. Paget's disease, fracture, tumour

Joint erosion

- Non-proliferative or proliferative
- Marginal or central

Joint-space narrowing

- Focal: osteoarthritis
- Generalised: inflammatory arthritis

New bone formation

- e.g. Osteophyte, enthesophyte, syndesmophyte and periosteal reaction

Calcification

- Cartilage (chondrocalcinosis), synovium, capsule, ligament, tendon, muscle, fat, blood vessels, skin
- Intra-articular osteochondral bodies

and targeting of certain bones or joints (Fig. 25.5) result in characteristic patterns that have high diagnostic specificity.

Joints to be X-rayed are usually selected on the basis of involvement identified at clinical assessment. An exception is seronegative spondyloarthritis where sacroiliac involvement is often asymptomatic. In this case, an anteroposterior (AP) view of the pelvis and a lateral view of the thoracolumbar spine are usually sufficient to show sacroiliitis or syndesmophytes (bony spurs that bridge adjacent vertebral bodies), if present. The selection of X-rays often differs depending on whether they are taken for diagnostic or disease assessment purposes. For example, to determine whether a patient with inflammatory polyarthritis has erosions typical of rheumatoid arthritis (RA), postero-anterior (PA) views of hands and feet are appropriate, since erosions appear first in wrists and

Fig. 25.5 Examples of different target sites of involvement in the forefoot for arthritis.

Fig. 25.6 Metacarpophalangeal joint. **A** Early dot-dash erosion of rheumatoid arthritis. **B** Later definite non-proliferative erosion of rheumatoid arthritis. **C** The proliferative erosion of psoriatic arthritis. **D** The intra- and extracapsular 'pressure erosions' of gout.

small joints of hands and feet. However, if the degree of structural damage in one large joint is a cause for concern, an X-ray of that joint is required.

Arthrography is mainly used to demonstrate a ruptured popliteal ('Baker's') cyst as the cause of calf pain and swelling. It may be combined with computed tomography (CT) or magnetic resonance imaging (MRI) to facilitate anatomical assessment.

Erosions

Cartilage and bone erosion is a hallmark of major inflammatory arthropathies. Intracapsular bone erosion first occurs at the joint margin ('marginal erosion') where bone is exposed directly to inflammatory synovium without the protection of overlying cartilage. Loss of the sharp cortical line is the first radiographic sign and precedes more definite scalloping of the bony contour (Fig. 25.6). Cartilage erosion also starts at the margin and slowly works centrally, resulting in loss of 'joint space'. Both RA and seronegative spondyloarthritis (especially psoriatic arthritis) can cause marginal erosions. In RA there is no bone or periosteal reaction, resulting in atrophic 'non-proliferative' erosions (Fig. 25.6B), often with juxta-articular osteopenia and soft tissue swelling. By contrast, in seronegative spondyloarthritis new bone formation and periosteal reaction with retained bone density are more common, resulting in 'proliferative' erosions (Fig. 25.6C). Accompanying ossifying enthesopathy (enthesophytes) and the targeting of different joints further assist differentiation.

In the first 1–2 weeks of acute septic arthritis the X-ray is often normal, apart from osteopenia and soft tissue swelling. However, erosion proceeds rapidly and results in generalised loss of joint space with loss of cortical integrity centrally (central erosion) as well as marginally. In chronic gout, bony defects develop slowly as massive crystal deposits ('tophi') cause pressure necrosis to surrounding bone. Such 'pressure erosions' (Fig. 25.6D) occur at extracapsular as well as intracapsular sites and are not accompanied by osteopenia.

Osteoarthritis

The two cardinal features of OA are joint space narrowing and osteophytes. Joint space narrowing in OA is focal rather than widespread as in inflammatory arthritis

(Fig. 25.7). Osteophytes are most noticeable at the joint margins. Subchondral sclerosis (focal increased density of bone), 'cysts' and osteochondral 'loose' bodies within the synovium are additional features, and there is an association with chondrocalcinosis. Bone density is normal or increased and there are no marginal erosions.

Calcification

Calcification of fibrocartilage and hyaline cartilage (chondrocalcinosis) is most commonly due to calcium pyrophosphate crystals. Calcification at extracapsular sites is mainly apatite. Spotty, multiple calcifications of soft tissues (calcinosis) mainly target peripheral and intermediate sites such as finger pulps, wrists and forearms, and are a feature of connective tissue disease.

Fig. 25.7 X-ray of hip showing changes of osteoarthritis. Note the superior joint space narrowing (N), subchondral sclerosis (S), marginal osteophytes (white arrows) and cysts (C).

Radionuclide bone scan

This is a useful investigation in patients who have bone pain. It involves gamma-camera imaging following an intravenous injection of ^{99m}Tc -bisphosphonate. Early post-injection images reflect vascularity and can show increased perfusion of inflamed synovium, Pagetic bone, or primary or secondary bone tumours (Fig. 25.8). Delayed images taken a few hours later reflect bone remodelling as the bisphosphonate localises to sites of active bone turnover. Scintigraphy has a high sensitivity for detecting important bone and joint pathology that is not apparent on plain X-rays (Box 25.5).

Computerised tomography (CT) and magnetic resonance imaging (MRI)

These techniques give detailed information on anatomy, allowing three-dimensional visualisation of anatomically complex structures such as the spinal canal and facet joints which may be inadequately assessed by plain X-rays. Drawbacks of CT are limited soft tissue resolution and a high radiation dose, and MRI is frequently preferred. It provides detailed information on both structure and physiology of cartilage, bone and other locomotor tissues, allows multiplanar imaging and avoids radiation exposure. T1-weighted short sequences are useful for defining anatomy and T2-weighted long sequences for assessing pathology. MRI, with or without enhancement with gadolinium, is particularly useful to detect and assess:

- early osteonecrosis
- intervertebral disc disease, root entrapment and spinal cord compression
- osteoarticular and soft tissue sepsis

25.5 Pathology detected by isotope bone scanning

- Presence and extent of Paget's disease of bone
- Bone metastases
- Bone or joint sepsis
- Early osteonecrosis
- Bone fractures (including stress fractures)
- Reflex sympathetic dystrophy (algodystrophy, p. 1125)
- Hypertrophic osteoarthropathy (p. 1127)

- osteoarticular and soft tissue malignancy
- bone marrow oedema in patients with recent fractures and reflex sympathetic dystrophy
- internal derangement of joints such as the knee
- soft tissue and periarticular pathology (e.g. early synovitis, rotator cuff tears, bursitis, tenosynovitis).

Ultrasonography

Ultrasonography is inferior to CT or MRI for definition of deep structures and abnormalities within bone, but is a useful outpatient investigation for confirmation of small joint synovitis/erosion, for anatomical confirmation of periarticular lesions, and for assistance in guiding accurate aspiration and injection of joints and bursae.

Bone mineral density

Measurement of bone mineral density (BMD) plays a pivotal role in the investigation and management of osteoporosis. The investigation of choice is dual energy X-ray absorptiometry (DEXA) of the spine and hip. Further details are discussed on page 1118.

Fig. 25.8 Isotope bone scan appearances in different bone diseases. **A** Patchy tracer uptake in the distal femur in a patient with reflex sympathetic dystrophy. **B** Homogeneous tracer uptake in the scapula in a patient with Paget's disease. **C** Multiple focal areas of tracer uptake in the skull and cervical spine of a patient with metastatic breast cancer.

Blood tests

C-reactive protein and erythrocyte sedimentation rate

Infections, inflammation and malignancy can trigger an acute phase response (APR) with alterations in C-reactive protein (CRP), full blood count (FBC) and erythrocyte sedimentation rate (ESR). CRP is the single most useful marker of the APR. A notable exception is in connective tissue diseases such as lupus and systemic sclerosis, where CRP may be normal in patients with active disease. However, patients with these diseases can mount an APR in response to sepsis, and elevations of CRP in a patient with lupus or scleroderma suggest an incidental cause such as sepsis rather than active disease. A discussion of the interpretation of CRP and ESR changes is given on page 82.

Full blood count

Changes in the FBC can occur in inflammatory rheumatic diseases but are non-specific (e.g. neutrophilia in vasculitis, acute gout and sepsis; neutropenia in lupus). Many disease-modifying antirheumatic drugs (DMARDs) have marrow toxicity and require regular monitoring of the FBC.

Autoantibodies

Autoantibody tests are a useful adjunct to clinical evaluation in the diagnosis of rheumatic diseases but false positive results are common. Those most commonly used in rheumatology are described below; antiphospholipid antibodies, which occur in systemic lupus erythematosus (SLE), are discussed on page 1050. High antibody titres or concentrations are generally of greater clinical significance but the results must be interpreted in light of the clinical picture and the different detection and assay systems used in different hospitals.

Rheumatoid factor

Rheumatoid factor (RF) is an antibody directed against the Fc fragment of human IgG and was so named because it was first identified in patients with RA. RFs may be of any immunoglobulin class but IgM is most commonly tested. RF also occurs in a wide variety of other conditions and in some normal adults (Box 25.6); it

therefore has low diagnostic specificity for RA and also lacks sensitivity, since about 30% of patients with typical signs of RA are negative for RF (so-called seronegative RA). The principal use of RF testing is for prognosis, since a high RF titre at presentation associates with more severe disease.

Antibodies to cyclic citrullinated peptides (anti-CCP antibodies)

Anti-CCP antibodies bind to peptides in which the amino acid arginine has been converted to citrulline by peptidylarginine deiminase, an enzyme abundant in inflamed synovium. They have similar sensitivity to RF for RA (70%) but much higher specificity (> 95%). Anti-CCP antibodies are increasingly being used in preference to RF to support a diagnosis of RA in patients with early polyarthritis. Anti-CCP antibodies are associated with more severe disease and can be detected in asymptomatic patients several years before the development of RA.

Antinuclear antibodies (ANA)

These are directed against one or more components of the nucleus. Box 25.7 gives the many causes of a positive ANA. Low titre ANA is common in normal individuals. The higher the ANA titre, the greater its diagnostic significance, but high titres do not imply more severe disease. The most common indication for ANA testing is in the diagnosis of SLE. ANA has high sensitivity for SLE (virtually 100%) but low specificity (10–40%); a negative ANA virtually excludes SLE but a positive result does not confirm it.

If an ANA result is positive, it is usual to test for the specific antigen. Anti-DNA antibodies bind to double-stranded DNA and are highly specific (95%) but only moderately sensitive (30%) for SLE. They can be useful in disease monitoring since very high titres are associated with more severe disease, including renal or central nervous system (CNS) involvement, and an increase in antibody titre may precede relapse.

Antibodies to specific 'extractable' nuclear antigens can have higher specificity for certain diagnoses or certain patterns of system involvement, although their sensitivity is low (Box 25.8). They are useful in the

25.6 Conditions associated with a positive rheumatoid factor

Disease	Frequency (%)
Rheumatoid arthritis with nodules and extra-articular manifestations	100
Rheumatoid arthritis (overall)	70
Sjögren's syndrome	90
Mixed essential cryoglobulinaemia	90
Primary biliary cirrhosis	50
Subacute bacterial endocarditis	40
Systemic lupus erythematosus	30
Tuberculosis	15
Old age (> 65 yrs)	20

N.B. Normal healthy people can be seropositive.

25.7 Conditions associated with a positive antinuclear antibody

Disease	Approximate frequency
Diseases for which an ANA is useful in diagnosis	
SLE	~100%
Systemic sclerosis	60–80%
Sjögren's syndrome	40–70%
Dermatomyositis or polymyositis	30–80%
Mixed connective tissue disease	100%
Autoimmune hepatitis	Part of diagnostic criteria
Diseases for which an ANA is not useful in diagnosis	
Rheumatoid arthritis	30–50%
Autoimmune thyroid disease	30–50%
Malignancy	Varies widely
Infectious diseases	Varies widely

N.B. 5% of healthy individuals have an ANA titre > 1:80.

25.8 Conditions associated with antibodies to extractable nuclear antigens	
Antibody	Disease association
Anti-centromere antibody	CREST variant of systemic sclerosis (sensitivity 60%, specificity 98%) Also occasionally found in primary Raynaud's syndrome
Anti-histone antibody	Drug-induced lupus
Anti-Jo-1 (anti-histidyl-tRNA synthetase)	Polymyositis, dermatomyositis or polymyositis-systemic sclerosis overlap (20–30%). Particularly associated with interstitial lung disease
Anti-La antibody (anti-SS-B)	Sjögren's syndrome SLE (20–60%)
Anti-ribonucleoprotein antibody (anti-RNP)	Mixed connective tissue disease SLE, usually in conjunction with anti-Sm antibodies
Anti-Ro antibody (anti-SS-A)	SLE (35–60%): associated with photosensitivity, thrombocytopenia and subacute cutaneous lupus Maternal anti-Ro antibodies associated with neonatal lupus and congenital heart block Sjögren's syndrome (40–80%)
Anti-RNA polymerase I	Rapidly progressive diffuse systemic sclerosis
Anti-Smith antibody (Anti-Sm)	Very specific for SLE (15–30%); associated with renal disease
Anti-topoisomerase I antibody (Anti-Scl-70)	Diffuse systemic sclerosis: associated with more severe organ involvement, including pulmonary fibrosis

evaluation of SLE and other connective tissue diseases and can give clues to the underlying diagnosis, especially when combined with clinical findings. For example, antibodies to Sm occur in 10% of Caucasian and 30% of black and Chinese patients with SLE. They have high diagnostic specificity and are associated with renal disease. Antibodies to Ro occur in SLE and in Sjögren's syndrome (in association with anti-La antibodies), and are associated with a high frequency of photosensitive rashes and risk of congenital heart block. Antibodies to ribonuclear protein (RNP) occur in SLE and also in mixed connective tissue disease, where features of lupus, myositis and systemic sclerosis coexist. Anti-topoisomerase 1 (also termed Scl-70) antibodies are specific for diffuse systemic sclerosis, whereas anti-centromere antibodies are more specific for limited systemic sclerosis.

Antineutrophil cytoplasmic antibodies (ANCA)

ANCA are IgG antibodies to the cytoplasmic constituents of granulocytes and are useful in the diagnosis of suspected systemic vasculitis. Two common patterns are described by immunofluorescence: cytoplasmic fluorescence (c-ANCA) and perinuclear fluorescence

(p-ANCA). c-ANCA are associated with antibodies to proteinase-3 (PR3), and occur in > 90% of patients with Wegener's granulomatosis with renal involvement. p-ANCA are associated with antibodies to other cytoplasmic enzymes, particularly myeloperoxidase (MPO), lactoferrin and elastase. A positive p-ANCA alone is a non-specific finding but, if due to MPO antibodies, is associated with microscopic polyarteritis and Churg–Strauss vasculitis. Atypical p-ANCA, which is not due to anti-myeloperoxidase antibodies, are commonly found in patients with ulcerative colitis and autoimmune liver disease but are not of diagnostic or prognostic significance. Serial measurement of anti-PR3 or anti-MPO antibodies may be useful for disease monitoring. Although ANCA are useful, they are not specific for vasculitis and may be found in malignancy, infection (bacterial and HIV), inflammatory bowel disease, rheumatoid arthritis, lupus and pulmonary fibrosis.

Biochemistry

Routine biochemistry is useful in the assessment of metabolic bone disease, muscle diseases and gout. Serum levels of uric acid are usually raised in gout but a normal level does not exclude the diagnosis, especially during an acute attack when urate levels temporarily fall. Equally, an elevated serum uric acid does not confirm the diagnosis, since most hyperuricaemic people never develop gout.

Serum creatinine kinase (CK) levels are useful in the diagnosis of myopathy or myositis, but the specificity and sensitivity are poor and raised levels may occur in a variety of conditions (Box 25.9).

Several bone diseases, including Paget's disease, renal bone disease and osteomalacia give a characteristic pattern on biochemical testing which can be useful diagnostically (Box 25.10). Other, more specific biochemical markers can reflect levels of bone resorption and bone formation. The best markers of bone resorption are N-telopeptide (NTX) and C-telopeptide (CTX) collagen cross-links, which can be measured in blood or urine samples, or deoxypyridinoline (DPD), which is measured in urine. Bone formation can be assessed by serum alkaline phosphatase (ALP), but this is non-specific and levels can also be raised in liver and kidney disease. Bone-specific alkaline phosphatase (BSAP) and the amino terminal fragment of procollagen (PINP) are more specific markers of bone formation. Measurement of these markers can be useful in patients with unusual presentations and to monitor the response to treatment, especially in osteoporosis.

25.9 Causes of an elevated serum creatine kinase

- Inflammatory myositis ± vasculitis
- Muscular dystrophy
- Motor neuron disease
- Alcohol, drugs
- Trauma, strenuous exercise
- Myocardial infarction*
- Hypothyroidism, metabolic myopathy

*The CK-MB cardiac-specific isoform is disproportionately elevated compared with total CK.

25.10 Biochemical abnormalities in various bone diseases

	Serum calcium	Serum phosphate	Serum alkaline phosphatase	Serum PTH	Serum 25(OH)D
Osteoporosis	N	N	N	N	N or ↓
Paget's disease	N	N	↑↑	N or ↑	N
Renal osteodystrophy	↓	↑↑	↑	↑↑↑	N
Vitamin D-deficient osteomalacia	N or ↓	N or ↓	↑↑	↑↑	↓
Hypo-phosphataemic rickets	N	↓↓↓	↑↑	N	N

N = normal.

Tissue sampling

Bone biopsy is helpful in the differential diagnosis of bone diseases when less invasive tests have proved inconclusive. If a systemic disease is suspected, the biopsy should be taken from the iliac crest using a large diameter (8 mm) trephine needle under local anaesthetic. For focal lesions, the biopsy should be taken under X-ray guidance or at open surgery, from an affected site. If osteomalacia is suspected, the sample should be processed without decalcification.

Synovial biopsy may be required in patients with chronic inflammatory monoarthritis or tenosynovitis to identify specific causes such as chronic mycobacterial infection or pigmented villonodular synovitis (p. 1129). It may be obtained arthroscopically or using ultrasound guidance under local anaesthetic.

Muscle biopsy is useful in the investigation of myopathy, myositis and systemic vasculitis. It is usually taken from the quadriceps or deltoid under local anaesthetic through a small skin incision. Immunohistochemical staining, together with plain histology, gives information on primary and secondary muscle and neuromuscular disease, as well as some forms of systemic vasculitis. Repeat biopsy can be useful for monitoring treatment response.

Electromyography

Electromyography (EMG, p. 1142) is used in the investigation of suspected myopathy or myositis. In inflammatory polymyositis, it may show a diagnostic triad of:

- spontaneous fibrillation
- short-duration action potentials in a polyphasic disorganised outline
- repetitive bouts of high-voltage oscillations produced by needle contact with diseased muscle.

PRESENTING PROBLEMS IN MUSCULOSKELETAL DISEASE

Pain in a single joint

Acute inflammatory monoarthritis

This is most commonly due to crystals or sepsis. Other causes are listed in Box 25.11. Acute monoarthritis can be the presentation of what subsequently evolves into oligo- or polyarthritis. Consideration of the following suggests the most likely diagnosis:

- *Age and gender of the patient.* Reactive arthritis is the most common cause in young men; gout typically presents in middle-aged men; pseudogout mainly targets older women.
- *Joint involved.* Classic target sites include the first metatarsophalangeal (MTP) joint (gout); the big toe interphalangeal joint (reactive/psoriatic arthritis); the elbow and ankle (haemarthrosis, seronegative spondyloarthritis); the wrist and shoulder (pseudogout); and finger joints (psoriasis, plant thorn synovitis). The knee can be affected in almost any disease.
- *Speed of onset.* Crystal synovitis develops very rapidly, often reaching maximum severity with extreme pain within just 6–12 hours, whereas sepsis is more subacute and continues to progress until treated.
- *Periarticular inflammation.* Synovitis with soft tissue swelling and erythema is a classic feature of sepsis and crystals, but may also occur with seronegative spondyloarthritis and erythema nodosum. Haemarthrosis can cause a very tense effusion, often splinting the joint in its loose-pack position, but there is no surrounding swelling or skin change. The combination of small joint synovitis and adjacent periarticular swelling in a digit ('dactylitis') is characteristic of psoriasis (fingers, toes) or reactive arthritis (toes).
- *Features preceding the onset of pain.* These include dysentery or new sexual contact preceding reactive arthritis; intercurrent illness or surgery triggering crystal synovitis; clinical features or a family history of psoriasis; and streptococcal sore throat triggering erythema nodosum.

25.11 Principal causes of acute monoarthritis in a previously normal joint

- Septic arthritis*
- Crystal synovitis: gout, pseudogout
- Monoarticular presentation of oligo- or polyarthritis
 - Reactive, psoriatic or other seronegative spondyloarthritis
 - Erythema nodosum
 - Rheumatoid arthritis
 - Juvenile idiopathic arthritis*
- Trauma: especially if associated with haemarthrosis
- Haemarthrosis associated with clotting abnormality
- Foreign body reaction (e.g. plant thorn)

*In children, sepsis and juvenile idiopathic arthritis are the most common causes, but osteomyelitis and leukaemia also present with monoarthritis.

25.12 Common causes of acute arthritis in a previously abnormal joint

Damaged joint

- Pseudogout in association with osteoarthritis
- Bone pathology
 - Secondary avascular necrosis
 - Subchondral collapse or fracture
- Cartilage damage
 - Fibrocartilage tear, cartilage debris
- Haemarthrosis
- Septic arthritis

Existing inflammatory disease (with or without damage)

- Septic arthritis
- Exacerbation of underlying disease

25.13 Causes of chronic single site synovitis

- Foreign body (e.g. plant thorn)
- Infection, including tuberculosis, fungi
- Chronic sarcoidosis (p. 708)
- Enteropathic arthritis (mainly Crohn's)
- Amyloidosis
- Pigmented villonodular synovitis
- Synovial chondromatosis
- Synovial sarcoma
- Monoarticular presentation of oligo-/polyarticular disease
 - Rheumatoid arthritis
 - Seronegative spondyloarthritis
 - Juvenile idiopathic arthritis

The differential diagnosis changes when acute monoarthritis occurs in a joint that is already abnormal (Box 25.12). For example, an acute flare of inflammation in a single joint in a patient with known RA suggests sepsis, as RA has a strong negative association with crystal deposition. Investigation of acute monoarthritis varies depending on the presentation, but joint aspiration is required if there is a possibility of sepsis or crystals.

Chronic inflammatory monoarthritis

There are various causes of chronic inflammatory monoarthritis that persists for more than 6 weeks (Box 25.13). The knee is the most common site but almost any joint may be involved. If no cause is apparent by 6 months, or if there are radiographic signs of osteopenia, erosion or periostitis, synovial biopsy is usually undertaken to exclude chronic infection or rare causes that have specific treatments. Retrospective studies suggest that about 25% of cases evolve to OA and about 25% to RA but 30% remain undiagnosed.

Oligoarthritis

Oligoarthritis affects 2–4 joints or joint groups (the wrist has many joints but counts as a single site). By far the most common cause is OA, which causes non-inflammatory symptoms that usually affect just one or a few sites at any one time, even though asymptomatic multiple joint OA may be apparent on examination.

Acute or subacute inflammatory oligoarthritis that targets the lower limbs in an asymmetric pattern is usually

25.14 Causes of inflammatory oligoarthritis

- Seronegative spondyloarthritis
 - Reactive arthritis
 - Psoriatic arthritis
 - Ankylosing spondylitis
 - Enteropathic arthritis
- Erythema nodosum
- Juvenile idiopathic arthritis
- Oligoarticular presentation of polyarthritis
- Infection, including
 - Infective endocarditis
 - Neisseria*
 - Mycobacteria*

due to seronegative spondyloarthritis (Box 25.14). Sequential joint involvement that ascends a limb—for example, a midfoot, followed by the ankle and then the knee—is almost always due to sepsis.

Polyarthritis

Polyarthritis is defined as the involvement of five or more joints or joint groups. Features helpful in determining the cause (Box 25.15) are:

- symmetry
- involvement of the upper and/or lower limbs
- involvement of large and/or small joints
- periarticular involvement
- extra-articular features (Box 25.16).

25.15 Causes of polyarthritis

Cause	Characteristics
Non-inflammatory	
Generalised osteoarthritis	Very common; symmetrical, small and large joints with only a few symptomatic at any one time, Heberden's nodes
Haemochromatosis (p. 959)	Rare; small and large joints
Acromegaly (p. 790)	Rare; mainly large joints, spine
Inflammatory	
Viral arthritis	Very acute, self-limiting
Rheumatoid arthritis	Symmetrical, small and large joints, upper and lower limbs
Seronegative spondyloarthritis (psoriasis, reactive, ankylosing spondylitis, enteropathic arthropathy)	Asymmetrical, large > small joints, lower > upper limbs, spondylitis
Systemic lupus erythematosus (SLE)	Symmetrical, small > large joints, joint damage uncommon
Chronic gout	Distal > proximal joints, preceded by acute attacks
Juvenile idiopathic arthritis	Symmetrical, small and large joints, upper and lower limbs
Chronic sarcoidosis	Symmetrical, small and large joints
Systemic sclerosis and polymyositis	Rare; small and large joints
Hypertrophic osteoarthropathy	Rare; large > small joints, clubbing

25.16 Extra-articular features of inflammatory arthritis

Clinical feature	Disease association
Skin, nails and mucous membranes	
Psoriasis, nail pitting and dystrophy	Psoriatic arthritis
Raynaud's phenomenon	SLE, systemic sclerosis
Photosensitivity	SLE
Livedo reticularis	SLE
Splinter haemorrhages, nail-fold infarcts	Vasculitis
Oral ulcers	SLE, reactive arthritis, Behçet's syndrome
Large nodules (mainly extensor surfaces)	RA, gout
Clubbing	Enteropathic arthritis, metastatic lung cancer, endocarditis
Eyes	
Uveitis	Seronegative spondyloarthritis
Conjunctivitis	Reactive arthritis
Episcleritis, scleritis	RA, vasculitis
Heart, lungs	
Pleuro-pericarditis	SLE, RA
Fibrosing alveolitis	RA, SLE, other connective tissue disease
Abdominal organs	
Hepatosplenomegaly	RA, SLE
Haematuria, proteinuria	SLE, vasculitis, systemic sclerosis
Urethritis	Reactive arthritis
Fever, lymphadenopathy	Infection, systemic juvenile idiopathic arthritis

Many viral infections can cause arthralgia (joint pain without abnormal examination findings), and an acute symmetrical inflammatory polyarthritis affecting small and large joints of upper and lower limbs that is usually self-limiting within 6 weeks. They include parvovirus, hepatitis B and C, mumps, rubella, chickenpox and infectious mononucleosis. The rapidity of onset, the presence of fever and the characteristic rash usually suggest the diagnosis. Arthritis usually precedes jaundice from hepatitis B. Rubella arthritis mainly affects girls and women, occurring 1–7 days after the rash or 2–6 weeks after vaccination. Rubella is exceptional in that although the symmetrical polyarthritis settles, oligoarthritis may persist for some months.

Polyarthritis that persists for more than 6 weeks is unlikely to be viral (see Box 25.15). A definitive diagnosis may initially be difficult but often becomes clearer as characteristic features develop. However, certain patterns are characteristic and may be present at or soon after presentation (Fig. 25.9). RA is by far the most common cause of chronic inflammatory, symmetrical polyarthritis affecting small and large joints of upper and lower limbs. Tenosynovitis and bursitis are the main periarticular manifestations. Marked asymmetry, lower limb predominance and greater involvement of large joints are all more characteristic of seronegative spondyloarthritis (p. 1092). Systemic lupus erythematosus (SLE) usually causes arthralgia and tenosynovitis rather than synovitis (p. 1107). Chronic polyarthritis due to gout is invariably preceded by a long history of acute attacks. Other causes of polyarthritis are rare.

A detailed history and examination often reveal the likely diagnosis and direct investigation. For inflammatory polyarthritis present for less than 6 weeks, an FBC, liver

Fig. 25.9 Contrasting patterns of involvement in polyarthritis. **A** Rheumatoid arthritis (symmetrical, small and large joints, upper and lower limbs). **B** Seronegative psoriatic arthritis (asymmetrical, large > small joints, associated periarticular inflammation giving dactylitis). **C** Seronegative spondyloarthritis (axial involvement, large > small joints, asymmetrical).

function tests and viral serology are useful. For early persistent polyarthritis of indeterminate cause, initial investigation should also include an ESR, CRP, anti-CCP, RF and anti-nuclear antibodies, and X-rays of hands and feet.

Fracture

The presentation is with localised bone pain usually occurring after trauma, which is worsened by movement of the affected limb or region. Fractures are divisible into three subtypes:

- *Fragility fractures* result from relatively minor trauma and are typical of osteoporosis. With vertebral fractures, the precipitating factor is often bending or lifting but with long bone fractures the trigger is usually a fall.
- *Pathological fractures* occur in bone that is structurally abnormal, such as in Paget's disease, osteomalacia, bone metastases and parathyroid bone disease. Like fragility fractures, they can occur spontaneously or follow minor trauma.
- *High-energy fractures* result from major trauma and can affect normal bones. The same is true of *stress (fatigue)* fractures in healthy individuals such as athletes and military recruits who are exposed to repetitive trauma.

The main differential diagnosis is soft tissue injury, but fracture should be suspected when there is marked pain and swelling, abnormal movement of the affected limb, crepitus or deformity. Femoral neck fractures typically produce a shortened, externally rotated leg that is painful to move. Presentation of vertebral fractures is highly variable. Some cause acute severe back pain with radiation to the anterior chest or abdominal wall. Others cause few symptoms and present insidiously with intermittent back pain and height loss. Osteoporotic rib fractures are characterised by aggravation of the pain by movement, local tenderness and pain on springing the rib cage.

Investigations include X-rays of the affected bone which should be taken in at least two planes and examined for discontinuity of the cortical outline (Box 25.17). If these are normal but clinical suspicion remains high, other imaging techniques may be used such as radioisotope bone scans for fatigue fractures or scaphoid fractures, and CT or MRI scans for fractures of the pelvis or spine. CT or MRI can also help differentiate pathological fractures of the spine due to tumour from fractures due to osteoporosis.

Treatment includes adequate pain relief with opiates, if necessary, reduction of the fracture to restore normal anatomy, and immobilisation to promote healing, either

by plaster cast or by internal fixation. Femoral neck fractures present a special management problem since non-union and avascular necrosis are common complications. This is especially true with intracapsular hip fractures, and these require surgical replacement of the femoral head with a prosthesis.

Rehabilitation is as important as reduction and fixation in determining outcome. A supervised exercise programme is required to avoid muscle-wasting and joint stiffness which impair long-term mobility, especially in old age. Older patients with hip fracture also benefit from nutritional supplementation. Patients with high-energy and fatigue fractures generally require no further investigation or treatment once the fracture has healed. Patients with fragility fractures, vertebral fractures and pathological fractures should be investigated for secondary causes (p. 1117).

Bone pain without fracture

Causes of this are shown in Box 25.18. It is often difficult to differentiate bone pain from joint or periarticular pain, but in the absence of fracture, bone pain is characteristically:

- localised to the affected bone, rather than the joint
- present at rest and worse at night
- not reproduced by joint movement

Relentlessly progressive pain suggests a destructive disease like malignancy or chronic infection. Malignancy may be associated with weight loss, fatigue and symptoms relating to the primary site. Pain experienced over a wider area associated with deformity suggests Paget's disease (p. 1124). Osteomalacia (p. 1121) is associated with bone tenderness and limb girdle weakness. Pain from osteonecrosis is initially bony and progressive but may change its characteristics as the adjacent joint cartilage collapses, with pain worse on usage or weight-bearing, with or without radiation, (mainly hips, shoulders or elbows). Investigation of bone pain includes plain X-rays of the symptomatic site, MRI, or radioisotope bone scan and other tests directed by the presumptive diagnosis.

25.18 Causes of bone pain without fracture

- Metastatic bone disease or primary bone tumour
- Paget's disease
- Osteomalacia
- Chronic infection (osteomyelitis)
- Osteonecrosis

25.17 How to investigate a suspected fracture

- Order X-rays in two projections at right angles to one another
- Include the whole bone and the joints at either end (this may reveal an additional unsuspected fracture)
- Check for evidence of displacement
- Check for a break in the cortex
- In suspected vertebral fracture, check for depression of the end-plate
- If clinical suspicion is high but no fracture is seen, consider further imaging (e.g. bone scan, CT, MRI)

Regional periarticular pain

Single regional pain

This usually results from an over-usage strain or injury affecting a periarticular structure. The patient can often identify an obvious provoking event or injury. The pain is non-progressive and reproduced by just one or a few movements; the patient is otherwise well. Examination reveals localised periarticular tenderness without signs of florid inflammation, and the pain may be reproduced by resisted active movement or by stress testing the

involved structure. Predisposing factors include increasing age, obesity, generalised hypermobility, and occupational and recreational usage.

Muscle injuries usually settle within days, whereas fibrous structures such as tendons and ligaments can take weeks or months to return to normal. The diagnosis is usually made clinically, although imaging, especially ultrasound and MRI, may confirm the anatomical structure involved and the extent of injury. Management is aimed towards:

- identifying and avoiding predisposing or adverse mechanical factors if possible
- pain relief (topical and/or oral analgesics, local injection for severe pain)
- appropriate exercise and rehabilitation to restore movement and function.

Surgery is only occasionally required for very resistant or disabling lesions.

Shoulder pain

Shoulder pain is a common complaint in both genders over the age of 40, principally due to rotator cuff lesions (Box 25.19). Varying pain patterns of common lesions are shown in Figure 25.10.

25.19 Examination findings in common periarticular lesions at the shoulder
Rotator cuff lesion
<ul style="list-style-type: none"> • Pain reproduced by resisted active movement: Abduction: supraspinatus External rotation: infraspinatus, teres minor Internal rotation: subscapularis
Subacromial bursitis
<ul style="list-style-type: none"> • No pain on resisted active abduction (cf. supraspinatus lesion, the other cause of a painful middle arc)
Bicipital (long head) tendinitis
<ul style="list-style-type: none"> • Tender over bicipital groove • Pain reproduced by resisted active wrist supination or elbow flexion

Fig. 25.10 Pain patterns around the shoulder. The dark shading indicates sites of maximum pain.

Adhesive capsulitis ('frozen shoulder') presents with upper arm pain that progresses over 4–10 weeks before subsiding over a similar time course. Glenohumeral restriction is present from the outset but progresses to its maximum as the pain settles. In the early phase, there is marked anterior joint/capsular tenderness and stress pain in a capsular pattern; later there is painless restriction, often of all movements. Frozen shoulder is more common in diabetes mellitus, and may be triggered by a rotator cuff tear, local trauma, myocardial infarction or hemiplegia. Treatment in the early stage is with analgesia, intra- and extracapsular steroid injection, and regular 'pendulum' exercises of the arm to prevent the capsule from over-tightening. Mobilising and strengthening exercises are the sole treatment in the painless 'frozen' stage. The natural history is for slow but complete recovery, sometimes taking up to 2 years.

Elbow pain

Pain from the three joint compartments is felt maximally at the elbow, close to its origin, with occasional radiation down the forearm. Lateral epicondylitis is the most common periarticular lesion (Box 25.20). Olecranon bursitis can follow local repetitive trauma but infection, gout and RA may also be responsible.

25.20 Periarticular lesions presenting as elbow pain

Lesion	Pain	Examination findings
Tennis elbow	Lateral epicondyle Radiation to extensor forearm	Tender over epicondyle Pain reproduced by resisted active wrist extension
Golfer's elbow	Medial epicondyle Radiation to flexor forearm	Tender over epicondyle Pain reproduced by resisted active wrist flexion
Olecranon bursitis	Olecranon	Fluctuant tender swelling over olecranon

Hand and wrist pain

Pain from hand or wrist joints is well localised to the affected joint, except for pain from the first carpometacarpal joint, commonly targeted by OA which, although maximal at the thumb base, often radiates down the thumb and back over the radial wrist. Non-articular causes of hand pain include:

- tenosynovitis: flexor or extensor (pain and swelling, with or without fine crepitus on volar or extensor aspect)
- median nerve compression (carpal tunnel syndrome, p. 1228)
- Raynaud's phenomenon (p. 601)
- C8/T1 radiculopathy
- algodystrophy (reflex sympathetic dystrophy, p. 1125).

Trigger finger results from stenosing tenosynovitis in the flexor tendon sheath, with intermittent locking of the finger in flexion. A local steroid injection often relieves the problem and surgical decompression is only occasionally required.

De Quervain's tenosynovitis involves the tendon sheaths of abductor pollicis longus and extensor pollicis

brevis, and produces pain maximal over the radial aspect of the distal forearm and wrist. There is tenderness (with or without warmth, linear swelling and fine crepitus) over the distal radius and marked pain on forced ulnar deviation of the wrist with the thumb held across the patient's palm (Finkelstein's sign). It is usually caused by over-usage.

Dupuytren's contracture results from fibrosis and contracture of the superficial palmar fascia. The patient is unable to extend the fingers fully and there is puckering of the skin with palpable nodules. The ring and little fingers are usually the first and worst affected. It is usually painless and the main symptoms relate to the curled fingers becoming snagged in pockets. It is age-related and usually bilateral, strongly predominates in men, and is often familial with dominant inheritance. It can be associated with plantar fibromatosis, Peyronie's disease, alcohol misuse and chronic vibration injury. It is very slowly progressive. Often no treatment is required, but fasciotomy may be necessary if symptoms are troublesome.

Hip pain

Pain from the hip joint is usually maximal deep in the anterior groin, with variable radiation to the buttock, anterolateral thigh, knee or shin (Fig. 25.11). Trochanteric bursitis is the most common periarticular lesion (Box 25.21), typically affecting obese women, and occurring in isolation or secondary to an abnormal gait, such as in hip or knee OA.

Hip pain may be referred from other structures. Back pain commonly radiates to the buttock and posterior thigh but the site of maximal pain is close to the spine or pelvic brim. Root entrapment can cause pain in the lateral thigh (T12–L1) or the inguinal region and lateral thigh (L2–4) but is worsened by coughing and straining

25.21 Periarticular lesions at the hip		
Lesion	Pain	Examination findings
Trochanteric bursitis	Upper lateral thigh, worse on lying on that side at night	Tender over greater trochanter
Gluteal enthesopathy	Upper lateral thigh, worse on lying on that side at night	Tender over greater trochanter Pain reproduced by resisted active hip abduction
Adductor tendinitis	Upper inner thigh Usually clearly sports-related	Tender over adductor origin/tendon/muscle Pain reproduced by resisted active hip adduction
Ischiogluteal bursitis	Buttock, worse on sitting	Tender over ischial prominence
Iliopectineal bursitis	Anterior groin	Tender (\pm fluctuant swelling) lateral to femoral pulse, not worsened by internal rotation of hip (cf. hip pain)

more than by movement and is often accompanied by sensory disturbance. A psoas abscess, retroperitoneal haemorrhage or pelvic inflammation can cause inguinal and lateral thigh pain that is aggravated by resisted hip flexion. Sacroiliac pain is maximal in the buttock, with radiation down the posterior thigh, worse on standing on that leg.

Knee pain

Pain arising from the patello-femoral or medial and lateral tibio-femoral compartments is anterior and well localised to the involved compartment. Patello-femoral pain is worse going up and down stairs or inclines. Locking—sudden painful inability to extend fully that often spontaneously unlocks, followed by aching—is usually due to mechanical derangement such as a meniscal tear or osteochondritis dissecans. Referred pain from the hip may present at the knee but is more diffuse and often relieved by rubbing; on examination, it is reproduced by hip not knee movement.

Pain from periarticular lesions is well localised to the involved structure (Box 25.22). Inflammation of any of the three bursae around the patella usually results from repetitive occupational kneeling, but also infection and gout.

Anterior knee pain syndrome is common, especially in adolescent girls. The pain has patello-femoral characteristics and is often aggravated by sports. In a small proportion, there is evidence of non-progressive fibrillation of the retropatellar cartilage ('chondromalacia patellae'). It is usually self-limiting and treatment is conservative.

Anterior tibial compartment syndrome is characterised by severe pain in the front of the lower leg, aggravated by exercise and relieved by rest. Symptoms result from fascial compression of the muscles in the anterior tibial compartment and may be associated with foot drop. Treatment is urgent surgical decompression.

Fig. 25.11 Pain patterns of hip disease and trochanteric bursitis. The dark shading indicates sites of maximum pain.

25.22 Periarticular lesions at the knee

Lesion	Pain	Examination findings
Pre-patellar bursitis	Anterior patella	Tender fluctuant swelling in front of patella
Superficial and deep infrapatellar bursitis	Anterior knee, inferior to patella	Tender fluctuant swelling in front of (superficial) or behind (deep) patella tendon
Anserine bursitis	Upper medial tibia	Tenderness (\pm warmth, swelling) over upper medial tibia
Inferior medial collateral ligament enthesopathy	Upper medial tibia	Localised tenderness of upper medial tibia Pain reproduced by valgus stress on mildly flexed knee
Popliteal ('Baker's') cyst	Popliteal fossa	Tender swelling of popliteal fossa, usually reducible by massage with knee in mid-flexion
Patella tendon enthesopathy (Osgood-Schlatter disease)	Anterior upper tibia Mainly energetic adolescents	Tenderness and firm swelling of tibial tubercle Pain on resisted active knee extension

Foot and ankle pain

Pain from the ankle joint is felt anteriorly between the two malleoli and is worse on standing or walking. Subtalar pain is mainly posterior between the malleoli and is particularly aggravated by walking on uneven surfaces, requiring eversion/inversion. Periarticular lesions that cause hindfoot pain are listed in Box 25.23.

25.23 Periarticular lesions causing hindfoot pain

Lesion	Pain	Examination findings
Plantar fasciitis	Under heel, worse on standing and walking	Tender under distal calcaneus/plantar fascia insertion site
Subcalcaneal bursitis	Under heel, worse on standing and walking	Tender under middle of calcaneus
Achilles tendinitis	Localised to tendon	Tender on squeezing tendon, \pm swelling of tendon Pain reproduced by standing on toes or resisted plantar flexion
Achilles enthesopathy	Localised to tendon insertion	Tender over insertion site, \pm firm swelling Pain reproduced by standing on toes or resisted plantar flexion
Retro-Achilles bursitis	Posterior heel	Tenderness and soft swelling posterior to tendon
Pre-Achilles bursitis	Posterior heel	Tenderness and fluctuant swelling anterior to tendon

Midtarsal disease causes pain in the 'bootlace' area, mainly during the late stance and toe-off phase of walking. Loss of the normal arches—pes planus ('flat foot')—may cause pain in the mid-sole. This is often congenital, but acquired causes include trauma, constitutional hyper-mobility, RA and neuropathic arthropathy. Medial arch supports in well-fitting shoes and/or intrinsic muscle-strengthening exercises usually relieve symptoms, but rigid splints may be required for hyperpronated feet, provided the foot is not rigid from fusion of the tarsal bones (tarsal coalition).

MTP joint pain is felt below the metatarsal heads (metatarsalgia) and is often described as 'like walking on marbles'. Hallux valgus deformity with secondary bursitis (bunions) and OA of the first MTP joint is often associated with flattening of the transverse metatarsal arch and is a common cause of forefoot pain. It predominates in women as a consequence of wearing narrow high-heeled shoes. Severe restriction of first MTP joint extension (hallux rigidus), usually due to OA, may cause marked pain during attempted toe-off. For both hallux problems, conservative treatment and appropriate footwear usually suffice, although surgery is required in a minority.

Pes cavus ('claw foot') is characterised by a high medial arch, secondary clawing of toes and metatarsal callosities. It can be caused by neurological disorders such as Friedreich's ataxia, spina bifida or poliomyelitis. Associated pain is often helped by medial arch supports and metatarsal insoles, and fasciotomy or osteotomy is rarely indicated.

Morton's neuroma is an entrapment neuropathy of the interdigital nerves, mostly between the third and fourth metatarsal heads in middle-aged women with ill-fitting shoes. The neuralgic, lancinating pain occurs mainly when the patient is wearing shoes and may associate with local sensory loss and a palpable tender swelling between the metatarsal heads. Footwear adjustment, with or without a local corticosteroid injection, is often sufficient but excision is occasionally required.

Multiple regional pain

Widespread pain localised to the soft tissues is most commonly due to fibromyalgia (p. 1105). Another important cause is joint hypermobility. This tends to be more common in women and in Afro-Caribbeans, and declines with age. The 10% of adults at the lax end of the spectrum of joint mobility are predisposed to ligament strain, traumatic enthesopathy, mechanical back pain, arthralgia and dislocation (mainly glenohumeral). For epidemiological purposes, generalised hypermobility is recognised in adults by a modified Beighton score (Box 25.24). Within this 10%

25.24 Modified Beighton score

- Extend little finger $> 90^\circ$ (1 point each side)
- Bring thumb back parallel to/touching forearm (1 point each side)
- Extend elbow $> 10^\circ$ (1 point each side)
- Extend knee $> 10^\circ$ (1 point each side)
- Touch floor with flat of hands, legs straight (1 point)

Hypermobility = 6 or more out of a possible 9 points for epidemiological studies, or 4 or more (with arthralgia in four or more joints) for clinical diagnosis of the benign joint hypermobility syndrome.

25.25 Causes of chronic multiple regional pain without arthritis

- Fibromyalgia (p. 1105)
- Joint hypermobility
- Seronegative spondyloarthritis (p. 1092)
- Osteomalacia (p. 1121)
- Polymyalgia rheumatica (p. 1115)
- Polymyositis (p. 1111)
- Diffuse idiopathic skeletal hyperostosis (DISH, p. 1129)
- Endocrine disease
 - Primary hyperparathyroidism (p. 766)
 - Hypothyroidism (p. 741)
 - Addison's disease (p. 775)
- Parkinson's disease (p. 1199)
- Drugs, e.g. retinoids (p. 1264), statins (p. 455)

are individuals with disease-associated hypermobility, such as in Marfan's syndrome (p. 602), Ehlers-Danlos syndrome (p. 1128) and acromegaly. For clinical purposes, the benign joint hypermobility syndrome (BJHS) has been defined and validated as a Beighton score of 4/9 or more (currently or historically) plus arthralgia for longer than 3 months in four or more joints. Other causes of multiple regional pain without arthropathy are shown in Box 25.25.

Back and neck pain

Low back pain

Back pain affects 60–80% of people at some time in their lives. Although the prevalence has not increased, reported disability from back pain has increased significantly in the last 30 years. In Western countries, back pain is the most common cause of sickness-related work absence, and in the UK 7% of adults consult their GP each year with back pain.

Only a small number of patients with back pain have a clear diagnosis. All structures in the spinal column, other than cartilage, are pain-sensitive. Although the

25.26 Specific causes of low back pain

- Spondylolysis (p. 1128)
- Spondylolisthesis (p. 1128)
- Spinal stenosis
- Prolapsed intervertebral disc
- Arachnoiditis
- Scheuermann's disease (p. 1129)
- Vertebral fracture (p. 1068)

exact mechanism of pain is often unclear, some specific causes are recognised (Box 25.26). The main purpose of clinical assessment is to identify the small number who have a serious spinal disorder. This should address the questions in Figure 25.12.

Mechanical pain

Mechanical pain accounts for more than 90% of episodes, usually affecting patients aged 20–55 years. The onset is often acute and associated with lifting or bending. It is related to activity and is generally relieved by rest (Box 25.27). It is usually confined to the lumbosacral region, buttock or thigh, is asymmetrical, and does not radiate beyond the knee (this implies nerve root irritation). On examination, there may be asymmetric local paraspinal muscle spasm and tenderness, and painful restriction of some but not all movements. Back pain precipitated by extension may relate to facet joint hypertrophy or spinal stenosis. Low back pain is more common in heavy

25.27 Features of simple mechanical low back pain

- Pain varies with physical activity (improved with rest)
- Sudden onset, precipitated by lifting or bending
- Recurrent episodes
- Pain limited to back or upper leg
- No clear-cut nerve root distribution
- No systemic features
- Prognosis good (90% recovery at 6 wks)

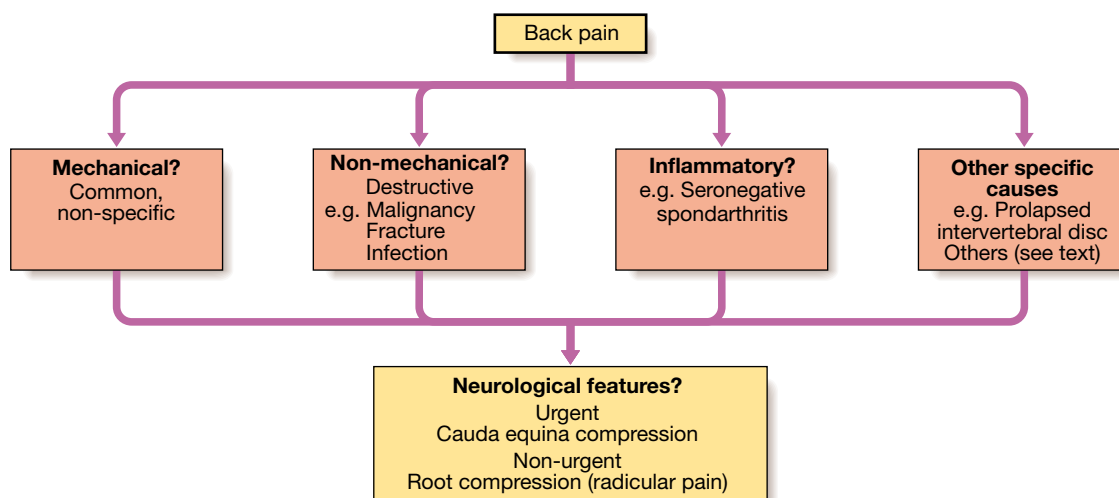

Fig. 25.12 Initial triage assessment of back pain.

manual workers, particularly those in occupations that involve heavy lifting and twisting. Psychological factors (e.g. job dissatisfaction, depression, anxiety) are important risk factors for both acute back pain and the transition to chronic pain and disability.

Non-mechanical pain

This is constant and often progressive, and has little variation in intensity or with activity. Anorexia, dyspepsia, change in bowel habit, prostatism or abnormal vaginal bleeding may indicate specific malignancies. Other 'red flags' for possible serious spinal pathology are indicated in Box 25.28. If there is evidence of a spinal cord or cauda equina lesion (Box 25.29), urgent neurosurgical assessment is required.

Inflammatory pain

Inflammatory pain due to spondylitis ('inflamed vertebrae/spine') has a more gradual onset and often occurs before the age of 30. It is usually axial, symmetrical and spread over many segments which may include the thoracic region. Pain from sacroiliitis is maximal in the buttock, with radiation down the posterior thigh. Inflammatory pain associates with marked morning and inactivity stiffness, and improves rather than worsens with activity.

25.28 Red flags for possible spinal pathology

History

- **Age:** presentation < 20 yrs or > 55 yrs
- **Character:** constant, progressive pain unrelieved by rest
- **Location:** thoracic pain
- **Past medical history:** carcinoma, tuberculosis, HIV, systemic corticosteroid use
- **Constitutional:** systemic upset, sweats, weight loss
- **Major trauma**

Examination

- Painful spinal deformity
- Severe/symmetrical spinal deformity
- Saddle anaesthesia
- Progressive neurological signs/muscle-wasting
- Multiple levels of root signs

25.29 Features of radicular pain

Nerve root pain

- Unilateral leg pain worse than low back pain
- Pain radiates beyond knee
- Paraesthesia in same distribution
- Nerve irritation signs (reduced straight leg raising which reproduces leg pain)
- Motor, sensory or reflex signs (limited to one nerve root)
- Prognosis reasonable (50% recovery at 6 wks)

Cauda equina syndrome

- Difficulty with micturition
- Loss of anal sphincter tone or faecal incontinence
- Saddle anaesthesia
- Gait disturbance
- Pain, numbness or weakness affecting one or both legs

Spinal stenosis

Spinal stenosis occurs when there is narrowing of the vertebral canal. The most common presentation is 'pseudoclaudication' with discomfort in the legs on walking that is relieved by rest, bending forwards or walking uphill. Common causes include Paget's disease where enlargement of the vertebrae may encroach on the spinal canal, and spondylosis of the spine where osteophytes can have the same effect. Patients may adopt a characteristic simian posture, with a forward stoop and slight flexion at the hips and knees. Decompression is indicated if mobility or quality of life is significantly impaired.

Prolapsed intervertebral disc

Age-related reductions in proteoglycans within the nucleus pulposus diminish its viscoelasticity, leading to focal damage and disc herniation. These changes occur most frequently at L4 and L5 due to the increased mechanical forces across this area. Most patients have their first episode between the ages of 20 and 30 years. Presentation is with radicular pain (invariably felt below the knee) in combination with evidence of root involvement (sensory deficit, motor weakness, asymmetrical reflexes) and a positive sciatic or femoral stretch test. About 70% of patients improve by 4 weeks. Persistent neurological deficit at 6 weeks is an indication for surgery.

Radicular pain

Radicular (nerve root) pain has a severe, sharp, lancinating quality, radiates down the back of the leg beyond the knee, and is aggravated by coughing, sneezing and straining at stool more than by back movement. On examination, there are signs of lumbar nerve root irritation (see Box 25.29). In contrast, referred pain is usually a dull, deep ache, poorly localised with indistinct boundaries.

Symptoms and signs of compression of multiple nerve roots in the cauda equina are shown in Box 25.29. It is vital to exclude compression of the spinal cord (p. 1223).

Arachnoiditis

Chronic inflammation of nerve root sheaths in the spinal canal can cause severe low back pain, sometimes combined with nerve root symptoms. Arachnoiditis can complicate meningitis or spinal surgery, but most frequently occurs as a late complication of myelography with oil-based contrast agents. No satisfactory treatment is available.

Investigations

Plain X-rays are rarely helpful in acute mechanical back pain unless red flags are present (see Box 25.28). Although advanced lumbar 'spondylosis' frequently accompanies low back pain, there is a poor correlation between pain and X-ray changes. Indeed, by the age of 50, 60% of women and 80% of men have radiographic features of spondylosis. Plain X-rays may be helpful in persistent pain in a young patient to confirm a diagnosis of ankylosing spondylitis, and in an older patient to detect vertebral osteoporotic fracture.

If red flags are present, MRI should be undertaken, even if plain X-rays are normal. CT is inferior to MRI for assessing soft tissue structures and nerves, but is useful for detecting minor abnormalities of bone architecture and in cases where MRI is contraindicated (e.g. pacemaker or metallic clips).

A low haemoglobin and raised CRP or ESR suggest inflammation or malignancy. A raised prostate-specific antigen (PSA) may indicate prostatic carcinoma, and raised alkaline phosphatase can occur in patients with bone metastases, osteomalacia and Paget's disease. Myeloma (p. 1041) is associated with a monoclonal band on serum immunoelectrophoresis and the presence of urinary light chains (Bence Jones proteinuria). EMG and nerve conduction studies are occasionally required to confirm and localise nerve root lesions.

Management

Most episodes of mechanical low back pain settle spontaneously with explanation, reassurance and simple analgesics. After 2 days, 30% are better and at 6 weeks 90% have recovered. Recurrences of pain are common, however, and the 10–15% of patients with acute back pain who develop chronic pain consume 85% of back pain resources.

Patient education is paramount and should emphasise that pain does not imply harm to the underlying structures and that exercise is helpful rather than damaging. Regular analgesia and/or non-steroidal anti-inflammatory drugs (NSAIDs) may be required to improve mobility and facilitate exercise. Return to work and normal activity should take place as soon as possible. Bed rest is not helpful and may increase the risk of chronic disability. Referral for physiotherapy or manipulation should be considered if a return to normal activities has not been achieved by 6 weeks. Low-dose tricyclic antidepressant drugs may help pain, sleep and mood.

Other treatment modalities occasionally used include epidural and facet joint injection, traction and lumbar supports. There is currently no evidence to support these (Box 25.30). Surgery is required in less than 1% of patients with low back pain.

EBM 25.30 Management of low back pain

'There is a reasonable evidence to support the following:

- Reassure patients (favourable prognosis)
- Advise patients to stay active
- Prescribe medication if necessary (preferably at fixed time intervals)
 - Paracetamol
 - NSAID
 - Consider opioids, muscle relaxants
- Discourage bed rest
- Consider spinal manipulation for pain relief
- Do not advise lumbar supports, back-specific exercises, traction, acupuncture, epidural or facet injections.'

• Koes BW. BMJ 2006; 332:1430–1434.

Neck pain

Neck pain is usually due to mechanical or degenerative problems, although serious spinal disease needs to be excluded using the same principles as for back pain. Most episodes of transient mechanical neck pain are not associated with demonstrable spinal pathology. Other causes of neck pain are listed in Box 25.31.

Pain arising from neck structures is often poorly localised. Pain from upper segments may radiate to the occiput, temple or face, and pain from lower segments to

the scapula, shoulder, arm and occasionally chest wall. Mechanical neck pain is often acute in onset and associated with asymmetrical restriction of neck movements and a history of awkward posture or trauma. Radicular pain may arise from compression from osteophyte or disc prolapse. Most (70%) affect the C6 disc, compressing the C7 root, but 20% affect C5 and compress the C6 root. Massive cervical osteophytes or DISH (p. 1129) occasionally cause dysphagia due to oesophageal indentation.

The principles of investigation and management are identical to those for low back pain. Surgery is only required when there are neurological signs of radiculopathy or progressive cervical myelopathy (p. 1222).

Muscle pain and weakness

Acute muscle weakness can arise from a variety of causes. It is important to distinguish between a subjective feeling of generalised weakness or fatigue, and an objective weakness with loss of muscle power and function. The former is a non-specific manifestation of many diseases, whereas the latter is often a sign of primary muscle disease.

Proximal muscle weakness suggests a proximal myopathy, which typically causes difficulty with standing from a seated position, squatting and lifting overhead. Distal power, such as grip, is usually preserved. The causes of proximal myopathy (Box 25.32) are either inflammatory (myositis) or non-inflammatory (endocrine or metabolic abnormalities or toxins).

Serum CK may be elevated with myopathy due to hypothyroidism, but is usually normal with Cushing's disease and steroid myopathy. Exercise intolerance, with post-exertional cramps (with or without a family history), suggests a metabolic myopathy, most commonly glycogen storage disorder (p. 448). A strong family history and

onset in childhood or early adulthood suggest muscular dystrophy (p. 1233). A drug history is important, notably alcohol, which can cause both inflammatory myopathy and muscle atrophy of type 2 fibres. Myopathy can associate with viral infections, including HIV, due to the virus itself or treatment with zidovudine.

Distal or generalised weakness usually indicates a neurological cause, which is even more likely if there are sensory abnormalities or if weakness is unilateral or focal. The weakness of myasthenia gravis (p. 1231) is characteristically worsened by repeated exertion (fatigability) and improved by rest, and usually involves the ocular muscles.

Physical examination should establish the presence, pattern and severity of muscle weakness, graded according to the Medical Research Council (MRC) 1–5 scale, and the presence of fasciculation, evidence of endocrine disease, malignancy, arthropathy or connective tissue disease.

Investigations and management

The most sensitive biochemical test is CK (p. 1064). A raised level suggests muscle pathology but does not establish the cause. Muscle biopsy and EMG are usually required to make the diagnosis, but MRI can be used to identify focal areas of muscle abnormality and increase the diagnostic yield from muscle biopsies. Management is determined by the cause. In all patients with muscle disease, physical therapy to maximise muscle function and conditioning may be helpful.

Rheumatic disease presenting as systemic illness

Systemic illness may be a dominant feature of rheumatic disease, with symptoms such as arthralgia and myalgia in combination with weight loss, night sweats, fever, skin

rashes, raised inflammatory markers and abnormal urinalysis. The differential diagnosis is potentially wide but important conditions to consider include sepsis, systemic vasculitis (p. 1112), adult-onset Still's disease (p. 1129), disseminated malignancy, atrial myxoma, cholesterol emboli and antiphospholipid syndrome (p. 1050).

If the patient is febrile, unwell or hypotensive, empirical broad-spectrum antibiotics should be initiated after appropriate samples have been taken for culture. Symptoms suggesting vasculitis are shown in Box 25.33. If these are present and there is evidence of critical organ involvement, immediate treatment with high-dose steroids may be required prior to diagnostic confirmation.

PRINCIPLES OF MANAGEMENT OF MUSCULOSKELETAL DISORDERS

The aims of management of MSK disorders are to:

- educate the patient
- control pain
- optimise function
- modify the disease process where possible.

These aims are interrelated and success in one often benefits the others. Successful management requires careful assessment of the whole person as well as his or her MSK system. The management plan needs to be individualised and patient-centred, to be agreed and understood by both patient and practitioner, and take into account:

- the person's daily activity requirements, and work and recreational aspirations
- risk factors and associations of the MSK condition (e.g. obesity, muscle weakness, non-restorative sleep)
- the person's perceptions and knowledge of their condition
- medications and coping strategies already tried by the patient

- comorbid disease and its therapy
- the availability, costs and logistics of appropriate evidence-based interventions.

Simple and safe interventions should be tried first. Symptoms and signs will change with time, so the plan requires review and possible readjustment. Effective management may require the expertise of a variety of health professionals, with a coordinated multidisciplinary team approach.

The core interventions that should be considered for everyone with a painful MSK condition are listed in Box 25.34. There are also other non-pharmacological and drug options, the choice depending largely on the nature and severity of the diagnosis.

Core interventions

Education

All doctors should inform patients about the nature of their condition and its investigation, treatment and prognosis, as education can improve outcome. Information and therapist contact can reduce pain and disability, improve self-efficacy and reduce the health-care costs of many MSK conditions, including osteoarthritis and RA. The mechanisms are unclear but in part may result from improved adherence. Benefits are modest but potentially long-lasting, safe and cost-effective (Box 25.35). Education can be provided through one-to-one discussion, written literature, patient-led group education classes and interactive computer programs. Inclusion of the patient's partner or carer is often appropriate; this is essential for childhood conditions but also helps in many chronic adult conditions such as RA or fibromyalgia.

Exercise

Two types of exercise should be prescribed (see Box 25.35):

- Aerobic fitness training can produce long-term reduction in pain and disability. It improves well-being, encourages restorative sleep and benefits common comorbidity such as obesity, diabetes, chronic heart failure and hypertension.
- Local strengthening exercise for muscles that act over compromised joints also reduces pain and disability, with improvements in the reduced muscle

EBM 25.35 Education and exercise in the management of arthritis

'Both patient education and exercise regimens have a modest, yet clinically important influence on patients' well-being.'

'Both aerobic walking and home-based quadriceps-strengthening exercises reduce pain and disability from knee osteoarthritis.'

- Devos-Combey L, et al. J Rheumatol 2006; 33:744–756.
- Roddy E, et al. Ann Rheum Dis 2005; 64:544–548.

strength, proprioception, coordination and balance that associate with chronic arthritis. 'Small amounts often' of strengthening exercise are better than protracted sessions performed infrequently.

Joint protection

Excessive impact-loading and adverse repetitive use of a compromised joint or periarticular tissue can often be reduced: for example, cessation of contact sports, or altered use of machinery or tools at the workplace. Simple 'pacing' of activities – dividing physically onerous tasks into shorter segments with brief breaks in between – is helpful. Use of shock-absorbing footwear with thick soft soles can reduce impact-loading through feet, knees, hips and back, and improve symptoms at these sites. A walking stick held on the contralateral side takes weight off a painful hip, knee or foot.

Weight loss

Obesity aggravates pain at most sites of the body through increased mechanical strain and is a risk factor for more rapid progression of joint damage in patients with arthritis. Obese patients should receive an explanation of this and be offered strategies on how to lose and then maintain an appropriate weight (p. 118).

Pharmacological options for direct symptom control

Analgesia

Paracetamol (1 g 6–8-hourly) is the oral analgesic of choice and, if successful, the preferred long-term oral analgesic. It inhibits prostaglandin synthesis in the brain but has less effect on peripheral prostaglandin production. It is generally well tolerated and has few adverse effects and drug interactions. There is a possible increased risk of both gastrointestinal events and cardiovascular disease with chronic usage, but it is uncertain whether this is due to the underlying disease or the drug itself.

Non-steroidal anti-inflammatory drugs (NSAIDs)

These are among the most commonly prescribed drugs, although their use has declined recently because of growing concern over their gastrointestinal and cardiorenal risk. Oral NSAIDs are particularly useful in the management of inflammatory arthritis, and a long-acting NSAID taken in the evening may help reduce early morning stiffness. There is marked variability in individual tolerance and response; patients who do not respond to one may still gain relief from another.

The mechanism of NSAID action is through inhibition of prostaglandin H synthase and cyclo-oxygenase (COX)

enzymes. Arachidonic acid, derived from membrane phospholipids, is metabolised to produce prostaglandins and leukotrienes by the COX and 5-lipoxygenase pathways respectively (Fig. 25.13). There are two isoforms of COX, encoded by different genes. COX-1 is constitutively expressed and fulfills a 'housekeeping' function in the gastric mucosa, platelets and kidneys. The COX-2 enzyme is largely induced at sites of inflammation, producing prostaglandins that cause local pain and inflammation, but COX-2 is also upregulated in the CNS, where it plays a role in the central mediation of pain and fever. Traditional NSAIDs such as ibuprofen, diclofenac and naproxen inhibit both COX enzymes, whereas newer NSAIDs such as celecoxib and etoricoxib selectively inhibit COX-2. Whilst NSAIDs have anti-inflammatory activity, they do not reduce peripheral cytokine production, acute phase reactants or ESR, and are not thought to have a disease-modifying effect in OA or RA.

Adverse effects

Traditional NSAIDs can damage the gastric mucosal barrier and are an important aetiological factor in up to 30% of gastric ulcers. They also reduce the integrity of the duodenal mucosa but are probably responsible for only a small proportion of duodenal ulcers. They greatly increase the risk of bleeding or perforation from pre-existing gastric and duodenal ulcers. The risks of gastrointestinal events with NSAIDs are appreciable:

- Approximately 1% of patients with RA or OA are hospitalised each year because of NSAID-associated gastroduodenal bleeding.
- Endoscopic evidence of peptic ulceration is found in 20% of NSAID users, even in the absence of symptoms.

Fig. 25.13 COX-1 and COX-2 pathways.

- About 2000 people in the UK and 16 000 in the USA die each year from NSAID-associated bleeding or perforation (i.e. higher than deaths from some cancers).

The adjusted increased risk (odds ratio) of bleeding or perforation from all NSAIDs is 4–5, though differences exist between NSAIDs (Box 25.36). Dyspepsia is a poor guide to the presence of NSAID-associated ulceration and bleeding, and the principal risk factors are shown in Box 25.37. Co-prescription of omeprazole (20 mg daily)

25.36 Commonly used NSAIDs and their relative risk of gastroduodenal bleeding and perforation

Drug	Daily adult dose	Doses/ day	Idiosyncratic side-effects, comments
Very low risk			
Celecoxib	100–200 mg	1–2	Selective COX-2 inhibitor
Etoricoxib	60–120 mg	1	Selective COX-2 inhibitor
Low risk			
Ibuprofen	600–1600 mg	3–4	Weak anti-inflammatory effect at this dose
Etodolac	600 mg	1	Partially selective COX-2 inhibitor
Meloxicam	7.5–15 mg	1	Partially selective COX-2 inhibitor
Nabumetone	1–2 g	1–2	Partially selective COX-2 inhibitor
Medium risk			
Ibuprofen	1600–2400 mg	3–4	Abnormal liver function tests
Naproxen	500–1000 mg	1–2	
Diclofenac	75–150 mg	2–3	
High risk			
Indometacin	50–200 mg	3–4	High incidence of dyspepsia and CNS side-effects (headache, dizziness, confusion)
Ketoprofen	100–200 mg	2–4	
Highest risk			
Piroxicam	20–30 mg	1–2	Restricted use, esp. in those > 60 yrs
Azapropazone	600–1200 mg	2–4	Marked uricosuric action Restricted use, esp. in those > 60 yrs

25.37 Risk factors for NSAID-induced ulcers

- Age > 60 yrs*
- Past history of peptic ulcer*
- Past history of adverse event with NSAIDs
- Concomitant corticosteroid use
- High-dose or multiple NSAIDs
- Individual NSAID: highest with azapropazone, piroxicam, ketoprofen; lower with ibuprofen

*The most important risk factors.

or misoprostol (200 µg 8–12-hourly) reduces but does not eliminate NSAID-induced ulceration and bleeding, but H_2 -antagonists are ineffective. The COX-2 selective NSAIDs celecoxib and etoricoxib are less likely to cause gastrointestinal toxicity but benefit is attenuated in patients on low-dose aspirin. In the UK, NICE guidelines advise that a proton pump inhibitor (PPI) should be co-prescribed with all NSAIDs, including COX-2 selective NSAID, even though the risk of gastrointestinal events with these is low. Since chronic PPI therapy is associated with an increased risk of hip fracture, the merits of giving PPI therapy with a COX-2 selective drug need to be weighed up carefully.

Chronic NSAID therapy has also been associated with an increased risk of cardiovascular disease. The mechanism is incompletely understood but may involve an increased risk of thrombosis due to inhibition of COX-2 in the endothelium. Other side-effects include fluid retention and renal impairment due to inhibition of renal prostaglandin production, non-ulcer-associated dyspepsia, abdominal pain and altered bowel habit, and rashes. Interstitial nephritis, asthma and anaphylaxis can also occur but are rare. Recommendations for NSAID prescribing are summarised in Box 25.38, and NSAIDs should generally be avoided altogether in the elderly (Box 25.39).

Nutriceuticals

A wide variety of nutritional supplements and health foods are marketed for relief of MSK symptoms. In most cases there is no rationale for their use, but some

25.38 Recommendations for the use of NSAIDs

- Current use of anticoagulants is a contraindication to NSAID use
- Avoid NSAIDs in the elderly and in those with important comorbidity, including heart failure and hypertension
- Start with the lowest dose of one of the safer established NSAIDs (e.g. ibuprofen) and only increase the dose if required
- If an unsatisfactory result is obtained with one NSAID, a trial of another NSAID may be warranted
- Never prescribe more than one NSAID at a time
- Allow a 2–3-week trial to assess efficacy of any particular NSAID or dose
- For a patient with recognised risk factors for gastrointestinal ulceration (see Box 25.37), co-prescribe omeprazole or misoprostol; in the UK, this is recommended for all adults

25.39 Use of oral NSAIDs in old age

- **Gastrointestinal complications:** age is a strong risk factor for complications (bleeding, perforation) of NSAID-associated peptic ulceration.
- **Prognosis:** older people, especially those with cardiovascular comorbidity, are more likely to die if they suffer NSAID-associated bleeding or perforation.
- **Other side-effects:** older people are at greater risk of renal and cardiovascular side-effects of NSAIDs (peripheral oedema, cardiac failure).
- **Paracetamol:** for many, oral paracetamol is as effective as oral NSAID for pain relief. Because of its greater safety and low expense, paracetamol remains the oral analgesic of choice.

supplements including glucosamine sulphate (not the hydrochloride), chondroitin sulphate and avocado/soya bean unsaponifiable have been shown to provide modest pain relief in knee OA in some randomised clinical trials. There is also some evidence that regular glucosamine or chondroitin sulphate may slow further structural damage. Currently, these agents remain largely unlicensed and are not recommended by NICE.

Topical agents

NSAID creams and gels and capsaicin (chilli extract; 0.025%) cream are safe and effective for pain relief from OA and superficial periarticular lesions affecting hands, elbows and knees. They may be used as monotherapy or as an adjunct to oral analgesics. Topical NSAIDs can penetrate superficial tissues and even reach the joint capsule, though intrasynovial levels mainly reflect blood-borne drug delivery. Capsaicin selectively binds to the protein transient receptor potential vanilloid type 1 (TRPV1), which is a heat-activated calcium channel on the surface of peripheral type C nociceptor fibres. Initial application causes a burning sensation but continued use depletes presynaptic substance P, with subsequent pain reduction that is optimal after 1–2 weeks.

Other analgesics

Opioid analgesics are sometimes required for moderate to severe pain which is unresponsive to other approaches. Codeine and dihydrocodeine are relatively weak analgesics, but when combined with paracetamol give better analgesia than paracetamol alone. Side-effects include constipation, headache and confusion, especially in old age. The centrally acting analgesics tramadol and mepizadol may be useful for temporary control of severe pain unresponsive to other measures. Both may cause nausea, bowel upset, dizziness and somnolence, and withdrawal symptoms after chronic use. Patients with severe or intractable pain may require stronger opioid analgesics such as oxycodon and morphine. The non-opioid analgesic nefopam (30–90 mg 8-hourly) can help moderate pain, though side-effects (nausea, anxiety, dry mouth) often limit its use. Adjuvant analgesics are described on page 283.

Disease-modifying antirheumatic drugs (DMARDs)

DMARDs are widely used in the treatment of inflammatory rheumatic diseases (Box 25.40). They reduce clinical signs of inflammation and improve or normalise objective parameters of the APR. They have a delayed onset of action and must be taken for weeks or months before benefit occurs. For some agents, there is evidence that a successful response may reduce target tissue damage. The main indications for DMARDs are:

- persistent inflammatory synovitis (> 6 weeks)
- systemic vasculitis
- SLE with cardiac, renal or CNS involvement
- as an adjunct to corticosteroid therapy in polymyalgia rheumatica and myositis.

Regular monitoring of DMARD therapy is essential (see Box 25.40) and most DMARDs are contraindicated in pregnancy, especially during the first trimester (Box 25.41). Traditionally, DMARDs were given as single agents, but drug combinations are increasingly used for resistant RA. DMARDs are given in addition to, rather

25.40 Commonly used disease-modifying antirheumatic drugs

Drug	Disease indications	Usual maintenance dose	Principal side-effects	Monitoring requirement	Monitoring frequency
Hydroxychloroquine	RA, SLE	200–400 mg/day	Rash, nausea, diarrhoea, headache, corneal deposits, retinopathy (rare)	Visual acuity, Amsler chart, fundoscopy	6–12-monthly
Sulfasalazine	RA, seroneg	2–4 g/day	Nausea, GI upset, rash, hepatitis, neutropenia, pancytopenia (rare)	FBC, LFTs	Monthly for 3 mths, then 3-monthly
D-penicillamine	RA	250–750 mg/day	Rash, stomatitis, metallic taste, proteinuria, thrombocytopenia	FBC, urine (protein)	Initially 1–2-weekly; 4–6-weekly for maintenance
Gold	RA	50 mg/mth by i.m. injection	Rash, stomatitis, alopecia, proteinuria, thrombocytopenia, myelosuppression	FBC, urine (protein)	Each injection
Methotrexate	RA, seroneg, SLE, CTD, vasculitis, PMR	5–30 mg/wk	GI upset, stomatitis, rash, alopecia, hepatotoxicity, acute pneumonitis	FBC, LFTs	Initially monthly, then every 3 months
Azathioprine	RA, seroneg, SLE, CTD, vasculitis, PMR	50–150 mg/day	GI upset, stomatitis, hepatitis, myelosuppression	FBC, LFTs	Initially weekly, then monthly
Leflunomide	RA	10–20 mg/day	Nausea, GI upset, rash, alopecia, hepatitis, hypertension	FBC, LFTs, blood pressure	2–4-weekly
Cyclophosphamide	Vasculitis, SLE, myositis	0.5–1 g by i.v. injection, 1–4-weekly	Nausea, GI upset, alopecia, cystitis, myelosuppression, azoospermia, anovulation	FBC, urine (blood)	Each i.v. injection
Ciclosporin	RA, psoriasis, SLE	150–300 mg/day	Nausea, GI upset, renal impairment, hypertension	FBC, LFTs, creatinine, blood pressure	2–4-weekly
Mycophenolate mofetil	SLE, vasculitis	1–3 g/day	Myelosuppression, GI upset (diarrhoea, vomiting, ulceration), hepatitis	FBC, LFTs	Initially weekly, then monthly in first year, then every 3 months

(CTD = connective tissue disease; FBC = full blood count; LFTs = liver function tests; PMR = polymyalgia rheumatica; RA = rheumatoid arthritis; seroneg = peripheral arthritis due to seronegative spondyloarthritis; SLE = systemic lupus erythematosus)

than instead of, the patient's pain-relieving drugs, but if treatment is successful, analgesic and NSAID requirements may fall. Box 25.40 gives the usual doses, principal toxicity and monitoring requirements of DMARDs.

Methotrexate

Methotrexate competitively inhibits dihydrofolate reductase, interfering with DNA synthesis and cell division. It is often the first-choice DMARD for RA and seronegative spondyloarthritis but is also used in SLE, vasculitis and other connective tissue disease. It works within 1–2 months. It is usually given as a weekly oral dose starting at 5–7.5 mg and increasing in 2.5 mg increments every 3–4 weeks until benefit occurs or toxicity develops. It is usually well tolerated but can cause nausea and malaise for 24–48 hours after ingestion. Marrow suppression is rare but hepatotoxicity and hepatic fibrosis may occur, especially at higher doses. Folic acid (5 mg/day) reduces the incidence of adverse effects without reducing efficacy. Patients should be warned of drug interaction with sulphonamides and to avoid excess alcohol, which enhances methotrexate hepatotox-

icity. Acute pulmonary toxicity (pneumonitis) is rare but can occur at any time during treatment. Patients should therefore be warned to seek early advice if they develop any new respiratory symptoms. Methotrexate should be stopped immediately if pneumonitis is suspected and high-dose steroids should be given.

Sulfasalazine

Sulfasalazine has a good benefit-to-risk profile and is used for RA and seronegative spondyloarthritis. Nausea and gastrointestinal intolerance are the main side-effects but can be reduced by use of enteric-coated tablets and taking them with food. The usual starting dose is 500 mg daily, building up to the maintenance dose over 2–4 weeks. The patient should be warned of possible orange staining of urine and contact lenses.

Hydroxychloroquine

This antimalarial is used for mild to moderate lupus, especially when skin or locomotor involvement predominates. It is also used for RA, usually in combination with other DMARDs, but has relatively weak activity and a

25.41 Treatment of rheumatic disease in pregnancy

- **Immunological changes in pregnancy:** may influence disease activity.
Approximately 75% of patients with RA go into remission during pregnancy.
Most patients with SLE remain stable but some worsen, especially those with renal disease.
Most patients with psoriatic arthritis show improvement.
- **Conception:** patients with systemic rheumatic diseases should be in clinical remission, if possible, prior to conception (for at least 6 mths for those with associated renal disease).
- **Disease control:** paramount during pregnancy, as uncontrolled inflammatory disease is a significant risk to both mother and baby.
- **Use of medication:** minimise or discontinue as appropriate. Treat symptoms and signs, not the diagnosis (e.g. only use steroids in SLE patients if disease is active).
- **Paracetamol:** the oral analgesic of choice during pregnancy.
- **Oral NSAIDs and selective COX-2 inhibitors:** can be used after implantation up until the last trimester.
- **Corticosteroids:** may be used to control disease flares; the main maternal risks are hypertension, glucose intolerance and osteoporosis.
- **DMARDs that may be used:** sulfasalazine, hydroxychloroquine, azathioprine or ciclosporin if required to control inflammation.
- **DMARDs that must be avoided:** methotrexate, leflunomide, cyclophosphamide, gold and penicillamine. Women should not conceive while taking methotrexate or leflunomide.
- **Biologic agents:** safety during pregnancy is currently unclear.
- **Breastfeeding:** methotrexate, leflunomide, cyclophosphamide, ciclosporin, azathioprine, sulfasalazine and hydroxychloroquine are contraindicated.

slow onset of action (2–4 months). Despite a wide range of potential side-effects, it is usually well tolerated.

Azathioprine

Azathioprine is most commonly employed as a steroid-sparing agent and to prevent relapse in patients with SLE and vasculitis. It is metabolised to 6-mercaptopurine (6-MP), which is then converted intracellularly to active purine thioanalogues, which inhibit DNA and RNA biosynthesis. Nausea, diarrhoea and mouth ulcers are common, but hepatitis and marrow suppression less so. Since 6-MP requires oxidation by xanthine oxidase before renal excretion, co-administration of allopurinol increases toxicity; if both drugs are required, the azathioprine dose should be reduced by 75%. Genotyping for alleles of thio-purine methyltransferase (TPMT), which are associated with reduced activity of this enzyme, can help predict azathioprine toxicity.

Leflunomide

Leflunomide is used for RA. It inhibits uridine monophosphate production and tyrosine kinases, and is an inhibitor of activated lymphocytes. It is usually well tolerated and has low marrow toxicity, but may cause liver dysfunction.

Gold, penicillamine and ciclosporin A

These drugs are used in RA, but have a high incidence of side-effects and tend to be reserved for patients who have failed on other DMARDs.

Gold (sodium aurothiomalate) is given by deep intramuscular injection. After an initial 10 mg test dose, 50 mg is given weekly until benefit occurs, when the frequency is reduced to fortnightly and then monthly. If there is a flare, a temporary return to weekly frequency may recapture control. If there is no benefit after 6 months, treatment should be stopped. Side-effects are potentially serious and preclude further therapy.

Penicillamine is given in a starting dose of 125–250 mg daily on an empty stomach, and the dose increased in 125 mg increments every 6 weeks until benefit occurs. Rarely, drug-induced lupus, myasthenia gravis or pemphigus may occur.

Ciclosporin A (150–300 mg/day) is a fungal cyclic polypeptide that blocks resting lymphocytes in the G0 or G1 phase of the cell cycle, inhibiting lymphokine production and release.

Cyclophosphamide

Cyclophosphamide is mainly used as pulse therapy in the treatment of systemic vasculitis and in SLE where there is renal, cardiac or CNS involvement. It is an alkylating agent that binds DNA, RNA and proteins, and is both mutagenic and teratogenic. It is inactive until converted by the cytochrome P-450 oxidase system to phosphoramide mustard and acrolein. It is usually given as 'pulse' intravenous injections of 0.5–1.5 g/m² weekly or monthly. The risk of haemorrhagic cystitis can be minimised by good hydration and ingestion of mesna, which binds urotoxic metabolites of cyclophosphamide. Because of the high risk of azoospermia and anovulation, which may be permanent, pre-treatment sperm or ova collection and storage may need consideration.

Mycophenolate mofetil

Mycophenolate mofetil (MMF) is an alternative to cyclophosphamide in inducing remission in SLE and vasculitis, and is also used as maintenance therapy to prevent relapse. MMF works by inhibiting purine synthesis, but its effects are relatively specific for lymphocytes because the molecular target (inosine monophosphate dehydrogenase) plays a critical role in production of guanine nucleotides in lymphocytes. Other cells can use purine salvage pathways for nucleotide production. A dose of 3 g daily is used initially, usually with high-dose steroids, and then the dose is reduced to 1–2 g daily, depending on the clinical response. Adverse affects include diarrhoea and leucopenia.

Biologic disease-modifying antirheumatic drugs

These synthesised antibodies or natural cytokine inhibitors have specificity for single targets; because they are proteins they require subcutaneous or parenteral administration.

Anti-TNF therapy

Anti-TNF therapy is widely used in the treatment of patients with RA, psoriatic arthritis and ankylosing spondylitis who have had an inadequate response to standard treatments. Three anti-TNF agents are now

in routine use. Infliximab is a chimeric human–murine anti-TNF- α monoclonal antibody which is administered by intravenous infusion (3mg/kg), typically every 6–8 weeks. It requires co-prescription of methotrexate to reduce immunogenicity. Etanercept is a synthetic human TNF receptor-Fc fusion protein, administered subcutaneously, either 50mg weekly or 25mg twice weekly. Adalimumab is a fully human monoclonal antibody to TNF- α , administered subcutaneously, 40mg every 2 weeks. Neither etanercept nor adalimumab requires the co-prescription of methotrexate, but combining either with methotrexate is more effective than either agent alone, without any increase in side-effects. All three drugs are more effective than standard DMARDs in RA but are much more expensive (approximately £7500 annually). Because of this, many countries have set guidelines restricting their use. Current UK recommendations are that anti-TNF therapy should be initiated only in active RA (DAS 28 > 5.1; see p. 1092) when an adequate trial of at least two other DMARDs (including methotrexate) has failed.

The main adverse effect of TNF blockade is the risk of serious infections, particularly reactivation of latent tuberculosis, which is more likely with infliximab than etanercept. There is also evidence of a possible increased risk of malignancy, but the contribution of TNF blockade as opposed to the underlying disease and other treatments is unclear.

Rituximab

Rituximab is an antibody directed against the CD20 receptor, expressed on B lymphocytes. It is given by two intravenous infusions (1g each) 2 weeks apart, usually in combination with intravenous corticosteroid. It causes depletion of peripheral B cells which is sustained for several months after administration. The treatment is repeated usually when signs of improvement are wearing off (anything from 6 months to 3 years). It is mostly used in the treatment of patients with resistant RA who have failed to respond to TNF blockade.

Abatacept

Abatacept is a biologic agent in which the Fc domain of IgG is fused to the extracellular domain of CTLA4. Abatacept blocks the interaction between CD28 and CTLA-4 which is required for full activation of T cells following antigen presentation. It is generally used in patients who have failed to respond to other treatments.

Anakinra

Anakinra is an IL-1 receptor antagonist which is used in RA. It appears to be less effective than anti-TNF therapy and is generally reserved for those who have failed to respond to other treatments.

Tocilizumab

This agent is an antibody directed against the IL-6 receptor. It has recently been licensed for the treatment of RA and has effects similar to those of TNF blockade. Its role in therapy remains to be defined.

Corticosteroids

Corticosteroids have a very rapid and dramatic anti-inflammatory action and there is evidence that systemic steroids favourably modify the disease outcome in RA,

25.42 Principal indications for systemic corticosteroids

- Short-term control of inflammatory arthritis whilst awaiting efficacy from DMARD
- Maintenance therapy in RA that cannot be adequately controlled by DMARD alone
- Systemic vasculitis
- SLE with involvement of CNS, renal or cardiovascular systems
- Polymyalgia rheumatica and giant cell arteritis
- Control of inflammatory disease during pregnancy

vasculitis and SLE. They are also used locally by injection in the treatment of soft tissue rheumatism and osteoarthritis. Since the adverse effects of corticosteroids are dose- and duration-dependent, the aim is always to use the smallest amount possible for the shortest time to achieve the desired therapeutic goal. Box 25.42 lists the main indications for oral or parenteral steroid. In RA, steroid therapy is initiated for rapid control of inflammatory disease at the same time as commencing a DMARD, and therapy is reduced and withdrawn as this takes effect.

Oral therapy

Prednisolone is the oral steroid of choice. It should be given as a single morning dose to coincide with peak levels of endogenous cortisol. Potential side-effects are numerous (p. 774) but osteoporosis, infection, diabetes, hypertension and cardiovascular disease are the major concerns. Patients receiving long-term oral corticosteroids (> 7.5mg for more than 3 months) should be given prophylaxis against osteoporosis (p. 1119).

Parenteral therapy

Parenteral treatment with corticosteroids is used in the treatment of inflammatory arthritis, SLE and vasculitis. For inflammatory arthritis, a single intramuscular injection of methylprednisolone (80–120mg) may quickly and effectively control inflammation for 2–6 weeks. Higher doses (500–1000mg) are used intravenously along with cyclophosphamide in the treatment of SLE and vasculitis.

Local injections

Intra-articular steroid injections are useful adjunctive therapy for short-term pain relief in OA and inflammatory arthritis and for temporary control of synovitis. The duration of benefit varies according to joint size and the nature and severity of the arthritis, but is in the order of 2–8 weeks. Frequently repeated injections may result in joint tissue atrophy and Cushing's syndrome, and some advise no more than four injections per year into a large joint like the knee. As long as precautions are taken (Box 25.43), the incidence of iatrogenic infection is

25.43 Aseptic precautions with intra-articular corticosteroid injection

- Never inject if the diagnosis is in doubt
- Never inject if there is local or systemic infection
- Use an aseptic technique: single ampoules, sterile needle and syringe, clean hands (with gloves), clean skin (alcohol/antiseptic)
- If aspirated fluid is very turbid, send it for culture

almost negligible. Other side-effects are facial flushing 24–72 hours post-injection, local skin atrophy, telangiectasia and permanent fat atrophy due to leakage along the needle track (especially with fluorinated triamcinolone preparations). Sometimes post-injection ‘flare’ in disease occurs, with temporary (1–3 days) exacerbation.

Injection of local steroid and/or anaesthetic can give rapid and effective control of pain from periarticular lesions such as bursitis, tenosynovitis and enthesopathy. It will not hasten, and may retard healing, but its analgesic effect may extend beyond the natural history of the lesion. Non-fluorinated steroids (e.g. hydrocortisone, methylprednisolone) should be used for superficial lesions (e.g. lateral epicondylitis, anserine bursitis) to avoid fat and skin atrophy. If anaesthetic is combined with the steroid, quick relief of pain confirms both the diagnosis and accurate placement of the injection. Injection of steroid into, or even adjacent to, certain tendons (e.g. long head of biceps tendon) can predispose to rupture and should be avoided. Steroid injection may also be used to confirm and temporarily relieve peripheral nerve entrapment syndromes (e.g. carpal tunnel injection for median nerve entrapment at the wrist).

Other treatments

Hyaluronan injections

In knee OA, intra-articular injection of one of several forms of hyaluronan (polymers of hyaluronate), mainly given as a course of weekly injections for 3–5 weeks, may give modest pain relief for several months. However, evidence for efficacy is heterogeneous and their expense and common requirement for serial injection mean that they are not recommended for OA in the UK.

Radiation-induced synovectomy

Intra-articular injection of radiocolloid (⁹⁰yttrium silicate for large to medium joints, ¹⁵⁹erbium for small joints) can give prolonged control of synovitis but should be avoided in patients under the age of 45. Joints should be immobilised for 24–72 hours post-injection to reduce spread to regional lymph nodes. The synovium often recovers with return of synovitis after 1–3 years. Indications include inflammatory synovitis where just one or a few joints are resistant to other measures, synovitis of chronic haemophilic arthropathy and pigmented villonodular synovitis.

Nerve blockade

Nerve blockade using steroids and/or long-acting anaesthetics may be helpful for control of severe chronic arthritis or periarticular pain resistant to other means (e.g. suprascapular nerve block for severe glenohumeral arthritis or chronic rotator cuff pain). Epidural injections of corticosteroid may also give temporary relief of troublesome root entrapment symptoms.

Non-pharmacological interventions

Physical therapy

Local heat, ice packs, wax baths and other local external applications can induce muscle relaxation and temporary relief of symptoms in a range of rheumatic diseases.

Hydrotherapy permits muscle relaxation and enhanced movement in a warm, pain-relieving environment without the restraints of gravity and normal load-bearing. Various manipulative techniques may also help improve restricted movement. The combination of these with education and therapist contact enhances their benefits.

Splints can give temporary rest and support for painful joints and periarticular tissues, and prevent disadvantageous involuntary postures during sleep. Prolonged rest, however, must be avoided.

Orthoses are more permanent appliances used to reduce instability and excessive abnormal movement. They include working wrist splints, knee orthoses, and iron and T-straps to control ankle instability. Orthoses are particularly suited to severely disabled patients in whom a surgical option is inappropriate, and often need to be custom-made for the individual.

Aids and appliances can provide dignity and independence to patients with respect to activities of daily living. Common examples are a raised toilet seat, raised chair height, extended handles on taps, a shower instead of a bath, thick-handled cutlery, and extended ‘hands’ to pull on tights and socks. Full assessment and advice from an occupational therapist can maximise the benefits.

Surgery

A variety of surgical interventions can relieve pain and conserve or restore function in patients with bone, joint and periarticular disease (Box 25.44). Soft tissue release and tenosynovectomy may reduce inflammatory symptoms, improve function and prevent or retard tendon damage for variable periods, sometimes indefinitely. Synovectomy of joints does not prevent disease progression but may be indicated for pain relief when drugs, physical therapy and intra-articular injections have provided insufficient relief. The main approaches for damaged joints are osteotomy (cutting bone to alter joint mechanics and load transmission), excision arthroplasty (removing part or all the joint), joint replacement (insertion of prosthesis in place of the excised joint) and arthrodesis (joint fusion). Surgical fixation of fractures is frequently required in patients with osteoporosis and other bone diseases.

The main aims of surgery are to provide pain relief and improve function and quality of life. If surgery is to be successful, the aims and consequences of each operation should be considered as part of an integrated programme of management and rehabilitation, by multidisciplinary teams of surgeons, allied health professionals and physicians, and carefully explained to the patient. Assessment of motivation, social support and environment is no less important than careful consideration of patients’ general health, their risks for major surgery, the extent of disease in other joints and their ability to mobilise following surgery. For some severely compromised people, pain relief and functional independence are better served by provision of a suitable wheelchair, home adjustments and social services than by surgery that is technically successful but following which the patient cannot mobilise.

Self-help and coping strategies

These help patients to cope better with, and to adjust to chronic pain and disability. They may be useful at any stage but are particularly so for patients with incurable

25.44 Examples of surgical procedures for MSK disorders	
Procedure	Indication
Soft tissue release	
Carpal tunnel	Median nerve compression
Tarsal tunnel	Posterior tibial nerve entrapment
Flexor tenosynovectomy	Relief of 'trigger' fingers
Ulnar nerve transposition	Ulnar nerve entrapment at elbow
Fasciotomy	Severe Dupuytren's contracture
Tendon repairs and transfers	
Hand extensor tendons	Extensor tendon rupture
Thumb and finger flexor tendons	Flexor tendon rupture
Synovectomy	
Wrist and extensor tendon sheath (+ excision of radial head)	Pain relief and prevention of extensor tendon rupture in RA, resistant inflammatory synovitis
Knee synovectomy	Resistant inflammatory synovitis
Osteotomy	
Femoral osteotomy	Early OA of hip
Tibial osteotomy	Unicompartmental knee OA Deformed tibia in OA Paget's disease
Excision arthroplasty	
First metatarsophalangeal joint (Keller's procedure)	Painful hallux valgus
Radial head	Painful distal radio-ulnar joint
Lateral end of clavicle	Painful acromioclavicular joint
Metatarsal head	Painful subluxed metatarsophalangeal joints
Joint replacement arthroplasty	
Knee, hip, shoulder, elbow	Painful damaged joints (mainly OA) Fractured neck of femur (hemiarthroplasty)
Arthrodesis	
Wrist	Damaged joint: pain relief, improvement of grip
Ankle/subtalar joints	Damaged joint: pain relief, stabilisation of hindfoot

problems, who have received all available treatment options. The aim is to increase self-management through self-assessment and problem-solving so that patients can recognise negative but potentially remediable aspects of their mood (stress, frustration, anger or low self-esteem) and their situation (physical, social, financial). These may then be addressed by changes in attitude and behaviour, as shown in Box 25.45.

25.45 Self-help and coping strategies	
<ul style="list-style-type: none"> • Yoga and relaxation techniques to reduce stress • Avoiding negative situations or activities that produce stress, and increasing pleasant activities that give satisfaction • Information and discussion to alter beliefs about and perspectives on disease • Reducing or avoiding catastrophising and maladaptive pain behaviour • Imagery and distraction techniques for pain • Expanding social contact and better utilising social services 	

Involvement of the spouse or partner in mutual goal-setting can improve partnership adjustment. Such approaches are often an element of group education classes and pain clinics, but may require more formal clinical psychological input.

OSTEOARTHRITIS

Osteoarthritis (OA) is by far the most common form of arthritis. It is strongly associated with ageing and is a major cause of pain and disability in older people. Pathologically, it may be defined as a condition of synovial joints characterised by focal loss of articular hyaline cartilage with proliferation of new bone and remodelling of joint contour. Inflammation is not a prominent clinical feature. OA preferentially targets certain small and large joints (Fig. 25.14) but is not a disease or a single condition. It is best viewed as the dynamic repair process of synovial joints that may be triggered by a variety of insults, some but not all of which result in symptomatic 'joint failure'.

Epidemiology

The prevalence of OA rises progressively with age, such that by 65 years 80% of people have radiographic evidence of OA, though only 25–30% are symptomatic. The knee and hip are the principal large joints involved, affecting 10–25% of those aged over 65 years. Even for joints less frequently targeted by OA, such as the elbow or ankle, OA remains the most common cause of arthritis.

OA is a complex disorder with multiple risk factors (Fig. 25.15). Twin and family studies show that genetic factors play a major role, particularly for hand and generalised OA, but also for hip and knee OA. The genes responsible remain to be identified. Knee OA is

Fig. 25.14 The distribution of osteoarthritis. Although OA can affect any synovial joint, those shown in red are the most commonly targeted.

Fig. 25.15 Risk factors for the development of osteoarthritis.

prevalent in all racial groups but hip, hand and generalised OA are particularly prevalent in Caucasians. OA is more prevalent and more commonly symptomatic in women, except at the hip where men are equally affected. Trauma is a recognised predisposing factor and repetitive adverse loading of joints during occupation or competitive sports also appears important, such as in farmers (hip OA), miners (knee OA) and professional footballers (knee OA).

Aetiology and pathogenesis

A variety of mechanical, metabolic, genetic or constitutional insults may damage a synovial joint and trigger the need for repair. Most often this remains unclear ('primary' OA) but sometimes there is an obvious cause such as trauma ('secondary' OA). Since all the joint structures depend on each other for health and function, an insult to one will impact on the others, leading to effects on the whole joint. The OA process involves production of

new tissue and remodelling of joint shape. Often this slow but efficient process compensates for the insults, resulting in an anatomically altered but pain-free functioning joint ('compensated' OA). Sometimes, however, because of an overwhelming insult or a defective repair response, the system fails, resulting in progressive tissue damage, more frequent association with symptoms, and presentation as 'joint failure'. This readily explains the clinical heterogeneity of OA.

Cartilage changes

There is enzymatic degradation of the major structural components aggrecan and collagen (see Fig. 25.3, p. 1059). Chondrocytes increase production of matrix components and divide to produce nests of metabolically active cells. Although the turnover of aggrecan components is increased, the concentration of aggrecan eventually falls. The decrease in size of the hydrophilic aggrecan molecules increases the water concentration and swelling pressure in cartilage, further disrupting the retaining scaffolding of type II collagen and making the cartilage vulnerable to load-bearing injury. Fissuring of the cartilage surface ('fibrillation') eventually occurs, leading to the development of deep vertical clefts, localised chondrocyte death and decreased cartilage thickness. Cartilage loss is focal rather than generalised and usually restricted to the maximum load-bearing part of the joint (Fig. 25.16). The changes in OA cartilage encourage deposition of calcium pyrophosphate and basic calcium phosphate crystals.

Bone changes

The subchondral bone shows a mixture of osteolysis and osteosclerosis. In some cases, this reflects healed trabecular microfractures. Subchondral 'cysts' often develop, possibly as the result of small areas of osteonecrosis caused by the increased pressure in bone as the cartilage fails in its load-transmitting function. There is production of new fibrocartilage at the joint margin which undergoes endochondral ossification to form osteophytes. With severe cartilage loss there may be attrition of bone as the two unprotected bone ends wear on each other. Such wear may ablate the trabeculae and lead to a smooth, shiny surface ('eburnation'), often with deep linear grooves.

Fig. 25.16 Pathological changes in osteoarthritis.

Bone remodelling and cartilage thinning slowly alter the shape of the OA joint, increasing its surface area.

Other changes

The synovium undergoes variable degrees of hyperplasia. Sometimes histological changes are as florid, though less widespread, as those of RA. Osteochondral bodies commonly occur within the synovium, reflecting chondroid metaplasia or secondary uptake and growth of damaged cartilage fragments. The outer capsule also thickens and contracts, usually retaining the stability of the remodelling joint. The muscles that act over the joint commonly show non-specific type II fibre atrophy.

Clinical features

The main presenting symptoms are pain and functional restriction. Pain may directly relate to the OA process through increased pressure in subchondral bone (mainly causing night pain), trabecular microfractures, capsular distension and low-grade synovitis, or may result from bursitis and enthesopathy secondary to altered joint mechanics. Typical OA pain has the characteristics listed in Box 25.46. For many people, functional restriction of the hands, knees or hips is an equal, if not greater, problem than pain. The clinical findings vary according to severity but are principally those of joint damage.

The correlation between the presence of structural OA (clinical signs, radiographic changes) and pain and disability varies according to site. It is stronger at the hip than the knee, and poor at most small joints. Risk factors for pain and disability may differ from those for structural change. At the knee, for example, reduced quadriceps muscle strength and adverse psychosocial factors (anxiety, depression) correlate more strongly with pain and disability than the degree of radiographic change.

OA is prevalent and commonly asymptomatic in middle-aged and older people, so the presence of OA may not necessarily be the explanation of a patient's problem. Because of their high prevalence, generalised OA, knee OA and hip OA will be considered individu-

ally. Apophyseal joint OA is part of 'spondylosis', and its presentation and management are those of common mechanical back and neck pain (p. 1072).

Nodal generalised OA

Characteristics of this common form of OA are shown in Box 25.47. Presentation is typically in women between 40 and 50 who develop pain, stiffness and swelling of one or a few finger interphalangeal joints (IPJs). Gradually, over many months, more finger IPJs (distal > proximal) are affected. These joints develop posterolateral swellings on each side of the extensor tendon which slowly enlarge and harden to become Heberden's (distal IPJ) and Bouchard's (proximal IPJ) nodes (Fig. 25.17). Typically, each joint goes through a phase of episodic symptoms (1–5 years) while the node evolves and OA develops in the underlying IPJ. Once OA is fully established, symptoms may subside and hand function often remains good. Affected IPJs often show characteristic lateral deviation, reflecting the asymmetric focal cartilage loss of OA. Involvement of the first carpometacarpal joint is also common. At this site, marked osteophyte and subluxation may result in 'thumb-base squaring'. Unlike IPJ OA, thumb-base OA may associate with more persistent symptoms and more severe functional impairment.

People with nodal OA are at increased risk of OA at other sites ('generalised OA'), especially the knee. Nodal generalised OA has a very strong genetic predisposition, the daughter of an affected mother having approximately a 1 in 3 chance of developing nodal OA. Nodal OA with multiple nodes and symptom onset in middle age should not be confused with just one or two asymptomatic nodes related to past trauma, a common finding, particularly in old age.

25.46 Typical characteristics of pain and clinical signs of osteoarthritis

Pain

- Age > 45 yrs (often > 60)
- Insidious onset over months or years
- Variable or intermittent over time ('good days, bad days')
- Mainly related to movement and weight-bearing, relieved by rest
- Only brief (< 15 mins) morning stiffness and brief (< 1 min) 'gelling' after rest
- Usually only one or a few joints painful (not multiple regional pain)

Clinical signs

- Restricted movement due to capsular thickening, or blocking by osteophyte
- Palpable, sometimes audible, coarse crepitus due to rough articular surfaces
- Bony swelling (osteophyte) around joint margins
- Deformity, usually without instability
- Joint-line or periarticular tenderness
- Muscle weakness, wasting
- No or only mild synovitis (effusion, increased warmth)

25.47 Characteristics of nodal generalised osteoarthritis

- Polyarticular finger interphalangeal joint OA
- Heberden's (± Bouchard's) nodes
- Marked female preponderance
- Peak onset in middle age
- Good functional outcome for hands
- Predisposition to OA at other joints, especially knees
- Strong genetic predisposition

Fig. 25.17 Nodal osteoarthritis. Heberden's nodes and lateral (radial/ulnar) deviation of distal interphalangeal joints, with mild Bouchard's nodes at the proximal interphalangeal joints.

Knee OA

OA principally targets the patello-femoral and medial tibio-femoral compartments of the knee. It may be isolated or occur as part of nodal generalised OA. Most knee OA, particularly in women, is bilateral and symmetrical. Trauma is a more important risk factor in men and may result in unilateral OA.

OA knee pain is usually localised to the anterior or medial aspect of the knee and upper tibia. Patello-femoral pain is usually worse going up and down stairs or inclines. Posterior knee pain suggests a complicating popliteal 'cyst'. Prolonged walking, rising from a chair, getting in or out of a car, or bending to put on shoes and socks may be difficult. Local examination findings may include:

- a jerky, asymmetric (antalgic) gait: less time weightbearing on the painful side
- a varus (Fig. 25.18), less commonly valgus, and/or fixed flexion deformity
- joint-line and/or periarticular tenderness (secondary anserine bursitis and medial ligament enthesopathy (see Box 25.22, p. 1071) are common, giving tenderness of the upper medial tibia)
- weakness and wasting of the quadriceps muscle
- restricted flexion/extension with coarse crepitus
- bony swelling around the joint line.

Calcium pyrophosphate dihydrate (CPPD) crystal deposition in association with OA is most common at the knee. This may result in a more overt inflammatory component (stiffness, effusions) and super-added acute attacks of synovitis ('pseudogout', p. 1101), which may predict more rapid radiographic and clinical progression.

Hip OA

Hip OA most commonly targets the superior aspect of the joint (Fig. 25.19). Such 'superior pole' OA is often unilateral at presentation, often progresses with superolateral migration of the femoral head, and has a poor prognosis. The less common central (medial) OA shows more central cartilage loss and is largely confined to women. It is

Fig. 25.18 Typical varus deformity resulting from marked medial tibio-femoral osteoarthritis.

Superior pole osteoarthritis

Medial osteoarthritis

Fig. 25.19 Patterns of hip osteoarthritis.

often bilateral at presentation, may associate with nodal generalised OA, uncommonly progresses with axial femoral migration, and has a better prognosis.

The hip shows the best correlation between symptoms and radiographic change. Hip pain is usually maximal deep in the anterior groin, with variable radiation to the buttock, anterolateral thigh, knee or shin. Lateral hip pain, worse on lying on that side with tenderness over the greater trochanter, suggests secondary trochanteric bursitis. Common functional difficulties are the same as for knee OA; in addition, restricted hip abduction in women may cause pain on intercourse. Examination may reveal:

- an antalgic gait
- weakness and wasting of quadriceps and gluteal muscles
- pain and restriction of internal rotation with the hip flexed — the earliest and most sensitive sign of hip OA; other movements may subsequently be restricted and painful
- anterior groin tenderness just lateral to the femoral pulse
- fixed flexion, external rotation deformity of the hip
- ipsilateral leg shortening with severe joint attrition and superior femoral migration.

Although obesity is not a major risk factor for development of hip OA, it is associated with more rapid progression.

Early-onset OA

Unusually, typical symptoms and signs of OA may present before the age of 45. In most cases, a single joint is affected and there is a clear history of previous trauma. However, in people with early-onset OA affecting several joints, especially those not normally targeted by OA, rare causes need to be considered (Box 25.48). Patients with endemic OA, due to unknown environmental cartilage toxins, will have grown up in just a few specific areas of the world: for example, eastern Russia and northern China ('Kashin-Beck disease').

Erosive OA

This term is used in connection with rare patients with IPJ OA who have a more prolonged symptom phase, more overt IPJ inflammation, more disability and worse outcome than those with nodal OA. Distinguishing features from nodal OA include preferential targeting of proximal IPJs, common develop-

 25.48 Causes of early-onset osteoarthritis (< 45 years)
Monoarticular
<ul style="list-style-type: none"> • Previous trauma, localised instability
Pauciarticular or polyarticular
<ul style="list-style-type: none"> • Prior joint disease (e.g. juvenile idiopathic arthritis) • Metabolic or endocrine disease <ul style="list-style-type: none"> Haemochromatosis (p. 959) Ochronosis Acromegaly (p. 790) • (Spondylo-)epiphyseal dysplasia • Late avascular necrosis • Neuropathic joint • Endemic OA

ment of IPJ lateral instability, subchondral erosions on X-rays, occasional eventual ankylosis of IPJs and lack of association with OA elsewhere. Some patients with nodal OA have one or a few joints with radiographic subchondral erosions, and whether erosive OA is part of the spectrum of hand OA or a discrete subset is uncertain.

Investigations

A plain X-ray may show one or more of the typical features of OA (see Fig. 25.7, p. 1061). Its main use is to assess severity of structural change, an issue if surgery is being considered. A non-weight-bearing PA view of the pelvis is adequate for assessing hip OA, but standing (stressed) AP radiographs are needed to assess tibio-femoral cartilage loss, and a flexed skyline view is best for assessing patello-femoral narrowing.

The FBC, ESR and CRP are normal in OA. Synovial fluid aspirated from OA knees shows variable characteristics but is predominantly viscous with low turbidity; accompanying CPPD and basic calcium phosphate may also be identified. Radioisotope bone scans performed for other reasons often show, as an incidental finding, discrete increased uptake in OA joints due to bone remodelling.

Unexplained early-onset OA requires additional investigation, guided by the suspected underlying condition. X-rays may show typical features of dysplasia or avascular necrosis, widening of joint spaces in acromegaly, multiple cysts and chondrocalcinosis in haemochromatosis (p. 959), or disorganised architecture in neuropathic joints.

Management

Treatment follows the principles on pages 1075–1082 and always requires:

- **Full explanation of the condition.** This should include relevant risk factors (obesity, heredity, trauma); the fact that established structural changes are permanent but that pain and function can improve; discussion of prognosis (good for nodal hand OA, more optimistic for knee than hip OA); and the fact that appropriate action can improve the prognosis of large joint OA.
- **Exercise.** This should cover both strengthening and aerobic exercise, preferably with reinforcement by a physiotherapist (see Box 25.35, p. 1076).
- **Reduction of adverse mechanical factors.** This includes weight loss if obese, shock-absorbing footwear,

pacing of activities, use of a walking stick for painful knee or hip OA, or provision of built-up shoes to equalise leg lengths.

- **Drug treatment.** Give an initial trial of paracetamol and consider the addition of a topical NSAID, and then capsaicin, for knee and hand OA. If required, consider escalating to combined analgesics or oral NSAIDs (p. 1076). Opiates may occasionally be required.

For temporary benefit of moderate to severe pain, consider intra-articular injection of corticosteroid (particularly for knee and thumb-base OA) and local physical therapies such as heat or cold. At present there are no licensed disease-modifying drugs for OA, but the measures above may reduce structural progression as well as improve symptoms. Box 25.49 describes the treatment aspects that are particularly pertinent in older people.

Surgery

Surgery should be considered for patients with OA whose pain, stiffness and reduced function impact significantly on their quality of life and are refractory to non-surgical core and adjunctive treatments. Osteotomy may prolong the life of malaligned joints and relieve pain by reducing intra-osseous pressure. Joint replacement, however, can transform the quality of life of people with severe knee or hip OA. Surgery for refractory OA should be considered before there is prolonged and established functional limitation and severe pain, since these may compromise the surgical outcome. Patient-specific factors such as age, gender, smoking and presence of obesity, should not be barriers to referral for joint replacement.

Total joint replacements are required for the minority of people with large joint OA. Over 95% of joint replacements continue to function well into the second decade after surgery and most provide life-long pain-free function. However, approximately 1 in 5 patients are not satisfied with the outcome, and a minority get little or no improvement in pain following surgery.

25.49 Osteoarthritis in old age

- **OA:** the major MSK cause of pain and disability in older people.
- **Functional impact:** the reduced muscle strength, proprioception and balance that accompany ageing all associate with and contribute to pain and disability from knee and hip OA.
- **Coexistent calcium pyrophosphate crystal deposition:** an age-associated phenomenon that may result in superimposed acute attacks of synovitis (pseudogout).
- **Regular strengthening exercise:** can safely reduce the pain and disability of knee OA with accompanying improvements in balance and reduced tendency to fall.
- **Oral paracetamol and topical NSAIDs:** safe in older people, with no important drug interactions or contraindications, and often effective for pain relief.
- **Intra-articular injection of corticosteroid:** a very safe and often effective treatment, particularly useful for tiding a patient over a special event.
- **Total joint replacement:** with appropriate rehabilitation, an excellent cost-effective treatment for severe disabling knee or hip OA in old age. Age per se is not a contraindication to considering joint replacement.

INFLAMMATORY JOINT DISEASE

Rheumatoid arthritis

Rheumatoid arthritis (RA) is the most common persistent inflammatory arthritis, occurring throughout the world and in all ethnic groups. The prevalence is lowest in black Africans and Chinese, and highest in Pima Indians. In Caucasians, it is 1.0–1.5%, with a female to male ratio of 3:1. The clinical course is prolonged, with intermittent exacerbations and remissions. Patients with RA have an increased mortality when compared with age-matched controls, primarily due to cardiovascular disease. This is most marked in those with severe disease, with a reduction in expected lifespan by 8–15 years. Around 40% of RA patients are registered disabled within 3 years; around 80% are moderately to severely disabled within 20 years; and 25% will require a large joint replacement. Functional capacity decreases most rapidly at the beginning of disease and the functional status of patients within their first year of RA is often predictive of long-term outcome. Factors that associate with a poorer prognosis are disability at presentation, female gender, involvement of MTP joints, smoking and a positive RF and anti-CCP. It is hoped that the prognosis of RA will improve as more aggressive early treatment is used but this has yet to be demonstrated.

Pathophysiology

Both genetic and environmental factors appear to be involved in the pathogenesis of RA. The concordance rate of RA is higher in monozygotic (12–15%) than in dizygotic twins (3%), and there is an increased frequency of disease in first-degree relatives of patients. Up to 50% of the genetic susceptibility is due to genes in the HLA region. HLA-DR4 is the major susceptibility haplotype in most ethnic groups, occurring in 50–75% of Caucasian patients with RA compared to 20–25% of the normal population. However, DR1 is more important in Indians and Israelis, and DW15 in Japanese. Severity is also under genetic influence, with DR4 positivity being more common in those with severe erosive disease. Although it is thought that RA may be triggered by an infectious agent in a genetically susceptible host, a specific pathogen has not been identified. Susceptibility is increased post-partum and by breastfeeding. Cigarette smoking is a strong risk factor for developing RA and also associates with greater severity.

Whatever the initiating stimulus, RA is characterised by infiltration of the synovial membrane with lymphocytes, plasma cells and macrophages. CD4⁺ T cells play a central role by interacting with other cells in the synovium. Activated T cells stimulate B cells to produce immunoglobulins including RF, and macrophages to produce pro-inflammatory cytokines. These act on endothelium, synovial fibroblasts, bone cells and chondrocytes to promote swelling and congestion of the synovial membrane and destruction of bone, cartilage and soft tissues (Fig. 25.20).

Fig. 25.20 Pathogenesis of rheumatoid arthritis. The figure summarises some of the cytokines and cellular interactions believed to be important in RA. The molecular targets for biologic agents currently used in the treatment of RA are shown. It is thought that TNF plays a particularly important role by orchestrating production of other cytokines. (IL = interleukins; MMP = matrix metalloproteinases; PGE = prostaglandin E; TCR = T-cell receptor; TNF = tumour necrosis factor; VEGF = vascular endothelial growth factor)

The pro-inflammatory cytokine TNF- α plays an important role in this process by regulating production of other cytokines, whose actions are shown in Figure 25.20. The B cells release immunoglobulins, including RF, which can form immune complexes within the joint and in extra-articular tissues, leading to vasculitis. Lymphoid follicles form within the synovial membrane. Inflammatory granulation tissue (pannus) spreads over and under the articular cartilage, which is progressively eroded and destroyed. Later, fibrous or bony ankylosis may occur. Muscles adjacent to inflamed joints atrophy and may be infiltrated with lymphocytes.

Rheumatoid nodules consist of a central area of fibrinoid material surrounded by a palisade of proliferating mononuclear cells. Similar granulomatous lesions may occur in the pleura, lung, pericardium and sclera. Lymph nodes in RA are often hyperplastic, showing many lymphoid follicles with large germinal centres and numerous plasma cells in the sinuses and medullary cords. Immunofluorescence confirms RF synthesis by plasma cells in synovium and lymph nodes.

Clinical features

The typical presentation is with pain, joint swelling and stiffness affecting the small joints of the hands, feet and wrists. Large joint involvement, systemic symptoms and extra-articular features may also occur. Clinical criteria for the diagnosis of RA are shown in Box 25.50, although it should be noted that these were designed for epidemiological studies rather than for the diagnosis of individual patients. By convention, symptoms need to have persisted for more than 6 weeks for the diagnosis of RA. Although somewhat arbitrary, this ensures that

patients with viral or other types of self-limiting arthritis are not prematurely labelled as having RA.

Sometimes RA has a very acute onset, with florid morning stiffness, polyarthritis and pitting oedema. This occurs more commonly in old age. Other patients may present with proximal muscle stiffness mimicking polymyalgia rheumatica (p. 1115). Occasionally, the onset is palindromic, with relapsing and remitting episodes of pain, stiffness and swelling which last only for a few hours or days.

Examination of the hands often provides a good reflection of overall disease activity. The typical features are symmetrical swelling of the metacarpophalangeal (MCP) joints and proximal IPJs. These and other joints are actively inflamed if they are tender on pressure, and have stress pain on passive movement or effusion/soft tissue swelling. Erythema is not usually a feature and its presence implies coexistent sepsis. Characteristic deformities develop with long-standing disease, including 'swan neck' deformity, the boutonnière or 'button hole' deformity, and a Z deformity of the thumb (Fig. 25.21). Dorsal subluxation of the ulna at the distal radio-ulnar joint is common and may contribute to rupture of the fourth and fifth extensor tendons. Triggering of fingers may occur because of nodules in the flexor tendon sheaths.

In the foot, dorsal subluxation of the MTP joints may result in 'cock-up' toe deformities. This causes pain on weight-bearing on the exposed MTP heads and development of secondary adventitious bursae and callosities. In the hindfoot, calcaneovalgus (eversion) is the most common deformity, reflecting damage to the ankle and subtalar joint. This is often associated with loss of the longitudinal arch (flat foot) due to rupture of the tibialis posterior tendon.

Popliteal ('Baker's') cysts usually occur in combination with knee synovitis, where synovial fluid communicates with the cyst but is prevented from returning to the joint by a valve-like mechanism. Rupture, often induced by knee flexion in the presence of a large effusion, leads to calf pain and swelling.

Extra-articular features

Anorexia, weight loss and fatigue are common and may occur throughout the disease course. Generalised osteoporosis and muscle-wasting (sarcopenia) result from systemic inflammation. Extra-articular features are most

25.50 Criteria for diagnosis of rheumatoid arthritis*

Diagnosis of RA is made with four or more of the following:

- Morning stiffness (> 1 hr)
- Arthritis of three or more joint areas
- Arthritis of hand joints
- Symmetrical arthritis
- Rheumatoid nodules
- Rheumatoid factor
- Radiological changes
- Duration \geq 6 wks

*American Rheumatism Association 1988 revision.

Fig. 25.21 The hand in rheumatoid arthritis. **[A]** Ulnar deviation of the fingers with wasting of the small muscles of the hands and synovial swelling at the wrists, the extensor tendon sheaths, the metacarpophalangeal and proximal interphalangeal joints. **[B]** 'Swan neck' deformity of the fingers.

common in patients with long-standing seropositive erosive disease but may occasionally occur at presentation, especially in men. Most are due to serositis, granuloma/nodule formation or vasculitis (Box 25.51).

Cutaneous and vascular features

Rheumatoid nodules occur almost exclusively in seropositive patients, usually at sites of pressure or friction such as the extensor surfaces of the forearm, sacrum, Achilles tendon and toes (Fig. 25.22). They may be complicated by ulceration and secondary infection.

Rheumatoid vasculitis usually occurs in older seropositive patients in the context of systemic symptoms and multiple extra-articular features. Vasculitis can vary from the relatively benign nail-fold infarcts to widespread cutaneous ulceration and skin necrosis. Involvement of medium-sized arteries can lead to mesenteric, renal or coronary artery occlusion.

Ocular involvement

The most common symptom is dry eyes (keratoconjunctivitis sicca) due to secondary Sjögren's syndrome. Painless

• Compression neuropathies	• Mononeuritis multiplex
Amyloidosis (p. 84)	

episcleritis frequently accompanies nodular seropositive disease; it may cause intense redness of superficial vessels but sight is unimpaired. Scleritis is more serious and potentially sight-threatening; the eye is red and painful, vision is often impaired and the sclera shows a deep red blush beneath the individual red superficial vessels. Scleromalacia is painless bilateral thinning of the sclera, with the affected area appearing blue or grey (the colour of the underlying choroid). Corneal melting is a rare but devastating manifestation. It usually occurs in long-standing disease and is associated with systemic vasculitis. It causes pain, redness and blurred vision with corneal thinning. If it is untreated, progression to perforation is common, so urgent high-dose steroid and immunosuppressive therapy are indicated.

Cardiac and pulmonary involvement

Cardiac involvement occurs in about 30% of patients with seropositive RA but is usually asymptomatic. Symptomatic pericardial effusions and constrictive pericarditis are rare. Occasionally, granulomatous lesions can cause heart block, cardiomyopathy, coronary artery occlusion or aortic regurgitation. Serositis is commonly asymptomatic but may cause pleurisy or breathlessness. Pulmonary fibrosis can occur in advanced RA and may cause dyspnoea (p. 714).

Neurological complications

Peripheral entrapment neuropathies may result from compression by hypertrophied synovium or by joint subluxation. Median nerve compression in the carpal tunnel is most common and bilateral compression can occur as an early presenting feature of RA. Other syndromes include ulnar nerve compression at the elbow or wrist, compression of the lateral popliteal nerve at the head of the fibula, and tarsal tunnel syndrome (entrapment of the posterior tibial nerve in the flexor retinaculum) which causes burning, tingling and numbness in the distal sole and toes. Diffuse symmetrical peripheral neuropathy and mononeuritis multiplex may occur in patients with rheumatoid vasculitis.

Cervical cord compression can result from subluxation of the cervical spine at the atlanto-axial joint or at a subaxial level (Fig. 25.23). Atlanto-axial subluxation is a common finding in long-standing RA and is due to erosion of the transverse ligament that is posterior to

Fig. 25.23 Subluxation of cervical spine. **A** Flexion, showing widening of the space (arrow) between the odontoid peg of the axis (behind) and the anterior arch of the atlas (in front). **B** Extension, showing reduction in this space.

the odontoid peg. On neck flexion, this allows the peg to move posteriorly and indent the cord. If unrecognised, it can lead to cord compression or sudden death following minor trauma or manipulation. Atlanto-axial subluxation should be suspected in any RA patient who describes new onset of occipital headache, particularly if symptoms of paraesthesia or electric shock are present in the arms. In some patients, the onset may be insidious, with subtle loss of function that is initially attributed to active disease. Reflexes and power can be very difficult to assess in the presence of marked joint damage and therefore sensory or upper motor signs are the most important to elicit. Patients with spinal cord compression may require operative stabilisation and fixation, though the outcome is poor if the patient already has tetraparesis.

Other complications

Amyloidosis is a rare complication of prolonged active disease and usually presents with nephrotic syndrome. Microcytic anaemia can occur due to iron deficiency resulting from NSAID-induced gastrointestinal blood loss, and normochromic, normocytic anaemia with thrombocytosis occurs in active disease. Felty's syndrome is the association of splenomegaly and neutropenia with RA (Box 25.52). Generalised and local lymphadenopathy affecting nodes draining actively inflamed joints may both occur. Patients with persistent lymphadenopathy should be biopsied since there is an increased risk of lymphoma in patients with long-standing RA.

Investigations

The diagnosis of RA is based on clinical criteria and there is no single diagnostic test. However, investigations are useful in confirming the diagnosis and assessing disease activity (Box 25.53). The DAS 28 score is frequently used to assess the response to treatment and the need for biologic therapy. It involves counting the number of swollen and tender joints in the upper limbs and knees, and combining this with the ESR and the patient's assessment of his/her general health on a visual analogue scale, to generate a numerical score. The higher the value, the greater the disease activity.

i

25.52 Felty's syndrome

Risk factors

- Age of onset 50–70 yrs
- Female > male
- Caucasians > blacks
- Long-standing RA
- Deforming but inactive disease
- Seropositive for RF

Common clinical features

- Splenomegaly
- Lymphadenopathy
- Weight loss
- Skin pigmentation
- Keratoconjunctivitis sicca
- Vasculitis, leg ulcers
- Recurrent infections
- Nodules

Laboratory findings

- Anaemia (normochromic, normocytic)
- Neutropenia
- Abnormal liver function
- Thrombocytopenia
- Impaired T- and B-cell immunity

i

25.53 Investigations and monitoring of rheumatoid arthritis

To establish diagnosis

- Clinical criteria
- Acute phase response (APR)
- Serological tests
- X-rays

To monitor disease activity and drug efficacy

- Pain (visual analogue scale)
- Early morning stiffness (minutes)
- Joint tenderness
- Joint swelling
- DAS 28 score
- APR

To monitor disease damage

- X-rays
- Functional assessment

To monitor drug safety

- Urinalysis
- Biochemistry
- Haematology

ESR and CRP are usually raised (acute phase response), but may not be in patients with isolated small joint arthritis. RF and anti-CCP antibodies are detected in 60–80% of patients but their absence does not exclude the diagnosis. A positive anti-CCP antibody is highly specific for RA and can occur before clinical onset of the disease. RF is non-specific; low titres are found in about 10% of the normal population and in other diseases (p. 1063). Plain X-rays of the hands, wrist and feet are useful. Periarticular osteoporosis is common during the early stages of disease and may be present within 6 months of onset. Non-proliferative marginal joint erosions on X-ray are characteristic, but uncommon within the first year. Ultrasound and MRI are more sensitive than X-rays at detecting early erosions. Patients who are suspected of having atlanto-axial disease should have lateral X-rays taken in flexion and extension, and the degree of cord compression should be established with MRI. In patients with Baker's cyst, Doppler ultrasound and an arthrogram may be required to establish the diagnosis, since deep venous thrombosis (DVT) and Baker's cyst may coexist.

Management

This follows the principles outlined on pages 1075–1082. Physical rest, targeted anti-inflammatory therapy and passive exercises are the mainstays, with the aim of relieving symptoms, suppressing inflammation, and conserving and restoring function in affected joints. A multidisciplinary approach is required, including doctors, nurses, physiotherapists and occupational therapists, and patient education and counselling play a key role. During treatment, periodic assessment of disease activity, progression and disability is essential. In the vast majority, management is outpatient-based, but hospital admission can be helpful in patients with very active disease for a period of bed rest, multiple joint injections, splinting, regular hydrotherapy, physiotherapy and education.

Drug therapy

Prompt introduction of DMARD therapy plays a central role. The patient should be advised that this will not improve symptoms immediately, but in the longer term there is a good chance that symptoms will come under control and joint damage will be prevented. If the first-choice drug fails to control disease activity, other DMARDs can be added. If adverse effects occur, the patient should be switched to another DMARD. If disease activity persists despite an adequate trial of two DMARDs including methotrexate, anti-TNF therapy should be considered. Because of the delayed onset of action, corticosteroids (prednisolone 7.5–10 mg daily for 3 months, or methylprednisolone 80–120 mg i.m.) are often given when DMARDs are commenced to give symptomatic relief. Most patients also require NSAID and other analgesics. Early DMARD use reduces radiographic progression in RA, at least in the medium term (Box 25.54), but anti-TNF therapy seems more effective in preventing joint erosions. Box 25.55 lists the special considerations in old age.

EBM 25.54 DMARD therapy for rheumatoid arthritis

'There is a therapeutic window of opportunity early in the course of RA associated with sustained benefit in radiographic progression for up to 5 years. Prompt initiation of antirheumatic therapy in persons with RA may alter the long-term course of the disease.'

• Finckh A, et al. *Arthritis Rheum* 2006; 55:864–872.

25.55 Rheumatoid arthritis in old age

- **Presentation:** may be atypical—for example, with an initial polymyalgic picture or with synovitis and marked peripheral oedema.
- **Increasing age and comorbidity** (e.g. cardiac, renal, gastrointestinal tract disease): increase the risks of NSAID gastrototoxicity; comorbidity can also make overall management more difficult.
- **Corticosteroid-induced osteoporosis:** increased risk in those aged > 65 yrs. Bisphosphonates should be co-prescribed in those on corticosteroid therapy for > 3 mths.
- **DMARD and biologic therapy:** age alone is not a contraindication.

Surgery

Synovectomy of the wrist or finger tendon sheaths of the hands may be required for pain relief or to prevent tendon rupture when medical interventions have failed. In later stages when joint damage has occurred, osteotomy, arthrodesis or arthroplasty may be required (see Box 25.44, p. 1083).

Seronegative spondyloarthritis

This describes a group of related inflammatory joint diseases distinct from RA, which show considerable overlap in their clinical features and shared immunogenetic association with the HLA B27 antigen (Box 25.56). The diseases included are:

- ankylosing spondylitis
- reactive arthritis, including Reiter's syndrome
- psoriatic arthritis
- arthropathy associated with inflammatory bowel disease.

The synovitis is non-specific and, apart from absence of granulomas, is often indistinguishable from RA. However, the distinctive feature of this group of diseases is the marked degree of extrasynovial inflammation, especially of the enthesis but also affecting the joint capsule, periarticular periosteum, cartilage and subchondral bone. Large central cartilaginous joints (sacroiliac, intervertebral, symphysis pubis) are particularly involved, but even when synovial joints are affected (often spinal apophyseal joints, hips, knees, shoulders) extrasynovial inflammation is prominent. Apart from targeting entheses, the other characteristic features are resolution of inflammation by extensive fibrosis and a tendency for the resulting scar tissue to calcify. This chronic inflammation, which largely targets extrasynovial tissue, may characteristically lead to joint fusion in the relative absence of joint synovitis. Similarly, periarticular osteitis and periostitis may result in bony spurs that bridge adjacent vertebral bodies (syndesmophytes) or protrude at sites of ligament attachment (e.g. calcaneal or olecranon 'spurs').

There is a striking association with carriage of the HLA-B27 allele, particularly for ankylosing spondylitis (> 95%) and Reiter's disease (90%), and when there is sacroiliitis, uveitis or balanitis. The mechanism is

25.56 Clinical features common to seronegative spondyloarthritis

- Asymmetrical inflammatory oligoarthritis (lower > upper limb)
- Sacroiliitis and inflammatory spondylitis
- Inflammatory enthesitis
- Tendency for familial aggregation
- No association with seropositivity for RF
- Absence of nodules and other extra-articular features of RA
- Typical overlapping extra-articular features:
 - Mucosal inflammation: conjunctivitis, buccal ulceration, urethritis, prostatitis, bowel ulceration
 - Pustular skin lesions and nail dystrophy
 - Anterior uveitis
 - Aortic root fibrosis (aortic incompetence, conduction defects)
 - Erythema nodosum

unclear. The suggested pathogenesis for the seronegative spondyloarthritides is an aberrant response to infection in genetically predisposed people: the 'reactive' concept. In some situations a triggering organism can be identified, as in Reiter's disease following bacterial dysentery or chlamydial urethritis, but in others the environmental trigger remains obscure. The seronegative spondyloarthritis 'group' concept is also supported by aggregation of the conditions within families, with each showing an increased familial incidence of the other conditions. Such families may thus share an inherited 'reactive' potential, but the phenotypic expression is modified according to the inciting trigger and other genetic and constitutional features of the individual.

Ankylosing spondylitis

Ankylosing spondylitis (AS) is characterised by a chronic inflammatory arthritis predominantly affecting the sacroiliac joints and spine, which can progress to bony fusion of the spine. It has a peak onset in the second and third decades, with a male:female ratio of about 3:1. In Europe, more than 90% of those affected are HLA-B27-positive. The overall prevalence is less than 0.5% in most communities. Over 75% of patients are able to remain in employment and enjoy a good quality of life. Even if severe ankylosis develops, functional limitation may not be marked as long as the spine is fused in an erect posture.

AS is thought to result from exposure to a common environmental pathogen in genetically susceptible individuals, although no specific trigger has been identified. Chronic prostatitis is more common than expected but appears to be non-infective in origin. Increased faecal carriage of *Klebsiella aerogenes* occurs in patients with established AS and may relate to exacerbation of both joint and eye disease.

Clinical features

The onset is usually insidious, with recurring episodes of low back pain and marked stiffness. Radiation of pain to the buttocks or posterior thighs may be misdiagnosed as sciatica. Unlike mechanical back pain, symptoms extend over many segments and are axial and symmetrical in distribution. Symptoms are most marked in the early morning and after inactivity, and are relieved by movement. Although the lumbosacral area is usually the first and worst affected region, some patients present with mainly thoracic or neck symptoms. The disease tends to ascend the spine slowly and eventually, after several years, the whole spine may be affected. As the spine becomes progressively ankylosed, spinal rigidity and secondary osteoporosis predispose to spinal fracture. Spinal cord compression is rare.

Early physical signs include failure to obliterate the lumbar lordosis on forward flexion, restriction of movements of the lumbar spine in all directions, and possible pain on sacroiliac stressing. As the disease progresses, stiffness increases throughout the spine, and chest expansion frequently becomes restricted. Spinal fusion varies in its extent and in most cases does not cause a gross flexion deformity, but a few develop marked kyphosis of the dorsal and cervical spine that may interfere with forward vision. This may prove incapacitating, especially when associated with fixed flexion contractures of hips or knees. Pleuritic chest pain aggravated by breathing is common and results from costovertebral joint involve-

ment. Plantar fasciitis, Achilles tendinitis and tenderness over bony prominences such as the iliac crest and greater trochanter are common, reflecting inflammation at the sites of tendon insertions (enthesitis).

Peripheral arthritis

Up to 40% of patients have peripheral arthritis. This is usually asymmetrical at first, mainly affecting hips, knees, ankles or shoulders. Involvement of a peripheral joint, most commonly ankle, knee or elbow, may precede the development of spinal symptoms in around 10% of cases. In a further 10%, symptoms begin in childhood as one variety of pauciarticular juvenile idiopathic arthritis.

Extra-articular disease

Fatigue is often a major complaint and may result from both chronic interruption of sleep due to pain, as well as chronic systemic inflammation. Acute anterior uveitis is the most common extra-articular feature. Occasionally, this precedes joint disease. Other extra-articular features are rare (Box 25.57).

25.57 Extra-articular features of ankylosing spondylitis

- Anterior uveitis (25%) and conjunctivitis (20%)
- Prostatitis (80% men): usually asymptomatic
- Cardiovascular disease
 - Aortic incompetence
 - Mitral incompetence
 - Cardiac conduction defects
 - Pericarditis
- Amyloidosis
- Atypical upper lobe pulmonary fibrosis

Investigations

X-ray changes are characteristic but may take years to develop. Sacroiliitis is often the first abnormality, beginning in the lower synovial parts of the joints with irregularity and loss of cortical margins, widening of the joint space and subsequently sclerosis, narrowing and fusion. MRI is more sensitive for detection of early sacroiliitis, but is seldom required. Lateral thoracolumbar spine X-rays may show anterior 'squaring' of vertebrae due to erosion and sclerosis of the anterior corners and periostitis of the waist. Bridging syndesmophytes are fine and symmetrical, and follow the outermost fibres of the annulus (Fig. 25.24). Ossification of the anterior longitudinal ligament and facet joint fusion may also be visible. The combination of these features may result in the typical 'bamboo' spine (Fig. 25.25). Erosive changes may be seen in the symphysis pubis, the ischial tuberosities and peripheral joints. Osteoporosis and atlanto-axial dislocation can occur as late features.

The ESR and CRP are usually raised in active disease. RF and other autoantibodies are usually negative. Testing for HLA-B27 can be a helpful investigation for pauciarticular juvenile idiopathic arthritis but is unhelpful in adults with spinal symptoms.

Management

The aims are to relieve pain and stiffness, maintain a maximal range of skeletal mobility and avoid the

Fig. 25.24 Radiographic syndesmophyte (arrows). [A] Fine symmetrical marginal syndesmophytes typical of ankylosing spondylitis. [B] Coarse, asymmetrical non-marginal syndesmophytes typical of psoriatic/Reiter's spondylitis.

development of deformities. Education and appropriate physical activity are the cornerstones of management. Early in the disease, patients should be taught to perform daily back extension exercises, including a morning 'warm-up' routine, and to punctuate prolonged periods of inactivity with regular breaks. Swimming is ideal exercise. Poor posture must be avoided.

NSAIDs and analgesics are often effective in relieving symptoms but do not alter the course of the disease. A long-acting NSAID at night is helpful for marked morning stiffness. Peripheral arthritis can be treated

with methotrexate or sulfasalazine, but these drugs have no effect on axial disease. Anti-TNF therapy should be considered for disease inadequately controlled by these measures since it often has a significant impact on axial symptoms.

Local corticosteroid injections can be useful for persistent plantar fasciitis, other enthesopathies and peripheral arthritis. Oral corticosteroids may be required for acute uveitis but do not help spinal disease. Severe hip, knee or shoulder restriction may require surgery. Total hip arthroplasty has largely removed the need for difficult spinal surgery in those with advanced deformity.

Reactive arthritis and Reiter's disease

Reactive arthritis is predominantly a disease of young men with a sex ratio of 15:1. It is the most common cause of inflammatory arthritis in men aged 16–35 but may

Fig. 25.25 'Bamboo' spine of severe late ankylosing spondylitis. Note the symmetrical marginal syndesmophytes (arrows), sacroiliac joint fusion and generalised osteopenia.

25.58 Reiter's disease

Classic triad*

- Non-specific urethritis
- Conjunctivitis (~50%)
- Reactive arthritis

Additional extra-articular features

- Circinate balanitis (20–50%)
- Keratoderma blennorrhagica (15%)
- Nail dystrophy
- Buccal erosions (10%)

Precipitated by

- Bacterial dysentery, mainly *Salmonella*, *Shigella*, *Campylobacter* or *Yersinia*
- Sexually acquired infection with *Chlamydia*

*Incomplete forms with just one or two of the classic triad are more frequent than the full syndrome.

occur at any age. Between 1 and 2% of patients with non-specific urethritis seen at genitourinary medicine clinics have reactive arthritis. Following an epidemic of *Shigella* dysentery, 20% of HLA-B27-positive men developed reactive arthritis. Reiter's disease is the triad described in Box 25.58 but many patients present with just arthritis.

Clinical features

The onset is typically acute or subacute, with an inflammatory oligoarthritis that is asymmetrical and targets lower limb joints, typically the ankles, midtarsal joints, metatarsophalangeal joints or knees. Achilles tendinitis or plantar fasciitis may also be present. There may be considerable systemic disturbance with fever and weight loss. It occasionally presents subacutely with single joint involvement and there may be no clear history of an infectious trigger. The first attack of arthritis is usually self-limiting, with spontaneous remission within 2–4 months. However, recurrent or chronic arthritis develops in more than 60% of patients. Low back pain and stiffness are common and 15–20% of patients develop spondylitis. Around 10% of patients have evidence of active disease 20 years after the onset. Spondylitis, chronic erosive arthritis, recurrent acute arthritis and uveitis are the major causes of long-term morbidity.

Extra-articular features (see Box 25.58)

Circinate balanitis starts as vesicles on the coronal margin of the prepuce and glans penis, later rupturing to form superficial erosions with minimal surrounding erythema, some coalescing to give the circular pattern. Lesions are often painless and may escape notice. Keratoderma blennorrhagica begins as discrete waxy yellow-brown vesico-papules with desquamating margins, occasionally coalescing to form large crusty plaques. The palms and soles are particularly affected but spread may occur to the scrotum, scalp and trunk. These lesions are indistinguishable from pustular psoriasis. Nail dystrophy with subungual hyperkeratosis is common and indistinguishable from psoriatic nail dystrophy. Mouth ulcers manifest as shallow red painless patches on tongue, palate, buccal mucosa and lips, lasting only a few days. Conjunctivitis may accompany the first acute episode. Uveitis is rare with the first attack but occurs in 30% of patients with recurring or chronic arthritis.

Other complications are rare but include aortic incompetence, conduction defects, pleuro-pericarditis, peripheral neuropathy, seizures and meningoencephalitis.

Investigations

The diagnosis is usually made clinically but joint aspiration may be required to exclude crystal arthritis and infection. Synovial fluid is inflammatory and often contains giant macrophages (Reiter's cells). ESR and CRP may be raised. Urethritis may be confirmed in the 'two-glass test' by demonstration of mucoid threads in the first-void specimen that clear in the second. High vaginal swabs may reveal *Chlamydia* on culture. Except for post-*Salmonella* arthritis, stool cultures are usually negative by the time the arthritis presents, but serum agglutinin tests may help confirm previous dysentery. RF, CCP and ANA are negative.

X-rays are seldom helpful during the acute attack, but in chronic or recurrent disease periarticular osteopenia, joint space narrowing and marginal proliferative

erosions may be observed. Another characteristic feature is periostitis, especially of metatarsals, phalanges and pelvis, and large 'fluffy' calcaneal spurs. In contrast to AS, radiographic sacroiliitis is often asymmetrical and sometimes unilateral, and syndesmophytes are predominantly coarse and asymmetrical, often extending beyond the contours of the annulus ('non-marginal') (see Fig. 25.24). X-ray changes in the peripheral joints and spine are identical to those in psoriasis.

Management

The acute attack should be treated with limited rest, oral NSAIDs and analgesics, and for marked synovitis, intra-articular injection of corticosteroids. Non-specific chlamydial urethritis is usually treated with a short course of tetracycline and this may reduce the frequency of arthritis in sexually acquired cases. Treatment with DMARDs should be considered for patients with persistent marked symptoms, recurrent arthritis or severe keratoderma blennorrhagica. Anterior uveitis is a medical emergency requiring topical, subconjunctival or systemic corticosteroids.

Psoriatic arthritis

Psoriatic arthritis (PsA) occurs in about 1 in 1000 of the general population and in 7% of patients with psoriasis. Approximately 20% of all patients with seronegative polyarthritis have PsA. The onset is usually between 25 and 40 years of age. Most patients (70%) have pre-existing psoriasis, but in 20% the arthritis predates its onset. Occasionally, the arthritis and psoriasis develop synchronously.

Clinical features

The presentation is with joint pain and swelling. Several different patterns of joint involvement are recognised but the course is generally one of intermittent exacerbation followed by varying periods of complete or near-complete remission. Destructive arthritis and disability are uncommon, except in the case of arthritis mutilans.

- *Asymmetrical inflammatory oligoarthritis* affects about 40% of patients and often presents abruptly with a combination of synovitis and adjacent periarticular inflammation; this occurs most characteristically in the hands and feet when synovitis of a finger or toe is coupled with tenosynovitis, enthesitis and inflammation of intervening tissue to give a 'sausage digit' or dactylitis (Fig. 25.26A). Large joints such as the knee and ankle may also be involved, sometimes with very large effusions.
- *Symmetrical polyarthritis* occurs in about 25% of cases. It predominates in women and may strongly resemble RA, with symmetrical involvement of small and large joints in both upper and lower limbs. Nodules and other extra-articular features of RA are absent and arthritis is generally less extensive and more benign. Much of the hand deformity often results from tenosynovitis and soft tissue contractures.
- *Distal IPJ arthritis* is an uncommon but characteristic pattern mainly affecting men. It targets finger distal IPJs and surrounding periarticular tissues, almost invariably with accompanying nail dystrophy (Fig. 25.26B).

Fig. 25.26 Psoriatic arthropathy. **A** 'Sausage' middle finger of a patient with psoriatic arthritis. **B** Typical distal interphalangeal joint pattern with accompanying nail dystrophy (pitting and onycholysis).

- *Psoriatic spondylitis* presents a similar clinical picture to AS but with less severe involvement. It may occur alone or with any of the other clinical patterns.
- *Arthritis mutilans* is a deforming erosive arthritis targeting the fingers and toes which occurs in 5% of cases. Marked cartilage and bone destruction results in marked instability. The encasing skin appears invaginated and 'telescoped' ('main en lorgnette') and traction can pull the finger back to its original length.

Nail changes include pitting, onycholysis, subungual hyperkeratosis and horizontal ridging. They are found in 85% of those with PsA and only 30% of those with uncomplicated psoriasis, and can occur in the absence of skin disease. The characteristic rash of psoriasis (p. 1260) may be widespread, or confined to the scalp, natal cleft and umbilicus, where it is easily overlooked. Conjunctivitis can occur, whereas uveitis is mainly confined to HLA-B27-positive individuals with sacroiliitis and spondylitis.

Investigations

The diagnosis is clinical but ESR and CRP may be raised, especially in patients with extensive disease. RF, CCP and ANA are generally negative. X-rays may be normal or show erosive change with joint space narrowing. Features that favour PsA over RA include proliferative marginal erosions, absence of periarticular osteoporosis and osteosclerosis of the phalanges ('ivory phalanx'). Arthritis mutilans and peripheral joint ankylosis can occur. The changes in the axial skeleton resemble those of chronic reactive arthritis, with coarse, asymmetri-

cal, non-marginal syndesmophytes and asymmetrical sacroiliitis.

Management

Therapy with NSAID and analgesics may be sufficient to control symptoms. Intra-articular injections of corticosteroid may help control synovitis in problem joints. In general, splints and prolonged rest should be avoided because of the tendency to fibrous and bony ankylosis. Patients with spondylitis should be prescribed the same exercise and posture regime as in AS.

Therapy with DMARDs should be considered for persistent synovitis unresponsive to conservative treatment. Methotrexate is the treatment of first choice since it may also help skin psoriasis, but other DMARDs may also be effective. Hydroxychloroquine is generally avoided, as it can cause exfoliative skin reactions. Anti-TNF treatment should be considered for patients with active synovitis who respond inadequately to standard DMARDs. This is effective for both PsA and psoriasis.

The retinoid acitretin (p. 1264) is effective for skin lesions and can also help the arthritis, but is teratogenic so must be avoided in young women. It also causes mucocutaneous side-effects, hyperlipidaemia, myalgias and extraspinal calcification. Photochemotherapy with methoxypsoralen and long-wave ultraviolet light (psoralen + UVA, PUVA) is primarily used for skin disease, but can also help those with synchronous exacerbations of inflammatory arthritis.

Arthritis associated with inflammatory bowel disease

An acute inflammatory oligoarthritis ('enteropathic arthritis') occurs in around 10% of patients with ulcerative colitis and 20% of those with Crohn's disease. It predominantly affects the large lower limb joints (knees, ankles, hips) but wrists and small joints of the hands and feet can also be involved. The arthritis usually coincides with exacerbations of the underlying bowel disease, and sometimes occurs with aphthous mouth ulcers, iritis and erythema nodosum. It improves with effective treatment of the bowel disease, and can be cured by total colectomy in patients with ulcerative colitis. Patients with inflammatory bowel disease may also develop sacroiliitis (16%) and AS (6%), which are clinically and radiologically identical to classic AS. These can predate or follow the onset of bowel disease and there is no correlation between activity of the spondylitis and bowel disease.

Crystal-associated disease

A variety of crystals can deposit in and around joints and associate with both acute inflammatory and chronic syndromes (Box 25.59). In some instances crystals are the primary pathogenic agents—true 'crystal deposition disease', e.g. gout. In others, MSK disease predisposes to secondary crystal formation: for example, predisposition to calcium pyrophosphate and apatite crystal formation in OA. Such crystals may subsequently amplify symptoms and damage, or be of no clinical consequence.

Several factors influence crystal formation (Fig. 25.27). There must be sufficient concentration of the chemical

25.59 Crystal-associated arthritis and deposition in connective tissue	
Crystal	Associations
Common	
Monosodium urate monohydrate	Acute gout Chronic tophaceous gout
Calcium pyrophosphate dihydrate	Acute 'pseudogout' Chronic (pyrophosphate) arthropathy Chondrocalcinosis
Basic calcium phosphates	Calcific periarthritis Calcinosis
Uncommon	
Cholesterol	Chronic effusions in RA
Calcium oxalate	Acute arthritis in dialysis patients
Extrinsic crystals/semi-crystalline particles	
Synthetic crystals	Acute synovitis
Plant thorns/sea urchin spines	Chronic monoarthritis, tenosynovitis

components (ionic product), but whether a crystal then forms depends on the balance of tissue factors that promote and inhibit crystal nucleation and growth. Many tissues are supersaturated for various products but depend on natural inhibitors to prevent crystallisation. Crystals can also dissolve and the yield of crystals at any one

Fig. 25.27 Factors relating to crystal formation and tissue concentration at any one time.

time will depend on the relative rates of crystallisation, growth and dissolution.

The inflammatory potential of crystals resides in their physical irregularity and high negative surface charge, which can induce inflammation and damage cell membranes. Crystals may also cause mechanical damage to tissues and act as wear particles at the joint surface. Crystals forming deep within cartilage or tendon are prevented from interaction with proteins and cells, and can paradoxically reside in MSK tissues for years without causing inflammation or symptoms. It is only when they are released ('crystal shedding') from these protected sites that they are exposed to inflammatory mediators and trigger acute inflammation. Such attacks may occur spontaneously, result from mechanical loosening (local trauma), partial dissolution and reduced crystal size (e.g. initiation of hypouricaemic treatment), or occur in association with an acute phase response due to intercurrent illness or surgery.

Gout

Gout is a true crystal deposition disease, and is defined as the pathological reaction of the joint or periarticular tissues to the presence of monosodium urate monohydrate (MSU) crystals. MSU crystals preferentially deposit in peripheral connective tissues in and around synovial joints, initially favouring lower rather than upper limbs and especially targeting the first MTP joint and small joints of feet and hands. As the crystal deposits slowly increase and enlarge, there is progressive involvement of more proximal sites and the potential for cartilage and bone damage, with 'secondary' OA. MSU crystals take months or years to grow to a detectable size, implying a long asymptomatic phase.

Epidemiology

The prevalence of gout varies between populations but is approximately 1–2%, with a strong male predominance (> 5:1). It is the most common inflammatory arthritis in men and in older women. Prevalence increases with increasing serum uric acid (SUA) and with age. The incidence and prevalence of gout have increased in many countries in recent decades, in parallel with increased longevity and the higher prevalence of metabolic syndrome, of which hyperuricaemia is an integral component.

SUA levels are distributed in the community as a continuous variable (p. 4). Levels are higher in men than women; they rise from the age of 20 in men and after the menopause in women, positively correlate with obesity and vary according to ethnicity (highest in New Zealand Maoris). Hyperuricaemia is defined as an SUA level greater than 2 standard deviations above the mean for the population. Only a minority of hyperuricaemic people develop gout, emphasising the importance of tissue factors in crystal formation.

Aetiology

Primary gout

About one-third of the body uric acid pool is derived from dietary sources and two-thirds from endogenous purine metabolism (Fig. 25.28). The concentration of uric acid in body fluids depends on the balance between its synthesis and elimination by the kidneys (two-thirds) and gut (one-third). Purine nucleotide synthesis and

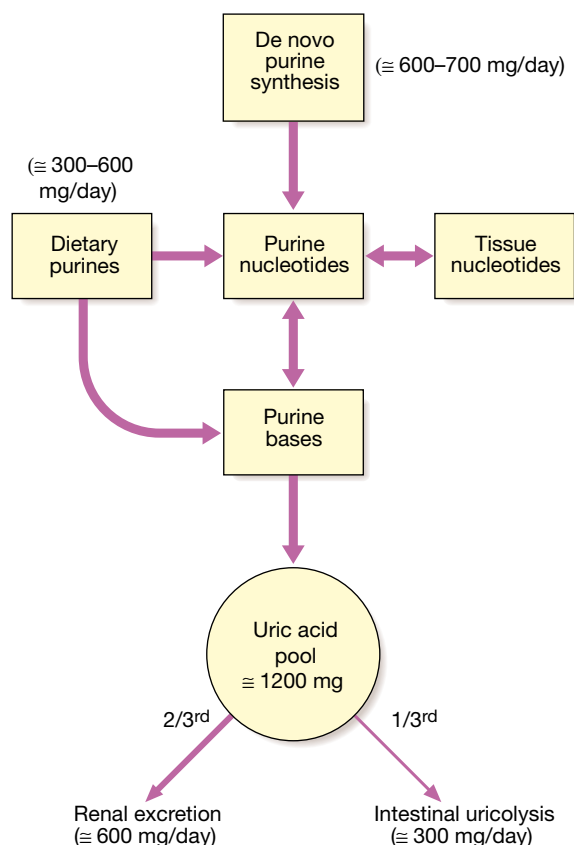

Fig. 25.28 The uric acid pool. Origins and disposal of uric acid in normal humans.

degradation are regulated by a network of enzyme pathways; xanthine oxidase catalyses the end conversion of hypoxanthine to xanthine and then xanthine to uric acid.

Causes of hyperuricaemia are shown in Box 25.60. In over 90% of patients with primary gout, hyperuricaemia results from an inherited defect in fractional uric acid excretion which impairs their ability to increase urate excretion in response to a purine load ('under-excretors'). Recent studies have identified polymorphisms in several genes that encode urate transporters which are associated with gout, the most important of which is *SLC2A9*. Some primary gout patients are intrinsic 'over-producers' of uric acid through no identifiable cause. Very rarely (< 1%), there may be an inherited defect in purine metabolism, which should be suspected particularly if gout develops under age 25, in patients with uric acid renal calculi, or if there is a strong family history of early-onset gout.

Risk factors and associations for primary gout include metabolic syndrome (p. 802), high alcohol intake (predominantly beer which contains guanosine), and diets relatively high in red meat or fructose or relatively low in vitamin C or coffee.

Secondary gout

Secondary gout results from hyperuricaemia due to renal impairment or chronic diuretic use. In diuretic-induced gout, nodal generalised OA is a further risk factor, especially in elderly women (Box 25.61). This presumably relates to a non-specific predisposition to crystallisation

25.60 Factors that predispose to chronic hyperuricaemia and gout

Diminished renal excretion (common)

- Inherited isolated renal tubular defect ('under-excretors')
- Renal failure
- Chronic drug therapy
 - Thiazide and loop diuretics
 - Low-dose aspirin
 - Ciclosporin
 - Pyrazinamide
- Lead toxicity (e.g. in 'moonshine' drinkers)
- Lactic acidosis (alcohol)

Increased production of uric acid (uncommon)

- Increased purine turnover
 - Chronic myeloproliferative or lymphoproliferative disorders (e.g. polycythaemia, chronic lymphatic leukaemia)
- Increased de novo synthesis ('over-producers')
 - Unidentified abnormality (most common)
 - Specific enzyme defect (rare)
 - Hypoxanthine-guanine phosphoribosyl transferase deficiency
 - Phosphoribosyl pyrophosphate synthetase over-activity
 - Glucose-6-phosphatase deficiency

25.61 Gout in old age

- **Aetiology:** predominantly primary gout, but a higher proportion of secondary gout (chronic diuretic therapy or chronic kidney disease) than in middle-aged patients.
- **Nodal generalised OA:** an important additional risk factor for gout.
- **Presentation:** more often atypical (e.g. presentation with painful tophi and chronic symptoms, rather than as classic acute attacks; presentation in upper rather than lower limbs).
- **Treatment of acute attacks:** best treated by aspiration and intra-articular injection of long-acting corticosteroid followed by early mobilisation. Oral NSAID and colchicine are best avoided because of increased toxicity.
- **Allopurinol:** because of increased toxicity, should be started at the low dose of 50–100 mg/day.

in osteoarthritic cartilage, possibly due to reduced levels of proteoglycan and other inhibitors of crystal formation. Lead poisoning is a rare cause of hyperuricaemia and secondary ('saturnine') gout.

Clinical features

Acute gout

In almost all first attacks a single distal joint is affected. The first MTP joint is affected in over 50% of cases—'podagra' ('seizing the foot', Fig. 25.29). Other common sites are, in order of decreasing frequency, the ankle, midfoot, knee, small joints of hands, wrist and elbow. The axial skeleton and large proximal joints are rarely involved and never as the first site. Typical attacks have the following characteristics:

- extremely rapid onset, reaching maximum severity in just 2–6 hours, often waking the patient in the early morning
- severe pain, often described as the 'worst pain ever'

Fig. 25.29 Podagra. Acute gout causing swelling, erythema and extreme pain and tenderness of the first metatarsophalangeal joint.

- extreme tenderness: the patient is unable to wear a sock or to let bedding rest on the joint
- marked swelling with overlying red, shiny skin
- self-limiting over 5–14 days, with complete return to normality.

During the attack the joint shows signs of marked synovitis but also periarticular swelling and erythema. There may be accompanying fever, malaise and even confusion, especially if a large joint such as the knee is involved. As the attack subsides, pruritus and desquamation of overlying skin are common. The main differential diagnosis is septic arthritis, infective cellulitis or another crystal disease. Sepsis, however, is usually more subacute in onset and progresses in severity until treated.

Acute attacks may also manifest as bursitis, tenosynovitis or cellulitis, which have the same clinical characteristics. Many patients describe milder episodes lasting just a few days ('petite attacks'). Some have attacks in more than one joint; sometimes one attack, by triggering the APR, triggers attacks in other joints a few days later ('cluster attacks'). Polyarticular attacks are rare.

Recurrent and chronic gout

After an acute attack, some people never have a second episode; in others the next episode occurs after years. In most, however, a second attack occurs within 1 year and the frequency of attacks gradually increases with time. Later attacks are more likely to involve several joints and be more severe. Eventually, continued MSU deposition causes joint damage and chronic pain. The interval between the first attack and the development of chronic symptoms is variable but averages around 10 years. The main determinant is the SUA; the higher it is, the earlier and more extensive the development of joint damage and MSU deposits. The joints most commonly involved are the same as those affected by acute attacks. Occasionally there may be severe

deformity and marked functional impairment, especially of feet and hands. As with tophi, asymmetry is characteristic.

Chronic tophaceous gout

Large MSU crystal deposits produce irregular firm nodules ('tophi') around extensor surfaces of fingers, hands, forearm, elbows, Achilles tendons and sometimes the helix of the ear. The white colour of MSU crystals may be evident and permits distinction from rheumatoid nodules (Fig. 25.30). Large nodules may ulcerate, discharging white gritty material and associating with local inflammation (erythema, pus), even in the absence of secondary infection. Although clinically apparent tophi are usually a very late feature, they may appear surprisingly rapidly, in under 1 year, in patients with chronic renal failure.

Secondary gout may present with painful, sometimes discharging, tophi without preceding acute attacks. This is particularly seen in older, mainly female patients with nodal OA who develop tophi in and around their osteoarthritic finger joints as a consequence of chronic (> 1–2 years) diuretic therapy (see Fig. 25.30).

Renal and urinary tract manifestations

Uric acid (not MSU) stones cause renal colic (p. 473) in around 10% of gout patients in Europe. The incidence is higher in hot climates and is favoured by purine overproduction, uricosuric drugs, defects in tubular reabsorption of uric acid, dehydration and lowering of urine pH (e.g. chronic diarrhoea or ileostomy). Hyperuricaemia and gout also predispose to calcium oxalate, calcium phosphate or mixed stones.

Progressive renal disease is an important complication confined to untreated severe chronic tophaceous gout. This results from MSU crystal deposition in the interstitium of the medulla and pyramids with consequent chronic inflammation, giant-cell reaction, fibrosis, glomerulosclerosis and secondary pyelonephritis.

Fig. 25.30 Tophus with white MSUM crystals visible beneath the skin. Diuretic-induced gout in a patient with pre-existing nodal OA.

Investigations

Definitive diagnosis requires identification of MSU crystals in the aspirate from a joint, bursa or tophus (see Fig. 25.4A, p. 1060). In acute gout, synovial fluid shows increased turbidity due to the greatly elevated cell count (> 90% neutrophils); chronic gouty fluid is more variable but occasionally appears white due to the high crystal load. Between attacks, aspiration of an asymptomatic first MTP joint or knee may still permit crystal identification.

Although hyperuricaemia is usually present, it does not confirm gout. Equally, a normal SUA, especially during an attack, does not exclude gout since it falls as part of the APR. Measurement of 24-hour urinary uric acid excretion on a low purine diet will identify an over-producer. Assessment of renal function (serum creatinine, urinalysis), hypertension, blood glucose and serum lipid profile should be undertaken. An FBC and ESR should detect chronic myeloproliferative disorders during remission of acute gout. During an attack, an elevated CRP and neutrophilia are usual; the ESR is often modestly raised in tophaceous gout.

X-rays can assess the degree of joint damage. In early disease they are usually normal, but changes of OA may develop in affected joints with time, or be present as a predisposing factor in secondary gout. Gouty 'erosions' (bony tophi) are a less common but more specific feature occurring as para-articular 'punched-out' defects with well-delineated borders and retained bone density (see Fig. 25.6, p. 1061). Tophi may also be visible as eccentric soft tissue swellings. In late disease, changes are similar to other forms of inflammatory polyarthritis. Ultrasound can detect subclinical microtophi and MSU deposits within cartilage of the first MTP joint, even at first clinical presentation.

Management

The acute attack

A fast-acting oral NSAID (plus a PPI) (p. 1076) can give effective pain relief and is the standard treatment, together with local ice packs. Patients can keep a supply of an NSAID and take it as soon as the first symptoms occur, continuing until the attack resolves. Oral colchicine (a potent inhibitor of neutrophil microtubular assembly) is also very effective but often causes vomiting and severe diarrhoea at high doses; a low-dose regimen (0.5mg 6-, 8- or 12-hourly) is therefore recommended. Joint aspiration can give instant relief and, when combined with an intra-articular steroid injection to prevent fluid reaccumulation, often effectively aborts the attack. For severe oligo- or polyarticular attacks, parenteral corticosteroid is sometimes used.

Long-term management

Once an acute attack has settled, predisposing factors should be corrected if possible. Weight loss and reduction of excess alcohol intake, especially beer, may significantly reduce hyperuricaemia. Diuretics should be stopped if possible. A very high purine diet (e.g. seafood, red meat, offal) should be tempered but there is no need for a highly restrictive diet. Associated comorbidity should be treated appropriately.

Indications for urate-lowering therapy (ULT) are shown in Box 25.62. Allopurinol is the drug of choice. It is a xanthine oxidase inhibitor, which reduces the

25.62 Indications for urate-lowering drugs

- Recurrent attacks of acute gout
- Tophi
- Evidence of bone or joint damage
- Associated renal disease and/or nephrolithiasis
- Gout with greatly elevated serum uric acid

conversion of hypoxanthine and xanthine to uric acid. The recommended starting dose is 100mg daily, but 50mg in older patients or if renal function is impaired. The reduction in tissue uric acid levels that follows initiation of ULT can partially dissolve MSU crystals and trigger acute attacks. The patient should be warned of this and told to continue ULT, even if an attack occurs. The risk can be minimised by using a low starting dose (50–100mg rather than 300mg), or by concurrent administration of oral colchicine (0.5mg 12-hourly) or an NSAID for the first few months.

The aim of ULT is to bring the SUA below the therapeutic target of 360µmol/L (i.e. the saturation point for MSU crystals) to ensure dissolution of existing crystals and to prevent new ones forming. The SUA should therefore be measured every 3–4 weeks and the dose of allopurinol increased in 100mg increments (50mg if the patient is elderly or there is renal impairment) until this is achieved (maximum 900mg daily). The lower the SUA is brought below this target, the faster the velocity of MSU crystal dissolution, the reduction in tophus size and the eventual cessation of acute attacks. Annual monitoring is advised subsequently to ensure maintenance of effective treatment. In most cases ULT will need to be continued indefinitely.

Febuxostat is a recently introduced xanthine oxidase inhibitor that is useful in patients in whom allopurinol is not tolerated or contraindicated. It commonly provokes attacks at the recommended starting dose (80mg daily) so prophylaxis with colchicine or NSAID is advised for the initial 6 months. It undergoes hepatic metabolism and so no dose adjustment is required for renal impairment.

Uricosuric drugs such as probenecid or sulfinpyrazone can be effective but require several doses each day and maintenance of a high urine flow to avoid uric acid crystallisation in renal tubules. Salicylates antagonise the uricosuric action of these drugs and should be avoided. Uricosurics are contraindicated in over-producers, in those with renal impairment and in urolithiasis (they increase stone formation). The uricosuric benzbromarone (50–200mg daily) can be very effective and safe in mild to moderate renal impairment but can rarely cause hepatotoxicity; availability is limited in most countries.

Asymptomatic hyperuricaemia

Although hyperuricaemia is an independent risk factor for hypertension, vascular disease, renal disease and cardiovascular events, there is no evidence that ULT is effective in the treatment of these diseases.

Calcium pyrophosphate dihydrate (CPPD) crystal deposition

CPPD crystal deposition in hyaline and fibrocartilage of joints causes chondrocalcinosis. Sporadic, familial and metabolic disease-associated forms are recognised (Box 25.63). Radiographic chondrocalcinosis is rare under the

25.63 Associations of CPPD crystal deposition

	Chondrocalcinosis	Structural arthritis
Ageing (sporadic) (most common)	+	–

Hypophosphatasia	+	–
Hypomagnesaemia	+	–
Wilson's disease	+	–

age of 55, but rises from 10–15% in those aged 65–75 to 30–60% in those over 85. The knee (hyaline cartilage and menisci) is by far the most common site, followed by the wrist (triangular fibrocartilage) and pelvis (symphysis pubis). It is often clinically occult, but can cause acute self-limiting synovitis ('pseudogout') or occur as a chronic arthritis showing a strong association/overlap with OA, especially at the knee (Fig. 25.31).

Aetiology

In OA, CPPD crystal deposition is favoured by a reduction in concentration of proteoglycan and other natural inhibitors of crystal formation, and by increased extracellular pyrophosphate levels due to increased chondrocyte metabolism. Other metabolic diseases are associated with CPPD deposition, but of these only haemochromatosis also predisposes to OA-like structural change. All of these conditions are characterised by elevated levels of extracellular pyrophosphate in joint tissues, mainly

Fig. 25.31 Knee X-ray showing chondrocalcinosis of the fibrocartilaginous menisci (M) and articular hyaline cartilage (H). There is also narrowing (N) and osteophyte (O) of the medial tibio-femoral compartment.

through reduced concentrations or activity of alkaline phosphatase and other pyrophosphatases, resulting in ectopic mineralisation.

Clinical features

Acute synovitis: 'pseudogout'

This is a common cause of acute monoarthritis in the elderly. The knee is by far the most common site, followed by the wrist, shoulder, ankle and elbow. It may be the first presentation of disease in the joint, or occur on a background of chronic symptomatic arthritis. Triggering factors include direct trauma and intercurrent illness or surgery.

The typical attack resembles acute gout and develops rapidly, with severe pain, stiffness and swelling, maximal within 6–24 hours of onset. Overlying erythema is common and examination reveals a very tender joint held in the flexed 'loose-pack' position with signs of marked synovitis (large/tense effusion, warmth, restricted movement with stress pain). Fever is common and the patient may appear confused and ill. The attack is self-limiting but can take 1–3 weeks to resolve.

Sepsis and gout are the main differential diagnoses. Although sepsis is often more subacute in onset and progressive, it should be considered especially when pseudogout has been triggered by chest infection or surgery, or if the patient is unwell. Furthermore, sepsis and pseudogout can coexist, so Gram stain and culture should still be undertaken, even if CPPD crystals are identified in aspirated fluid. Gout is unlikely in patients over the age of 65 without a preceding history of primary gout or chronic diuretic therapy and seldom involves the knee in a first attack.

Chronic (pyrophosphate) arthritis

This largely affects elderly women. The distribution is similar to that of pseudogout, with knees being the worst affected, then wrists, shoulders, elbows, hips and mid-tarsals. In the hand, the second and third MCP joints are most affected. Symptoms are chronic pain, variable early morning and inactivity stiffness, and functional impairment. Acute attacks may be superimposed. Affected joints show features of OA (bony swelling, crepitus, restriction) with varying degrees of synovitis. Effusion and synovial thickening are usually most apparent at knees and wrists; wrist involvement may result in carpal tunnel syndrome. Examination often reveals more widespread but asymptomatic signs of OA.

Inflammatory features may be sufficiently pronounced to suggest RA, but tenosynovitis and extra-articular involvement are absent, and large and medium rather than small joints are targeted. Severe damage and instability of knees or shoulders may occasionally lead to consideration of a neuropathic joint, but neurological findings are normal.

Incidental findings

Due to its high prevalence, radiographic chondrocalcinosis often occurs as an incidental finding in older people. Thorough history and examination are always required to determine the relevance of such findings to symptom causation.

Investigations

In acute pseudogout, examination of synovial fluid using compensated polarised microscopy will demonstrate CPPD crystals (see Fig. 25.4B, p. 1060) and permit

distinction from urate gout. The aspirated fluid is often turbid and may be uniformly blood-stained, reflecting the severity of inflammation. Gram stain and culture of the fluid will exclude sepsis. CPPD crystals may also be identified in fluid aspirated from chronic pyrophosphate arthritis.

X-rays may show chondrocalcinosis in hyaline cartilage and/or fibrocartilage (occasionally capsule or ligament) with or without associated structural changes of OA (see Fig. 25.31). Chondrocalcinosis is not always evident, especially in joints showing some degree of cartilage loss, and its absence does not exclude the diagnosis.

Screening for metabolic or familial predisposition (see Box 25.63) should be undertaken in patients with CPPD deposition aged under 55; florid polyarticular, as opposed to pauciarticular, chondrocalcinosis; recurrent acute attacks without chronic arthropathy; or additional clinical or radiographic features of predisposing disease.

Management

For acute pseudogout, aspiration quickly reduces pain and may be sufficient. Fluid reaccumulation, however, is common, particularly early in an attack, and intra-articular injection of corticosteroid is usually required. Oral NSAIDs (plus PPI) and colchicine are also effective, as in gout, but should be avoided if possible in older people. Early active mobilisation is also important. For chronic arthropathy, management is as for OA (p. 1087).

Basic calcium phosphate (BCP) deposition

Hydroxyapatite (apatite) is the principal mineral in bone and teeth. Apatite and other basic, as opposed to acidic, calcium phosphates (octacalcium phosphate, tricalcium phosphate) are also the usual minerals to deposit in extraskeletal tissues. In MSK tissues, abnormal deposition may occur in:

- periarticular tissues, particularly tendon
- hyaline cartilage in association with OA
- subcutaneous tissue and muscle, principally in connective tissue diseases.

Aetiology

Mineralisation of soft tissues is normally prevented by inhibitors such as pyrophosphate and proteoglycans. When these protective mechanisms break down, abnormal calcification due to BCP occurs. There are many causes (Box 25.64). In most situations, calcification is of no consequence, possibly because of encasement by protein and surrounding fibrous tissue. However, BCP crystals have inflammatory potential and their deposition in MSK tissues sometimes causes clinical problems. Individual apatite crystals are too small to be viewed by light microscopy but their aggregated spherulites can be seen using calcium stains. Sophisticated analytical techniques are required to identify individual BCPs, but for clinical purposes presumptive diagnosis based on radiographic calcification or non-specific calcium staining of synovial fluid or histological tissue is sufficient.

Calcific periarthritis

Deposition of BCP in the supraspinatus tendon (Fig. 25.32) is an incidental X-ray finding in around 7% of adults. It occasionally results in acute inflammation

25.64 Causes of ectopic calcification

High calcium $[Ca^{2+}] \times$ phosphate $[PO_4^{2-}]$ ionic product (metastatic calcification)

- Hyperparathyroidism (especially tertiary, p. 766)
- Renal dialysis
- Vitamin D intoxication
- Basal ganglia in pseudohypoparathyroidism

Altered tissue balance of inhibitors and promoters of crystal formation (dystrophic calcification)

- Calcific periarthritis
- Atherosclerotic arteries
- Fibrotic lymph nodes
- Scarred lung parenchyma
- Scarred adrenal glands (tuberculosis)
- Polymyositis
- Systemic sclerosis (calcinosis)
- Tumours (e.g. craniopharyngioma)

of the subacromial/subdeltoid bursa and periarticular tissues through crystal shedding from the tendon into and around the bursa. Periarticular sites around the greater trochanter of the hip, foot or hand are less commonly affected.

The acute episode may occur spontaneously or follow local trauma. Within just a few hours, shoulder pain and tenderness are extreme and the area appears swollen, hot and sometimes red. Modest systemic upset and fever are common. X-rays show tendon calcification. If the subacromial bursa is aspirated, inflammatory fluid containing many calcium-staining (alizarin red S) aggregates may be obtained.

The condition usually resolves spontaneously over 1–3 weeks, often accompanied by radiographic dispersal and disappearance of small to modest-sized deposits (i.e. complete crystal shedding). Calcific periarthritis may

Fig. 25.32 Shoulder X-ray showing supraspinatus tendon calcification (arrow).

result from renal failure, hyperparathyroidism or hypophosphatasia, but measurements of serum creatinine, calcium and alkaline phosphatase are usually normal. The CRP is elevated during the episode.

Oral analgesics and NSAIDs ameliorate symptoms and the attack may be shortened by aspiration and injection of corticosteroid. Exceptionally large deposits may cause mechanical blocking and painful impingement on abduction rather than acute peri-arthritis, and require surgical removal.

Osteoarthritis and BCP crystal deposition

Modest amounts of BCP aggregates are commonly found in synovial fluid from osteoarthritic joints, either alone or with CPPD crystals ('mixed crystal deposition'). Whether they contribute to joint damage or cause minor inflammatory episodes remains unclear. Large amounts of BCP, however, have been associated with an uncommon but distinctive form of OA that is largely confined to elderly people, mainly women, and characterised by:

- involvement of knee, hip or shoulder (large joints) only
- rapid progression, leading to severe pain and disability in just a few months
- development of marked instability and large effusions of knees or shoulders
- atrophic X-ray appearances with marked loss of cartilage and bone.

Aspiration yields large volumes of relatively non-inflammatory fluid containing abundant BCP aggregates and often cartilage fragments. The differential diagnosis is end-stage avascular necrosis, chronic sepsis or neuropathic joint. Unlike in sepsis, the APR is not triggered and synovial fluid cultures are negative.

Treatment is with analgesics, intra-articular injection of corticosteroids, local physical treatments and physiotherapy. The clinical outcome, however, is poor and most patients require joint replacement. It is most likely that the BCP aggregates, rather than being causal pathogenic agents, are a marker of the speed of joint damage in such 'apatite-associated destructive arthritis', which represents the most severe end of the OA spectrum.

Bone and joint infection

Septic arthritis

Septic arthritis is a medical emergency. It is the most rapid and destructive joint disease, and has significant morbidity and a mortality of 10%. This has not improved over the last 20 years despite advances in antimicrobial therapy. The incidence is 2–10 per 100 000 in the general population and 30–70 per 100 000 in those with pre-existing joint disease or joint replacement.

Septic arthritis is usually due to haematogenous spread from either skin or upper respiratory tract; infection from direct puncture wounds or secondary to joint aspiration is uncommon. Risk factors include increasing age, pre-existing joint disease (principally RA), diabetes mellitus, immunosuppression (by drugs or disease) and intravenous drug misuse. In RA, the skin is a frequent portal of entry because of maceration of skin between the toes due to joint deformity and difficulties with foot hygiene due to hand deformity. Box 25.65 describes the particular considerations in old age.

25.65 Joint and bone infection in old age

- **Vertebral infection:** more common. Recognition may be delayed, as symptoms may be attributed to compression fractures caused by osteoporosis.
- **Peripheral vascular disease:** leads to more frequent involvement of the bones of the feet, and diabetic foot ulcers are also commonly complicated by osteomyelitis.
- **Prosthetic joint infections:** now more common because of the increased frequency of prosthetic joint insertion in older people.
- **Gram-negative bacilli:** more frequent pathogens than in youth.

Lyme disease (p. 329) may present with monoarthritis, often with headaches, neurological signs and fatigue. There is usually a history of rash (erythema migrans) occurring 7–10 days after a tick bite. Diagnosis is confirmed by *Borrelia* serology, although false positives may occur.

Clinical features

The usual presentation is with acute or subacute monoarthritis and fever. The joint is usually swollen, hot and red and is held in the 'loose-pack' position, with an effusion, rest pain and stress pain on movement. Although any joint can be affected, lower limb joints, such as the knee and hip, are commonly targeted. In patients with pre-existing arthritis, involvement of one or more joints is not uncommon and all should be examined.

In adults, the most likely organism is *Staphylococcus aureus*, particularly in patients with RA and diabetes. In young, sexually active adults, disseminated gonococcal infection occurs in up to 3% of untreated gonorrhoea, usually presenting with migratory arthralgia, low-grade fever and tenosynovitis, which may precede the development of oligo- or monoarthritis. Painful pustular skin lesions may also be present. Amongst the elderly and intravenous drug misusers, Gram-negative bacilli or group B, C and G streptococci are important causes. Group A streptococci, pneumococci, meningococci and *Haemophilus influenzae* are occasionally isolated.

Investigations

The pivotal investigation is joint aspiration but blood cultures should also be taken. The synovial fluid is usually turbid or blood-stained but may appear normal. If the joint is not readily accessible, aspiration should be performed under imaging guidance or in theatre. Prosthetic joints should only be aspirated in theatre.

Synovial fluid should be sent for Gram stain and culture; cultures are positive in around 90% of cases, but the Gram stain is positive in only 50%. In contrast, synovial fluid culture is positive in only 30% of gonococcal infections, making it important to obtain concurrent cultures from the genital tract (positive in 70–90% of cases). There is a leucocytosis with raised ESR and CRP in most patients, but these features may be absent in elderly or immunocompromised patients or early in the disease course.

Management (Box 25.66)

Hospitalisation is essential for:

- pain relief
- parenteral antibiotics

Box 25.66 Emergency management of suspected septic arthritis

Admit patient to hospital

Perform urgent investigations

- Aspirate joint
 - Send synovial fluid for Gram stain and culture
 - Use imaging guidance if required (e.g. for hip)
- Send blood for Gram stain and culture, FBC, CRP, LFTs, renal function
- Consider sending other samples (e.g. sputum, urine) for culture, depending on patient history, to determine primary source of infection

Commence intravenous antibiotic

- Flucloxacillin 2 g 6-hourly
- If penicillin allergic, give clindamycin 450–600 mg 6-hourly
- If at high risk of Gram-negative sepsis (e.g. elderly, frail, recurrent urinary tract infection), add a cephalosporin (e.g. cefuroxime 1.5 g 8-hourly)

Relieve pain

- Oral and/or intravenous analgesics
- Consider local ice-packs

Keep joint decompressed

- Serial needle aspiration to dryness (1–3 times/day as required)
- If loculated fluid or technically difficult aspiration, consider lavage or arthroscopy

Physiotherapy from first day

- Early regular passive movement, progressing to active movements once pain controlled and effusion not re-accumulating

- adequate drainage
- early active rehabilitation.

Flucloxacillin (2 g i.v. 6-hourly) is the antibiotic of first choice since it will cover most staphylococcal and streptococcal infections until the organism is identified and its antibiotic sensitivity defined. Intravenous treatment is usually continued for 2–3 weeks, followed by oral treatment for 6 weeks in total. Initially, the joint should be aspirated once or twice daily to minimise the effusion. If this proves unsuccessful or the joint is inaccessible, surgical drainage may be required. Regular passive movement should be undertaken from the outset, and active movements encouraged once the condition has stabilised. Infected prosthetic joints require management by the orthopaedic team, but often prolonged antibiotic treatment on its own is ineffective and removal of the prosthesis is required for eradication of the infection.

Viral arthritis

Most forms of viral arthritis are self-limiting. The usual presentation is with acute polyarthritis, fever or viral prodrome and rash. Human parvovirus (mainly B19, p. 311) arthropathy is the most common in Europe; adults may not have the characteristic 'slapped cheek' facial rash, and joint symptoms with prominent stiffness may be recurrent or persistent for months or even years. Diagnosis is confirmed by a rise in specific IgM. Polyarthritis may also occur rarely with hepatitis B and C, rubella (including rubella vaccination) and HIV infection. A variety of mosquito-borne viruses may cause epidemics of acute polyarthritis, including Ross River

virus (Australia, Pacific), Chikungunya and O'nyong-nyong viruses (Asia, Africa), and Mayaro virus (South America). A wide variety of articular symptoms have been associated with HIV, mainly in the later stages of infection (Box 25.67).

Osteomyelitis

Some degree of adjacent bone infection is usual with septic arthritis, but bone or bone marrow is the primary site of infection in osteomyelitis. Any part of a bone may be involved but there is preferential targeting of the juxta-epiphyseal regions of long bones adjacent to joints. The usual source is via haematogenous spread, although directly introduced infection may complicate trauma or orthopaedic surgery. Organisms most frequently implicated are staphylococci, *Pseudomonas* and *Mycobacterium tuberculosis*. Risk factors include childhood and adolescence, diabetes mellitus (especially involving the foot), compromised immunity (including AIDS) and sickle cell disease, which particularly increases the risk of *Salmonella* infection. Pathologically, the infection often results in a florid inflammatory response, greatly increased intra-osseous pressure and localised areas of osteonecrosis (bone death). A separated shard of dead bone in this context is called a 'sequestrum'. Eventual perforation of the cortex by pus stimulates local new bone formation ('involucrum') by the subperiosteum and periosteum, often with sinuses that discharge through the skin.

Clinical features and investigations

The presentation is with localised bone pain and tenderness, often with malaise, night sweats and pyrexia. The adjacent joint may be painful to move and may develop a sterile ('sympathetic') effusion or secondary septic arthritis. The earliest X-ray abnormality is localised osteopenia adjacent to an epiphysis, which may be followed by more obvious areas of bone lucency mixed with patchy sclerosis (osteonecrosis) and adjacent periosteal new bone formation. X-rays may be normal for the first few weeks, but bone technetium scans, labelled white cell scans and MRI are much more sensitive and show clear abnormalities at presentation. The diagnosis may be confirmed on blood cultures and/or culture of a bone aspirate or biopsy.

Management

Early recognition and management is critical; once osteomyelitis becomes established and chronic, it may prove very hard to eradicate the infection with antibiotics alone. The principles are those for septic arthritis, with parenteral antibiotics for at least 2 weeks, followed

by oral antibiotics for at least 4 weeks. Resection of the infected bone and subsequent reconstruction are often required: e.g. with callus distraction and external fixators. Complications of chronic osteomyelitis include secondary amyloidosis (p. 84) and skin malignancy at the margin of a discharging sinus (Marjolin's ulcer).

Tuberculosis of bone and joints

This is discussed on page 691. X-ray changes are non-specific and mycobacteria are often not identified from synovial fluid, so definite diagnosis requires biopsy of synovium (peripheral joint) or bone (spinal involvement). Management is as for pulmonary tuberculosis (p. 693), although additional surgical débridement may be required for extensive joint or bone disease, and spinal involvement may require surgical stabilisation and decompression.

FIBROMYALGIA

This is a common cause of multiple regional pain and disability, which is commonly associated with medically unexplained symptoms in other systems (p. 238).

The prevalence in the UK and US is about 2–3%. Although fibromyalgia can occur at any age, including adolescence, it increases in prevalence with age, to reach a peak of 7% in women aged over 70. There is a strong female predominance of around 10:1. Risk factors include life events that cause psychosocial distress such as marital disharmony, alcoholism in the family, injury or assault, low income and self-reported childhood abuse (Box 25.68). The condition is reported in a wide variety of races and cultures.

Aetiology

Despite intensive investigation, no structural, inflammatory, metabolic or endocrine abnormality has been identified. However, two abnormalities which may interrelate (Fig. 25.33) have been reported consistently:

- *Sleep abnormality.* Delta waves are characteristic of deep stages of non-rapid eye movement (non-REM) sleep, usually occurring in the first few hours and thought to have an important restorative function. People with fibromyalgia have reduced delta sleep in a pattern distinct from that seen with depression. Furthermore, deprivation of delta but not REM sleep in normal volunteers produces the symptoms and signs of fibromyalgia, supporting fibromyalgia as a non-restorative sleep disorder.
- *Abnormal peripheral and central pain processing.* A reduced threshold to pain perception and tolerance at characteristic sites throughout the body is characteristic of fibromyalgia. Affected people have peripheral sensitisation and spinal cord 'wind-

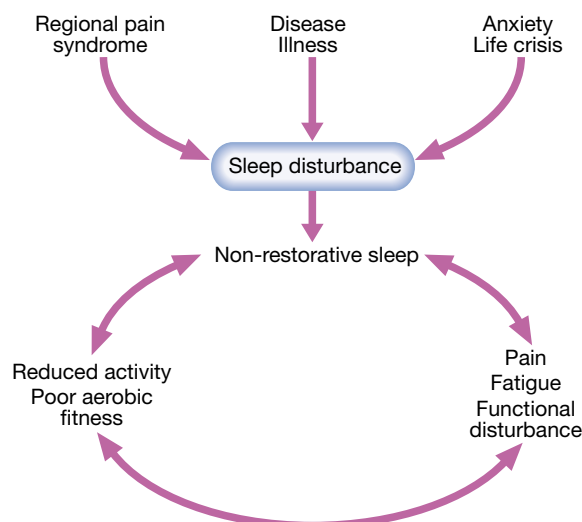

Fig. 25.33 Possible mechanisms involved in fibromyalgia.

up' (pain amplification), with an exaggerated skin flare response to topically applied capsaicin and frequent occurrence of dermatographism and allodynia (allodynia is when normally non-noxious stimuli become painful). Abnormal central pain processing is suggested by altered cerebrospinal fluid levels of substance P (increased) and 5-HT (5-hydroxytryptamine or serotonin – reduced); reduced basal levels of regional cerebral blood flow in the caudate and thalamus with an augmented processing response on functional MRI; low basal free cortisol and reduction in evening trough of cortisol; and altered descending inhibition via the hypothalamo-pituitary-adrenal and growth hormone somatomedin axes.

Clinical features

The main presenting feature is multiple regional pain, often focusing on the neck and back (Box 25.69). At presentation, just one or a few regions may dominate the

25.69 Symptoms of fibromyalgia

Usual symptoms

- Multiple regional pain
- Marked fatigability
- Marked disability
- Broken non-restorative sleep
- Low affect, irritability, weepiness
- Poor concentration, forgetfulness

Variable locomotor symptoms

- Early morning stiffness
- Swelling of hands, fingers
- Numbness, tingling of all fingers

Additional, variable, non-locomotor symptoms

- Non-throbbing bifrontal headache (tension headache)
- Colicky abdominal pain, bloating, variable bowel habit (irritable bowel syndrome)
- Bladder fullness, nocturnal frequency (irritable bladder)
- Hyperacusis, dyspareunia, discomfort when touched (allodynia)
- Frequent side-effects with drugs (chemical sensitivity)

EBM 25.68 Associations of fibromyalgia

'Epidemiological studies show that widespread body pain, fatigue, psychological distress and multiple hyperalgesic tender sites cluster together and associate with stressful life events.'

- Wolfe F, et al. *Arthritis Rheum* 1995; 38:19–28.
- Croft P, et al. *BMJ* 1994; 309:696–699.

Fig. 25.34 Major tender sites that become hyperalgesic with fibromyalgia.

picture, but over the preceding months pain will have affected all body quadrants: both arms, both legs, neck and back. The pain is characteristically diffuse and unresponsive to analgesics and NSAIDs, and physiotherapy often makes it worse. Fatigability, most prominent in the morning, is another major problem and disability is often marked. Although people can usually dress, feed and groom themselves, they may be unable to perform tasks such as shopping or housework. They may have experienced major difficulties at work or even retired because of pain and fatigue.

Examination usually reveals no synovitis or damage, and no overt neurological defect or wasting. Depending on their age, people may have signs of OA or other prevalent MSK conditions, but of insufficient severity to explain such widespread symptoms and severe disability. The principal finding is hyperalgesia at tender sites (Fig. 25.34). Moderate digital pressure at each site may be uncomfortable in a normal subject but in fibromyalgia it produces a wince/withdrawal response. Metered dolorimeters are used for research purposes but moderate digital pressure, enough just to whiten the nail, is sufficient for clinical diagnosis.

People with other MSK diseases can develop fibromyalgia. Assessment may prove challenging since many of the symptoms could relate to activity of their multisystem disease. Marked discordance between the severity of reported and observed abnormality is an important feature that suggests fibromyalgia, and widespread hyperalgesic tender sites are not explained by polyarticular disease.

Investigations and management

There are no abnormalities on routine blood tests or imaging, but it is important to screen for other clinically

occult conditions that could contribute to some of the symptoms (Box 25.70).

The aims of management are to educate the patient about the condition, to achieve pain control and to improve sleep. Principles of management of medically unexplained symptoms are outlined on pages 251–252.

Wherever possible, discussion should include the spouse, family or carer. It should be acknowledged that, although we recognise this condition, it is not fully understood but we do know that the chronic widespread pain does not reflect inflammation, damage or disease. The model of a self-perpetuating cycle of poor sleep and pain (see Fig. 25.33) is often readily accepted and is a useful framework for problem-based management. Ascribing the symptoms to a cause for which the patient cannot be blamed, and knowing that it is common often help. Repeat or drawn-out investigation may reinforce beliefs in occult serious pathology and should be avoided.

Low-dose amitriptyline (10–75 mg at night) with or without fluoxetine may help by encouraging delta sleep and reducing spinal cord wind-up. Many people with

25.70 Minimum investigation screen in fibromyalgia

Test	Condition screened
FBC	Anaemia, lymphopenia of SLE
ESR, CRP	Inflammatory disease
Thyroid function	Hypothyroidism
Calcium, alkaline phosphatase	Hyperparathyroidism, osteomalacia
ANA	SLE

fibromyalgia, however, are intolerant of even small doses of amitriptyline. There is limited evidence for the use of tramadol, serotonin-noradrenaline (norepinephrine) reuptake inhibitors (SNRIs) such as duloxetine, and the anticonvulsants pregabalin and gabapentin. A graded increase in aerobic exercise can improve well-being and sleep quality. The use of self-help strategies and a cognitive behavioural approach with relaxation techniques should be encouraged. Sublimated anxiety relating to distressing life events should be specifically explored with appropriate counselling. There are patient organisations which provide additional information and support.

The prognosis for hospital-diagnosed fibromyalgia is poor. Although treatment may improve quality of life and ability to cope, most people do not lose their symptoms or diagnostic criteria over 5 years. Subjects diagnosed in primary care, or who have sublimated anxiety that can be successfully addressed, may fare better.

SYSTEMIC CONNECTIVE TISSUE DISEASE

The connective tissue diseases are a group of chronic inflammatory disorders that involve multiple body systems and exhibit a wide spectrum of clinical manifestations. Their aetiology is multifactorial, involving genetic and environmental factors. Although each disease displays different clinical and pathological features, the group shares enough characteristics to be considered a family of overlapping conditions.

Systemic lupus erythematosus (SLE)

SLE is the most common connective tissue disease. Its prevalence varies according to geographical and racial background from 3/10 000 in Caucasians to 20/10 000 in Afro-Caribbeans. Around 90% of affected individuals are women, and the peak age at onset is between 20 and 30 years. The overall 5-year survival of SLE is over 90%. Mortality within 5 years of diagnosis is usually due to organ failure or overwhelming sepsis, both of which are modifiable by early effective intervention. However, compared to the normal population, patients with lupus have a fivefold increased mortality. This mainly results from premature cardiovascular disease to which chronic steroid therapy makes a major contribution.

Pathophysiology

The cause of SLE is incompletely understood but genetic factors play an important role. There is a higher concordance in monozygotic twins and associations with multiple polymorphisms in the HLA locus on chromosome 6 have been identified. In a few instances, SLE is associated with inherited mutations in complement components C1q, C2, and C4; in the immunoglobulin receptor FcγRIIb or in the DNA exonuclease *TREX1*. Recent studies have identified common polymorphisms that predispose to SLE, including the *ITGAM* gene which encodes an integrin; the *IRF5* and *STAT4* genes which are involved in interferon signalling; and the *BLK* gene which is involved in B-cell signalling. From an immunological standpoint, the characteristic feature of SLE is

the production of autoantibodies. These have specificity for a wide range of targets but many are directed against antigens present within the cell or within the nucleus. This has led to the suggestion that patients with SLE have defects in apoptosis or in the clearance of apoptotic cells, which causes inappropriate exposure of intracellular antigens on the cell surface, leading to polyclonal B- and T-cell activation and autoantibody production. This is supported by the fact that environmental factors that cause flares of lupus, such as ultra-violet (UV) light, pregnancy and infections, increase oxidative stress and/or stimulate apoptosis; by the association with complement deficiency; and by the defect in the *TREX1* nuclease. Whatever the underlying cause, immune complex formation is thought to be an important mechanism of tissue damage in active SLE, leading to widespread vasculitis and organ damage.

Clinical features

General symptoms

Patients often have non-specific symptoms. Some, such as fever, weight loss and mild lymphadenopathy, reflect active inflammatory disease, whereas others, such as fatigue, malaise and fibromyalgia-like symptoms, are not necessarily associated with flares in disease activity, at least as assessed by standard laboratory tests.

Arthritis and arthralgia

A variety of joint problems occur, including migratory arthralgia and early morning stiffness, tenosynovitis and small joint synovitis that can mimic rheumatoid. However, joint deformities and erosions are rare and synovitis is seldom obvious clinically. When joint deformities do occur, they result more from tendon inflammation and damage than from bone destruction (Jaccoud's arthropathy).

Raynaud's phenomenon

Raynaud's (p. 601) is common and may antedate other symptoms by months or years. A common presentation is Raynaud's in combination with arthralgia or arthritis (Fig. 25.35). Raynaud's associated with SLE and other connective tissue disease needs to be differentiated from primary Raynaud's, which is common in healthy young women. Features in favour of secondary Raynaud's include age at onset of over 25 years, absence of a family history of

Fig. 25.35 Severe secondary Raynaud's phenomenon leading to digital ulceration.

Raynaud's, and occurrence in a male. Examination of capillary nail-fold loops using an ophthalmoscope (and oil placed on the skin) may help distinguish primary from secondary Raynaud's. Loss of the normal loop pattern, with capillary 'fallout' and dilatation and branching of loops, supports connective tissue disease.

Rash

This is common in SLE and is classically precipitated by exposure to UV light. Three distinct types of rash occur:

- The classic butterfly facial rash (up to 20% of patients). This is erythematous, raised and painful or itchy, and occurs over the cheeks with sparing of the nasolabial folds (Fig. 25.36).
- Subacute cutaneous lupus erythematosus (SCLE) rashes are migratory, non-scarring and either annular or psoriaform.
- Discoid lupus lesions are characterised by hyperkeratosis and follicular plugging, and may cause scarring alopecia if present on the scalp.

Diffuse, usually non-scarring alopecia may occur with active disease. Other skin manifestations include periungual erythema (reflecting dilated capillary loops), vasculitis and livedo reticularis, which is also a common feature of the antiphospholipid syndrome (Fig. 25.37).

Fig. 25.36 Butterfly (malar) rash of systemic lupus erythematosus, sparing the nasolabial folds.

Fig. 25.37 Livedo reticularis in systemic lupus erythematosus.

Renal involvement

This is one of the main determinants of prognosis, and regular monitoring of urinalysis and blood pressure is essential. The typical renal lesion is a proliferative glomerulonephritis (p. 500), characterised by heavy haematuria, proteinuria and casts on urine microscopy.

Cardiovascular features

The most common manifestation is pericarditis. Myocarditis and Libman-Sacks endocarditis can also occur. The latter comprises non-infectious vegetations on the heart valves and is thought to be a manifestation of hypercoagulability associated with antiphospholipid antibodies. Cardiovascular disease is increased in patients with long-standing SLE.

Pulmonary features

These are common and most frequently manifest as pleurisy or pleural effusion. Other features include pneumonitis, atelectasis, reduced lung volume and pulmonary fibrosis leading to breathlessness. The risk of thromboembolism is increased, especially in patients with antiphospholipid antibodies.

Neurological features

Fatigue, headache and poor concentration are common, and often occur without laboratory evidence of active disease. More specific features of cerebral lupus include visual hallucinations, chorea, organic psychosis, transverse myelitis and lymphocytic meningitis.

Haematological features

A variety of abnormalities may occur, including neutropenia, lymphopenia, thrombocytopenia or haemolytic anaemia, due to antibody-mediated destruction of peripheral blood cells. The degree of lymphopenia is a good guide to disease activity.

Gastrointestinal features

Mouth ulcers may occur, which may or may not be painful. Mesenteric vasculitis is a serious complication which can present with abdominal pain, bowel infarction or perforation.

Investigations

The diagnosis is based on a combination of clinical features and laboratory abnormalities. To fulfil the classification criteria for SLE, at least 4 of the 11 factors shown in Box 25.71 must be present or have occurred in the past. Patients should be screened for ANA and antibodies to extractable nuclear antigens, and have complement levels checked along with routine haematology and biochemistry. Patients with active SLE almost always test positive for ANA, but ANA-negative SLE can very rarely occur in the presence of antibodies to the Ro antigen. Anti-dsDNA antibodies are characteristic of severe active SLE but occur in only around 30% of cases. Similarly, patients with active disease tend to have low levels of C3 and C4, but this may be the result of inherited complement deficiency which predisposes to SLE. Studies of other family members can help to differentiate inherited deficiency from complement consumption. A raised ESR, leucopenia and lymphopenia are typical of active SLE, along with anaemia, haemolytic anaemia and thrombocytopenia. CRP levels are often normal in

25.71 Revised American Rheumatism Association criteria for systemic lupus erythematosus ¹	
Features	Characteristics
Malar rash	Fixed erythema, flat or raised, sparing the nasolabial folds
Discoid rash	Erythematous raised patches with adherent keratotic scarring and follicular plugging
Photosensitivity	Rash due to unusual reaction to sunlight
Oral ulcers	Oral or nasopharyngeal ulceration, which may be painless
Arthritis	Non-erosive, involving two or more peripheral joints
Serositis	Pleuritis (history of pleuritic pain or rub, or pleural effusion) or pericarditis (rub, ECG evidence or effusion)
Renal disorder	Persistent proteinuria > 0.5 g/day or cellular casts (red cell, granular or tubular)
Neurological disorder	Seizures or psychosis, in the absence of provoking drugs or metabolic derangement
Haematological disorder	Haemolytic anaemia or leucopenia ² ($< 4 \times 10^9/L$), or lymphopenia ² ($< 1 \times 10^9/L$), or thrombocytopenia ² ($< 100 \times 10^9/L$) in the absence of offending drugs
Immunological disorder	Anti-DNA antibodies in abnormal titre or presence of antibody to Sm antigen or positive antiphospholipid antibodies
Antinuclear antibody (ANA) disorder	Abnormal titre of ANA by immunofluorescence
¹ A person has SLE if any 4 out of these 11 features are present serially or simultaneously.	
² On two separate occasions.	

active SLE, except in the presence of serositis, and an elevated CRP suggests co-existing infection.

Management

The therapeutic goals are to educate the patient about the nature of the illness, to control symptoms and to prevent organ damage. Patients should be advised to avoid sun and UV light exposure, and to employ sun blocks (factor 25–50). Cardiovascular risk factors, such as hypertension and hyperlipidaemia, should be controlled and patients advised to stop smoking. Patients with mild disease restricted to skin and joints can often be managed satisfactorily with analgesics and/or NSAIDs, and if necessary hydroxychloroquine (200–400 mg daily). Short courses of oral steroids may be required for rash, synovitis, pleurisy and pericarditis.

Life-threatening disease affecting the kidney, CNS or cardiovascular system requires high-dose steroids and immunosuppressives. A commonly used regimen is pulse methylprednisolone (500 mg–1 g i.v.) coupled with cyclophosphamide (2 mg/kg i.v.), repeated at 2–3 weekly intervals on 6–8 occasions, depending on the clinical response. Mycophenolate mofetil (MMF) has been used successfully in combination with high-dose steroids for renal involvement in SLE, with results

equivalent to those of pulse cyclophosphamide but with fewer adverse effects. Following control of the acute episode, the patient should be switched to oral prednisolone (40–60 mg daily) and azathioprine, methotrexate or MMF. The long-term aim is to continue the lowest dose of corticosteroids and immunosuppressive required to maintain remission. Co-trimoxazole is sometimes given prophylactically (960 mg thrice weekly) with the aim of preventing *Pneumocystis pneumonia*, and mesna is given with bolus cyclophosphamide to reduce the risk of haemorrhagic cystitis. Lupus patients with the antiphospholipid antibody syndrome (p. 1050) who have had previous thrombosis require life-long warfarin. It has been suggested that if repeated thromboses occur despite warfarin, the INR target range should be 3.0–4.0.

Systemic sclerosis

Systemic sclerosis is a generalised disorder of connective tissue affecting the skin, internal organs and vasculature. It is characterised by sclerodactyly in combination with Raynaud's or digital ischaemia (Fig. 25.38). The peak age of onset is in the fourth and fifth decades, and overall prevalence is 10–20 per 100 000 with a 4:1 female preponderance. It is subdivided into diffuse cutaneous systemic sclerosis (DCSS; 30% of cases) and limited cutaneous systemic sclerosis (LCSS; 70% of cases). Many patients with LCSS have features which are phenotypically grouped into the 'CREST' syndrome (Calcinosis, Raynaud's, oEsophageal involvement, Sclerodactyly and Telangiectasia). The prognosis in DCSS is poor, with a 5-year survival of approximately 70%. Features that associate with a poor prognosis include older age, diffuse skin disease, proteinuria, high ESR, a low TLCO (gas transfer factor for carbon monoxide) and pulmonary hypertension.

Pathophysiology

The cause of systemic sclerosis is poorly understood. There is evidence for a genetic component and associations with alleles at the HLA locus. The disease occurs in all ethnic groups, and race may influence severity since DCSS is significantly more common in black compared to white women. Isolated cases are reported of systemic sclerosis-like disease that has been triggered

Fig. 25.38 Systemic sclerosis. Hands showing tight shiny skin, sclerodactyly, flexion contractures of the fingers and thickening of the left middle finger extensor tendon sheath.

by exposure to silica dust, vinyl chloride, hypoxysresins and trichloroethylene. There is clear evidence of immunological dysfunction; T lymphocytes infiltrate the skin and there is abnormal fibroblast activation leading to increased production of extracellular matrix in the dermis, primarily type I collagen. This results in symmetrical thickening, tightening and induration of the skin (sclerodactyly). Arterial and arteriolar narrowing occurs due to intimal proliferation and vessel wall inflammation. Endothelial injury causes release of vasoconstrictors and platelet activation, resulting in further ischaemia, which is thought to exacerbate the fibrotic process.

Clinical features

Skin

Initially there is non-pitting oedema of fingers and flexor tendon sheaths. Subsequently, the skin becomes shiny and taut, and distal skin creases disappear. This is accompanied by erythema and tortuous dilatation of capillary loops in the nail-fold bed, readily visible with an ophthalmoscope or dissecting microscope (and oil placed on the skin). The face and neck are usually involved next, with thinning of the lips and radial furrowing. In some patients, skin thickening stops at this stage. Skin involvement restricted to sites distal to the elbow or knee (apart from the face) is classified as 'limited disease' or CREST syndrome (Fig. 25.39). Involvement proximal to the knee and elbow and on the trunk is classified as 'diffuse disease'.

Raynaud's phenomenon

This is a universal feature and can precede other features by many years. Involvement of small blood vessels in the extremities may cause critical tissue ischaemia, leading to skin ulceration over pressure areas, localised areas of infarction and pulp atrophy at the fingertips.

Musculoskeletal features

Arthralgia, morning stiffness and flexor tenosynovitis are common. Restricted hand function is due to skin rather than joint disease and erosive arthropathy is uncommon. Muscle weakness and wasting can occur due to myositis.

Gastrointestinal involvement

Smooth muscle atrophy and fibrosis in the lower two-thirds of the oesophagus lead to reflux with erosive oesophagitis. Dysphagia and odynophagia may also

Fig. 25.39 Typical facial appearance in the CREST syndrome.

occur. Involvement of the stomach causes early satiety and occasionally outlet obstruction. Recurrent occult upper gastrointestinal bleeding may indicate a 'watermelon' stomach (antral vascular ectasia), which occurs in up to 20% of patients. Small intestine involvement may lead to malabsorption due to bacterial overgrowth and intermittent bloating, pain or constipation. Dilatation of large or small bowel due to autonomic neuropathy may cause pseudo-obstruction with nausea, vomiting, abdominal discomfort and distension, often worse after food.

Pulmonary involvement

This is a major cause of morbidity and mortality. Pulmonary hypertension complicates long-standing disease and is six times more prevalent in LCSS than in DCSS. It presents with rapidly progressive dyspnoea (more rapid than interstitial lung disease), right heart failure and angina, often in association with severe digital ischaemia. Fibrosing alveolitis mainly affects patients with DCSS who have topoisomerase 1 antibodies.

Renal involvement

One of the main causes of death is hypertensive renal crisis characterised by rapidly developing malignant hypertension and renal failure. Hypertensive renal crisis is much more likely to occur in DCSS than in LCSS, and in patients with topoisomerase 1 antibodies.

Investigations

Scleroderma is a clinical diagnosis but various laboratory abnormalities are characteristic.

The ESR is usually elevated and raised levels of IgG are common, but CRP values tend to be normal unless there is severe organ involvement or coexisting infection. ANA is positive in about 70%, and approximately 30% of patients with DCSS have antibodies to topoisomerase 1 (Scl-70). About 60% of patients with CREST syndrome have anticentromere antibodies (p. 1064).

Management

The focus of management is to ameliorate the effects of the disease on target organs. No treatments are available that halt or reverse the fibrotic changes which underlie the disease.

- *Raynaud's syndrome and digital ulcers* should be treated by avoidance of cold exposure and use of mittens (heated mittens are available), supplemented if necessary with calcium antagonists or angiotensin II receptor blockers. Intermittent infusions of epoprostenol may benefit severe digital ischaemia. Infections occur commonly in ulcerated skin lesions and require treatment with antibiotics, but as these penetrate tissues poorly in scleroderma they need to be given at higher doses for longer courses than usual.
- *Oesophageal reflux* should be treated with PPIs and anti-reflux agents. Antibiotics may be required for bacterial overgrowth syndromes and metoclopramide or domperidone may help patients with symptoms of pseudo-obstruction.
- *Hypertension* should be treated aggressively with angiotensin-converting enzyme (ACE) inhibitors, even if renal impairment is present. The benefit of prophylactic ACE inhibitors in patients with DCSS to prevent deterioration of renal function is uncertain.

- *Joint involvement* may be treated with analgesics.
- *Pulmonary hypertension* may be treated with the endothelin 1 antagonist, bosentan, and in selected patients heart-lung transplantation may be considered. Corticosteroids and cytotoxic drugs are indicated in patients who have coexisting myositis or fibrosing alveolitis.

Mixed connective tissue disease

This is an overlap condition in which there are clinical features of SLE, systemic sclerosis and myositis. It commonly presents with synovitis and oedema of the hands in combination with Raynaud's phenomenon and muscle pain/weakness. Most patients have anti-ribonucleoprotein (RNP) antibodies, but these can occur in SLE without overlap features. Management focuses on treating the individual components of the syndrome.

Sjögren's syndrome

This is an autoimmune disorder of unknown cause characterised by lymphocytic infiltration of salivary and lacrimal glands, leading to glandular fibrosis and exocrine failure. The typical age of onset is between 40 and 50 with a 9:1 female preponderance. The disease may be primary or secondary to other autoimmune diseases.

Clinical features

The eye symptoms, termed keratoconjunctivitis sicca, are due to lack of lubricating tears. Conjunctivitis and blepharitis are frequent, and may lead to filamentary keratitis due to tenacious mucous filaments binding to the cornea and conjunctiva. Oral involvement manifests as a dry mouth and typically the patient needs water to swallow food. There is a high incidence of dental caries. Other sites of extraglandular involvement are listed in Box 25.72. The disease is associated with a 40-fold increased lifetime risk of lymphoma.

Investigations

The diagnosis can be established by the Schirmer tear test, which measures tear flow over 5 minutes using absorbent paper strips placed on the lower eyelid; a normal result is more than 6 mm of wetting. Staining with rose Bengal may show punctate epithelial abnormalities over the area not covered by the open eyelid. If the diagnosis remains in doubt, it can be confirmed by lip biopsy which shows focal lymphocytic infiltrate of the minor salivary glands. Most patients have an elevated ESR and hypergammaglobulinaemia, and one or more autoantibodies, including ANF and RF. Anti-Ro and anti-La antibodies are commonly present (see Box 25.8, p. 1064).

Management

Treatment is symptomatic. Lacrimal substitutes such as hypromellose should be used during the day in combination with more viscous lubricating ointment at night. Soft contact lenses can be useful for corneal protection in patients with filamentary keratitis, and occlusion of the lacrimal ducts is occasionally needed. Artificial saliva and oral gels can be tried for xerostomia but are often not effective. Stimulation of saliva flow by sugar-

free chewing gum or lozenges may be helpful. Adequate post-prandial oral hygiene and prompt treatment of oral candidiasis are essential. Vaginal dryness is treated with lubricants such as K-Y jelly. Extraglandular and MSK manifestations may respond to steroids, and if so, immunosuppressive drugs can be added for their steroid-sparing effect. Fatigue is difficult to treat; this is usually due to non-restorative sleep (often because of xerostomia) and is unresponsive to steroids. Immunosuppression does not improve sicca symptoms. If lymphadenopathy or salivary gland enlargement develops, biopsy should be performed to exclude malignancy.

Polymyositis and dermatomyositis

Polymyositis is characterised by an inflammatory process affecting skeletal muscle. Dermatomyositis describes the same disease but with skin involvement. They are rare, with an incidence of 2–10 cases per million/year. Polymyositis can occur in isolation or in association with other autoimmune diseases such as SLE, systemic sclerosis and Sjögren's syndrome. The cause is unknown, although there is evidence for a genetic contribution.

Clinical features

The typical presentation of polymyositis is with symmetrical proximal muscle weakness, usually affecting the lower limbs more than the upper limbs. The onset is usually between 40 and 60 years of age and is typically gradual, over a few weeks. Myositis is usually widespread but focal disease can also occur (e.g. orbital myositis). Affected patients report difficulty rising from a chair, climbing stairs and lifting, sometimes in combination with muscle pain. Systemic features of fever, weight loss and fatigue are common. Respiratory

Fig. 25.40 Typical eyelid appearance in dermatomyositis. Note the oedema and telangiectasia.

or pharyngeal muscle involvement can lead to ventilatory failure or aspiration that requires urgent treatment. Interstitial lung disease occurs in up to 30% of patients and is strongly associated with the presence of antisynthetase (Jo-1) antibodies.

Dermatomyositis presents similarly but in combination with characteristic skin lesions. These include Gottron's papules, which are scaly erythematous or violaceous psoriaform plaques occurring over the extensor surfaces of proximal and distal IPJs, and a heliotrope rash which is a violaceous discoloration of the eyelid in combination with periorbital oedema (Fig. 25.40). Similar rashes occur on the upper back, chest and shoulders ('shawl' distribution). Periungual nail-fold capillaries are often enlarged and tortuous. There is about a three-fold increased risk of malignancy in patients with dermatomyositis and polymyositis. This may be apparent at the time of presentation, but the risk remains increased for at least 5 years following diagnosis.

Investigations

Muscle biopsy is a pivotal investigation and shows the typical features of fibre necrosis, regeneration and inflammatory cell infiltrate (Fig. 25.41). EMG can confirm the presence of myopathy and exclude neuropathy. Occasionally, however, a biopsy may be normal, particu-

Fig. 25.41 Muscle biopsy from a patient with inflammatory myositis. The sample shows an intense inflammatory cell infiltrate in an area of degenerating and regenerating muscle fibres.

larly if myositis is patchy. In such cases, MRI will identify areas of abnormal muscle for biopsy. Serum levels of CK are usually raised and are a useful measure of disease activity, although a normal CK does not exclude the diagnosis, particularly in juvenile myositis. Screening for underlying malignancy should be undertaken routinely, and should include chest/abdomen/pelvis CT, gastrointestinal tract imaging and mammography (in women).

Management

Oral corticosteroids (e.g. prednisolone 40–60 mg daily) are the mainstay of initial treatment but high-dose intravenous methylprednisolone (1 g/day for 3 days) may be required in patients with respiratory or pharyngeal weakness. If there is a good response, steroids should be reduced by approximately 25% per month to a maintenance dose of 5–7.5 mg. Although most patients have an initial response to steroids, most need additional immunosuppressive therapy. Azathioprine and methotrexate are the agents of first choice, but ciclosporin, cyclophosphamide, tacrolimus or MMF can be used as alternatives. Intravenous immunoglobulin may be effective in refractory cases. Relapses may occur associated with a rising CK, and indicate the need for additional therapy. If the patient relapses or fails to respond to treatment, this may be due to steroid-induced myopathy. This is an indication for further biopsy which may show type 2 fibre atrophy in steroid-induced myopathy, as opposed to necrosis and regeneration in active myositis.

SYSTEMIC VASCULITIS

This is a heterogeneous group of diseases characterised by inflammation and necrosis of blood vessel walls, with associated damage to skin, kidney, lung, heart, brain and gastrointestinal tract. There is a wide spectrum of involvement and disease severity, ranging from mild and transient disease affecting the skin, to life-threatening fulminant disease with multiple organ failure. Vasculitis may occur secondary to a variety of inflammatory and infectious diseases, including SLE, Sjögren's syndrome, RA, endocarditis and hepatitis B or C, when it is thought to be due to deposition of immune complexes in small vessels. Primary vasculitis occurs in the absence of a known cause. It is uncommon, with an estimated incidence of 18–40 per million per year, and has a peak onset between the ages of 65 and 75. Vasculitis is usually classified on the basis of the size of vessel involved (Box 25.73).

i

25.73 Size of vessel involvement in vasculitis

Large vessel

- Giant cell arteritis
- Takayasu's arteritis

Medium vessel

- Classical polyarteritis nodosa
- Kawasaki disease (in childhood)

Small vessel

- Microscopic polyangiitis
- Wegener's granulomatosis
- Churg–Strauss syndrome
- Henoch–Schönlein purpura
- Mixed essential cryoglobulinaemia

The clinical features of vasculitis result from a combination of local tissue ischaemia (due to vessel inflammation and narrowing) and the systemic effects of widespread inflammation. Systemic vasculitis should be considered in any patient with fever, weight loss, fatigue, evidence of multisystem involvement, rashes, raised inflammatory markers and abnormal urinalysis. The symptoms of vasculitis are shown in Box 25.33 (p. 1075). Other conditions that may mimic vasculitis include sepsis (particularly infective endocarditis and meningococcaemia), malignancy, cholesterol emboli, atrial myxoma and the antiphospholipid syndrome. This may lead to diagnostic delay, but early diagnosis and management are essential to prevent irreversible organ damage.

Takayasu's arteritis

Takayasu's disease predominantly affects the aorta, its major branches and occasionally the pulmonary arteries. The typical age at onset is between 25 and 30 years, with an 8:1 female preponderance. It has a world-wide distribution but is most common in Asia. In contrast to other vasculitides, Takayasu's is characterised by granulomatous inflammation of the vessel wall leading to vessel occlusion or weakening of the vessel wall. It presents with claudication, fever, arthralgia and weight loss. The vessels most commonly affected are the aorta, carotid, ulnar, brachial, radial and axillary arteries. Clinical examination may reveal loss of pulses, bruits, hypertension and aortic incompetence. Investigation shows an APR and normocytic, normochromic anaemia, but the diagnosis is based on angiographic findings of coarctation, occlusion and aneurysmal dilatation. The distribution of involvement is classified into four types:

- type 1: localised to the aorta and its branches
- type 2: localised to the descending thoracic and abdominal aorta
- type 3: combines features of 1 and 2
- type 4: involves the pulmonary artery.

Treatment is with high-dose steroids and immunosuppressives. With appropriate treatment, the 5-year survival is 83%.

Polyarteritis nodosa (PAN)

PAN can affect any age group but the peak incidence is between 40 and 50, with a male preponderance of 2:1. The annual incidence is around 2/1 000 000. Hepatitis B is an important risk factor, and the incidence of PAN is 10 times higher in the Inuit of Alaska, in whom hepatitis B infection is endemic. Presentation is with fever, myalgia, arthralgia and weight loss, in combination with manifestations of multisystem disease. The most common skin lesions are palpable purpura (Fig. 25.42), ulceration, infarction and livedo reticularis (see Fig. 25.37, p. 1108). Pathological changes comprise necrotising inflammation and vessel occlusion, and in 70% of patients arteritis of the vasa nervorum leads to neuropathy which is typically symmetrical and affects both sensory and motor function. Severe hypertension and/or renal impairment may occur due to multiple renal infarctions but glomerulonephritis is rare (in contrast to microscopic polyangiitis). The diagnosis is confirmed by angiographic demonstration of multiple aneurysms and smooth narrowing of mesenteric, hepatic or renal systems, or by histology (muscle or sural nerve biopsy). Mortality is less

Fig. 25.42 Rash of systemic vasculitis (palpable purpura).

than 20% with treatment but relapse occurs in up to 50% of patients.

Kawasaki disease

Kawasaki disease is an acute systemic disorder of childhood that predominantly occurs in Japan. Presentation is with fever, generalised rash including the palms and soles, inflamed oral mucosa and conjunctival injection resembling a viral exanthem or Stevens-Johnson syndrome. Although the causative trigger is unknown, it has been associated with *Mycoplasma* and HIV infection. Cardiovascular complications include transient coronary dilatation, myocarditis, pericarditis, myocardial infarction, peripheral vascular insufficiency and gangrene. Treatment is with aspirin (5 mg/kg daily for 14 days) and intravenous gammaglobulin (400 mg/kg daily for 4 days).

Microscopic polyangiitis (MPA)

This has an annual incidence of about 8/1 000 000 and is characterised by necrotising vasculitis affecting small vessels. Typical presentation is with rapidly progressive glomerulonephritis, often associated with alveolar haemorrhage. Cutaneous and gastrointestinal involvement is common and other features include neuropathy (15%) and pleural effusions (15%). Patients are usually p-ANCA (myeloperoxidase)-positive (see below).

Wegener's granulomatosis (WG)

WG has an incidence of 5–10/1 000 000 and is characterised by granulomatous inflammation and necrotising vasculitis affecting the nasal passages, airways and kidney. The most common presentation is with upper airway involvement (typically epistaxis, nasal crusting and

Fig. 25.43 Eye involvement in Wegener's granulomatosis.

sinusitis), haemoptysis, mucosal ulceration and deafness due to serous otitis media. Proptosis may occur due to inflammation of the retro-orbital tissue, causing diplopia due to entrapment of the extra-ocular muscles, or loss of vision due to optic nerve compression. Disturbance of colour vision is an early feature of optic nerve compression (Fig. 25.43). Untreated nasal disease ultimately leads to destruction of bone and cartilage. Migratory pulmonary infiltrates and nodules occur in 50% of patients. A minority of patients present with glomerulonephritis. Patients are usually c-ANCA-positive.

Churg–Strauss syndrome (CSS)

CSS has an incidence of 1–3/1 000 000. Pathologically, it is similar to WG but eosinophilic infiltration of the vessel wall also occurs. Most patients have a prodromal period for many years characterised by allergic rhinitis, nasal polyposis and late-onset asthma that is often difficult to control. The typical acute presentation is with a triad of skin lesions (purpura or nodules), asymmetric mononeuritis multiplex and eosinophilia on a background of resistant asthma. Pulmonary infiltrates and pleural or pericardial effusions due to serositis may be present. Up to 50% of patients have abdominal symptoms due to mesenteric vasculitis. Either c-ANCA or p-ANCA is present in around 40% of cases.

Henoch–Schönlein purpura (HSP)

HSP usually occurs in children and young adults and generally has a good prognosis. It is characterised by immune complex deposition in small vessels with associated vasculitis. The typical presentation is with purpura over the buttocks and lower legs, abdominal symptoms (pain and bleeding) and arthritis (knee or ankle) following an upper respiratory tract infection. Nephritis is found in 40% of patients and may occur up to 4 weeks after the onset of other symptoms. The diagnosis can be confirmed by tissue biopsy, which demonstrates IgA deposition within and around blood vessel walls. The prognosis is determined by the severity of renal involvement. Adverse prognostic features at presentation in adults include hypertension, abnormal renal function and proteinuria > 1.5 g/day, but only 1% of patients develop end-stage renal failure.

Cryoglobulinaemic vasculitis

Cryoglobulins are circulating immunoglobulins that precipitate out in the cold. They are classified into three types (Box 4.14, p. 87); types II and III are associated

with cryoglobulinaemic vasculitis. Pathology is similar to HSP. The typical clinical features are palpable purpura over the lower extremities, arthralgia, Raynaud's phenomenon and neuropathy. Type II cryoglobulinaemia is secondary to hepatitis C virus (HCV) infection in most patients, the virus being present in the vasculitic lesions complexed with IgG and IgM. For HCV-positive patients, interferon-alpha (IFN- α) is currently the treatment of choice; for high HCV loads, combination with ribavirin may be more effective (p. 953).

Investigations in systemic vasculitis

Angiography and tissue biopsy are the pivotal investigations. Biopsies can be taken from the nasal septal tissue or from areas of ulceration in patients suspected of having WG, from muscle or nerve in PAN or CSS, from kidney in patients with renal involvement, or from skin in HSP and cryoglobulinaemic vasculitis. Angiography is useful in PAN and Takayasu's disease.

Complement levels are useful; C3 and C4 are typically reduced in active disease, reflecting complement consumption, and can be used as an index of disease activity. Screening for ANCA is important, although they are not specific for the diagnosis of vasculitis and can occur in other diseases (p. 1064). The presence of c-ANCA is particularly associated with WG and CSS, whereas p-ANCA is associated with MPA. Urinalysis for protein and blood should always be performed with subsequent microscopy, since the prognosis of vasculitis is often determined by the degree of renal involvement. Routine biochemistry should be performed to identify renal impairment. CRP and ESR are elevated in active disease and are useful in monitoring disease activity.

Management of systemic vasculitis

Treatment is with high-dose corticosteroids and immunosuppressives, as described for life-threatening involvement in SLE (p. 1109). If cyclophosphamide fails to induce a remission, the diagnosis should be reconsidered. ANCA-positive patients with acute renal failure have a better outcome when also treated with adjunctive plasma exchange. Patients with PAN who have evidence of hepatitis B infection should also be treated with antiviral therapy (p. 951). In Takayasu's arteritis, reconstructive vascular surgery may benefit selected patients, especially those with hypertension secondary to aortic or renal lesions.

Behçet's syndrome

This is a vasculitis of unknown aetiology that characteristically targets venules. It is rare in Western Europe but more common in 'Silk Route' countries around the Mediterranean and Japan, where there is a strong association with HLA-B51.

There is a wide range of clinical features, with unpredictable exacerbations. Oral ulcers are universal (Fig. 25.44). Unlike aphthous ulcers, they are usually deep and multiple, and last for 10–30 days. Genital ulcers are less common (60–80%). The usual skin lesions are erythema nodosum or acneiform lesions but migratory thrombophlebitis and vasculitis also occur. The pathergy reaction is hyper-reactivity at the site of minor trauma. A formal pathergy test involves intradermal skin pricking with a needle, and is positive if a pustule develops within 48 hours. Ocular involvement is usually bilateral

Fig. 25.44 Oral ulceration in Behçet's syndrome.

and may include anterior or posterior uveitis or retinal vasculitis. Neurological involvement occurs in 5% and mainly involves the brain stem, although the meninges, hemispheres and cord can also be involved, causing pyramidal signs, cranial nerve lesions, brain-stem symptoms or hemiparesis. Recurrent thromboses also occur. Renal involvement is extremely rare.

There are no defining investigations and the diagnosis is clinical (Box 25.74). Oral ulceration can be managed with topical steroid preparations (e.g. soluble prednisolone mouthwashes, steroid pastes). Colchicine can be effective for erythema nodosum and arthralgia. Thalidomide (100–300 mg per day for 28 days initially) is very effective for resistant oral and genital ulceration but is teratogenic and neurotoxic. Steroids and immunosuppressives are indicated for systemic disease.

25.74 Criteria for the diagnosis of Behçet's syndrome

- Recurrent oral ulceration: minor aphthous, major aphthous or herpetiform ulceration at least three times in a 12-month period

Plus two of the following:

- Recurrent genital ulceration
- Eye lesions: anterior uveitis, posterior uveitis, cells in vitreous on slit-lamp examination, retinal vasculitis
- Skin lesions: erythema nodosum, pseudofolliculitis, papulopustular lesions, acneiform nodules
- Positive pathergy test

Giant cell arteritis (GCA) and polymyalgia rheumatica (PMR)

GCA and PMR are related diseases associated with a granulomatous arteritis of medium-sized vessels of the head and neck. They are sometimes considered as separate diseases but many patients with PMR also have symptoms of GCA and vice versa. Since the management of both is similar, they are considered together here. Both are diseases of the elderly, with a prevalence of approximately 20 per 100 000 over the age of 50 years. The average age at onset is 70, and they are rare under

the age of 60. There is a female preponderance of about 3:1. The clinical features result from occlusion of vessels and subsequent tissue ischaemia.

Clinical features

The cardinal features of PMR are symmetrical muscle pain and stiffness affecting the shoulder and pelvic girdles. Constitutional symptoms such as weight loss, fatigue, malaise and night sweats are common. The onset of symptoms is usually fairly sudden, over a few days, but may be more insidious. On examination, there may be stiffness and painful restriction of active shoulder movement but passive movements are preserved. Muscles may be tender to palpation but weakness and muscle-wasting are absent. The cardinal symptom of GCA is headache, which is often localised to the temporal or occipital region and may be accompanied by scalp tenderness. Jaw pain develops in some patients, brought on by chewing or talking, and due to ischaemia of the masseter muscles. Visual disturbance can occur and a catastrophic presentation is blindness in one eye due to occlusion of the posterior ciliary artery. On fundoscopy the optic disc may appear pale and swollen with haemorrhages, but these changes may take 24–36 hours to develop and the fundi may initially appear normal. Other visual symptoms include loss of visual acuity, reduced colour perception and papillary defects. Rarely, neurological involvement may occur, with transient ischaemic attacks, brain-stem infarcts and hemiparesis. Other conditions that mimic PMR are shown in Box 25.75.

Investigations

The typical laboratory abnormality is an elevated ESR, often with a normochromic, normocytic anaemia. CRP may also be elevated and in some cases this precedes elevation of the ESR. Occasionally, PMR and GCA occur with a normal ESR. The diagnosis is usually based on a combination of the typical clinical features, raised ESR and prompt response to steroid. However, if there is doubt concerning the diagnosis of GCA, a temporal artery biopsy may be undertaken. Characteristic biopsy findings are fragmentation of the internal elastic lamina with necrosis of the media in combination with a mixed inflammatory cell infiltrate. Whilst a positive biopsy is helpful, a negative biopsy does not exclude the diagnosis because the lesions are focal. Ultrasound or arteriography may be used to help guide the biopsy.

Management

Corticosteroids are the treatment of choice and should be commenced urgently in suspected GCA because of the risk of visual loss (Box 25.76). Response to treatment is dramatic, such that symptoms will have completely resolved within 48–72 hours of starting corticosteroid therapy in virtually all patients. It is customary to use higher doses in GCA (60 mg prednisolone) than in PMR (20–30 mg), although the

25.75 Conditions that may mimic polymyalgia rheumatica

- Fibromyalgia
- Hypothyroidism
- Cervical spondylosis
- RA
- Systemic vasculitis
- Inflammatory myopathy (particularly inclusion body myositis, p. 1128)
- Malignancy

Box 25.76 Emergency management of giant cell arteritis

- Take blood for ESR and CRP
- Commence prednisolone 40–60 mg daily
- Review patient in 3–4 days
- Continue steroids in patients whose symptoms have resolved, with gradual reduction in dose
- Organise temporal artery biopsy in patients with poor or equivocal response

evidence base for this is weak. In both conditions the steroid dose should be progressively reduced, guided by symptoms and ESR, with the aim of reaching a dose of 10–15 mg by about 8 weeks. Thereafter reduction is slower by 1 mg per month until an acceptable dose is achieved (5–7.5 mg daily). If symptoms recur, the dose should be increased to that which previously controlled the symptoms, and reduction attempted in another few months. Most patients need steroids for an average of 12–24 months. Some patients require steroid-sparing agents, such as methotrexate or azathioprine, if they require a maintenance dose of prednisolone of more than 7.5 mg daily. Osteoporosis prophylaxis should be given for the duration of treatment.

DISEASES OF BONE

Osteoporosis

The defining feature of osteoporosis is reduced bone density, which causes a micro-architectural deterioration of bone tissue and leads to an increased risk of fracture. The prevalence of osteoporosis increases with age, reflecting the fact that bone density declines with age, especially in women (Fig. 25.45). The age-related decline

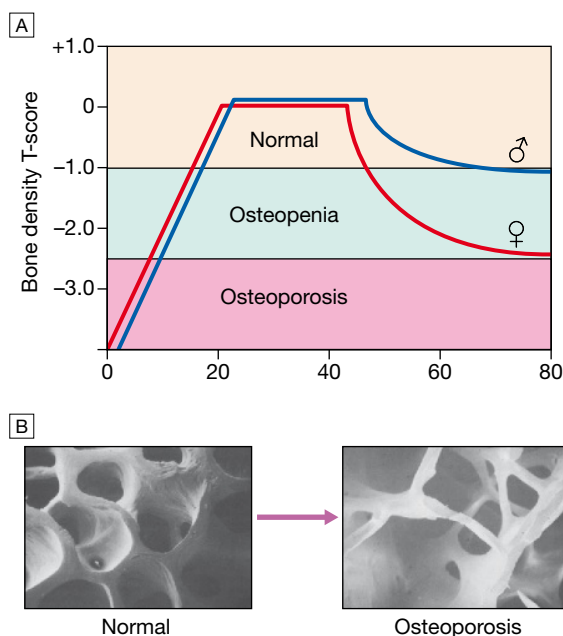

Fig. 25.45 Changes in bone mass and microstructure with age. **A** Changes in bone mass with age in men (blue line) and women (pink line). **B** Scanning electron micrographs of normal bone (left) and osteoporotic bone (right).

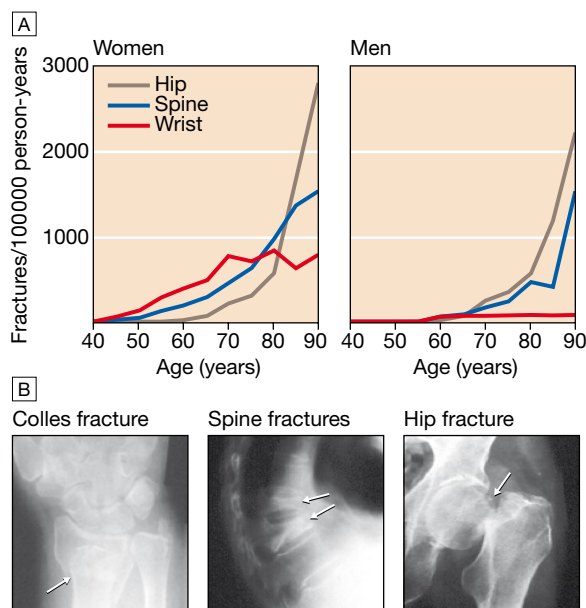

Fig. 25.46 Relation between age and the incidence of osteoporotic fractures. **A** Changes in the incidence of wrist fractures, vertebral fractures and hip fractures with age. **B** X-rays showing Colles fracture, vertebral fractures and hip fracture.

in bone mass is accompanied by an increased risk of fractures (Fig. 25.46A). This is due in part to the fall in bone density, but more importantly to the increased risk of falling which increases with age (p. 170). Fractures related to osteoporosis are estimated to affect around 30% of women and 12% of men at some point in developed countries and are a major public health problem. In the UK alone, fractures are sustained by over 250 000 individuals annually, with treatment costs of about £1.75 billion. Osteoporotic fractures can affect any bone, but the most common sites are the forearm (Colles fracture), spine (vertebral fracture) and hip (Fig. 25.46B); of these, hip fractures are the most serious. The immediate mortality is about 12% and there is a continued increase in mortality of about 20% when compared with age-matched controls. Treatment of hip fracture accounts for the majority of the health-care costs associated with osteoporosis.

Pathophysiology

Osteoporosis can occur because of a defect in attaining peak bone mass and/or because of accelerated bone loss. In normal individuals, bone mass increases during skeletal growth to reach a peak between the ages of 20 and 40 years but falls thereafter (see Fig. 25.45). In women there is an accelerated phase of bone loss after the menopause due to oestrogen deficiency which causes uncoupling of bone resorption and bone formation, such that the amount of bone removed by osteoclasts exceeds the rate of new bone formation by osteoblasts. Age-related bone loss is a distinct process that accounts for the gradual bone loss that occurs with advancing age in both genders. Bone resorption is not particularly increased but bone formation is reduced and fails to keep pace with bone resorption. Accumulation of fat in the bone marrow space also occurs because of an age-related decline in the ability of bone marrow stem cells to differentiate

into osteoblasts and an increase in their ability to differentiate into adipocytes (see Fig. 25.45).

Peak bone mass and bone loss are regulated by both genetic and environmental factors. Genetic factors account for up to 80% of the population variance in peak bone mass and other determinants of fracture risk, such as bone turnover and bone size. Polymorphisms have been identified in several genes that contribute to the pathogenesis of osteoporosis, including the oestrogen receptor gene (*ESR1*); the lipoprotein receptor-related protein 5 gene (*LRP5*); and the genes that encode osteoprotegerin (*TNFRSF11B*), RANK (*TNFRSF11A*) and the alpha 1 chain of type I collagen (*COL1A1*). However, these account for only a small proportion of the genetic contribution to osteoporosis and many genetic variants remain to be discovered.

Environmental factors such as exercise and calcium intake during growth and adolescence are important in maximising peak bone mass and in regulating rates of post-menopausal bone loss. Smoking has a detrimental effect on BMD and is associated with an increased fracture risk, partly because female smokers have an earlier menopause than non-smokers. Heavy alcohol intake is a recognised cause of osteoporosis and fractures, but moderate intake does not substantially alter risk.

Postmenopausal osteoporosis

This is the most common cause of osteoporosis because of the effects of oestrogen deficiency, as described above. Early menopause (below the age of 45 years) is a particularly important risk factor.

Osteoporosis in men

Osteoporosis is less common in men and a secondary cause can be identified in about 50% of cases. The most common are hypogonadism, corticosteroid use (see below) and alcoholism. In hypogonadism, the pathogenesis is as described for postmenopausal osteoporosis, as testosterone deficiency results in an increase in bone turnover and uncoupling of bone resorption from bone formation. Genetic factors are probably important in the 50% of cases with no identifiable cause.

Corticosteroid-induced osteoporosis

This is an important cause of osteoporosis which relates to dose and duration of corticosteroid therapy. Although there is no 'safe' dose of corticosteroid, the risk increases when the dose of prednisolone exceeds 7.5mg daily and is continued for more than 3 months. Corticosteroids have adverse effects on calcium metabolism and bone cell function. A key abnormality is reduced bone formation due to a direct inhibitory effect on osteoblast function and steroid-induced osteoblast and osteocyte apoptosis. Corticosteroids also inhibit intestinal calcium absorption and cause renal leak of calcium, and this tends to reduce serum calcium, leading to secondary hyperparathyroidism with increased osteoclastic bone resorption. Hypogonadism may also occur with high-dose steroids.

Pregnancy-associated osteoporosis

This is a rare condition that typically presents with back pain and multiple vertebral fractures during the second or third trimester. The cause is unknown but may relate to an exaggerated bone loss that normally occurs during pregnancy, in patients with pre-existing low bone mass.

Other causes

Osteoporosis can occur as a complication of many diseases and drug treatments (Box 25.77). Primary hyperparathyroidism causes bone loss because sustained elevation in PTH increases bone turnover, and bone formation cannot keep pace with resorption. A similar mechanism operates in thyrotoxicosis, driven by raised levels of thyroid hormones. Cushing's disease is a rare cause, identical in mechanism to corticosteroid-induced osteoporosis. Anorexia nervosa causes osteoporosis through calcium deficiency, weight loss and hypogonadism, whereas malabsorption predisposes to it through calcium and vitamin D deficiency and consequent secondary hyperparathyroidism. Chronic HIV infection predisposes to osteoporosis because of low body weight, chronic immune activation and anti-retroviral therapy. Inflammatory diseases increase bone resorption and suppress bone formation through release of pro-inflammatory cytokines such as IL-1 and TNF and increased expression of RANK by lymphocytes. Similar mechanisms operate in certain cancers which release a variety of bone-resorbing factors, including TNF, lymphotoxin and parathyroid hormone-related protein (PTHrP). Gaucher's disease (p. 449) and systemic mastocytosis also cause release of bone resorbing factors. Thiazolidinediones such as rosiglitazone inhibit osteoblast differentiation and promote adipocyte differentiation in the bone marrow, leading to reduced bone formation and bone loss. Aromatase inhibitors cause osteoporosis by reducing peripheral conversion of adrenal androgens to oestrogen, whereas gonadotrophin-releasing hormone agonists predispose to osteoporosis by causing hypogonadism.

Clinical features

Patients with osteoporosis are asymptomatic until a fracture occurs. Osteoporotic spinal fracture may

*Hypogonadism plays an important role in osteoporosis associated with these conditions.

present with acute back pain or gradual onset of height loss and kyphosis with chronic pain. The pain of acute vertebral fracture can occasionally radiate to the anterior chest or abdominal wall and be mistaken for a myocardial infarction or intra-abdominal pathology, but worsening of pain by movement and local tenderness both suggest vertebral fracture. Peripheral osteoporotic fractures present with local pain, tenderness and deformity, often after an episode of minimal trauma. In patients with hip fracture, the affected leg is shortened and externally rotated. Many patients present with incidental osteopenia on an X-ray performed for other reasons.

Investigations

The pivotal investigation is dual energy X-ray absorptiometry (DEXA) at the lumbar spine and hip, which works on the principle that calcium in bone attenuates passage of X-ray beams in proportion to the amount of mineral present. The DEXA provides an image of the region studied, a BMD measurement (expressed as grams of hydroxyapatite/cm²) and T-score and Z-score values. The T-score is a measure of how many standard deviations the patient's BMD value differs from that of a young healthy control, whereas the BMD Z-score is a measure of how many standard deviations the BMD deviates from age-matched controls (Fig. 25.47). Osteoporosis is diagnosed when the T-score value falls to -2.5 or below (shaded red in the figure), whereas osteopenia is diagnosed when the T-score lies between -1.0 and -2.5 (pink in the figure). Many healthy people, especially above the age of 50, have BMD values in the osteopenic range and this is not considered an indication for drug treatment. Values of BMD above -1.0 are considered normal.

DEXA should be considered in patients with one or more clinical risk factors for osteoporosis (Box 25.78). Traditionally the presence of a single risk factor has been considered sufficient indication for DEXA, but recently a prediction tool has been developed (FRAX[®]; website listed at end of chapter) which synthesises information from several risk factors, allowing the calculation of a 10-year fracture probability in individuals. Figure 25.48 gives an algorithm for the investigation of patients with suspected osteoporosis using FRAX and DEXA.

A history should be taken to identify any predisposing causes, such as early menopause, excessive alcohol intake, smoking and corticosteroid therapy. Signs of endocrine disease, neoplasia and inflammatory disease should be sought on clinical examination. A falls history should be taken and a 'get up and go' test performed, especially in elderly patients (p. 165). Renal function, liver function, thyroid function, immunoglobulins and ESR, with screening for coeliac disease (TTG antibodies), should be performed. Serum 25(OH)D and PTH measurements are useful to exclude vitamin D deficiency and secondary hyperparathyroidism. Primary hyperparathyroidism should be suspected if hypercalcaemia is present (p. 766). Levels of sex hormones and gonadotrophins should be measured in men with osteoporosis and women under the age of 50. Transiliac bone biopsy is sometimes required in early-onset osteoporosis of unknown cause or when coexisting osteomalacia is suspected.

Fig. 25.47 Typical output from a DEXA scanner. **A** DEXA scan of the hip. **B** Bone mineral density (BMD) values plotted in g/cm² (left axis) and as the T-score values (right axis). The solid line represents the population average plotted against age, and the interrupted lines are ± 2 standard deviations from the average. The patient shown, aged 80, has an osteoporotic T-score of -3.0 , but has a Z-score of -1.0 , which is within the 'normal range' for that age, reflecting the fact that bone is lost with age.

25.78 Indications for bone densitometry

- Low trauma fracture (fall from standing height or less)
- Clinical features of osteoporosis (height loss, kyphosis)
- Osteopenia on plain X-ray
- Corticosteroid therapy (> 7.5 mg prednisolone daily for > 3 mths)
- Family history of osteoporotic fracture
- Low body weight (body mass index < 19)
- Early menopause (< 45 yrs)
- Diseases associated with osteoporosis
- Assessing response of osteoporosis to treatment
- High fracture risk on FRAX analysis

Management: lifestyle advice and falls prevention

The aim of treatment is to reduce the risk of fracture and this can be achieved by a combination of non-pharmacological and pharmacological approaches. Advice on lifestyle factors, such as smoking cessation, moderation of alcohol intake, dietary calcium intake and

Fig. 25.48 Algorithm for the investigation of patients with suspected osteoporosis.

exercise, should be given. Those with recurrent falls or unsteadiness on a 'get up and go' test should be referred to a multidisciplinary falls prevention team (p. 170). Hip protectors can reduce the risk of hip fracture in selected patients but compliance is often poor.

Drug treatment

Several drugs have been shown to reduce the risk of osteoporotic fractures in randomised controlled trials (Box 25.79). Their effects on vertebral and non-vertebral fractures are summarised in Box 25.80.

Drug treatment should be considered in patients with BMD T-score values below -2.5 or below -1.5 in corticosteroid-induced osteoporosis because there is evidence that fractures occur at a higher BMD value in steroid users and that drugs prevent fracture in patients with T-scores at this level. Treatment should also be considered in patients with vertebral fractures, irrespective of BMD, unless they resulted from significant trauma.

Bisphosphonates

Bisphosphonates inhibit bone resorption by binding to hydroxyapatite crystals on the bone surface. When osteoclasts attempt to resorb bone that contains bisphosphonate, the drug is released within the cell, where it inhibits key signalling pathways that are essential for osteoclast function. Although bisphosphonates primarily target the osteoclast, bone formation is also suppressed because of coupling

between bone formation and bone resorption and an inhibitory effect on osteoblasts. However, the balance of effect on bone turnover is favourable, resulting in a gain in bone density due partly to increased mineralisation of bone. Bisphosphonate treatment typically leads to an increase in spine BMD of about 5–8% and hip BMD of 2–4% during the first 3 years of treatment and plateaus thereafter.

Alendronate is the bisphosphonate used most frequently. It reduces risk of vertebral fractures by 40%

25.80 Effects of drugs on the risk of osteoporotic fractures			
Drug	Regimen	Vertebral fracture	Non-vertebral fracture
Alendronate	70 mg/week orally	+	+
Risedronate	35 mg/week orally	+	+
Ibandronate	150 mg/month orally 3 mg/3 mths i.v.	+	+/-
Zoledronate	5 mg/12 mths i.v.	+	+
Denosumab	60 mg/6 mths s.c.	+	+

and non-vertebral fractures by about 25% in postmenopausal women with osteoporosis. Risedronate is an alternative with similar efficacy, but may be better tolerated in patients with a history of gastrointestinal upset. Both drugs are also effective in the treatment of corticosteroid-induced osteoporosis. They can also be used to treat male osteoporosis but neither has been shown to prevent non-vertebral fractures in men. Ibandronate is sometimes used but the evidence for prevention of non-vertebral fractures is less robust. Zoledronate is effective in the treatment of postmenopausal osteoporosis, corticosteroid-induced osteoporosis and osteoporosis in men. It is also useful for secondary prevention of fractures in elderly patients with hip fracture and reduces mortality in this group, being the only treatment that has been shown to modify this. Etidronate is still occasionally used and is generally well tolerated but has been largely superseded by the drugs mentioned above.

Oral bisphosphonates are poorly absorbed from the gastrointestinal tract and should be taken on an empty stomach with plain water and no food taken for 30–45 minutes after administration. Upper gastrointestinal upset occurs in about 5% and bisphosphonates should be used with caution in patients with existing gastro-oesophageal reflux disease. They should be avoided in patients with oesophageal stricture or achalasia, since tablets may stick in the oesophagus, causing ulceration and perforation. The most common side-effect with intravenous bisphosphonates is a transient influenza-like illness characterised by fever, malaise, anorexia and generalised aches which occurs 24–48 hours after administration. This is self-limiting but can be treated with paracetamol or NSAID if necessary. It predominantly occurs after the first exposure and tolerance develops thereafter. Rare side-effects of bisphosphonates include uveitis, atrial fibrillation (zoledronate), osteonecrosis of the jaw (ONJ) and subtrochanteric fractures. ONJ is characterised by the presence of necrotic bone in the mandible or maxilla, typically occurring after tooth extraction when the socket fails to heal. Most ONJ cases have occurred in cancer patients with coexisting morbidity such as infection and diabetes, who have received high doses of intravenous bisphosphonates; this complication is very rare in patients who are treated with the dose regimes used in osteoporosis. None the less, all patients receiving bisphosphonates for any reason should be advised to pay attention to good oral hygiene. Some advise that bisphosphonates should be temporarily stopped in patients undergoing tooth extraction but there is no evidence that this is necessary or alters the occurrence of ONJ. Atypical subtrochanteric fractures have been described recently in patients who have received long-term bisphosphonates, and it is thought that this might result from over-suppression of normal bone remodelling. In the vast majority of patients with osteoporosis the benefits of bisphosphonate therapy far outweigh the risks, but it is important that treatment is targeted to patients with low BMD who are most likely to benefit.

Calcium and vitamin D

Calcium and vitamin D have limited efficacy in the prevention of osteoporotic fractures when given in isolation but are widely used as an adjunct to other treatments, most often as combination preparations containing 500mg calcium and 800U vitamin D (e.g. AdCalD3,

25.81 Osteoporosis in old age

- **Bone loss:** due to increased bone turnover, with an age-related defect switch in differentiation of bone marrow stromal cells to form adipocytes as opposed to osteoblasts.
- **Fractures due to osteoporosis:** common cause of morbidity and mortality, although fracture healing is not delayed by age.
- **Recurrent fractures:** those who suffer a fragility fracture are at increased risk of further fracture, so should be investigated for osteoporosis and treated if this is confirmed.
- **Falls:** risk factors for falls (such as visual and neuromuscular impairments) are independent risk factors for hip fracture in elderly women, so intervention to prevent falls is as important as treatment of osteoporosis (p. 170).
- **Intravenous zoledronic acid:** reduces mortality and subsequent fracture in elderly patients who have suffered hip fractures.
- **Calcium and vitamin D:** reduce the risk of fractures in those who are housebound or living in care homes.

Calcichew D3). They are of greatest value in preventing fragility fractures in elderly or institutionalised patients who are at high risk of calcium and vitamin D deficiency (Box 25.81).

Strontium ranelate

Strontium ranelate reduces vertebral fracture risk by about 40% after 3 years and non-vertebral fracture risk by 12%. The mechanism of action is poorly understood. It has a weak inhibitory effect on bone resorption, stimulates biochemical markers of bone formation and is incorporated within hydroxyapatite crystals in place of calcium. Large changes in BMD (12%) occur, although this is partly an artefact due to substitution of heavier strontium atoms for calcium atoms in bone mineral. The most common adverse effect is diarrhoea. There is also a slight increased risk of venous thromboembolism (VTE) for reasons that are unclear. Rarely, a severe rash occurs, and this is an indication to stop treatment.

Parathyroid hormone

PTH is an anabolic agent that works by stimulating new bone formation. The most widely used preparation is the 1–34 fragment of PTH given by single daily subcutaneous injection of 20 µg. Teriparatide increases BMD by 10% or more in osteoporotic subjects and reduces risk of vertebral fractures by about 65% and non-vertebral fractures by 50%. It is also effective in corticosteroid-induced osteoporosis and appears superior to alendronate in terms of BMD gain and vertebral fracture reduction. It is also effective in male osteoporosis. PTH is expensive and is usually reserved for patients with severe osteoporosis (BMD T-score of –3.5 to –4.0 or below) and those who have failed to respond adequately to other treatments. The recommended duration of treatment is 24 months, after which patients should receive an anti-resorptive drug, such as a bisphosphonate, to maintain the increase in BMD. Teriparatide should not be administered at the same time as bisphosphonates, as this blunts the anabolic effect. In patients who are being treated with teriparatide because of failure to respond, existing treatment is stopped. The 1–84

fragment of PTH acts in a similar way to teriparatide but the evidence for prevention of non-vertebral fracture is less robust than for 1-34 PTH.

Calcitonin

This osteoclast inhibitor is occasionally used for treatment of postmenopausal osteoporosis. Its efficacy in preventing fractures is less robust than that of the drugs described above. Calcitonin may have analgesic properties and it is therefore sometimes used in the short to medium term in patients with acute vertebral fracture. It can be given by subcutaneous or intramuscular injection (100–200 U daily) or by intranasal spray (200 U daily).

Hormone replacement therapy (HRT), raloxifene and tibolone

Cyclical HRT with oestrogen and progestogen prevents postmenopausal bone loss and reduces the risk of vertebral and non-vertebral fractures in postmenopausal women. It is primarily indicated for the prevention of osteoporosis in women with an early menopause (p. 757) and for treatment of women with osteoporosis in their early fifties who have troublesome menopausal symptoms. HRT should be avoided in older women with established osteoporosis because it significantly increases the risk of breast cancer and cardiovascular disease. Raloxifene acts as a partial agonist at oestrogen receptors in bone and liver but as an antagonist in breast and endometrium, and is classified as a selective oestrogen receptor modulator (SERM). It results in a modest increase in BMD (2%) and a 40% reduction in vertebral fractures, but does not influence the risk of non-vertebral fracture and can provoke muscle cramps and worsen hot flushes. It increases the risk of VTE to a similar extent as HRT but reduces the risk of breast cancer; it does not influence the risk of cardiovascular disease. Bazedoxifene is a related SERM which has similar effects to raloxifene. Tibolone is a steroid which has partial agonist activity at oestrogen, progestogen and androgen receptors. It has similar effects on BMD as raloxifene and has been found to prevent vertebral and non-vertebral fractures in postmenopausal osteoporosis. Treatment is associated with a slightly increased risk of stroke but a reduced risk of breast cancer.

Other drugs

Calcitriol ($1,25(\text{OH})_2\text{D}_3$), the active metabolite of vitamin D, is licensed for treatment of osteoporosis, but it is seldom used since the data on fracture prevention are less robust than for other agents.

Denosumab is a monoclonal antibody which inhibits RANKL (see Fig. 25.2, p. 1058) and is a powerful inhibitor of bone resorption. It has recently been approved for the treatment of osteoporosis, with effects similar to those of zoledronate, and is given by subcutaneous injection every 6 months.

Surgery, kyphoplasty and vertebroplasty

Surgery is frequently required to reduce and immobilise osteoporotic fractures. Patients with intracapsular fracture of the femoral neck generally require partial or total hip replacement in view of the high risk of avascular necrosis. Kyphoplasty is used in the treatment of acute vertebral compression fractures where there is a significant degree of vertebral collapse and severe pain. It involves introducing a needle into the affected vertebral body and inflating

a balloon filled with methyl methacrylate cement in an attempt to restore vertebral shape. The procedure often relieves pain, but potential adverse effects include spinal cord compression, fat embolus and triggering of vertebral fractures on either side of the injected vertebra. Vertebroplasty is similar but the injection is with cement alone and no attempt is made to restore vertebral shape. It is indicated for painful vertebral fractures which fail to settle with medical management.

Duration of treatment and monitoring response

For established osteoporosis, treatment is generally given long-term. Exceptions are teriparatide and 1-84 PTH, for which the course of treatment lasts for 24 months.

The response to drug treatment can be assessed by repeating BMD measurements after 2–3 years. However, changes in BMD do not predict anti-fracture efficacy well and there is little evidence that monitoring by BMD or markers improves adherence. It may, however, reassure the patient that the treatment is working. Since the precision of spine BMD (approximately 1%) is better than hip (approximately 2.5%), spine BMD is best for monitoring. To be sure that a change has occurred in a patient, about twice the precision (i.e. 2% for spine, 5% for hip) is required. Biochemical markers of bone turnover, such as NTX (p. 1064), respond more quickly than BMD and can be used to assess adherence, but the correlation with anti-fracture efficacy is modest. Treatment response can also be established by measuring change in height to assess progression of vertebral osteoporosis and documenting the occurrence of clinical fractures. However, a fracture during drug therapy does not necessarily indicate treatment failure, as even the most effective interventions only reduce fracture risk by 25–50%. A pragmatic approach is to restrict repeat BMD measurements to patients who have suffered a fracture on treatment, and to consider changing to another agent if there is evidence of bone loss, assuming that the patient has been complying with therapy.

Osteomalacia and rickets

These conditions are characterised by defective mineralisation of bone due to vitamin D deficiency, resistance to the effects of vitamin D or hypophosphataemia. Osteomalacia describes a syndrome in adults of defective bone mineralisation, bone pain, increased bone fragility and fractures. Rickets is the equivalent syndrome in children and is characterised by enlargement of the growth plate and bone deformity. The disease remains prevalent in frail older people who have a poor diet and limited sunlight exposure, and in some Muslim women who live in northern latitudes. There are four main causes of osteomalacia and rickets (Box 25.82).

Vitamin D deficiency

The most common cause is lack of sunlight exposure since maintenance of normal levels of vitamin D depends on UV sunlight exposure to catalyse synthesis of cholecalciferol from 7-dehydrocholesterol in the skin (p. 764). Dietary deficiency can also play a role, but vitamin D occurs in only small quantities in most foods,

25.82 Causes of osteomalacia and rickets

Cause	Predisposing factor	Mechanism
Vitamin D deficiency		
Classical	Lack of sunlight exposure and poor diet	Reduced cholecalciferol synthesis in the skin/low levels of vitamin D in diet
Gastrointestinal disease	Malabsorption	Malabsorption of dietary vitamin D and calcium
Failure of 1,25 vitamin D synthesis		
Chronic renal failure	Hyperphosphataemia and kidney damage	Impaired conversion of 25(OH) ₂ D ₃ to 1,25(OH) ₂ D ₃
Vitamin D-resistant rickets type I (autosomal recessive)	Mutation in renal 25(OH)D-1-alpha-hydroxylase enzyme	Impaired conversion of 25(OH) ₂ D ₃ to 1,25(OH) ₂ D ₃
Vitamin D receptor defects		
Vitamin D-resistant rickets type II (autosomal recessive)	Inactivating mutations in vitamin D receptor	Impaired response to 1,25(OH) ₂ D ₃
Defects in phosphate and pyrophosphate metabolism		
Hypophosphataemic rickets (X-linked dominant)	Mutations in <i>PHEX</i> gene	FGF23 not degraded normally
Autosomal dominant hypophosphataemic rickets	Mutation in <i>FGF23</i>	Mutant FGF23 is resistant to degradation
Autosomal recessive hypophosphataemic rickets	<i>DMP1</i> mutation	Increased expression of FGF23 by osteocytes and local effect of DMP1 deficiency on mineralisation
Tumour-induced hypophosphataemic osteomalacia	Ectopic production of FGF23 by tumour	Over-production of FGF23
Hypophosphatasia	Mutations in bone-specific alkaline phosphatase	Inhibition of bone mineralisation due to accumulation of pyrophosphate in bone
Iatrogenic and other		
Bisphosphonate therapy	High-dose etidronate/pamidronate	Drug-induced impairment of mineralisation
Aluminium	Use of aluminium-containing phosphate binders or aluminium in dialysis fluids	Aluminium-induced impairment of mineralisation
Fluoride	High fluoride in water	Fluoride inhibits mineralisation

except oily fish, so the amount present in average diets is insufficient to meet requirements. Lack of cholecalciferol results in reduced hepatic production of 25(OH)D₃ and thus reduced renal production of the biologically active metabolite 1,25(OH)₂D₃. The lack of 1,25(OH)₂D₃ impairs intestinal calcium absorption and lowers serum calcium, which stimulates PTH secretion. This causes phosphate wasting and increased bone resorption in an attempt to maintain serum calcium levels within the normal range, causing progressive demineralisation of bone.

Clinical features

Vitamin D deficiency in children causes delayed development, muscle hypotonia, craniotabes (small unossified areas in membranous bones of the skull that yield to finger pressure with a cracking feeling), bossing of the frontal and parietal bones and delayed anterior fontanelle closure, enlargement of epiphyses at the lower end of the radius, and swelling of the rib costochondral junctions ('rickety rosary'). Osteomalacia in adults presents insidiously. Mild osteomalacia can be asymptomatic or present with fractures and mimic osteoporosis. More severe osteomalacia presents with muscle and bone pain, general malaise and fragility fractures. Proximal muscle weakness is prominent and the patient may walk with a waddling gait and struggle to climb stairs or get out of a chair. There may be bone and muscle tenderness on pressure and focal bone pain can occur due to fissure fractures of the ribs and pelvis.

Investigations

The diagnosis can usually be made on a routine biochemical screen with measurement of serum 25(OH)D and PTH. Typically, serum alkaline phosphatase levels are raised, 25(OH)D levels are low or undetectable, and PTH is elevated. Serum calcium and phosphate levels may also be low but normal values do not exclude the diagnosis. X-rays are normal until advanced disease, when focal radiolucent areas (pseudofractures or Looser's zones) may be seen in ribs, pelvis and long bones (Fig. 25.49A). Radiographic osteopenia is common and the presence of vertebral crush fractures may cause confusion with osteoporosis. In children, there is thickening and widening of the epiphyseal plate. Radionuclide bone scan can show multiple hot spots in the ribs and pelvis at the site of fractures and the appearance may be mistaken for metastases. Where there is doubt, the diagnosis can be confirmed by bone biopsy, which shows the pathognomonic features of increased thickness and extent of osteoid seams (Fig. 25.49B).

Management

Osteomalacia and rickets respond promptly to treatment with ergocalciferol (250–1000 µg daily), showing rapid clinical improvement, an elevation in 25(OH)D and a reduction in PTH. Serum alkaline phosphatase levels sometimes rise initially as mineralisation of bone increases, but eventually fall to within the normal range as the bone disease heals. After 3–4 months, treatment

Fig. 25.49 Osteomalacia. **A** X-ray of the pelvis showing Looser's zones (arrow). **B** Photomicrograph of bone biopsy from osteomalacic patient showing thick osteoid seams (stained light blue) which cover almost all of the bone surface. Calcified bone is stained dark blue.

can generally be stopped or the dose of vitamin D reduced to a maintenance level of 10–20 µg cholecalciferol daily, except in patients with underlying disease such as malabsorption, in whom higher doses may be required.

Vitamin D-resistant rickets (VDRR)

This term describes osteomalacia and rickets caused by:

- inactivating mutations in the 25-hydroxyvitamin D-1-alpha-hydroxylase (*CYP27B1*) enzyme which converts 25(OH)D to the active metabolite 1,25(OH)₂D₃ (type I VDRR)
- inactivating mutations in the vitamin D receptor which impair its ability to activate transcription (type II VDRR).

Clinical features are similar to those of infantile rickets and the diagnosis is usually first suspected when the patient fails to respond to vitamin D supplementation. Since both are recessive disorders, consanguinity is common but there may or may not be a positive family history. Biochemical features of type I disease are similar to vitamin D deficiency, except that levels of 25(OH)D are normal. In type II disease, 25(OH)D is normal but PTH and 1,25(OH)₂D₃ values are raised. Type I can be treated with the active vitamin D metabolites, 1-alpha hydroxyvitamin D (1–2 µg daily orally) or 1,25 dihydroxyvitamin D (0.25–1.5 µg daily orally), with or without calcium supplements, depending upon the patient's diet. Type II VDRR is extremely difficult to treat but sometimes responds partially to very high doses of active vitamin D metabolites and calcium and phosphate supplements.

Renal rickets and osteomalacia

Osteomalacia and rickets occur in patients with chronic renal failure due to defects in synthesis of renal 1,25(OH)₂D₃ or due to over-aggressive treatment with oral phosphate binders. Pathogenesis and management are discussed on page 490.

Hypophosphataemic rickets and osteomalacia

Rickets and osteomalacia can occur as the result of inherited or acquired defects in renal tubular phosphate reabsorption, and rarely in patients with tumours that secrete phosphaturic substances (see Box 25.82).

Pathophysiology

Circulating levels of FGF23 play a critical role in regulating serum phosphate by modulating expression of sodium-dependent phosphate transporters in the kidney which are responsible for renal tubular phosphate reabsorption. Osteocytes are the main source of FGF23 and levels of expression are regulated by the proteins DMP1 and PHEX, which are also produced by osteocytes (see Fig. 25.2, p. 1058). Inherited mutations affecting these proteins are summarised in Box 25.82 and account for most cases of hypophosphataemic rickets. Acquired hypophosphataemic rickets is mostly caused by overproduction of FGF23 by tumours.

Clinical features and diagnosis

The hereditary disorders usually present in childhood with rickets. The diagnosis is made on the basis of the early age at onset and presence of hypophosphataemia with renal phosphate wasting in the absence of vitamin D deficiency. Molecular diagnosis can define the causal mutation. Tumour-induced hypophosphataemic osteomalacia presents with severe, rapidly progressive symptoms in patients with no obvious predisposing factor for osteomalacia. Strenuous efforts should be made to identify the underlying, usually occult tumour. This often requires whole-body MRI or CT.

Management

Treatment is with phosphate supplements (1–4 g daily) and active metabolites of vitamin D (1-alpha hydroxyvitamin D 1–2 µg daily or 1,25 dihydroxyvitamin D 0.25–1.5 µg daily) to promote intestinal calcium and phosphate absorption. The aim is to ameliorate symptoms, restore normal growth, maintain serum phosphate levels within the normal range and normalise alkaline phosphatase levels. Levels of calcium, phosphate and alkaline phosphatase, along with renal function, should be monitored. Tumour-induced osteomalacia can be managed in the same way but surgical excision of the tumour is curative.

Hypophosphatasia

Hypophosphatasia is an autosomal recessive disorder caused by inactivating mutations in the alkaline phosphatase gene that impair alkaline phosphatase function, resulting in accumulation of pyrophosphate and inhibition of bone mineralisation. Chondrocalcinosis may also occur. The diagnosis should be suspected in osteomalacic patients with low or undetectable levels of serum alkaline phosphatase but normal levels of calcium,

phosphate, PTH and vitamin D metabolites. There is no medical treatment but bone marrow transplantation has been used successfully in severe cases.

Other causes of osteomalacia

These are summarised in Box 25.82. Aluminium intoxication is now rare due to reduced use of aluminium-containing phosphate binders and removal of aluminium from water supplies used in dialysis. If aluminium intoxication is suspected, the diagnosis can be confirmed by demonstration of aluminium at the calcification front in a bone biopsy. Osteomalacia due to bisphosphonates has mostly been described in patients with Paget's disease receiving etidronate and high-dose pamidronate. It is usually asymptomatic and healing occurs when treatment is stopped. Excessive fluoride intake causes osteomalacia due to direct inhibition of mineralisation and is common in parts of the world where there is a high fluoride content in drinking water. The condition reverses when fluoride intake is reduced.

Paget's disease

Paget's disease of bone (PDB) is a common condition characterised by focal areas of increased and disorganised bone remodelling. It mostly affects the axial skeleton, and bones that are commonly affected include the pelvis, femur, tibia, lumbar spine, skull and scapula. It is seldom diagnosed before age 40, but gradually increases in incidence thereafter to affect up to 8% of the UK population by the age of 85. The disease is common in Caucasians from north-west and southern Europe but is rare in Scandinavians, Asians, Chinese and Japanese. These ethnic differences persist after migration, supporting the importance of genetic factors in the aetiology, but the incidence of PDB has fallen in some countries over the past 25 years, suggesting that environmental triggers also play a role.

Pathophysiology

The primary abnormality is increased osteoclastic bone resorption, accompanied by marrow fibrosis, increased vascularity of bone and increased osteoblast activity. Bone in PDB is architecturally abnormal and has reduced mechanical strength. Osteoclasts in PDB are increased in number, are unusually large, and contain characteristic nuclear inclusion bodies. Genetic factors are important and mutations in the *SQSTM1* gene are a common cause of classical PDB. The presence of nuclear inclusion bodies in osteoclasts has fuelled speculation that PDB might be caused by a slow virus infection with measles or distemper but the evidence is conflicting. Biomechanical factors may help determine the pattern of involvement, since PDB often starts at sites of muscle insertions into bone and, in some cases, localises to bones or limbs that have been subjected to repetitive trauma or overuse. Involvement of subchondral bone can compromise the joint and predispose to OA ('Pagetic arthropathy').

Clinical features

The classic presentation is with bone pain, deformity, deafness and pathological fractures, but many patients are asymptomatic and are diagnosed as a result of an

abnormal X-ray or blood test performed for another reason. Clinical signs include bone deformity and expansion, increased warmth over affected bones, and pathological fracture. Bone deformity is most evident in weight-bearing bones such as the femur and tibia, but when the skull is affected the patient may complain that hats no longer fit properly due to cranial enlargement. Neurological problems, such as deafness, cranial nerve defects, nerve root pain, spinal cord compression and spinal stenosis, are recognised complications due to enlargement of affected bones and encroachment upon the spinal cord and nerve foraminae. Surprisingly, deafness seldom results from compression of the auditory nerve, but is conductive due to osteosclerosis of the temporal bone. The increased vascularity of Pagetic bone makes operative procedures difficult and, in extreme cases, can precipitate high-output cardiac failure in elderly patients with limited cardiac reserve. Osteosarcoma is a rare but serious complication which presents with subacute onset of increasing pain and swelling of an affected site.

Investigations

The characteristic features are an elevated serum alkaline phosphatase and, on X-ray, bone expansion with alternating areas of radiolucency and osteosclerosis (Fig. 25.50B). Alkaline phosphatase is normal in about 10% of cases, usually because of monostotic involvement. Radionuclide bone scanning is useful to define the presence and extent of disease (Fig. 25.50A). If the bone scan is positive, X-rays should be taken of an affected bone to confirm the diagnosis. Bone biopsy is not usually required but may help in cases of diagnostic uncertainty to exclude osteosclerotic metastases.

Management

The main indication for treatment is bone pain. Patients sometimes have pain due to the increase in bone turnover, but it is more commonly caused by complications such as deformity and coexisting OA. Pain secondary to OA should be managed as described on page 1087. Pain

25.83 Medical management of Paget's disease			
Drug	Route of administration	Dose	Inhibitory effect on bone turnover
Etidronate	Oral	400 mg daily for 3–6 mths	+
Tiludronate	Oral	400 mg daily for 3–6 mths	++
Risedronate	Oral	30 mg daily for 2 months	+++
Pamidronate	Intravenous	1–3 × 60 mg	+++
Zoledronate	Intravenous	1 × 5 mg	++++
Calcitonin	Subcutaneous	100–200 U 3 times weekly for 2–3 mths	+
+ moderately effective; ++ effective; +++ highly effective; ++++ extremely effective			

Fig. 25.50 Paget's disease. [A] Isotope bone scan from a patient with Paget's disease, illustrating the intense tracer uptake and deformity of the affected femur. [B] The typical radiographic features with expansion of the femur, alternating areas of osteosclerosis and radiolucency of the trochanter, and pseudofractures breaching the bone cortex (arrows).

due to increased bone turnover can be treated either by administration of analgesics and NSAIDs or by bisphosphonates (Box 25.83). The aminobisphosphonates pamidronate, zoledronate and risedronate are more effective than simple bisphosphonates such as etidronate and tiludronate at suppressing bone turnover in PDB, but their effects on pain are similar. Calcitonin can be used as an alternative but is less convenient to administer and more expensive. Repeated courses of bisphosphonates or calcitonin can be given if symptoms recur. The role of bisphosphonates in preventing complications is unclear, and no benefit has been demonstrated from 'intensive' bisphosphonate therapy aimed at suppressing bone turnover as compared with symptomatic treatment.

Primary tumours of the musculoskeletal system

Primary MSK tumours are rare, have a peak incidence in childhood and adolescence, and can be benign or malignant (Box 25.84). PDB accounts for most cases of osteosarcoma occurring above the age of 40. Presentation

is with local pain, swelling and tenderness. Rapid growth and overlying erythema suggest malignancy. In the case of bone tumours, X-rays may show expansion of the bone with a surrounding soft tissue mass, often containing islands of calcification, but further evaluation by MRI or CT is necessary to determine the extent of tumour. The diagnosis can be confirmed by biopsy but this should be done after referral to a specialist team. Treatment depends on histological type but generally involves surgical removal of the tumour followed by chemotherapy and radiotherapy. The prognosis is excellent with benign tumours and also generally good in cases that present in childhood and adolescence. The prognosis is poor in elderly patients with osteosarcoma related to PDB.

Metastatic bone disease

This may present in a variety of ways with localised or generalised progressive bone pain, generalised regional pain, symptoms of spinal cord compression, or acute pain due to pathological fracture. Systemic features, such as weight loss and anorexia, and symptoms referable to the primary tumour are often present. Tumours which most commonly metastasise to bone are myeloma and tumours of the bronchus, breast, prostate, kidney and thyroid. Management is discussed in Chapter 11.

Other bone diseases

Reflex sympathetic dystrophy

Reflex sympathetic dystrophy (RSD) or algodystrophy presents with gradual onset of severe pain, swelling and local tenderness, usually affecting a limb extremity. It is characterised by localised osteoporosis of the affected limb and evidence of regional autonomic dysfunction, such as abnormal sweating, colour and temperature change. It is commonly triggered by fracture, occurring in up to 25% of patients with Colles' fracture. It can also associate with

25.84 Primary tumours of the musculoskeletal system

Cell type	Benign	Malignant
Osteoblast	Osteoid osteoma	Osteosarcoma
Chondrocyte	Chondroma Osteochondroma	Chondrosarcoma
Fibroblast	Fibroma	Fibrosarcoma
Bone marrow cell	Eosinophilic granuloma	Ewing's sarcoma
Endothelial cell	Haemangioma	Angiosarcoma
Osteoclast precursor	Giant cell tumour	Malignant giant cell tumour

Fig. 25.51 Lateral X-ray of the foot in a patient with reflex sympathetic dystrophy. There is generalised osteopenia and also some more focal areas of patchy osteolysis (arrows).

soft tissue injury, pregnancy and intercurrent illness, or can develop spontaneously. The cause is unknown but overactivity of the sympathetic nervous system is thought to be responsible for many of its features.

The diagnosis is clinical but supported by patchy osteoporosis of the affected region on X-ray, by a local increase in isotope uptake on bone scanning (see Fig. 25.8A, p. 1062) and by bone marrow 'oedema' on MRI. The differential diagnosis includes infection, inflammation and malignancy. Usually, RSD is distinguished from infection and inflammation by the absence of an APR and lack of synovitis. The X-ray appearances in RSD are also distinct from those of focal osteolytic malignant lesions (Fig. 25.51), but in doubtful cases biopsy of the affected site can be undertaken. This usually shows non-specific changes and osteopenia.

Management is difficult but analgesics, NSAIDs, amitriptyline, gabapentin, calcitonin, corticosteroids, β -adrenoceptor antagonists (β -blockers), sympathectomy and bisphosphonates can all be tried. Typically, patients end up on a combination of these, as none is particularly effective. Although some cases resolve with time, many have persistent symptoms and fail to regain normal function.

Polyostotic fibrous dysplasia

This is an acquired disorder due to mutations in the *GNAS1* gene, characterised by focal or multifocal bone pain, bone deformity and expansion, and pathological fractures. Associated features include endocrine dysfunction, especially precocious puberty, and café-au-lait skin pigmentation (McCune-Albright syndrome). The diagnosis is made by skeletal imaging, which shows

focal, predominantly osteolytic lesions and bone expansion on X-ray, and focal increased uptake on bone scan. The condition can resemble PDB but the earlier age of onset and pattern of involvement are usually distinctive. Management is symptomatic. Surgery is sometimes required for treatment of fracture and deformity. Very rarely, malignant change can occur and should be suspected by a sudden increase in pain and swelling. There is limited evidence that intravenous pamidronate may help bone pain and promote healing of lytic lesions.

Rare inherited disorders of bone

Osteogenesis imperfecta (OI)

This condition usually presents with severe osteoporosis and multiple fractures in infancy and childhood. Other common features include blue sclerae and abnormal dentition. Most cases are due to mutations in the *COL1A1* and *COL1A2* genes which encode the proteins that constitute type I collagen, resulting in reduced collagen production or formation of abnormal collagen chains that are rapidly degraded. Most cases of OI show dominant inheritance but recessive forms of OI have been described which are caused by mutations in the *CRTAP* and *LEPRE* genes which are involved in proline hydroxylation of collagen. Some have no family history and result from new mutations. Severity varies from neonatal lethal (type II), through very severe with multiple fractures in infancy and childhood (types III and IV), to mild (type I) which is classically accompanied by blue sclerae and less marked bone deformity. Severe OI is usually diagnosed clinically, but in milder cases osteoporosis enters the differential diagnosis. In these cases, mutation screening of *COL1A1* and *COL1A2* can be helpful but molecular testing is not widely available. Treatment is multidisciplinary, involving surgical reduction and fixation of fractures and correction of limb deformities, and physiotherapy and occupational therapy for rehabilitation of patients with bone deformity. Bisphosphonates are widely used but there is limited evidence that they prevent fractures or deformity.

Osteopetrosis

Osteopetrosis is the name given to a rare group of inherited diseases caused by failure of osteoclast function. Presentation is highly variable, ranging from a lethal disorder that presents with bone marrow failure in infancy to a milder and sometimes asymptomatic form that presents in adulthood. Severe osteopetrosis is inherited in an autosomal recessive manner and presents with failure to thrive, delayed dentition, cranial nerve palsies (due to absent cranial foramina), blindness, anaemia and recurrent infections due to bone marrow failure. The adult-onset type (Albers-Shonberg disease) shows autosomal dominant inheritance and presents with bone pain, cranial nerve palsies, osteomyelitis, OA or fracture, or is sometimes detected as an incidental radiographic finding. The responsible mutations either affect the genes that regulate osteoclast differentiation (*RANK*, *RANKL*), causing 'osteoclast-poor' osteopetrosis, or affect the genes involved in bone resorption, causing 'osteoclast-rich' osteopetrosis. These include mutations in the *TCIRG1* gene which encodes a component of the osteoclast proton pump, and mutations in the *CLCN7* gene which

encodes the osteoclast chloride pump. Management is difficult. IFN- γ treatment can improve blood counts and reduce frequency of infections, but in severe cases bone marrow transplantation is required to provide a source of osteoclasts that resorb bone normally.

Sclerosing bone dysplasias

These constitute a rare heterogeneous group of diseases characterised by osteosclerosis due to increased bone formation.

Van Buchem's disease and sclerosteosis are recessive disorders caused by mutations of the *SOST* gene which normally suppresses bone formation. This is characterised by enlargement of the cranium and jaw, tall stature and cranial nerve palsies. Treatment is symptomatic.

Camurati-Engelmann disease is an autosomal dominant condition caused by activating mutations in the *TGFB1* gene, characterised by bone pain, muscle weakness and osteosclerosis mainly affecting the diaphysis of long bones. Corticosteroid treatment can help the bone pain but required doses are often unacceptably high.

High bone mass syndrome is characterised by unusually high bone density. Most patients are asymptomatic but bone overgrowth in the palate can occur. Treatment is not usually required.

MUSCULOSKELETAL PRESENTATIONS OF DISEASE IN OTHER SYSTEMS

Many systemic diseases can cause symptoms and signs in the MSK system and sometimes this may be the presentation of the disease. Furthermore, drugs used for other systemic disease may result in MSK complications

25.85 Drug-induced effects on the musculoskeletal system	
Musculoskeletal problem	Principal drug
Secondary gout	Thiazides, furosemide, alcohol
Osteoporosis	Corticosteroids, heparin, glitazones, aromatase inhibitors, GnRH agonists
Osteomalacia	Anticonvulsants, etidronate and pamidronate (high-dose)
Osteonecrosis	Corticosteroids, alcohol
Drug-induced lupus syndrome	Procainamide, hydralazine, isoniazid, chlorpromazine
Arthralgias or arthritis	Corticosteroid withdrawal, glibenclamide, methyl dopa, ciclosporin, isoniazid, barbiturates
Myalgias	Corticosteroid withdrawal, L-tryptophan, fibrates, statins
Myopathy	Corticosteroid, chloroquine
Myositis, myasthenia	Penicillamine, statins
Cramps	Corticosteroid, adrenocorticotrophic hormone (ACTH), diuretics, carbenoxolone
Vasculitis	Amphetamines, thiazides

25.86 Rheumatological manifestations of malignancy

- Polyarthritis
- Dermatomyositis/polymyositis
- Hypophosphataemic osteomalacia
- Hypertrophic osteoarthropathy
- Bone metastases, pathological fracture
- Polymyalgia rheumatica syndrome

(Box 25.85). The following examples illustrate the variety of conditions that may be encountered but the list is not exhaustive. Bone disease in sarcoidosis is described on page 709, in haemophilia on page 1047 and sickle cell anaemia on page 1028.

Malignant disease

MSK manifestations of malignancy are summarised in Box 25.86. An unusual but striking presentation is with hypertrophic osteoarthropathy, which is characterised by clubbing and painful swelling of the limbs, periosteal new bone formation and arthralgia/arthritis. The most common causes are bronchial carcinoma and mesothelioma (p. 729), but the condition can be inherited; in this case, it is caused by inactivating mutations in the *HPGD* gene, which is responsible for degradation of PGE₂, suggesting that over-production of prostaglandins may generally play a causal role in clubbing. Bone scans show increased periosteal uptake before new bone is apparent on X-ray. The course follows that of the underlying malignancy and resolves if this is cured.

Endocrine disease

Hypothyroidism (p. 741) may present with carpal tunnel syndrome, or rarely with severely painful, symmetrical proximal myopathy with muscle hypertrophy. Both resolve with thyroxine replacement. Hyperparathyroidism (p. 766) predisposes to chondrocalcinosis and pseudogout and to calcific periarthritis, especially in patients with renal disease.

Diabetes mellitus (Ch. 21) commonly causes diabetic 'stiff hands' (cheiroarthropathy) characterised by tightening of skin and periarticular structures, giving flexion deformities of the fingers which are sometimes painful. Diabetic osteopathy presents as forefoot pain and shows radiographic progression from osteopenia to complete osteolysis of the phalanges and metatarsals. Diabetes also predisposes to 'frozen shoulder', Dupuytren's contracture, septic arthritis and neuropathic joints.

Acromegaly (p. 790) can be associated with mechanical back pain, with normal or excessive (not restricted) movement; carpal tunnel syndrome; Raynaud's syndrome; and an arthropathy (50%). The arthropathy mainly affects the large joints and has clinical similarities to OA but with normal or increased movement. X-rays may show widening of joint spaces, squaring of bone ends, generalised osteopenia and tufting of terminal phalanges. It does not improve with treatment of the acromegaly.

Metabolic disease

Approximately 50% of people with haemochromatosis (p. 959) develop an arthropathy, usually between the age of 40 and 50, which may predate other features of

the disease. It predominantly affects the small joints of the hands and wrists but hips, shoulders and knees are also commonly affected. X-ray changes resemble OA but cysts are often multiple and prominent, with little osteophyte formation, and atypical sites are targeted (radiocarpal joint, MCP joints). About 30% have pseudogout and radiographic chondrocalcinosis as additional diagnostic clues. Treatment of the haemochromatosis does not influence the arthropathy.

Neuropathic (Charcot) joints

Neurological disease may result in rapidly destructive arthritis of joints, first described by Charcot in association with syphilis. Although repetitive microtrauma following sensory loss was thought to be the cause, the more likely pathogenesis is altered blood flow secondary to impaired sympathetic nervous system control. The following are the principal predisposing diseases and sites of involvement:

- diabetic neuropathy (hindfoot)
- syringomyelia (shoulder, elbow, wrist)
- leprosy (hands, feet)
- tabes dorsalis (knees, spine).

The presentation is with subacute or insidious monoarthritis or dislocation. Pain can occur, especially at the onset, but once the joint is severely deranged, pain is often minimal and signs become disproportionately greater than symptoms. The joint is often grossly swollen, with effusion, crepitus, marked instability and deformity, though usually no increased warmth. It may eventually become flail and be complicated by peripheral nerve entrapment or spinal cord compression. X-rays show disorganisation of normal joint architecture and often multiple loose bodies (Fig. 25.52), and either no (atrophic) or gross (hypertrophic) new bone formation. Management principally involves orthoses and occasionally arthrodesis.

Fig. 25.52 Wrist X-ray showing a neuropathic (Charcot) joint in a patient with syringomyelia. Note the disorganised architecture with complete loss of the proximal carpal row, bony fragments and soft tissue swelling.

MISCELLANEOUS CONDITIONS

Inherited connective tissue diseases

Ehlers–Danlos syndrome is characterised by generalised hypermobility, skin laxity and easy bruising, with scoliosis, short stature, ocular fragility and visceral vascular catastrophes. It may result from mutations in several genes, including *COL1A2*, lysyl oxidase, fibronectin and elastin. Marfan's syndrome is described on page 602 and homocystinuria, which may cause osteoporosis, on page 447.

Relapsing polychondritis

Relapsing polychondritis is an idiopathic condition of cartilage that classically presents with acute pain and swelling of one or both ear pinnae, sparing the lower non-cartilaginous portion. Around 30% of patients have coexisting autoimmune or connective tissue disease. In a minority, involvement of tracheobronchial cartilage leads to hoarse voice, cough, stridor or expiratory wheeze. Manifestations at other cartilage sites include collapse of the bridge of the nose, scleritis, hearing loss and cardiac valve dysfunction. Diagnosis is made by ear cartilage biopsy. Pulmonary function tests, including flow volume loops, should be performed to assess the degree of laryngotracheal disease, since this is an important cause of mortality. Mild ear disease usually responds to low-dose steroid or NSAIDs. Major organ involvement requires high-dose steroids in combination with cytotoxic drugs. Rarely, tracheostomy or tracheal stents are required.

Inclusion body myositis

This is the most common muscle disease in patients aged over 50 and predominates in men. Although proximal weakness does occur, distal involvement is more usual and may be asymmetrical. Investigation is the same as for polymyositis (p. 1111). CK may be marginally elevated and both myopathic and neurogenic abnormalities may be present on EMG. The characteristic findings on muscle biopsy are abnormal fibres containing rimmed vacuoles and filamentous inclusions in the nucleus and cytoplasm. These inclusions contain paired helical filaments resembling those seen in the brain in Alzheimer's disease. Treatment is less successful than for polymyositis, but some patients respond to corticosteroids and immunosuppressives.

Mucopolysaccharidoses

This is a group of inborn errors of metabolism in which lysosomal enzyme defects lead to abnormal accumulation of glycosaminoglycans. All are associated with stiff joints and short stature, except for the Morquio syndrome, which is associated with hypermobility and atlanto-axial subluxation. The diagnoses are confirmed by identification of the urinary glycosaminoglycan metabolites and detection of the enzyme defects in fibroblast cultures.

Spondylolysis and spondylolisthesis

Spondylolysis describes a break in the integrity of the neural arch. The principal cause is an acquired defect in pars interarticularis due to a fracture, mainly seen in

gymnasts, dancers and runners in whom it is an important cause of back pain. Spondylolisthesis is where a defect causes slippage of a vertebra on the one below. This may be congenital, post-traumatic or degenerative. Rarely, it can result from metastatic destruction of the posterior elements.

Uncomplicated spondylolysis does not cause symptoms but spondylolisthesis can cause low back pain aggravated by standing and walking. More severe cases can result in nerve root compression or a lumbar stenosis syndrome and the vertebral slip is occasionally palpable. Spondylolysis and spondylolisthesis can usually be diagnosed from lateral X-rays of the lumbar spine. MRI may be required if there is nerve root involvement. Advice on posture and muscle-strengthening exercises is required in mild cases. Surgical fusion is indicated for severe and recurrent low back pain, and surgical decompression is mandatory prior to fusion in patients with significant lumbar stenosis or symptoms of cauda equina compression.

Diffuse idiopathic skeletal hyperostosis (DISH)

DISH is a common disorder in old age, affecting 10% of men and 8% of women over the age of 65. It associates with obesity, hypertension and type 2 diabetes mellitus. It is characterised by florid new bone formation along the anterolateral aspect of at least four contiguous vertebral bodies (Fig. 25.53). It is distinguished from lumbar spondylosis by the absence of disc space narrowing and marginal vertebral body sclerosis, and from spondylitis by the absence of sacroiliitis or apophyseal joint fusion. It rarely causes pain and is usually an asymptomatic radiographic finding. Ossifying enthesopathy at peripheral sites may cause pain: for example, under the heel with calcaneal spur formation.

Fig. 25.53 Diffuse idiopathic skeletal hyperostosis (DISH).

Anteroposterior X-ray of thoracic spine showing right-sided flowing new bone joining more than four contiguous vertebrae. The disc spaces are preserved.

Scheuermann's osteochondritis

This disorder predominates in adolescent boys, who develop a painless dorsal kyphosis in association with irregular radiographic ossification of the vertebral end plates. Back pain, aggravated by exercise and relieved by rest, may occur if upper lumbar vertebrae are affected, and secondary spondylosis can follow in middle age. Excessive exercise and heavy manual labour before epiphyseal fusion has occurred may aggravate symptoms. Treatment is avoidance of excessive activity and protective postural exercises. Surgery may be required for severe deformity.

Pigmented villonodular synovitis

Pigmented villonodular synovitis (PVNS) is an uncommon proliferative disorder of synovium which typically affects young adults. The presentation is with joint swelling, limitation of movement and pain. The diagnosis can be confirmed by synovial biopsy. Treatment is by surgical or radiation synovectomy.

Adult-onset Still's disease

This is a rare systemic inflammatory disorder of unknown cause typically affecting young adults, which presents with intermittent fever, rash and arthralgia.

Splenomegaly, hepatomegaly and lymphadenopathy may be present. Investigations typically show evidence of an acute phase response, with a markedly elevated serum ferritin. Tests for RF and ANA are negative. Most patients respond to corticosteroids but DMARDs may be required as steroid-sparing agents. Anecdotal reports indicate that anakinra (p. 1081) and anti-TNF therapy may be helpful in patients with resistant disease.

1+9 Examination of gait and posture

Step	Procedure	Abnormality	Disease
1	Examine posture	Stooped	Parkinsonism
	Axial tone	Axial tone increased	Parkinsonism (Parkinson's plus syndrome)
	Retropulsion/antropulsion	Postural instability	Parkinsonism
2	Examine arms during walking	Reduced arm swing	Parkinsonism, upper motor neuron lesion
3	Examine routine walking	Circumduction (stiff leg moves outwards in 'circular' manner)	Upper motor neuron lesion
		'Slapping' due to foot drop	Lower motor neuron lesion
		Narrow-based, short strides	Parkinsonism
		Wide-based, short strides (marche à petits pas, magnetic gait)	Frontal lobe lesion
		Wide-based, irregular strides	Cerebellar lesion
		High-stepping gait	Dorsal column lesion/sensory neuropathy
4	Examine tandem gait	Inability to perform task	Cerebellar lesion, dorsal column lesion
5	Perform Romberg test	Patient falls with eyes shut	Loss of joint position sense at ankles

5 Examination of cranial nerves

Nerve	Name	Tests
I	Olfactory	Ask patient about sense of smell
II	Optic	Visual acuity Visual fields 'Swinging' torch test for relative afferent pupillary defect Ophthalmoscopy
III	Oculomotor	Eye movements (nystagmus) Eyelid movement Pupil size, symmetry, reactions
IV	Trochlear	Eye movements (nystagmus)
V	Trigeminal	Sensation to face Corneal reflex Jaw movements (deviates on opening to side of lesion)
VI	Abducens	Eye movements (nystagmus)
VII	Facial	Facial symmetry and movements Ask patient about taste
VIII	Vestibulocochlear	Hearing (whisper to each ear) Tuning fork tests (Rinne and Weber) Look for nystagmus
IX	Glossopharyngeal	Gag reflex (sensory)
X	Vagus	Palatal elevation (uvula deviates to side opposite lesion) Gag reflex (motor) Cough (bovine cough)
XI	Accessory	Look for wasting Elevation of shoulders Turning head to right and left
XII	Hypoglossal	Look for wasting/fasciculation Tongue protrusion (deviates to side of lesion)

7 Root values of tendon reflexes

Reflex	Root value
Upper limb	
Biceps jerk	C5/C6
Supinator jerk	C5/C6
Triceps jerk	C7
Finger jerk	C8
Lower limb	
Knee jerk	L3/L4
Ankle jerk	S1/S2

Neurological examination in old age

- **Limb tone assessment:** often difficult because of increased difficulty in relaxing the limbs and concomitant joint disease.
- **Ankle reflexes:** may be bilaterally absent without diagnostic significance.
- **Gait assessment:** more difficult because of concurrent musculoskeletal disease and pre-existing neurological deficits.
- **Sensory testing:** especially difficult when there is cognitive impairment.
- **Vibration sense:** may be reduced in the lower extremities without diagnostic significance.

The brain, spinal cord and peripheral nerves constitute an organ responsible for perception of the environment, a person's behaviour within it, and the maintenance of the body's internal milieu in readiness for this behaviour. Some 10% of the population in the United Kingdom consult their general practitioner each year with a neurological symptom, and neurological disorders account for about one-fifth of acute medical admissions and a large proportion of chronic physical disability in the UK. However, neurological symptoms are often not associated with disease, and considerable clinical skill is needed to distinguish those with significant disease from those who need sympathetic reassurance.

A carefully taken history of the pattern of presenting neurological symptoms should suggest a short list of diagnoses that can then be tested on examination. During the neurological examination, knowledge of the relevant anatomy and physiology of the nervous system helps to determine the site of the lesion. The underlying pathology is often suggested by the time course of the symptoms and the epidemiological context. Increasingly sophisticated investigations, particularly imaging, are available to refine this clinical diagnosis.

Once the patient's neurological lesion (the deficit) is identified, the clinician needs to assess what impact this has had on the patient's functioning (the disability) and,

in turn, how this is affecting his or her life (the handicap). Even when a complete cure cannot be effected, much can be done to improve the disability by pharmacological correction of the pathophysiology and through rehabilitation (p. 174).

FUNCTIONAL ANATOMY AND PHYSIOLOGY

Cells of the nervous system

The nervous system comprises a complex network of specialised blood vessels, ependymal cells which line the cerebral ventricles, neurons and glial cells, of which there are three types. Astrocytes form the structural framework for neurons and control their biochemical environment. Astrocyte foot processes are intimately associated with blood vessels and form the blood-brain barrier (Fig. 26.1). Oligodendrocytes are responsible for the formation and maintenance of the myelin sheath, which surrounds axons and is essential for the rapid transmission of action potentials by saltatory conduction. Microglial cells are cells of the monocyte/macrophage lineage which play a role in fighting infection and removing damaged cells. Peripheral neurons have axons invested in myelin made by Schwann cells.

Fig. 26.1 Cells of the nervous system.

Generation and transmission of the nervous impulse

Function of the nervous system rests upon two physiological processes: the generation of an action potential and its conduction down axons, and the synaptic transmission of impulses between neurons and muscle cells. These processes depend upon the energy-demanding maintenance of an electrochemical gradient across neuron cell membranes, and alterations in this are effected by specialised ion channels in the membrane. Synaptic transmission involves the release of neurotransmitters. These modulate function of the target cell by interacting with various molecules on the cell surface, including ion channels and other cell surface receptors (Fig. 26.2). At least 20 different neurotransmitters have been identified which act at different sites in the nervous system,

and all are potentially amenable to pharmacological manipulation.

The neuronal cell bodies are acted upon by synapses with large numbers of other neurons. Each neuron therefore acts as a microprocessor, reacting to the influences upon it by changes to its cell membrane potential, causing it to be more or less able to discharge an impulse down its axon(s). The synapsing neuron terminals are also subject to regulation by receptor sites on their pre-synaptic membrane, which modify the release of transmitter across the synaptic cleft. The effect of some neurotransmitters is to produce long-term modulation of metabolic function or gene expression rather than simply to change the membrane potential. This effect probably underlies more complex processes in cognition, such as long-term memory.

Functional anatomy of the nervous system

Major components of the nervous system and their inter-relationships are depicted in Figure 26.3.

Cerebral hemispheres

The cerebral hemispheres coordinate the highest level of nervous function, the anterior half dealing with executive ('doing') functions and the posterior half constructing a perception of the environment ('receiving and perceiving'). Each cerebral hemisphere has four functionally specialised lobes (Fig. 26.4 and Box 26.1). Many of the functions are lateralised and this depends on which of the two hemispheres is 'dominant', i.e. the one in which language function is represented. In right-handed

Fig. 26.2 Neurotransmission and neurotransmitters. (1) An action potential arriving at the nerve terminal depolarises the membrane and this opens voltage-gated calcium channels. (2) Entry of calcium causes the fusion of synaptic vesicles containing neurotransmitters with the pre-synaptic membrane and release of the neurotransmitter across the synaptic cleft. (3) The neurotransmitter binds to receptors on the postsynaptic membrane to either (A) open ligand-gated ion channels which, by allowing ion entry, depolarise the membrane and initiate an action potential (4), or (B) bind to metabotropic receptors which activate an effector enzyme (e.g. adenylyl cyclase) and thus modulate gene transcription via the intracellular second messenger system leading to changes in synthesis of ion channels or modulating enzymes. (5) Neurotransmitters are taken up at the pre-synaptic membrane and/or metabolised.

Fig. 26.3 The major anatomical components of the nervous system.

26.1 Cortical lobar functions

Lobe	Function	Effects of damage		
		Cognitive/behavioural	Associated physical signs	Positive phenomena
Frontal	Personality Emotional control Social behaviour Contralateral motor control Language Micturition	Disinhibition Lack of initiation Antisocial behaviour Impaired memory Expressive dysphasia Incontinence	Impaired smell Contralateral hemiparesis Frontal release signs ¹	Versive seizures Focal motor seizures (Jacksonian march) Continuous partial seizures (epilepsia partialis continua)
Parietal: dominant	Language Calculation	Dysphasia Dyscalculia Dyslexia Apraxia ⁴ Agnosia ⁵	Contralateral hemisensory loss Astereognosis ² Agraphaesthesia ³ Contralateral homonymous lower quadrantanopia Asymmetry of optokinetic nystagmus (OKN)	Focal sensory seizures
Parietal: non-dominant	Spatial orientation Constructional skills	Neglect of contralateral side Spatial disorientation Constructional apraxia Dressing apraxia	Contralateral hemisensory loss Astereognosis Agraphaesthesia Contralateral homonymous lower quadrantanopia Asymmetry of OKN	Focal sensory seizures
Temporal: dominant	Auditory perception Language Verbal memory Smell Balance	Receptive aphasia Dyslexia Impaired verbal memory	Contralateral homonymous lower quadrantanopia	Complex hallucinations (smell, sound, vision, memory)
Temporal: non-dominant	Auditory perception Melody/pitch perception Non-verbal memory Smell Balance	Impaired non-verbal memory Impaired musical skills (tonal perception)	Contralateral homonymous upper quadrantanopia	Complex hallucinations (smell, sound, vision, memory)
Occipital	Visual processing	Visual inattention Visual loss Visual agnosia	Homonymous hemianopia (macular sparing)	Simple visual hallucinations (e.g. phosphenes, zigzag lines)

¹ Grasp reflex, palmomental response, rooting reflex.² Inability to determine 3-D shape by touch.³ Inability to 'read' numbers or letters drawn on hand, with eyes shut.⁴ Inability to perform complex movements in the presence of normal motor, sensory and cerebellar function.⁵ Inability to recognise or discriminate.

individuals the left hemisphere is almost always dominant, while in left-handers either hemisphere may be dominant with about equal frequency.

The frontal lobes are concerned with executive function, movement and behaviour. In addition to the primary and supplementary motor cortex, there are specialised areas for the control of eye movements, speech (Broca's area) and micturition.

The parietal lobes are concerned with the integration of sensory perception. The primary sensory cortex lies in the post-central gyrus of the parietal lobe. Much of the remainder is devoted to 'association' cortex, which integrates the input from the various sensory modalities. The supramarginal and angular gyri of the dominant parietal lobe form part of the language area (p. 1160). Close to these are regions dealing with

numerical function. The non-dominant parietal lobe houses areas concerned with spatial awareness and orientation.

The temporal lobes contain the primary auditory cortex and primary vestibular cortex. On the medial side lie the olfactory cortex and the parahippocampal cortex which is involved in memory function. The temporal lobes also contain many structures associated with the limbic system, including the hippocampus and the amygdala, which are involved in the processing of memory and emotions. The dominant temporal lobe also participates in language functions, particularly verbal comprehension (Wernicke's area). Music processing occurs in both temporal lobes, rhythm being processed on the dominant side and melody/pitch more on the non-dominant side.

Fig. 26.4 The anatomy of the cerebral cortex.

The occipital lobes are principally concerned with visual processing. The contralateral visual hemifield is represented in the primary visual (striate) cortex, and areas immediately surrounding this are involved in the processing of specific visual submodalities such as colour, movement or depth, and the analysis of more complex visual patterns such as faces.

Collections of cells in the depths of the hemispheres deal with motor control (the basal ganglia), the appropriate attention to sensory perception (the thalamus), emotion and memory (the limbic system), and internal bodily functions such as temperature and appetite control (the hypothalamus). The cerebral ventricles contain the choroid plexus and this produces the cerebrospinal fluid (CSF), which cushions the brain within the cranium. The CSF flows through the third and fourth ventricles and exits the brain through foramina in the brain stem to circulate down and around the spinal cord and over the brain surface where it is reabsorbed into the cerebral venous system (see Fig. 26.51, p. 1220).

The brain stem

In addition to containing all the sensory and motor pathways entering and leaving the hemispheres, the brain stem houses the nuclei of the cranial nerves and nuclei projecting to the cerebrum and cerebellum, as well as other important collections of neurons in the reticular formation (Fig. 26.5). The cranial nerve nuclei provide motor control to muscles of the head (including the face and eyes) and some in the neck, along with coordinating sensory input from the special sense organs and the face, nose, mouth, larynx and pharynx. They also control autonomic functions including pupillary, salivary

and lacrimal functions. The reticular formation is predominantly involved in the control of conjugate eye movements, the maintenance of balance, cardiorespiratory control and the maintenance of arousal.

Fig. 26.5 Anatomy of the brain stem.

The spinal cord

The spinal cord contains not only the afferent and efferent fibres arranged in functionally discrete bundles but also, in the grey matter, collections of cells which are responsible for lower-order motor reflexes and the primary processing of sensory information, including pain.

The peripheral nervous system

The sensory cell bodies of peripheral nerves are situated in the dorsal root ganglia in the spinal exit foramina, whilst the distal ends of their neurons are invested with various specialised endings for the transduction of external stimuli into nervous impulses. The motor cell bodies are in the anterior horns of the spinal cord. Motor neurons initiate muscle contraction by the release of acetylcholine across the neuromuscular junction, which results in change in potential in the muscle end plate. To increase the speed of impulse conduction, peripheral nerve axons are variably invested in myelin sheaths consisting of the wrapped membranes of Schwann cells. Thus, any peripheral nerve is made up of a combination of large, fast, myelinated axons (which carry information about joint position sense and commands to muscles) and smaller, slower, unmyelinated axons (which carry information about pain and temperature, as well as autonomic function).

The autonomic system

The autonomic system plays a key role in regulating the cardiovascular and respiratory systems, the smooth muscle of the gastrointestinal tract, and many exocrine and endocrine glands throughout the body. The autonomic system is controlled centrally by diffuse modulatory systems in the brain stem, limbic system and frontal lobes, which are concerned with arousal and background behavioural responses to threat. The output of the autonomic system is divided functionally and pharmacologically into two divisions: the parasympathetic and sympathetic systems.

The motor system

A programme of movement formulated by the pre-motor cortex is converted into a series of signals in the motor cortex which are transmitted to the spinal cord in the pyramidal tract (Fig. 26.6). This passes through the internal capsule and the ventral brain stem before decussating in the medulla to enter the lateral columns of the spinal cord. The pyramidal tract 'upper motor neurons' end by synapsing with the anterior horn cells of the spinal cord grey matter, which form the 'lower motor neurons'.

Movement of a body part necessitates changes in posture and alteration in the tone of many muscles, some quite distant from the part being moved. The motor system consists of a hierarchy of control mechanisms that maintain body posture and baseline muscle tone upon which a specific movement is superimposed. The lowest order of this hierarchy resides in the grey matter of the spinal cord which controls the muscle tone response to stretch, and the reflex withdrawal response to noxious stimuli. The afferent side of the stretch reflex is detected by muscle spindles that sense lengthening of the muscle and initiate a monosynaptic reflex leading to muscle contraction. The predominantly inhibitory descending input from the brain stem and cerebral hemispheres

Fig. 26.6 The motor system. Neurons from the motor cortex descend as the pyramidal tract in the internal capsule and cerebral peduncle to the ventral brain stem, where most cross low in the medulla (A). In the spinal cord the upper motor neurons form the cortico-spinal tract in the lateral column before synapsing with the lower motor neurons in the anterior horns. The activity in the motor cortex is modulated by influences from the basal ganglia and cerebellum. Pathways descending from these structures control posture and balance (B).

modulates the sensitivity of the stretch reflex. It is the state of this stretch reflex that is tested clinically when a patient's tendon reflexes are elicited and muscle tone is assessed. Polysynaptic connections in the spinal cord grey matter control more complex reflex actions of flexion and extension of the limbs that form the basic building blocks of coordinated actions, but these require control from the extrapyramidal system and the cerebellum to function usefully.

Lower motor neurons

Lower motor neurons in the anterior horn of the spinal cord innervate a group of muscle fibres termed a 'motor unit'. Loss of function of lower motor neurons causes loss of contraction within this unit, resulting in weakness and reduced muscle tone. Subsequently, denervated muscle fibres atrophy, causing muscle wasting, and depolarise spontaneously, causing 'fibrillations'. Except in the tongue, these are usually only perceptible on an electromyogram (EMG; p. 1143). With the passage of time, re-innervation from neighbouring intact motor neurons occurs but the neuromuscular junctions of the enlarged motor units are unstable and depolarise spontaneously, causing fasciculations (which are visible to the naked eye because the motor units are larger than normal). Fasciculations therefore imply chronic partial denervation with re-innervation.

Upper motor neurons

Upper motor neurons have an inhibitory influence on the function of anterior horn motor neurons. When upper motor neuron lesions occur, motor units have an exaggerated response to stretch. In the limbs, this results in reflex patterns of movement, such as flexion withdrawal to noxious stimuli and spasms of extension. An upper motor neuron lesion therefore manifests clinically with an increased muscle tone greater in the extensors of the lower limbs and the flexors of the upper limbs (spasticity), brisk tendon reflexes, and extensor plantar responses. On clinical examination, the increase in muscle tone varies with both the degree and the speed of stretch. The increased tone is more obvious with rapid stretch ('spastic catch'), but may suddenly give way with sustained tension (the 'clasp-knife' phenomenon). Spasticity takes time to develop and may not be present for weeks after the onset of an upper motor neuron lesion. Spasticity will be exacerbated by increased sensory input into the reflex arc, as may be caused by a pressure sore or urinary tract infection in a patient with a spinal cord lesion. The weakness found in upper motor neuron lesions is more pronounced in the extensors of the upper limbs and the flexors of the lower limbs.

The extrapyramidal system

Circuits between the basal ganglia and the motor cortex constitute the extrapyramidal system, which controls muscle tone, body posture and the initiation of movement (see Fig. 26.6). Lesions of the extrapyramidal system produce an increase in tone which is not an exaggerated response to stretch but is continuous throughout the range of movement at any speed of stretch ('lead pipe' rigidity). Involuntary movements are also a feature of extrapyramidal lesions (p. 1154), and tremor combined with rigidity produces typical 'cogwheel' rigidity. Rapid movements are slowed and clumsy (bradykinesia). Extrapyramidal lesions also cause postural instability which often precipitates falls.

The cerebellum

The cerebellum is responsible for fine-tuning and coordinating goal-directed movements initiated by the motor cortex. It also participates in the planning and learning of skilled movements through its reciprocal connections with the thalamus and cortex and in controlling speech. A lesion in a cerebellar hemisphere causes lack of coordination on the same side of the body. The initial part of movement is normal, but as the target is approached, the accuracy of the movement deteriorates, producing an 'intention tremor'. The distances of targets are misjudged (dysmetria), resulting in 'past-pointing'. The ability to produce rapid, accurate, regularly alternating movements is also impaired (dysdiadochokinesis). The central vermis of the cerebellum is concerned with the coordination of gait and posture. Disorders of this part therefore produce a characteristic ataxic gait (see below).

Speech

Speech is the process whereby vocal sounds are used to convey meaning between individuals. A large volume of the cerebral cortex is involved in this complex process, mostly in the dominant hemisphere (see Box 26.1,

Fig. 26.7 Areas of the cerebral cortex involved in the generation of spoken language.

p. 1136). The decoding of speech sounds (phonemes) is a function of the upper part of the posterior temporal lobe. The perception of these sounds as meaningful language, as well as the formulation of the language required for the expression of ideas and concepts, occurs predominantly in the lower parts of the anterior parietal lobe (the angular and supramarginal gyri). The temporal speech comprehension region is referred to as Wernicke's area. Other parts of the temporal lobe contribute to language processing in areas specialising in verbal memory, where lexicons of meaningful words are 'stored'. Parts of the non-dominant parietal lobe appear to contribute to non-verbal aspects of language in the recognition of meaningful intonation patterns of spoken words (prosody).

The language information generated in the temporal and parietal lobes passes anteriorly via the arcuate fasciculus to Broca's area in the posterior end of the inferior frontal gyrus on the dominant side. The motor commands generated in Broca's area then pass to the cranial nerve nuclei in the pons and medulla, as well as to the anterior horn cells in the spinal cord. Nerve impulses then travel to the lips, tongue, palate, pharynx, larynx and respiratory muscles via the facial nerve and cranial nerves 9, 10 and 12, and result in the series of ordered sounds known as speech (Fig. 26.7). The cerebellum also plays an important role in coordinating speech, and lesions of the cerebellum lead to a speech disorder termed dysarthria.

The somatosensory system

Somatic sensory information from the limbs ascends the nervous system in two anatomically discrete systems (Fig. 26.8). Fibres from proprioceptive organs and those mediating well-localised touch (including vibration) enter the spinal cord at the posterior horn and pass without synapsing into the ipsilateral posterior columns. Neural fibres conveying pain and temperature sensory information (nociceptive neurons) synapse with second-order neurons which cross the midline in the spinal cord before ascending in the

Fig. 26.8 The main somatic sensory pathways.

contralateral anterolateral spinothalamic tract to the brain stem.

The second-order neurons of the dorsal column sensory system cross the midline in the upper medulla to ascend through the brain stem. Here they lie just medial to

the (already crossed) spinothalamic pathway. Brain-stem lesions can therefore cause sensory loss affecting all modalities of the contralateral side of the body. Sensory loss on the face due to brain-stem lesions is dependent upon the anatomy of the trigeminal fibres within the brain stem. Fibres from the back of the face (near the ears) descend within the brain stem to the upper part of the spinal cord before synapsing, the second-order neurons crossing the midline and then ascending with the spinothalamic fibres. Fibres conveying sensation from progressively more forward areas of the face descend a shorter distance in the brain stem. Thus, sensory loss in the face from low brain-stem lesions is in a 'balaclava helmet' distribution, as the longer descending trigeminal fibres are affected. Both the dorsal column and spinothalamic tracts end in the thalamus, relaying from there to the parietal cortex.

Pain

Pain is a complex percept that is only partly related to activity in nociceptor neurons (Fig. 26.9). In the posterior horn of the spinal cord, the second-order neuron of the spinothalamic tract is subject to modulation by a number of influences in addition to its synapse with the fibres from nociceptors. Branches from the larger mechanoreceptor fibres destined for the posterior column also synapse with the second-order spinothalamic neurons and with interneurons of the grey matter of the posterior horn. The nociceptor neurons release neurotransmitters (such as substance P), in addition to excitatory transmitters, which influence the excitability of the spinothalamic neurons. Neurons in the posterior horn are also subject to modulation by fibres descending from the peri-aqueductal grey matter of the midbrain and raphe nuclei of the medulla. Neurons of this 'descending analgesia system' are activated by endogenous opiate (endorphin) peptides. The spinal cord's posterior horn is therefore much more than a way-station in the

Fig. 26.9 The pain perception system.

transmission of nociceptive sensory information; it is a complex organ for gating and modulating information about painful stimuli before this ascends in the spinothalamic tract. In the diencephalon the perception of pain is further influenced by the rich interconnections of the thalamus with the limbic system.

Sleep

The function of sleep is unknown but it appears to be necessary for the normal functioning of the brain. Normal sleep is controlled by the reticular activating system in the upper brain stem and diencephalon. During overnight sleep, a series of repeated cycles of electroencephalogram (EEG) patterns can be recorded. As drowsiness occurs, alpha rhythm disappears and the EEG gradually becomes dominated by deepening slow-wave activity. After 60–80 minutes this slow-wave pattern is replaced by a short spell of low-amplitude EEG background on which are superimposed rapid eye movements (REM). After a few minutes of REM sleep, another slow-wave spell starts and the cycle repeats several times throughout the night. The REM periods tend to become longer as the sleep period progresses. Dreaming takes place mostly during REM sleep. This is accompanied by muscle relaxation, penile erection and loss of tendon reflexes. REM sleep seems to be the most important part of the sleep cycle for refreshing cognitive processes. Deprivation of REM sleep causes tiredness, irritability and impaired judgement.

INVESTIGATION OF NEUROLOGICAL DISEASE

In the investigation of neurological disease, tests of function have a somewhat more restricted application than tests of structure (imaging). Nevertheless, recording

of electrical activity over the brain and assessment of nerve and muscle function are essential in certain conditions. The major tests are electroencephalography, evoked potentials, nerve conduction studies and electromyography.

Electroencephalography

The electroencephalogram (EEG) is used to detect electrical activity arising in the cerebral cortex. Although the EEG can only detect 0.1–1% of the brain's electrical activity at any one time, it is a clinically useful technique in the investigation of neurological disorders. The EEG involves placing an array of electrodes on the scalp to provide spatial information, and recording the resulting waveforms which are distinguished by their amplitude and frequency. When the eyes are shut, the most obvious frequency over the occipital cortex is 8–13 Hz; this is known as alpha rhythm, and disappears when the eyes are opened. Other frequency bands seen over different parts of the brain in different circumstances are beta (faster than 13/s), theta (4–8/s) and delta (slower than 4/s). Lower frequencies predominate in the very young and during sleep.

Various diseases cause abnormalities in the EEG. These may be continuous or episodic, focal or diffuse. Examples of continuous abnormalities include a global increase in fast frequencies (beta) seen with sedating drugs such as benzodiazepines, or marked focal slowing seen over a structural lesion such as a tumour or an infarct. The EEG is now seldom used to localise lesions, except in some patients with epilepsy (see p. 1176 and Fig. 26.10). It is useful in the investigation of patients who have disturbance of consciousness or disorders of sleep, in the diagnosis of cerebral diseases such as encephalitis, and in certain dementias such as sporadic Creutzfeldt-Jakob disease.

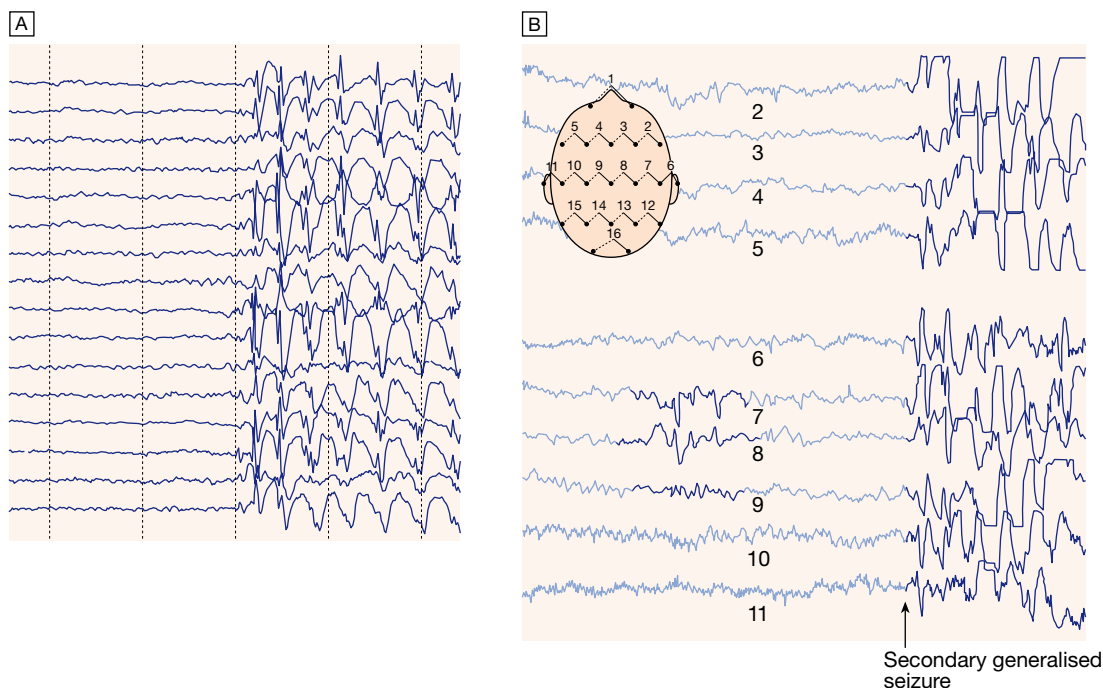

Fig. 26.10 EEGs in epilepsy. **A** Primary generalised epileptic discharge. **B** Focal sharp waves over the right parietal region (between electrodes 7 and 8—shown in purple) with secondary generalised discharge.

The EEG is predominantly used in the diagnosis and assessment of epilepsy, to distinguish the type of epilepsy and to determine the location of an epileptic focus, particularly if surgery is contemplated. It must be stressed that only in rare circumstances will an EEG provide unequivocal evidence of epilepsy; some 50% of patients with proven epilepsy have a normal 'routine' EEG, and, conversely, the presence of features often seen in association with epilepsy does not of itself make a diagnosis (although the false-positive rate for clear-cut epileptiform features is $< 1/1000$). In view of this, the EEG should be used as an adjunct to clinical evaluation in the assessment of patients with suspected epilepsy. During an epileptic seizure, high-voltage disturbances of the background activity ('transients') can occur. These may be generalised, as in the 3 cycle/s 'spike and wave' of childhood absence epilepsy (petit mal), or more focal, as in partial epilepsies (see Fig. 26.10). However, it is unusual to record a seizure itself, except in the case of childhood absence epilepsy which can often be provoked by hyperventilation. Nevertheless, it is often possible to detect 'epileptiform' abnormalities in between seizures in the form of 'spikes' and 'sharp waves' that lend support to a clinical diagnosis. The likelihood of detecting these abnormalities is enhanced by hyperventilation, photic flicker, sleep and some drugs.

It is possible to enhance the information provided by EEG using a variety of techniques. For example, the usual 30-minute recording session can be lengthened to 24 hours by the use of a lightweight tape recorder. The addition of video information to the EEG allows comparison of behaviour with cerebral activity. In special circumstances, electrodes can be surgically positioned, e.g. through the foramen ovale, to record from the inferior temporal surface.

Evoked potentials

The EEG can also be used to study evoked potentials (EPs), which can be measured following visual, auditory or somatosensory stimuli if the electrodes are appropriately positioned. If a stimulus is provided—for example, to the eye—it would normally be impossible to detect the small EEG response evoked over the occipital cortex as the signal would be lost in background noise. However, when assessing EPs, EEG data from 100–1000 repeated stimuli are averaged electronically, the noise is removed and an EP is recorded whose latency (the time interval between stimulus onset and the maximum positive value of the evoked potential, P_{100}) and amplitude can be measured. In clinical practice, visual EPs are the most commonly used, but with the advent of MRI are now restricted to specialised indications, such as providing a semi-objective measure of visual function (Fig. 26.11). Abnormalities of the EP indicate damage to the relevant pathway, in the form of either a conduction delay (increased latency) or reduced amplitude, or both.

Nerve conduction studies

Nerve conduction studies (NCS) involve placing electrodes on the skin overlying peripheral nerves and recording compound action potentials (the sum of all the individual nerves' action potentials) following nerve stimulation as the impulse travels down the nerve. A normal compound action potential has an amplitude

Fig. 26.11 Visual evoked responses (VER) recording showing abnormal delay on right. The latency of the P_{100} (the point of maximum positivity) on the left is 90 ms, that on the right 115 ms.

of 5–30 microvolts, depending upon the nerve; if the recorded potential is smaller than expected, this provides evidence of a reduction in the overall number of functioning axons. By measuring the response latency to stimulation of a nerve at two different points along its length, it is possible to calculate nerve conduction velocities (NCVs). This can be done for both sensory and motor nerves; typical values are 50–60 m/s. Slowing of conduction velocity is suggestive of peripheral nerve demyelination, which may be either diffuse (as in a demyelinating peripheral neuropathy) or focal (as in pressure palsies or conduction block). The principal use of NCS is to identify damage to peripheral nerves, and to determine whether the pathological process is focal or diffuse, and whether the damage is principally axonal or demyelinating. It is also possible to obtain some information about nerve roots by more sophisticated analysis of responses to impulses initially conducted antidromically (the 'wrong' way) back up to the spinal cord, and then returning orthodromically (the 'right' way) down to the stimulation point ('F waves'). Central conduction times can also be measured using electromagnetic induction of action potentials in the cortex or spinal cord by the local application of specialised coils. This is particularly useful in the investigation of disorders of the spinal cord and non-organic illness.

Electromyography

Electromyography (EMG) involves recording compound motor action potentials (CMAPs) over muscles in response to motor nerve stimulation (Fig. 26.12). These are easier to record than nerve potentials because the muscle amplifies the response, typical amplitudes being 1–20 millivolts. Fine concentric needle electrodes are inserted into muscle belly and the potentials from individual motor units recorded. It is also possible to

Fig. 26.12 Motor nerve conduction tests. Bipolar electrodes (R) on the muscle (abductor pollicis brevis here) record the compound motor action potential (CMAP) from stimulation at the median nerve at the elbow (S_1) and from the wrist (S_2). The CMAP amplitude is related to the number of axons, and the velocity can be determined if the distance between the two stimulating electrodes (d) is known. The latency (L) of the F wave is a measure of the conduction time in the nerve proximal to the elbow (see text). (NCV = nerve conduction velocity)

record abnormal spontaneous activity arising from muscles at rest, such as fibrillations (a sign of denervation) or myotonic discharges. Abnormalities in the shape and size of muscle potentials can help in the differential diagnosis of denervation and structural muscle diseases. Myopathies caused by metabolic abnormalities (causing electromechanical dissociation rather than loss of fibre structure) show no changes on needle EMG. Electromyography can also be used to investigate the neuromuscular junction. Repetitive stimulation of a nerve with trains of electrical impulses at 3–15/s does not normally result in a significant fall-off in the amplitude of the resulting muscle action potential. However, such a decrement is seen in myasthenia gravis (p. 1231) and provides one of the key diagnostic features. Augmentation of the response to repetitive stimulation is seen in the Lambert-Eaton myasthenic syndrome, though usually at higher stimulation frequencies.

Neuroimaging

Imaging is crucial to the identification of lesions of the nervous system in disease. Various techniques are used, including X-rays (plain X-rays, computed tomography (CT), CT angiography, myelography and angiography), magnetic resonance (MR imaging—MRI, or MR angiography—MRA), ultrasound (Doppler imaging of blood vessels) and radioisotopes (single photon emission computed tomography—SPECT, and positron emission tomography—PET). The indications, usefulness and limits of each technique are listed in Box 26.2. The choice of technique depends upon the area of the neuraxis that is being investigated.

Head and orbit

The use of plain skull X-rays is largely restricted to the diagnosis of fractures and sinus disease, and CT or MRI is needed to image pathology inside the skull. Which is used depends on what information is being sought. CT will show bone and calcium well, and will easily image collections of blood. It will also detect abnormalities of the brain and ventricles, such as atrophy, tumours, cysts, abscesses, vascular lesions and hydrocephalus. Diagnostic yield is often improved by the use of intravenous contrast and spiral CT methods. It is, however, limited in its ability to image the posterior fossa (because of the surrounding bone density), and it is poor at detecting abnormalities of white matter and at allowing detailed analysis of grey matter.

MRI is much more useful in the investigation of posterior fossa disease, as it is not affected by the surrounding bone. It is much more sensitive than CT to abnormalities of white and grey matter and is therefore useful in the investigation of inflammatory conditions such as multiple sclerosis, and in investigating epilepsy. Diffusion weighted MRI is particularly useful in diagnosing acute ischaemic stroke. MRI can also provide additional information about structural brain lesions, which may complement that available from CT. It is also useful in imaging the orbits, where special imaging sequences can be used to compensate for orbital fat and thereby allow clear views of extraocular muscles, optic nerve and other orbital structures.

Blood flow and metabolic function of the cerebral hemispheres can be assessed by using either SPECT or PET. Examples of brain imaged by the various techniques are shown in Figure 26.13.

26.2 Techniques available for imaging the nervous system

Technique	Principle	Applications	Advantages	Disadvantages	Comments
X-ray	Attenuation of X-ray beam by radio-opaque tissues and substances (bone, calcium, metal, iodinated contrast)	Plain X-rays CT, CTA Radiculography Myelography Intra-arterial angiography	Widely available Relatively cheap Relatively quick	Ionising radiation Reactions to contrast Myelography and angiography are invasive and thus carry risk	X-rays only used for showing fractures or foreign bodies. CT investigation of choice for stroke Intra-arterial angiography still 'gold standard' for vascular lesions
Magnetic resonance imaging (MRI)	Magnetic resonance of different tissues depends largely on free hydrogen/water content; signals changed by movement (e.g. flowing blood)	Structural imaging MRA Functional MRI MR spectroscopy	High-quality soft tissue imaging Good views of posterior fossa and temporal lobes No ionising radiation Non-invasive	Expensive Less widely available MRA looks at blood flow not vessel anatomy Scanners claustrophobic Pacemakers contraindicate MRI. Complications of contrast (gadolinium)	Increasing application Functional MR and spectroscopy still mainly research tools
Ultrasound	Echoes from high-frequency sound source localise structure; Doppler principle used to measure flow rate	Doppler Duplex scans	Cheap Quick Non-invasive	Operator-dependent Poor anatomical definition	Useful as screening tool to assess need for carotid endarterectomy
Radio-isotope	Radio-labelled isotopes	Isotope brain scan SPECT PET	In vivo imaging of functional anatomy (ligand binding, blood flow)	Poor spatial resolution Ionising radiation Expensive (especially PET) Not widely available	Isotope scans obsolete. SPECT and PET mainly research tools but being introduced clinically for management of epilepsy and dementia

(CT = computed tomography; MRA = magnetic resonance angiography; MRI = magnetic resonance imaging; PET = positron emission tomography; SPECT = single photon emission computed tomography)

Cervical and thoracic spine

Plain X-rays are useful in the investigation of structural damage to vertebrae, such as that resulting from trauma and from degenerative and inflammatory disease. They can also provide implicit information about intervertebral disc disease, but not detailed information about the spinal cord or nerve roots, for which myelography or MRI is needed. Use of myelography has declined with the advent of MRI, which is the imaging modality of first choice. However, myelography is still used if MRI is not available, if it is contraindicated, or if the patient cannot tolerate lying within the scanner because of claustrophobia. Myelography involves injecting radio-opaque contrast into the lumbar theca and then moving the contrast up to the cervical region by tilting the patient. The contrast outlines the nerve roots and spinal cord, thereby providing information about abnormal structure. Examples of the neck imaged by plain X-rays, myelography and MRI are shown in Figure 26.14.

Lumbo-sacral region

Plain X-rays are of value in the investigation of structural abnormalities of the lumbar spine and but are of no value in the assessment of nerve roots or the spinal canal. Contrast injection into the thecal space can be used to outline the lower nerve roots (radiculography), or it can be run up to outline the conus and spinal cord (myelography). The information obtained may be enhanced by the additional use of CT following myelography (contrast CT). Non-contrast CT of the lumbar spine can only be used to image the vertebrae and discs. As with the cervical spine, MRI provides a non-invasive way of obtaining high-resolution images of both the vertebral column and the relevant neural structures.

Blood vessels

Various techniques are available to investigate extra-ranial and intracranial blood vessels. The least invasive is ultrasound (Doppler or duplex scanning), which is

Fig. 26.13 Different techniques of imaging the head and brain. **A** Skull X-ray showing lytic vault lesion (eosinophilic granuloma—arrow). **B** CT showing complete middle cerebral artery infarct (arrows). **C** MRI showing widespread areas of high signal in multiple sclerosis (arrows). **D** SPECT after caudate infarct showing relative hypoperfusion of overlying right cerebral cortex (arrows).

used to investigate the carotid and the vertebral arteries in the neck, usually as part of the investigation of stroke. In skilled hands, reliable information can be provided about the degree of arterial stenosis, and the technique often gives useful anatomical information, such as the presence of ulcerated plaques. Information concerning the blood flow in the intracerebral vessels is also becoming increasingly possible to obtain using transcranial Doppler. While the anatomical resolution of Doppler imaging is limited, it is improving with increased experience and many centres no longer require formal angiography before performing carotid endarterectomy (p. 1189). This has the advantage of eliminating the small but significant risk of stroke or even death associated with catheter angiography.

Blood vessels can be outlined by the injection of radio-opaque contrast intravenously or intra-arterially. The X-ray images obtained can be enhanced by the use of computer-assisted digital subtraction or of spiral CT. Using the intravenous route, large amounts of contrast need to be injected and the images obtained are not generally as good as with the intra-arterial route. However, intra-arterial injections are accompanied by a higher complication rate. Intra-arterial angiography is still required to delineate lesions of the extracranial carotid artery prior to endarterectomy, and is also used to investigate abnormalities of intracerebral vessels such as arterial (berry) aneurysms or arteriovenous malformations, or to delineate the blood supply of tumours prior to surgery.

Fig. 26.14 Different techniques of imaging the cervical spine. **A** Lateral X-ray showing bilateral C6/7 facet dislocation. **B** Myelogram showing widening of cervical cord due to astrocytoma (arrows). **C** MRI showing posterior epidural compression from adenocarcinomatous metastasis to the posterior arch of T1 (arrows).

Fig. 26.15 Different techniques of imaging blood vessels. **A** Doppler scan showing 80% stenosis of internal carotid artery (arrow). **B** 3-D reconstruction of CT angiogram showing stenosis at the carotid bifurcation (arrow). **C** MR angiogram showing giant aneurysm at the middle cerebral artery bifurcation (arrow). **D** Intra-arterial angiography showing arteriovenous malformation (arrow).

Flowing blood can be detected by specialised MR sequences in MR angiography. The anatomical resolution is still not comparable to that of intra-arterial angiography, but the investigation is non-invasive and is replacing angiography in most diagnostic settings, except when MRI cannot be performed because of contraindications, such as in patients with pacemakers or in claustrophobic individuals who cannot tolerate entering the MRI scanner. Examples of these different techniques are given in Figure 26.15.

Routine blood tests

Many systemic conditions that affect the nervous system can be diagnosed with the help of blood tests: for example, confusion due to hypothyroidism, a stroke due to systemic lupus erythematosus, ataxia due to vitamin B₁₂ deficiency, myelopathy due to syphilis. Acanthocytes may assist in the diagnosis of neuroacanthocytosis, creatine kinase in muscle diseases, and copper studies in Wilson's disease. Blood tests relating to general medical conditions that affect the nervous system are described in the sections dealing with individual conditions.

Immunological tests

A number of specific immunological tests are used in the diagnosis of neurological disorders. These include antibodies to acetylcholine receptors and muscle-specific tyrosine kinase (MuSK), seen in myasthenia gravis, and to voltage-gated calcium channels in Lambert-Eaton myasthenic syndrome. Antibodies to different types of ganglioside (glycoproteins expressed on nerve membranes) can be seen in various types of neuropathy, including multifocal motor neuronopathy and the Guillain-Barré syndrome (particularly the Miller-Fisher variant). Also, antineuronal antibodies provide markers of paraneoplastic cerebellar or neuropathic syndromes. Antibodies to basal ganglia neurons are found in Sydenham's chorea and encephalitis lethargica.

Genetic testing

An increasing number of inherited neurological conditions can now be diagnosed by DNA analysis (p. 56). These include diseases caused by increased numbers of trinucleotide repeats, such as Huntington's disease, myotonic dystrophy and some types of spinocerebellar ataxia. Also, defects of mitochondrial DNA can be detected in many conditions, including Leber's hereditary optic neuropathy, some syndromes causing epilepsy and stroke-like syndromes.

Lumbar puncture

Lumbar puncture is indicated in the investigation of infections (meningitis or encephalitis), subarachnoid haemorrhage, inflammatory conditions (multiple sclerosis, sarcoidosis and cerebral lupus) and some neurological malignancies (carcinomatous meningitis, lymphoma and leukaemia); it is also used to measure CSF pressure (in idiopathic intracranial hypertension). It is, of course, part of the procedure of myelography, and can be used in therapeutic procedures, either to lower CSF pressure or to administer drugs. Lumbar puncture involves inserting a needle between lumbar spinous processes (usually between L3 and L4) through the dura and into the CSF under local anaesthetic. Intracranial pressure can be measured and CSF removed for analysis. CSF is normally clear and colourless and the tests that are usually performed include a naked eye examination of the CSF, centrifugation to determine the colour of the supernatant (yellow, or xanthochromic, some hours after subarachnoid haemorrhage), biochemical analysis (glucose, total protein, and protein electrophoresis to detect oligoclonal bands), microbiological analysis (polymerase chain reaction (PCR) for herpes simplex or tuberculosis), immunology (paraneoplastic antibodies) and cytology (to detect malignant cells). Normal values and various abnormalities found in diseases are shown in Box 26.3.

26.3 How to interpret CSF results

	Normal	Subarachnoid haemorrhage	Acute bacterial meningitis	Viral meningitis	Tuberculous meningitis	Multiple sclerosis
Pressure	50–250 mm of water	Increased	Normal/increased	Normal	Normal/increased	Normal
Colour	Clear	Blood-stained Xanthochromic	Cloudy	Clear	Clear/cloudy	Clear
Red cell count ($\times 10^6/L$)	0–4	Raised	Normal	Normal	Normal	Normal
White cell count ($\times 10^6/L$)	0–4	Normal/slightly raised	1000–5000 polymorphs	10–2000 lymphocytes	50–5000 lymphocytes	0–50 lymphocytes
Glucose	> 60% of blood level	Normal	Decreased	Normal	Decreased	Normal
Protein	< 0.45 g/L	Increased	Increased	Normal/increased	Increased	Normal/increased
Microbiology	Sterile	Sterile	Organisms on Gram stain and/or culture	Sterile/virus detected	Ziehl-Nielsen/auramine stain or tuberculosis culture positive	Sterile
Oligoclonal bands	Negative	Negative	Can be positive	Can be positive	Can be positive	Often positive

If there is a space-occupying lesion in the head, lumbar puncture can result in a shift of intracerebral contents downwards, towards and into the spinal canal. This process is known as coning, and is potentially fatal (p. 1216). Consequently, lumbar puncture is contraindicated if there is any clinical suggestion of raised intracranial pressure (papilloedema), depressed level of consciousness, or focal neurological signs suggesting a cerebral lesion, until imaging of the head (by CT or MRI) has excluded a space-occupying lesion or hydrocephalus. Lumbar puncture is contraindicated in the presence of thrombocytopenia or disseminated intravascular coagulation, and in those on warfarin or heparin therapy, unless specific measures are taken to compensate for the clotting deficit on a temporary basis. Lumbar puncture can be safely performed in patients on antiplatelet drugs such as aspirin, clopidogrel and low-dose heparin.

About 30% of lumbar punctures are followed by a headache, which is thought to be due to reduced CSF pressure. The risk of this can be reduced by using smaller needles. Other minor complications involve transient radicular pain, and pain over the lumbar region during the procedure. Infections such as meningitis are extremely rare following lumbar puncture, provided that an aseptic technique is used.

Biopsy

Nerve and muscle biopsies are occasionally required for the diagnosis of a number of neurological conditions, and it is occasionally necessary to biopsy the brain or meninges.

Nerve biopsies are sometimes necessary to investigate the cause of peripheral neuropathy. Usually, the sural nerve is biopsied at the ankle or the radial nerve at the wrist. Histological examination can help identify underlying causes such as vasculitides or infiltrative disorders like amyloid. Nerve biopsy should not be undertaken lightly since there is an appreciable morbidity; the procedure should be reserved for cases where the diagnosis is in doubt after routine investigations and where it will influence management.

Muscle biopsy is performed much more frequently and is indicated for investigation of primary muscle disease to distinguish neurogenic wasting from myositis and myopathy. These conditions can usually be distinguished by histological examination, and enzyme histochemistry can also be performed when mitochondrial diseases and storage diseases are suspected. The quadriceps muscle is most commonly biopsied but other muscles may also be sampled if they are involved clinically. Although pain and infection can follow the procedure, these are much less of a problem than after nerve biopsy.

Brain biopsy is seldom required since, in most cases, the cause of intracerebral lesions can be inferred from clinical evaluation and neuroimaging. However, there are situations in which it is important to obtain tissue for histological examination: for example, in unexplained degenerative diseases such as unusual cases of dementia and in patients with brain tumour. Most intracranial lesions can now be biopsied stereotactically through a burrhole in the skull and the complication rate of this technique is much lower than that of open craniotomy. Nevertheless, haemorrhage, infection and death still occur and brain biopsy should only

be considered if a diagnosis cannot be reached in any other way.

PRESENTING PROBLEMS IN NEUROLOGICAL DISEASE

Headache and facial pain

Headache is a common presenting complaint but, unless it is accompanied by other symptoms or neurological signs, is seldom associated with significant neurological disease. Nevertheless, patients suffering from headache usually fear serious brain disease and, in order to manage them effectively, it is important to be aware of this. The likely underlying cause of headache or facial pain can usually be identified after taking a careful history and performing the appropriate general and neurological examinations (Box 26.4). Unless the history is suggestive of structural disease or another secondary cause, patients with headache who are normal on neurological examination are unlikely to have a serious disorder, however distressing their symptoms. The features of a patient's history that are helpful in making a clear diagnosis of the cause of a headache are shown in Box 26.5. In such cases, further investigations should be avoided if possible, and the patient can be reassured and provided with symptomatic treatment.

26.4 Common and important headache and facial pain syndromes

Primary headache syndromes

- Tension-type headache (persistent daily headache)
- Migraine
- Cluster headache
- Trigeminal neuralgia
- Atypical facial pain
- Benign paroxysmal headaches (see Box 26.29, p. 1170)

Secondary causes of headache

- Intracerebral bleeding (subdural haematoma, subarachnoid or intracerebral haemorrhage)
- Raised intracranial pressure (brain tumour, idiopathic intracranial hypertension)
- Infection (meningitis, encephalitis, brain abscess)
- Inflammatory disease (temporal arteritis, other vasculitis, arthritis)
- Post-herpetic neuralgia
- Referred pain from other structures (orbit, temporomandibular joint, neck)

26.5 How to take a history of headache

During history-taking, determine

- The overall pattern (intermittent or continuous)
- The speed of onset
- The time of day of onset of maximal pain
- The effect of posture, coughing and straining
- The location of the pain
- Any associated symptoms

Serious acute neurological disease should always be considered in patients with headaches of very sudden onset. Subarachnoid haemorrhage (p. 1190) causes a very sudden headache which may or may not be localised, although only one person in eight who has such a 'thunderclap' headache will have had a subarachnoid haemorrhage. A patient with subarachnoid haemorrhage almost invariably develops other symptoms including vomiting and neck stiffness, although the latter may take some hours to develop. The main differential diagnosis in a patient with a sudden severe headache is between subarachnoid haemorrhage (see Fig. 26.35, p. 1190) and a migraine variant. Meningitis occasionally presents apoplectically, but the headache is usually less dramatic in onset.

Headache coming on over a matter of hours is less likely to be associated with structural disease and more likely to be due to migraine, unless accompanied by other significant symptoms or signs. Patients with bacterial meningitis are usually generally ill and pyrexial, and exhibit meningism (p. 1205). Patients with viral meningitis may present with a pyrexia and quite sudden and severe headache coming on over an hour or so, but are less likely to have neck stiffness or other signs of meningism. Migraine headaches (p. 1169) may be accompanied or preceded by vomiting and focal neurological symptoms (usually in the form of zigzag 'fortification spectra' or tingling moving slowly over part of the body).

When headaches are intermittent rather than continuous over a period of days or weeks, they are most likely to be migrainous but it is worth while paying attention to the time of day they occur and to the presence or absence of precipitating factors. The headache of raised intracranial pressure is present on waking and often resolves or improves as the patient becomes upright (reducing the intracranial pressure) or takes simple analgesia (Box 26.6). It is unusual for a patient to present with such a headache alone since it is usually not sufficiently severe to cause alarm; the presentation of the causative mass lesion is more often provoked by a seizure or by focal neurological dysfunction (aphasia, hemiplegia etc.). The exceptions to this are patients with acute hydrocephalus who present with a more severe headache. As with other causes of raised intracranial pressure, this is worse when lying, bending forward or coughing, and frequently causes vomiting in the morning (especially in children). Hydrocephalus may cause no other symptoms except gait ataxia, although examination may reveal papilloedema.

Headaches that persist for weeks, are present all day and are poorly responsive to simple analgesia are very likely to be tension-type headaches, whatever their other characteristics. Headaches so well localised by the patient that a finger is used to locate the exact

26.7 Headaches in old age

- **Prevalence:** less common than in younger people.
- **Important causes:** giant cell arteritis, trigeminal neuralgia and post-herpetic neuralgia.
- **Less common causes:** migraine and tension headache.

spot on the skull are never associated with significant disease.

In a patient over 60 years with head pain localised to one or both temples, giant cell arteritis (p. 1115) should be considered, especially if the temporal pulses are not palpable and/or the arteries are enlarged and tender (Box 26.7).

Ocular pain

Pain in and around the eye, when not caused by ocular disease, can operationally be considered as a type of headache. This includes the dramatic pain of cluster headache (p. 1170) and rarer variants. Rarely, inflammatory or infiltrative lesions at the apex of the orbit or the cavernous sinus may cause pain in or around the eye, but tell-tale signs from involvement of the ocular motor nerves usually accompany this. Pain in the eye may accompany disorders of the carotid artery, particularly dissections, and may then be accompanied by a Horner's syndrome.

Facial pain

Pain in other parts of the face can be due to problems with the teeth or the temporo-mandibular joint. Inflamed nasal sinuses are seldom the cause of lasting facial pain in the absence of obvious nasal congestion. The very rare but serious condition of subdural empyema (p. 1212) needs to be considered if 'sinusitis' is followed by very severe unilateral facial pain and signs of cerebral irritation (seizures and/or obtundation). Destructive lesions of the trigeminal nerve causing pain are extremely rare since such lesions usually cause loss of sensation in the nerve's territory rather than pain.

Most patients with persisting pain in the face have trigeminal neuralgia, atypical facial pain or post-herpetic neuralgia. The main distinction between these is in the nature of the pain. In trigeminal neuralgia, the pain is very brief, though severe and recurrent, described as 'like lightning' and most frequently felt in the second and third divisions of the nerve. Atypical facial pain, on the other hand, is continuous and unremitting, and is centred over the maxilla, usually on the left side. It occurs most frequently in middle-aged women. Post-herpetic neuralgia is continuous and is felt as a burning pain throughout the affected territory, which is often very sensitive to light touch. The cause is usually obvious from a history of 'shingles' in the ophthalmic division of the trigeminal nerve.

26.6 Headache of raised intracranial pressure

- Worse in morning, improves through the day
- Associated with morning vomiting
- Worse bending forward
- Worse with cough and straining
- Relieved by analgesia
- Dull ache, often mild

Dizziness, blackouts and 'funny turns'

Episodes of lost or altered consciousness are a frequent symptom in primary care and in hospital practice (Box 26.8). A patient may complain of 'black-ing out', 'going dizzy', 'having a funny turn' or other

26.8 Dizziness in old age

- **Prevalence:** common, affecting up to 30% of people aged > 65 years.
- **Symptoms:** most frequently described as a combination of unsteadiness and lightheadedness.
- **Most common causes:** postural hypotension, cardiovascular disease, cervical spondylosis. Many patients have more than one underlying cause.
- **Arrhythmia:** can present with lightheadedness either at rest or on activity.
- **Anxiety:** frequently associated with dizziness, but rarely the only cause.
- **Falls:** multidisciplinary work required if dizziness is associated with falls.

local variants. The first task is to discover exactly what the patient means by the term used (Fig. 26.16). Some patients, for example, mean by 'blackout' that their vision darkens without alteration in consciousness (defined here as an awareness of the environment and ability to respond to it). More often 'blackout' is used to describe

an episode of lost consciousness with or without falling down. The terms 'blackout' and 'funny turn' can also be used to refer to transient periods of amnesia, when the patient loses memory for a period of time. 'Dizziness' is used frequently to describe an abnormal perception of movement of the environment (vertigo), but may be used to mean a feeling of faintness, some other alteration of consciousness, or unsteadiness (p. 1171).

After a careful history from the patient, supplemented by a witness account, it should be clear whether the patient is describing an episode of loss of consciousness, altered consciousness, vertigo, transient amnesia or something else. The former two symptoms suggest a problem in mechanisms maintaining normal awareness. Vertigo is caused by an alteration in function of the peripheral vestibular organs or the central control mechanisms of balance and posture.

Loss of consciousness

Loss of consciousness, other than in sleep, suggests a global dysfunction of the brain. This most commonly occurs because of a recoverable loss of blood supply to the whole brain (syncope or faint, see below). Alternatively, loss of consciousness can occur due to

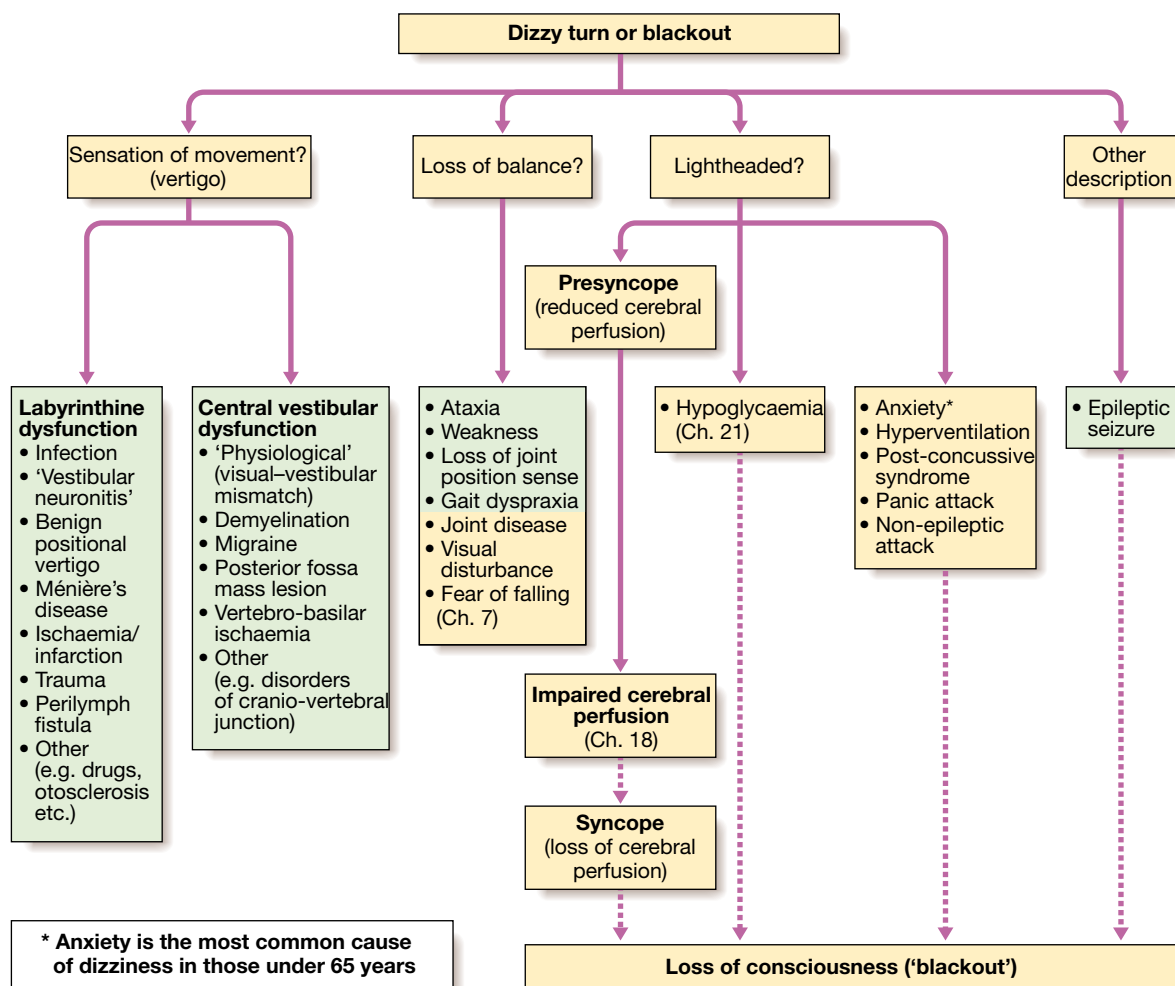

Fig. 26.16 A diagnostic approach to the patient with dizziness, funny turns or blackouts. (Neurological causes are shown in green.)

26.9 How to differentiate seizures from syncope

	Seizure	Syncope
Aura (e.g. olfactory)	+	–
Cyanosis	+	–
Tongue-biting	+	–
Post-ictal confusion	+	–
Post-ictal amnesia	+	–
Post-ictal headache	+	–
Rapid recovery	–	+

a sudden electrical dysfunction of the brain, as occurs during a seizure. Whilst most episodes of loss of consciousness are due to syncope or seizures, psychogenic blackouts or non-epileptic seizure can also occur and need to be considered in the differential diagnosis.

The distinction of a seizure from syncope can only be made from the patient's history, with help from a witness to the attack. No amount of investigation can replace a clear history in these circumstances. Features in the history useful in distinguishing a seizure from syncope are shown in Box 26.9.

Syncope

Typically, syncope is preceded by a brief feeling of light-headedness. There then follows a darkening of vision and there may be a ringing in the ears. Vasovagal syncope (p. 551) may be provoked by an emotional event or venepuncture, and usually occurs from the standing position. Cardiac syncope (p. 551), caused by a sudden decline in cardiac output, may be provoked by exertion in patients with severe aortic stenosis or may occur without warning in patients with cardiac arrhythmia. In vasovagal syncope, the loss of consciousness is gradual and brief, and the patient recovers quickly without confusion as long as he or she has assumed the horizontal position. It is rare for the syncope to cause injury and there is no amnesia for events that occur after regaining awareness. During a syncopal attack, incontinence of urine can occur and there is often stiffening and brief twitching of the limbs, but tongue-biting never occurs.

Seizures

The diagnosis of major seizures in which there is loss of consciousness, falling to the ground and convulsion (p. 1172) is easy but patients may also present with just a history of 'blackouts', particularly if the attacks were witnessed. Minor seizures, such as absences (p. 1175) or complex partial seizures (p. 1175), which cause alteration of consciousness without the patient falling to the ground, may also be described by patients as 'blackouts'.

Vertigo

Vertigo is defined as an abnormal perception of movement of the environment and occurs because of an abnormality in sensory information from the eyes, limb proprioception and the vestibular system about a person's position in space. Vertigo commonly arises from inappropriate input from the labyrinthine apparatus and is within the experience of most people, since this is the 'dizziness' which occurs after someone has spun round

vigorously and then stops. Vertigo caused by labyrinthine disorders is usually short-lived, though it may recur, whilst vertigo arising from central (brain-stem) disorders is often persistent and accompanied by other signs of brain-stem dysfunction. A careful analysis of the history will reveal the likely cause in most patients.

Sleep disturbance

Disturbances of sleep are common and in many cases are not due to neurological disease. Patients may complain of insomnia (difficulty sleeping), excessive daytime sleepiness, disturbed behaviour during night-time sleep, parasomnia (sleep walking and talking, or night terrors) or disturbing subjective experiences during sleep and/or its onset (nightmares, hypnagogic hallucinations, sleep paralysis). A careful history usually allows specific causes of sleep disturbance to be identified and these are discussed in more detail on page 1179.

Weakness

Establishing the diagnosis in a patient with weakness requires the application of basic anatomy, physiology and some pathology to the interpretation of the history and clinical findings. Points to consider are shown in Box 26.10, while physical signs and different patterns of motor loss are described in Box 26.11 and Fig. 26.17.

Weakness in only some muscles in a limb suggests a problem in the peripheral nerve(s) or motor root(s). Weakness of the whole of one limb may be due to problems in the brachial or lumbosacral plexus, or to a central lesion. Weakness in both lower limbs (paraparesis) or in all four limbs (tetraparesis) suggests either a spinal cord lesion or a diffuse peripheral nerve problem such as Guillain-Barré syndrome (p. 1129). In such cases the condition of the reflexes is the most discriminating sign. The reflexes are absent in the Guillain-Barré syndrome (or other lower motor nerve lesions) and brisk in spinal cord (upper motor neuron) lesions. The paraparesis or tetraparesis of spinal cord lesions may be associated with a specific pattern of sensory loss (p. 1156) which gives a clue to the site of the cord lesion.

Patients with a bradykinetic limb often complain of weakness. Therefore if there are no reflex, wasting or

26.10 How to assess weakness

Distribution

- A few muscles
- A limb
- Both lower limbs (paraparesis)
- Both limbs on one side (hemiparesis)

Type of weakness

- Upper motor neuron lesion
- Lower motor neuron lesion

Evolution of the weakness

- Sudden and improving
- Gradually worsening over days or weeks
- Evolving over months or years

26.11 Physical signs in different types of motor deficit

Clinical sign	Upper motor (pyramidal) lesion	Lower motor lesion	Extrapyramidal lesion	Cerebellar lesion	Functional
Power	Weak Upper limbs: extensors weaker Lower limbs: flexors weaker	Weak	No weakness	No weakness	Give-way weakness
Wasting	None	Yes, after interval	None	None	None
Fasciculation	None	Yes, after interval	None	None	None
Tone	Spastic increase (after interval)	Flaccid from onset	Rigidity (cogwheel)	Normal/reduced	Normal
Reflexes	Increased	Reduced/absent	Normal	Normal	Normal
Plantar response	Extensor	Flexor	Flexor	Flexor	Flexor
Coordination	Reduced by weakness	Reduced by weakness	Normal (but slowed)	Impaired	Normal (may be laborious)

sensory changes when a patient is complaining of weakness in a limb, extrapyramidal signs of rigidity (cogwheel or leadpipe) and bradykinesia should be sought. Patients with Parkinson's disease usually present with symptoms in one limb that may be described as weak and clumsy, especially for fine manipulations. Often the typical rest tremor is a clue to the diagnosis.

Weakness down one side of the body (hemiparesis) is almost always due to a cerebral hemisphere lesion, although it can be caused by spinal cord or brain-stem lesions. The lesion is of upper motor neuron type, and the site and often the size of the lesion can be deduced

by the coexistence of other signs and symptoms, such as higher cerebral function abnormalities or sensory change. The evolution of a motor deficit over time can give a clue to the underlying pathology (Box 26.12).

Some patients may present with weakness which is not due to organic disease but which is caused by psychiatric illness such as a conversion disorder (p. 251). This type of weakness does not conform to known pathophysiological patterns and the deficit cannot be attributed to a lesion in a specific anatomical site in the nervous system. During formal testing of power, a patient's strength may appear to 'give way', yet demon-

Fig. 26.17 Patterns of motor loss according to the anatomical site of the lesion.

26.12 Limb weakness: assessing the cause from typical patterns of evolution

Vascular lesions

- Sudden onset (over minutes) followed by a stable period and gradual recovery

Neoplastic lesions

- Gradual in onset and progressive over weeks or months

Inflammatory lesions

- Fairly acute in onset (over a few days), persist for a time and then improve (e.g. in multiple sclerosis)

Degenerative disorders

- Evolve over months or years (e.g. motor neuron disease or cervical spondylotic myelopathy)

strate bursts of full power at other times. Alternatively, if a 'weak' limb is held up and then suddenly allowed to drop, the limb may be momentarily held up, something which does not happen in organic weakness. Sometimes 'non-organic' weakness may occur in combination with weakness due to a neurological disorder and physical signs such as 'give-way weakness' therefore do not necessarily imply absence of pathology. Great care should therefore be exercised in making the diagnosis of functional weakness and all unusual manifestations of nervous system disease should be considered before such a diagnosis is made.

Abnormal gait

Many neurological disorders are associated with an abnormal gait and observing a patient walk can be very informative and assist in coming to a neurological diagnosis. It is also an important element of assessing disability. Various patterns of weakness, loss of coordination and proprioceptive sensory loss produce an abnormal gait. Neurogenic gait disorders need to be distinguished from those due to skeletal abnormalities, usually characterised by pain producing an antalgic gait, or limp. Gaits that do not fit either pattern may be due to psychiatric disorders and are usually incompatible with any anatomical or physiological deficit.

Pyramidal gait

Upper motor neuron lesions cause a so-called pyramidal gait in which the upper limb is held in flexion while the ankle joint in the lower limb is kept relatively extended. This causes a tendency for the toes to strike the ground while walking and in an attempt to overcome this, the leg is swung outwards at the hip (circumduction). Nevertheless, the affected foot still scuffs along the ground and the shoe on the affected side may be worn at the toes as evidence of this type of gait. In hemiplegia, the asymmetry between the affected and normal sides is obvious in walking, but in paraparesis both lower limbs swing slowly from the hips in extension and are dragged stiffly over the ground. This can often be heard as well as seen.

Foot drop

Toe strike follows heel strike in a normal gait. If there is a lower motor neuron lesion affecting the lower limb,

weakness of ankle dorsiflexion occurs, disrupting this pattern. The result is a less controlled descent of the foot which makes a slapping noise as it hits the ground. If the distal weakness is severe, the foot will have to be lifted higher at the knee to allow room for the inadequately dorsiflexed foot to swing through, resulting in a high-stepping gait.

Myopathic gait

During walking, alternating transfer of the body's weight through each leg requires careful control of hip abduction by the gluteal muscles. In proximal muscle weakness, usually caused by muscle disease, the hips are not properly fixed by these muscles and trunk movements are exaggerated, producing a rolling or waddling gait.

Ataxic gait

An ataxic gait can occur as the result of lesions in the cerebellum, vestibular apparatus or peripheral nerves. Patients with lesions of the central portion of the cerebellum (the vermis) walk with a characteristic broad-based gait 'like a drunken sailor' (cerebellar function is particularly sensitive to alcohol). Patients with acute vestibular disturbances walk in a similar fashion, but the accompanying vertigo distinguishes them from those with cerebellar lesions. Less severe degrees of cerebellar ataxia can be detected by asking the patient to walk heel to toe; patients with vermis lesions are unable to do this. Defects in proprioception can also cause an ataxic gait. The impairment of joint position sense makes walking unreliable, especially in poor light. The feet tend to be placed on the ground with greater emphasis, presumably in an attempt to increase what proprioceptive input is available. This results in a 'stamping' gait which is often combined with foot drop when caused by a peripheral neuropathy, but it can also occur in disorders of the dorsal columns in the spinal cord.

Apraxic gait

In an apraxic gait, there is normal power in the legs, no cerebellar ataxia and no proprioception loss, and yet the patient still cannot formulate the motor act of walking. In this higher cerebral dysfunction, the feet appear stuck to the floor and the patient cannot walk, even though leg movement is normal on the examination couch. Gait apraxia occurs in bilateral hemisphere disease such as normal pressure hydrocephalus and diffuse frontal lobe disease.

Marche à petits pas

This gait is characterised by small, slow steps and marked instability. This looks different from the festinant gait of Parkinson's disease (see below) in that it does not have the variable pace and freezing. The usual cause is multiple small-vessel cerebrovascular disease and there are often signs of bilateral upper motor neuron disease.

Extrapyramidal gait

Patients with Parkinson's disease (p. 1199) and other extrapyramidal diseases have difficulty initiating walking and difficulty controlling the pace of their gait. Patients may get stuck whilst trying to start walking or when walking through doorways ('freezing'). Once started, they may shuffle and have problems controlling

the speed of their walking and sometimes have difficulty stopping. This produces the festinant gait: initial stuttering steps that quickly increase in frequency while decreasing in length.

Disorders of balance

Balance is a complicated process which involves modification of both axial and limb muscle function to compensate for the effects of gravity and alterations in body position and load (and hence centre of gravity) in order to prevent a person from falling. This process involves input from a variety of sensory modalities (visual, vestibular and proprioceptive), processing by the cerebellum and brain stem, and output via a number of descending pathways (e.g. vestibulospinal, rubrospinal and reticulospinal tracts). The process also results in a cognitive perception of vertical which is mediated through the cerebral cortex.

Disorders of balance can therefore arise from a number of different abnormalities which may affect input (loss of vision, vestibular disorders or lack of joint position sense), processing (damage to vestibular nuclei or cerebellum) or motor function (spinal cord lesions, leg weakness of any cause). The patient may complain of different symptoms depending on what is actually wrong. For example, loss of joint position sense or cerebellar function may result in a sensation of unsteadiness, while damage to the vestibular nuclei or labyrinth may result in vertigo which is an illusory sensation of movement (p. 1151). A careful history is vital. Patients may well have other associated symptoms depending on the site of damage, such as dysarthria in a cerebellar lesion. Since vision can often compensate for lack of joint position sense, patients with peripheral neuropathies or dorsal column loss will often find their problem more noticeable in the dark.

Examination of such patients may yield physical signs that depend on the site of the problem. Sensory abnormalities may be manifest as altered visual acuities or visual fields, possibly with abnormalities on fundoscopy, altered eye movements (including nystagmus), impaired vestibular function (p. 1171) or lack of joint position sense. Disturbance of cerebellar function may be manifest as nystagmus (p. 1165), dysarthria or ataxia, demonstrated as abnormalities of finger-nose testing or heel-shin testing, inability to perform alternating movements (dysdiadochokinesis) or difficulty with gait (unsteadiness or inability to perform tandem gait, p. 1153). Leg weakness, if present, will be detectable on examination of the limbs.

Abnormal movements

Abnormal movements are often caused by a disorder in the basal ganglia, in which there is disinhibition of the activity of intrinsic rhythm generators or a disorder of postural control. Some abnormal movements, like tremor, are commonplace and can be defined as a rhythmic oscillating movement of a limb or part of a limb, or of the head. Tremors can be usefully subclassified into action tremors and rest tremors. Action tremors are more common than rest tremors and the potential causes are

26.13 Causes of tremor on action

- Exaggerated physiological tremor (see Box 26.14)
- Essential tremor (may be familial)
- Parkinson's disease (rest tremor more usual)
- Wilson's disease
- Postural ('Holmes' or 'rubral') tremor
 - Multiple sclerosis
 - Other lesions in cerebellar outflow/red nucleus
- Intention tremor
 - Cerebellar hemisphere disease

more numerous (Box 26.13). Other involuntary movements, like chorea, athetosis and dystonia, have become more common as a result of adverse effects from drugs used in the treatment of Parkinson's disease and psychiatric disease.

Rest tremor

This is pathognomonic of Parkinson's disease (p. 1199). The tremor is characteristically 'pill-rolling' and usually presents asymmetrically. However, patients with Parkinson's disease may have an abnormal action tremor as well. Tremor of the head in the upright position ('titubation') is not a rest tremor since this is a postural tremor, disappearing when the head is supported.

Physiological tremor

This is the most common type of action tremor and occurs at a frequency of 8–12 Hz. It is common in normal subjects and exaggeration occurs in anxiety and in the other situations listed in Box 26.14.

Essential tremor

Essential tremor is distinct from physiological tremor, but can resemble it superficially. It is slower and may become quite disabling. Essential tremor is often inherited and in some families is most obvious during certain specific actions such as writing or holding a glass; there is an overlap with focal dystonia (see below). Alcohol often suppresses essential tremor, sometimes to the extent that the patient becomes dependent. Centrally

26.14 Causes of exaggerated physiological tremor

Anxiety

Fatigue

Endocrine

- Thyrotoxicosis
- Cushing's disease
- Pheochromocytoma
- Hypoglycaemia

Drugs

- β -agonists (e.g. salbutamol)
- Theophylline
- Caffeine
- Lithium
- Dopamine agonists
- Sodium valproate
- Tricyclics
- Phenothiazines
- Amphetamines

Toxins

- Mercury
- Lead
- Arsenic

Alcohol withdrawal

acting β -adrenoceptor antagonists (β -blockers) such as propranolol are often effective in treatment.

Intention tremor

This is characterised by oscillation at the end of a movement and typically occurs in cerebellar disease, due to the breakdown of control of targeted, ballistic movements. A more dramatic intention tremor occurs with lesions in the superior cerebellar peduncle (the site of the cerebellar outflow towards the red nucleus). Known variously as a 'peduncular', 'rubral' or 'Holmes' tremor, this is a violent, large-amplitude postural tremor that worsens as a target is approached. It is common in advanced multiple sclerosis and may be a source of considerable disability. Stereotactic thalamotomy can reduce the tremor, although the overall functional result is often disappointing.

Flapping tremor

Flapping tremor or asterixis is typical of metabolic disturbances (Box 26.15). It occurs as the result of intermittent failure of the parietal mechanisms required to maintain a posture. On attempts to hold the arms out with hands extended at the wrists, the posture is periodically dropped, allowing the hands to drop transiently before the posture is taken up again. Occasionally, unilateral asterixis can be seen in an acute parietal lesion, usually vascular.

26.15 Causes of asterixis

- Renal failure
- Liver failure
- Drug toxicity
- Hypercapnia
- Acute focal parietal or thalamic lesions

Chorea, athetosis and ballismus

Non-rhythmic involuntary movements may be combinations of fragments of purposeful movements and abnormal postures. All of these abnormal movements represent disorders of the balance of activity in the complex basal ganglia circuitry. Jerky, small-amplitude, purposeless involuntary movements are termed 'chorea' (the Greek for 'dance'). In the limbs they resemble fidgety movements, and in the face, grimaces; they suggest disease in the caudate nucleus (as in Huntington's disease, p. 1203) or excessive activity in the striatum due to dopaminergic drugs used to treat Parkinson's disease. There is a range of other causes (Box 26.16). More dramatic unilateral ballistic movements of the limbs (hemiballismus) can occur in vascular lesions of the subthalamic structures. Slower writhing movement of the limbs is called athetosis. This is often combined with chorea (and has a similar list of causes) and is then termed 'choreo-athetoid' movement.

Dystonia

The term 'dystonia' is used to describe sustained involuntary contraction that causes abnormal posture or movement. This may be generalised in various diseases of the basal ganglia, or may be focal or segmental as in spasmodic torticollis when the head involuntarily turns to one side. Other segmental dystonias may cause abnormal disabling postures of a limb to be taken up during certain specific actions, such as in writer's cramp or

26.16 Causes of chorea

Hereditary

- Huntington's disease
- Wilson's disease
- Neuroacanthocytosis
- Porphyria
- Paroxysmal choreoathetosis

Cerebral birth injury (including kernicterus)

Cerebral trauma

Drugs

- Levodopa
- Dopamine agonists
- Phenothiazines
- Tricyclics
- Oral contraceptive

Endocrine

- Pregnancy
- Oral contraceptive
- Thyrotoxicosis
- Hypoparathyroidism
- Hypoglycaemia

Infective/inflammatory

- Post-streptococcal (Sydenham's chorea)
- Henoch-Schönlein purpura
- Creutzfeldt-Jakob disease
- Antiphospholipid antibody syndrome
- Systemic lupus erythematosus (SLE)

Vascular

- Lacunar infarction
- Arteriovenous malformation

numerous other occupational 'cramps'. Segmental dystonias can be treated by the administration of botulinum toxin to a few of the responsible muscles, which seems to overcome the abnormal distribution of muscle activity for a period of time.

Myoclonus

Myoclonus refers to brief, isolated, random, non-purposeful jerks of muscle groups in the limbs. Myoclonic jerks occur normally at the onset of sleep (hypnic jerks). Similarly, a myoclonic jerk is a component of the normal startle response which may be exaggerated in some rare (mostly genetic) disorders. Unlike the movement disorders discussed so far, myoclonus may occur in disorders of the cerebral cortex, when groups of pyramidal cells fire spontaneously. Such myoclonus occurs in some forms of epilepsy in which the jerks are fragments of seizure activity. Alternatively, myoclonus can arise from subcortical structures or, more rarely, from diseased segments of the spinal cord. Myoclonus, especially of cortical origin, often responds to clonazepam, sodium valproate or piracetam.

Tics

Tics are repetitive semi-purposeful movements such as blinking, winking, grinning or screwing up of the eyes. They are distinguished from other involuntary movements by the ability of the patient to suppress their occurrence, at least for a short time. An isolated tic may be no more than a mild embarrassment, but may become frequent at certain times in childhood and then disappear. The uncommon syndrome of Gilles de la Tourette consists of a tendency to multiple tics and odd vocalisations, with obsessive behavioural abnormalities. The pathogenic basis is not understood, but there may be some response to major tranquillisers.

Sensory disturbance

Sensory symptoms are common but the accuracy of patients in describing sensory disturbances is very variable and so skill is often required to sift through the history in order to make anatomical and pathophysiological sense of the complaints. Although sensory symptoms are often due to neurological disease, this is not always the case; for example, tingling in the fingers of both hands and around the mouth can occur as the result of hyperventilation (p. 654) or hypocalcaemia (p. 765). Symptoms such as paraesthesia (tingling), numbness and pain may all be caused by damage to the afferent nervous pathways. When there is dysfunction of the cerebral mechanisms of somatic sensation there may be distortion of the patient's perception of the wholeness or actual presence of the relevant part of the body.

Numbness and paraesthesia

The most useful features on history are the anatomical distribution and mode of onset of the symptom. Certain patterns of onset of sensory symptoms can be recognised. For example, in a migraine attack the aura may consist of a front of tingling paraesthesia followed by numbness which takes 20–30 minutes to spread over one half of the body, often splitting the tongue. On the other hand, sensory loss due to a vascular lesion will occur more or less instantaneously and this is typically not associated with positive sensory phenomena like tingling. The rare, unpleasant paraesthesia of sensory epilepsy 'shoots' down one side of the body in seconds.

The numbness and paraesthesia of inflammatory spinal cord lesions often ascend from one or both lower limbs to a distinct level on the trunk over hours to days. Sensory symptoms of tingling and numbness can be of 'functional' or non-organic origin, as a manifestation of anxiety or as part of a conversion disorder (p. 251). The pattern of sensory symptoms in this circumstance usually does not conform to a known anatomical distribution or fit with any known pattern of sensory involvement in organic disease. As with weakness (see above), care should be taken to avoid misdiagnosing an unusual organic sensory impairment as a functional disorder.

Examination of the sensory system needs to be approached with care; it is easy to produce confusing false positive results because of the inescapably subjective nature of sensory testing. However, the distribution of sensory loss is often very useful in making a diagnosis when combined with the coexisting deficits of motor and and/or cranial nerve function (Fig. 26.18).

Peripheral nerve lesions

Here the symptoms are usually of sensory loss and paraesthesia. Single nerve lesions cause disturbance in the sensory distribution of that nerve whereas in diffuse neuropathies the longest neurons are affected first, giving a characteristic 'glove and stocking' distribution. If the smaller nerve fibres are preferentially affected (e.g. in alcoholic neuropathy), temperature and pin-prick (pain) are lost, whilst vibration sense and proprioception (modalities served by the larger, well-myelinated, sensory nerves) may be spared. In contrast, vibration and proprioception are particularly affected if the

Fig. 26.18 Patterns of sensory loss. **A** Generalised peripheral neuropathy. **B** Sensory roots. **C** Single dorsal column lesion (proprioception and some touch loss). **D** Transverse thoracic spinal cord lesion. **E** Unilateral cord lesion (Brown-Séquard): ipsilateral dorsal column (and motor) deficit and contralateral spinothalamic deficit. **F** Central cord lesion: 'cape' distribution of spinothalamic loss. **G** Mid-brain stem lesion: ipsilateral facial sensory loss and contralateral loss on body below the vertex. **H** Hemisphere (thalamic) lesion: contralateral loss on one side of face and body.

neuropathy is demyelinating in character (p. 1226), producing symptoms of tightness and swelling with impairment of proprioception and vibration sensation.

Nerve root lesions

These typically present with pain as a prominent feature, either within the spine or in the limb plexuses. It is often felt in the muscles innervated by the root rather than the skin. The site of nerve root lesions may be deduced from the dermatomal pattern of sensory loss, although this is often smaller than would be expected because of the overlap of sensory 'territories'.

Spinal cord lesions

Transverse lesions of the spinal cord produce loss of all sensory modalities below that segmental level, although the level obtained clinically may differ from the level of the lesion by two or three segments. Very often there is a band of paraesthesia or hyperaesthesia at the top of the area of sensory loss. If the transverse lesion is vascular due to anterior spinal artery thrombosis, the posterior one-third of the spinal cord (the dorsal column modalities) may be spared, as this has a different blood supply.

Lesions damaging one side of the spinal cord will produce loss of spinothalamic modalities (pain and temperature) on the opposite side and of dorsal column modalities (joint position and vibration sense) on the same side of the body. This is the pattern seen in the Brown-Séquard syndrome (p. 1223).

Lesions in the centre of the spinal cord (such as syringomyelia (see Box 26.108 and Fig. 26.56 (p. 1225)) spare the dorsal columns but affect the spinothalamic fibres crossing the cord from both sides over the length of the lesion. The sensory loss is therefore dissociated (in terms of the modalities affected) and suspended (in the sense that segments above and below the lesion are spared), often with reflex loss if afferent fibres of the reflex arc within the cord are affected.

An isolated lesion of the dorsal columns is not uncommon in multiple sclerosis. This produces a characteristic unpleasant tight feeling over the limb(s) involved and, while there is no loss of pin-prick or temperature sensation, the associated loss of proprioception may severely affect the function of the limb(s).

Brain-stem lesions

Lesions in the brain stem can be associated with sensory loss, but the distribution depends on the site of the lesion. A lesion limited to the trigeminal nucleus or its sensory projections will cause sensory disturbance on that side of the face. For example, a picture resembling trigeminal neuralgia can be seen in young patients with multiple sclerosis. Because of the anatomy of the trigeminal connections, lesions in the medulla or spinal cord can give rise to 'balaclava helmet' patterns of sensory loss (p. 1140). The sensory pathways running up from the spinal cord can also be damaged in the brain stem, resulting in sensory loss of arm(s) and/or leg(s); the exact pattern depends on the site of the lesion.

Hemisphere lesions

Lesions in the hemispheres usually affect all modalities of sensation in the area(s) involved. In the thalamus, discrete lesions such as small lacunar strokes can cause isolated loss of sensation over the whole contralateral half of

the body. Pure sensory loss from a lesion of the sensory cortex can occur, but the lesion has to be very small to avoid affecting the adjacent motor cortex or motor tracts deeper in the hemispheres; the resultant sensory loss is therefore usually restricted to a small area of the body such as the hand. A mixture of motor and sensory loss is much more common with cortical lesions. Substantial lesions of the parietal cortex (as in large strokes) can cause severe loss of proprioception and may even cause loss of conscious awareness of the existence of the affected limb(s). The resulting loss of function in the limb may be impossible to distinguish from paralysis.

Neuropathic pain

Neuropathic pain is caused by dysfunction of the pain perception apparatus itself, in contrast to nociceptive pain, which arises from a pathological process such as inflammation. Neuropathic pain has distinctive features and is typically described as a very unpleasant, persistent burning sensation. There is often increased sensitivity to touch, so that light brushing of the affected area causes exquisite pain (hyperpathia). Painful stimuli are felt as though they arise from a larger area than that touched and spontaneous bursts of pain may also occur. Pain may be elicited by other modalities such as loud sounds (allodynia) and this is considerably affected by emotional influences. The most common syndromes of neuropathic pain are seen where there is partial damage to a peripheral nerve ('causalgia'), to the trigeminal nerve (post-herpetic neuralgia) or to the thalamus. Treatment of these syndromes is very difficult. Drugs which modulate various parts of the nociceptive system, such as carbamazepine, tricyclics or phenothiazines, may help but usually only do so partially. Neurosurgical attempts to interrupt various pain pathways sometimes succeed but often increase the sensory deficit and may worsen the situation. Implantation of electrical stimulators has occasionally proved successful. For further information, see Chapter 12.

Coma

Persistent loss of consciousness or coma indicates disorder of the arousal mechanisms in the brain stem and diencephalon, and indicates bilateral hemisphere or brain-stem disease. There are many causes of coma (Box 26.17). The history of the mode of onset of coma and of any precipitating event is crucial to establishing the cause, and this should be obtained from family or other witnesses. As with any medical emergency, the top priority is assessment and stabilisation of the vital functions. Neurological examination may reveal important findings, such as evidence of head injury, papilloedema, meningism or an eye movement disorder. In the majority of cases, however, there are no focal neurological signs since drug overdose and metabolic disturbance are the most common causes of unexplained coma requiring hospital admission.

Assessment of conscious level is an essential component of the neurological examination of a comatose patient. This should include clear description of the patient's level of arousal and response to stimuli such as by application of the Glasgow Coma Scale (GCS) in which there is grading of coma using a numerical scale

26.17 Causes of coma

Metabolic disturbance	
• Drug overdose	• Uraemia
• Diabetes mellitus	• Hepatic failure
• Hypoglycaemia	• Respiratory failure
• Ketoacidosis	• Hypothermia
• Hyperosmolar coma	• Hypothyroidism
• Hyponatraemia	• Thiamin deficiency
Trauma	
• Cerebral contusion	• Subdural haematoma
• Extradural haematoma	
Cerebrovascular disease	
• Subarachnoid haemorrhage	• Intracerebral haemorrhage
• Brain-stem infarction/haemorrhage	• Cerebral venous sinus thrombosis
Infections	
• Meningitis	• Cerebral abscess
• Encephalitis	• General sepsis
Others	
• Epilepsy	• Functional ('pseudo-coma')
• Brain tumour	

26.18 How to use the Glasgow Coma Scale

Eye-opening (E)	
• Spontaneous	4
• To speech	3
• To pain	2
• Nil	1
Best motor response (M)	
• Obeys	6
• Localises	5
• Withdraws	4
• Abnormal flexion	3
• Extensor response	2
• Nil	1
Verbal response (V)	
• Orientated	5
• Confused conversation	4
• Inappropriate words	3
• Incomprehensible sounds	2
• Nil	1
Coma score = E + M + V	
• Minimum	3
• Maximum	15

which permits serial comparison over time and may also provide prognostic information, particularly in traumatic coma (Box 26.18).

Brain death

Patients with prolonged coma as the result of severe and irreversible brain damage may nowadays survive for prolonged periods with supportive care and mechanical ventilation. In this situation diagnostic criteria for brain death have been established in order that patients

26.19 UK criteria for the diagnosis of brain death

Preconditions for considering a diagnosis of brain death

- The patient is deeply comatose
 - (a) There must be no suspicion that coma is due to depressant drugs, such as narcotics, hypnotics, tranquillisers
 - (b) Hypothermia has been excluded—rectal temperature must exceed 35 °C
 - (c) There is no profound abnormality of serum electrolytes, acid–base balance or blood glucose concentrations, and any metabolic or endocrine cause of coma has been excluded
- The patient is maintained on a ventilator because spontaneous respiration had been inadequate or had ceased. Drugs, including neuromuscular blocking agents, must have been excluded as a cause of the respiratory failure
- The diagnosis of the disorder leading to brain death has been firmly established. There must be no doubt that the patient is suffering from irremediable structural brain damage

Tests for confirming brain death

- All brain-stem reflexes are absent
- The pupils are fixed and unreactive to light
- The corneal reflexes are absent
- The vestibulo-ocular reflexes are absent—there is no eye movement following the injection of 20 mL of ice-cold water into each external auditory meatus in turn
- There are no motor responses to adequate stimulation within the cranial nerve distribution
- There is no gag reflex and no reflex response to a suction catheter in the trachea
- No respiratory movement occurs when the patient is disconnected from the ventilator long enough to allow the carbon dioxide tension to rise above the threshold for stimulating respiration (P_{aCO_2} must reach 6.7 kPa (50 mmHg))

The diagnosis of brain death should be made by two experienced doctors, one of whom should be a consultant and the other a consultant or specialist registrar. The tests are usually repeated after an interval of 6–24 hours, depending on the clinical circumstances, before brain death is finally confirmed

without functioning brains who have no chance of recovery may be identified and have their ventilation discontinued. The diagnosis of brain death depends on meeting a set of preconditions, all of which must coexist, and then applying a series of clinical tests (Box 26.19), all of which must be fulfilled.

Acute confusional state

This is an extremely common disorder which occurs most often in the elderly. Patients demonstrate disturbance of arousal with a global impairment of mental function. This disturbance usually takes the form of drowsiness with disorientation, perceptual errors and muddled thinking. Patients typically fluctuate, and confusion is often worse at night. There may be associated emotional disturbance (anxiety, irritability or depression) or psychomotor changes (agitation, restlessness or

retardation). The assessment and management of this condition is covered in more detail on page 171.

Memory loss

Loss of memory for a period of time may be due to a transient toxic confusional state, a psychological fugue state, the post-ictal period after seizure or the syndrome known as transient global amnesia. These are usually distinguished on the basis of the history. A period of amnesia often follows either a complex partial or a generalised seizure, and this may cause diagnostic confusion if the seizure was not witnessed—for example, if it occurred in sleep.

Transient global amnesia

This is a syndrome affecting predominantly middle-aged patients in which there is an abrupt, discrete loss of short-term memory function which lasts for a period of a few hours at most. During this time patients know who they are and can perform motor acts normally, but they act in a bemused way, repeatedly asking the same questions. During the attack there is retrograde amnesia for the events of the past few weeks. After 4–6 hours, memory function and behaviour return to normal but the patient has persistent, complete amnesia for the duration of the attack itself. There are none of the phenomena associated with seizures and, unlike epileptic amnesia, transient global amnesia tends not to recur. There are no associated cerebrovascular risk factors, making a vascular aetiology unlikely. Transient global amnesia is thought to be due to a benign process similar to that causing a migrainous aura, occurring in the hippocampus. The patient has no physical signs and further investigation may not be needed if epilepsy can be excluded.

Persistent amnesia

Patients with persistent memory disturbance should be assessed to exclude serious neurological disease. In general, memory problems which have been observed by relatives or colleagues are likely to be more significant than those of which only the patient is aware. Problems of concentration must be distinguished from true problems with memory, as concentration difficulties are much more likely to be due to underlying depressive or anxiety disorders.

It is important to determine for how long the problem has existed, and exactly which aspects of memory are affected. Complaints of getting lost or of forgetting to switch off burners on the kitchen stove are more likely to be significant than simply forgetting names. Disturbance of episodic memory (previously called 'short-term memory') must be distinguished from semantic memory (memory for concept-based knowledge unrelated to specific experiences). The former can be selectively impaired in Korsakoff's syndrome (often secondary to alcohol) or bilateral temporal lobe damage, but is seen in conjunction with other disturbance of cortical function in different types of dementia. Progressive deterioration over many months suggests the possibility of an underlying dementia, but it is important to take a full medical history to detect any underlying medical problem which could be responsible. A family history of a memory disorder such as dementia is clearly important.

It is important to look for features of depression (p. 233) in patients with memory loss for two reasons. First, depression can present as a 'pseudo-dementia' with concentration and memory impairment as a dominant feature, and this is often reversible with antidepressant medication. Second, many patients with dementia may develop depression in the early stages of their illness, and this is also potentially treatable.

Personality change

While this is most often due to psychiatric illness (Ch. 10), many neurological conditions present with altered personality and behaviour. This particularly applies to conditions which alter the function of the frontal lobes where control of executive function, movement and behaviour resides (see Box 26.1, p. 1136). Personality change due to a frontal lobe disorder may occur as the result of structural damage due to stroke, trauma, tumour or hydrocephalus or as the result of a metabolic disturbance.

Personality can be affected in three broad directions as a result of frontal lobe damage.

- Patients with mesial frontal lesions become increasingly withdrawn, unresponsive and mute (abulic), and this is often associated with urinary incontinence, gait apraxia and an increase in tone known as *gegenhalten*, in which the patient varies the resistance to movement in proportion to the force exerted by the examiner.
- Patients with lesions of the dorsolateral prefrontal cortex develop difficulties with speech and motor planning and organisation. This is known as *dysexecutive syndrome*.
- Those with orbitofrontal lesions of the frontal lobes become disinhibited, sometimes to the point of grandiosity, or exhibit irresponsible behaviour. Memory is substantially intact, and there may be focal physical signs such as a grasp reflex, palmo-mental response or pout. As the frontal lobe overlies the olfactory bulb and tracts, structural lesions such as tumours in the inferior frontal lobes may be associated with anosmia.

Personality can also be affected by damage to the temporal lobes, usually as a result of memory impairment. Disturbance to the cortical areas responsible for speech can result in speech difficulties which may be interpreted as changes in personality.

Speech and language disturbance

There are three broad categories of speech disturbance; dysphonia, which is usually caused by a local problem in the larynx; dysarthria, which can occur in association with lesions affecting the brain stem, muscle or cerebellum; and dysphasia, which is due to lesions of the cerebral cortex.

Dysphonia

Dysphonia is the term used to describe hoarse or whispered speech. This can occur because the vocal cords fail to generate sounds properly during speech, or can be due to a higher-level problem of vocal cord operation

(dystonia). The most common cause is laryngitis, but dysphonia can also result from a lesion of the 10th cranial nerve or a problem with the vocal cords.

Dysarthria

Dysarthria is characterised by poorly articulated or slurred speech and can occur in association with lesions of the cerebellum, brain-stem disease and lower cranial nerves, as well as in myasthenia and patients with muscle disease. Dysarthric patients have no problem with choice of words, but there is a defect in delivery of speech which can sometimes be unintelligible, depending on severity of the underlying disorder. The quality of the speech tends to differ somewhat depending on the cause, but it can be very difficult to distinguish the different types clinically (Box 26.20).

Dysphasia

Dysphasia (also termed aphasia) is a disorder of the language content of speech. It can occur with lesions over a wide area of the dominant hemisphere. The inability to produce the correct word is termed anomia. When patients with anomia are asked to name objects or parts of objects, either no word will be produced or the wrong word or a nonsense word will be produced (paraphasia). Dysphasia can be subclassified according to whether the speech output is 'fluent' or not. In fluent dysphasia, a normal or increased number of (wrong) words are produced, whereas in non-fluent dysphasia, verbal output is reduced. Patients with lesions anterior to the central (Rolandic) fissure have non-fluent aphasia whilst those with lesions posterior to the central fissure in the speech areas have a fluent aphasia (and are often mistakenly thought to be confused). If patients are tested for the comprehension of words and their ability to repeat, their aphasia can be further classified into distinct syndromes of aphasia which have localising and prognostic implications (Fig. 26.19).

If a patient is found to have difficulty with speech comprehension there is likely to be a lesion in the superior part of the posterior temporal lobe and/or the adjoining part of the parietal lobe (Wernicke's area). Patients with small lesions around the lateral (Sylvian) fissure will have difficulty with repetition, whilst those

Fig. 26.19 Classification of aphasia, according to the site of the lesion and type of language deficit. All have naming difficulty (anomia). Fluent aphasias arise from lesions posterior to the central fissure; repetition is affected by lesions around the Sylvian fissure. (1) Wernicke aphasia: fluent aphasia with poor comprehension and poor repetition. (2) Conduction aphasia: fluent aphasia with good comprehension and poor repetition. (3) Broca aphasia: non-fluent aphasia with good comprehension and poor repetition. (4) Transcortical sensory aphasia: fluent aphasia with poor comprehension and good repetition. (5) Transcortical motor aphasia: non-fluent aphasia with good comprehension and good repetition. Large lesions affecting all of regions 1–5 cause global aphasia.

with lesions away from the Sylvian fissure can repeat and may do so compulsively. Patients with large lesions over much of the speech area are not testable in such a refined manner because they have no language production, and they are said to have 'global aphasia'. Patients with fluent aphasia tend not to have an associated hemiparesis since the pyramidal tract is not involved, whilst those with the more anteriorly placed lesions causing non-fluent aphasia often do have a hemiparesis.

Disorders of perception

The temporal, parietal and occipital lobes receive sensory information regarding the various different modalities

26.20 Causes of dysarthria

Type	Site	Characteristics	Associated features
Myopathic	Muscles of speech	Indistinct, poor articulation	Weakness of face, tongue and neck
Myasthenic	Motor end plate	Indistinct with fatigue and dysphonia Fluctuating severity	Ptosis, diplopia, facial and neck weakness
Bulbar	Brain stem	Indistinct, slurred, often nasal	Dysphagia, diplopia, ataxia
'Scanning'	Cerebellum	Slurring, impaired timing and cadence, 'sing-song' quality	Ataxia of limbs and gait, tremor of head/ limbs Nystagmus
Spastic ('pseudo-bulbar')	Pyramidal tracts	Indistinct, breathy, mumbling	Poor rapid tongue movements, increased reflexes and jaw jerk
Parkinsonian	Basal ganglia	Indistinct, rapid, stammering, quiet	Tremor, rigidity, slow shuffling gait
Dystonic	Basal ganglia	Strained, slow, high-pitched	Dystonia, athetosis

of touch, vision, hearing and balance (see Box 26.1, p. 1136). The initial points of entry into the cortex are the respective primary cortical areas (see Fig. 26.4, p. 1137). Damage to any of these primary areas will result in reduction or loss of the ability to perceive that particular modality. This is referred to as 'negative' symptomatology. Abnormal excitation of these areas can occur in disorders such as epilepsy and migraine and result in an apparent perception which is not based in physical reality. Such 'positive' stimuli can be visual (flashing lights or formed images), somatosensory (tingling, burning or pain), auditory (noises) or vestibular (vertigo).

The parietal lobes are also involved in the higher processing and integration of the primary sensory information. This occurs in areas which may be highly specialised (e.g. the areas involved in the production and understanding of speech, p. 1159) or less specialised. Less specialised areas are referred to as 'association' cortex. Damage to the association cortex gives rise to sensory (including visual) inattention and disorders of spatial perception, and hence the disruption of spatially orientated behaviour leading to apraxia. Apraxia is the inability to perform complex, organised activity in the presence of normal basic motor, sensory and cerebellar function (after weakness, numbness and ataxia have been excluded as causes). Such complex activities include dressing, using cutlery and finding one's way around geographically. Other abnormalities which may result from damage to association cortex involve difficulty reading (dyslexia) or writing (dysgraphia), or the inability to detect that something is wrong (agnosia). The results of damage to particular lobes of the brain are given in Box 26.1 (p. 1136).

Brain-stem lesions

Lesions of the brain stem typically present with a constellation of symptoms due to cranial nerve, cerebellar and upper motor neuron dysfunction and are most commonly caused by vascular disease. This is because many different functional areas are tightly packed into the brain stem (p. 1137 and Fig. 26.5) and damage to even a small area causes major disturbance of several systems. Since the anatomy of the brain stem is very precisely organised, it is usually possible to localise the site of a lesion on the basis of careful history and examination to determine exactly which tracts/nuclei are affected. Lesions can occur singly, multiply or diffusely, but the standard neurological approach is to try to explain all of a patient's problems on the basis of a minimum number of lesions (ideally just one).

An example would be a patient presenting with sudden onset of upper motor neuron features affecting the right face, arm and leg in association with a left 3rd nerve palsy. The lesion would have to be in the left cerebral peduncle in the brain stem where the pathology is likely to have been a small stroke as the onset was sudden. This combination of signs is known as Weber's syndrome, and this is one of several well-described brain-stem syndromes which are listed in Box 26.21.

The effects of damage to the individual cranial nerves which arise in the brain stem, or to their nuclei, are discussed in the sections on eye movements (p. 1162) and on nerve and muscle, below (p. 1233). The lower cranial

26.21 Major focal brain-stem syndromes

Name of syndrome	Site of lesions	Clinical features
Weber	Anterior cerebral peduncle (mid-brain)	Ipsilateral 3rd palsy Contralateral upper motor neuron 7th palsy Contralateral hemiplegia
Claude	Cerebral peduncle involving red nucleus	Ipsilateral 3rd palsy Contralateral cerebellar signs
Parinaud	Dorsal mid-brain (tectum)	Vertical gaze palsy Convergence disorders Convergence retraction nystagmus Pupillary and lid disorders
Millard–Gubler	Ponto-medullary junction	Ipsilateral 6th palsy Ipsilateral lower motor neuron 7th palsy Contralateral hemiplegia
Wallenberg	Lateral medulla	Ipsilateral 5th, 9th, 10th, 11th palsy Ipsilateral Horner's syndrome Ipsilateral cerebellar signs Contralateral spinothalamic sensory loss Vestibular disturbance

nerves, 9, 10, 11 and 12, are frequently affected bilaterally, producing dysphagia (see below) and dysarthria (see above). The term 'bulbar palsy' is used if this results from lower motor neuron lesions, at either nuclear or fascicular level within the medulla, or from bilateral lesions of the lower cranial nerves outside the brain stem. The tongue is wasted and fasciculating and the palate moves very little. A 'pseudobulbar palsy' arises from an upper motor neuron lesion of the bulbar muscles from lesions of the corticobulbar pathways in the pyramidal tracts. Here the tongue is small and contracted, and moves

26.22 Causes of pseudobulbar and bulbar palsy

	Pseudobulbar	Bulbar
Genetic		Kennedy's disease (X-linked bulbo-spinal neuronopathy)
Vascular	Bilateral hemisphere (lacunar) infarction	Medullary infarction
Degenerative	Motor neuron disease (p. 1204)	Motor neuron disease Syringobulbia
Inflammatory/infective	Multiple sclerosis (p. 1191) Cerebral vasculitis	Myasthenia (p. 1231) Guillain–Barré (p. 1229) Poliomyelitis (p. 1210) Lyme disease (p. 329) Vasculitis
Neoplastic	High brain-stem tumours	Brain-stem glioma Malignant meningitis

slowly; the jaw jerk is brisk. Causes of bulbar and pseudobulbar palsies are shown in Box 26.22.

Swallowing difficulty

Swallowing is a complex activity involving the coordinated action of lips, tongue, soft palate, pharynx and larynx, which are innervated by the facial nerve and cranial nerves 9, 10, 11 and 12. This mechanism is potentially vulnerable to damage in many different areas of the nervous system, resulting in dysphagia which is usually accompanied by dysarthria. Structural causes of dysphagia are considered on page 850. Acute onset of dysphagia may occur as a result of brain-stem stroke, a rapidly developing neuropathy such as the Guillain-Barré syndrome or diphtheria. The upper motor neuron innervation of the cranial nerves responsible for swallowing is bilateral, so persistent dysphagia is unusual with a unilateral upper motor lesion. However, dysphagia may occur in the early stages of such a lesion if it is very acute, such as a hemispheric stroke. Dysphagia developing subacutely may be seen in myasthenia gravis, motor neuron disease, polymyositis, basal meningitis and inflammatory brain-stem disease. More slowly developing dysphagia suggests a myopathy or possibly a brain-stem or skull-base tumour.

Visual disturbance and other ocular abnormalities

Disturbances of vision are common and often related to problems with the eye rather than disorders of the nervous system. A common reason for presentation is loss of vision, but patients may also present with posi-

tive visual symptoms, such as hallucinations. The movements of both eyes may be disturbed giving rise to double vision (diplopia) or blurred vision. Alternatively, patients may present with disordered appearance of their visual apparatus, which includes the eyelids, the globe, the eye movements, the pupils or the appearance of the optic disc on fundoscopy (e.g. papilloedema).

Visual loss

Visual loss can occur as the result of lesions anywhere from the retina to the visual cortex. Fibres from ganglion cells in the retina pass to the optic disc and then backwards through the lamina cribrosa to the optic nerve. Nasal optic nerve fibres (subservicing the temporal visual field because the image on the retina is inverted) cross at the chiasm, but temporal fibres do not. Hence, all fibres in the optic tract and further posteriorly subserve both eyes' representation of contralateral visual space. From the lateral geniculate nucleus, lower fibres pass through the temporal lobes on their way to the primary visual area in the occipital cortex, while the upper fibres pass through the parietal lobe. Patterns of visual field loss are explained by this anatomy, as seen in Figure 26.20, and associated clinical manifestations are described in Box 26.23.

Transient visual loss is quite common and sudden visual loss lasting less than about 15 minutes is likely to have a vascular cause. This can affect one eye (amaurosis fugax) or one visual hemifield. Whether the field loss was monocular (carotid circulation) or a homonymous hemianopia (vertebro-basilar circulation) is crucial to further management, and this must be distinguished by careful history (e.g. did the patient try shutting each eye in turn?). Transient visual loss lasting about 20–30 minutes suggests migraine, especially if accompanied by headache and/or positive visual phenomena.

Fig. 26.20 Visual pathways and visual field defects. Schematic representation of eyes and brain in transverse section.

26.23 Clinical manifestations of visual field loss

Site	Common causes	Complaint	Visual field loss	Associated physical signs
Retina/optic disc	Vascular disease (including vasculitis) Glaucoma Inflammation	Partial/complete visual loss depending on site	Altitudinal field defect Arcuate scotoma	Reduced acuity Visual distortion (macula) Abnormal retinal appearance
Optic nerve	Optic neuritis Sarcoidosis Tumour Leber's hereditary optic neuropathy	Partial/complete loss of vision in one eye Often painful Central vision particularly affected	Central scotoma Paracentral scotoma Monocular blindness	Reduced acuity Reduced colour vision Relative afferent pupillary defect Optic atrophy (late)
Optic chiasm	Pituitary tumours Craniopharyngioma Sarcoidosis	May be none Rarely diplopia ('hemifield slide')	Bitemporal hemianopia	Pituitary function abnormalities
Optic tract	Tumour Inflammatory disease	Disturbed vision to one side of midline	Incongruous contralateral homonymous hemianopia	
Temporal lobe	Stroke Tumour Inflammatory disease	Disturbed vision to one side of midline	Contralateral homonymous upper quadrantanopia	Memory/language disorders
Parietal lobe	Stroke Tumour Inflammatory disease	Disturbed vision to one side of midline Bumping into things	Contralateral homonymous lower quadrantanopia	Contralateral sensory disturbance Asymmetry of optokinetic nystagmus
Occipital lobe	Stroke Tumour Inflammatory disease	Disturbed vision to one side of midline Difficulty reading Bumping into things	Homonymous hemianopia (may be macula-sparing)	Damage to other structures supplied by posterior cerebral circulation

Visual disturbance

The most common cause of a visual disturbance is migraine, in which patients may see silvery zigzag lines (fortification spectra) or flashing coloured lights (teichopsia) which precede the headache. Simple flashes of light (phosphenes) can also be seen as a result of damage to the retina (e.g. detachment) or damage to the primary visual cortex. Visual hallucinations may also be caused by drugs, or may be due to structural damage resulting in epilepsy or 'release phenomena', such as hallucinations which can occur in a blind visual field.

Double vision

Double vision (diplopia) arises when eye movement is impaired so that the image of an object is not projected to homologous points on the two retinæ. This may result from central disorders or from disturbance of the ocular motor nerves, muscles or the neuromuscular junction. The pattern of double vision, along with any associated features, usually allows localisation of the lesion, whilst the mode of onset and subsequent behaviour (such as fatigability in myasthenia) can give a clue to the underlying cause.

Under normal circumstances, the eyes move conjugately, though horizontal vergence allows visual fusion of objects at different distances. The control of eye movements begins in the cerebral hemispheres, particularly within the frontal eye fields, and the pathway then descends to the brain stem with input from the visual cortex, superior colliculus and cerebellum. Horizontal

and vertical gaze centres in the pons and midbrain, respectively, coordinate output to the ocular motor nerve nuclei (3, 4 and 6), which are connected to each other by the medial longitudinal fasciculus (MLF) (Fig. 26.21). The MLF is particularly important in coordinating horizontal movements of the eyes. The extraocular muscles are then supplied by the oculomotor (3rd), trochlear (4th) and abducens (6th) nerves.

The trochlear (4th) nerve innervates the superior oblique muscle, and the abducens (6th) nerve innervates the lateral rectus. The oculomotor (3rd) nerve innervates the remainder of the extraocular muscles along with the levator palpebrae superioris and the ciliary body (pupil constriction and accommodation). Causes of ocular motor nerve palsies are listed in Box 26.24.

Complete oculomotor (3rd) nerve lesions cause ptosis and a dilated pupil, and the eye tends to rest in a 'down and out' position due to unopposed tonic activity of the unaffected lateral rectus and superior oblique muscles. The pupil is often spared in ischaemic lesions (e.g. in diabetes), and its involvement requires that compressive lesions such as aneurysm be excluded. Trochlear (4th) nerve palsy presents with vertical diplopia (especially noticeable going downstairs), and the patient may have a head tilt to the contralateral side and double vision when looking down to the side opposite the lesion. Abducens (6th) nerve palsy causes horizontal double vision when trying to look towards the side of the lesion. In diplopia of any cause, the image projected furthest away from primary position arises from the paretic eye, and covering each eye in turn can often determine this.

Fig. 26.21 Control of conjugate eye movements. Downward projections pass from the cortex to pontine lateral gaze centre (A). Pontine gaze centre projects to the 6th cranial nerve nucleus (B), which innervates the ipsilateral lateral rectus and projects to the contralateral 3rd nerve nucleus (and hence medial rectus) via the medial longitudinal fasciculus (MLF). Tonic inputs from the vestibular apparatus (C) project to the contralateral 6th nerve nucleus via the vestibular nuclei.

Note that this image is not necessarily any less clear than the image from the non-paretic eye; it is the relative position, not the clarity, of the images which is important in determining which muscle is weak.

Myasthenia gravis (p. 1231) can cause diplopia by affecting any or all of the extraocular muscles. It is often associated with ptosis, and the hallmark is fatigability. Similarly, diseases of the extraocular muscles themselves can cause diplopia. These include thyroid eye disease, myopathies and orbital myositis.

Central lesions can also give rise to diplopia. Brain-stem lesions affecting the 3rd, 4th or 6th nerves or nuclei will cause diplopia, as will lesions of the MLF. The hallmark of an MLF lesion is an internuclear ophthalmoplegia (INO), most commonly seen in multiple sclerosis (p. 1194). The lateral gaze centre in the pons sends fibres to the ipsilateral 6th nerve nucleus. The nucleus contains two populations of neurons. Half the cells send their axons directly into the 6th nerve to supply the lateral rectus, while the remaining half send their fibres into the contralateral MLF and up to the contralateral 3rd nerve nucleus, where they synapse with neurons destined for the medial rectus (see Fig. 26.21). Hence, damage to the 6th nerve nucleus itself will prevent both eyes from moving ipsilaterally (gaze palsy), and a lesion of the MLF will interfere with adduction of the ipsilateral eye (INO). In this situation, the ipsilateral eye will either fail to adduct past midline if the lesion is complete, or adduct very slowly if it is partial. Nystagmus may sometimes be seen

26.24 Common causes of damage to cranial nerves 3, 4 and 6

Site	Common pathology	Nerve(s) involved	Associated features
Brain stem	Infarction Haemorrhage Demyelination Intrinsic tumour	3 (midbrain) 6 (ponto-medullary junction)	Contralateral pyramidal signs Ipsilateral lower motor neuron facial palsy Other brain-stem/cerebellar signs
Intrameningeal	Meningitis (infective/malignant)	3, 4 and/or 6	Meningism, features of primary disease course
	Raised intracranial pressure	6	Papilloedema
	Aneurysms	3 (uncal herniation) 3 (posterior communicating artery) 6 (basilar artery)	Features of space-occupying lesion Pain Features of subarachnoid haemorrhage
	Cerebello-pontine angle tumour	6	8, 7, 5 nerve lesions Ipsilateral cerebellar signs
	Trauma	3, 4 and/or 6	Other features of trauma
Cavernous sinus	Infection/thrombosis Carotid artery aneurysm Caroticocavernous fistula	3, 4 and/or 6	May be 5th nerve involvement also Pupil may be fixed, mid-position (sympathetic plexus on carotid may also be affected)
Superior orbital fissure	Tumour (e.g. sphenoid wing meningioma) Granuloma	3, 4 and/or 6	May be proptosis, chemosis
Orbit	Vascular (e.g. diabetes, vasculitis) Infections Tumour Granuloma Trauma	3, 4 and/or 6	Pain Pupil often spared in vascular 3rd nerve palsy

in the other (abducting) eye, giving rise to the archaic term 'ataxic nystagmus'.

Nystagmus

Nystagmus is the term given to describe a repetitive to-and-fro movement of the eyes. Usually the drifts are slower than the corrections giving rise to slow and fast phases. Nystagmus occurs because the control systems of the eyes are defective, causing them to drift off target; corrections then become necessary to return fixation to the object of interest, causing nystagmus. The direction of the fast phase is usually designated as the direction of the nystagmus because it is easier to see, although the abnormality is the slower drift of the eyes off target. Nystagmus may be horizontal, vertical or torsional, and is usually conjugate in that both eyes move together. Nystagmus is seen as a physiological phenomenon in response to sustained vestibular stimulation or movement of the visual world (optokinetic nystagmus). There are many different causes of pathological nystagmus, the most common being disorders of the vestibular system, the brain stem and the cerebellum.

In lesions of the vestibular system, damage to the horizontal canal or its connections on one side will allow the tonic output from the healthy, contralateral side to cause the eyes to drift towards the side of the lesion. This causes recurrent compensatory fast movements away from the side of the lesion; hence unidirectional horizontal nystagmus to the opposite side is seen. Vertical and torsional components can be seen with damage to other parts of the vestibular apparatus. The nystagmus of peripheral labyrinthine lesions disappears (fatigues) quite quickly and is always accompanied by vertigo and quite often nausea and vomiting. Central vestibular nystagmus is more persistent.

The brain stem and the cerebellum are involved in maintaining eccentric positions of gaze. Lesions will therefore allow the eyes to drift back in towards primary position. This produces nystagmus whose fast component beats in the direction of gaze (gaze-evoked nystagmus). This is the most common type of 'central' nystagmus and is most commonly bi-directional and not

usually accompanied by vertigo, but there may be other signs of brain-stem dysfunction. Brain-stem disease may also cause vertical nystagmus.

Unilateral cerebellar lesions may result in gaze-evoked nystagmus when looking in the direction of the lesion, where the fast phases are directed towards the side of the lesion. Cerebellar hemisphere lesions also cause 'ocular dysmetria', an overshoot of target-directed, fast eye movements (saccades) resembling 'past-pointing' in limbs.

Nystagmus also occurs as a result of toxicity (especially drugs) and nutritional (thiamin) deficiency. The severity is variable, and it may or may not result in visual degradation, though it may be associated with a sensation of movement of the visual world (oscillopsia). Nystagmus may occur as a congenital phenomenon, in which case the nystagmus is often quasi-sinusoidal ('pendular') rather than having alternating fast and slow phases ('jerk').

Ptosis

Various disorders may cause drooping of the eyelid (ptosis) and these are listed in Box 26.25.

Abnormal pupillary responses

Abnormalities of the pupil or its response to light can develop as the result of lesions at several points between the retina and brain stem. The pupillary response to light is due to a combination of parasympathetic and sympathetic activity. Parasympathetic fibres originate in the Edinger-Westphal subnucleus of the 3rd nerve, and pass with the 3rd nerve to synapse in the ciliary ganglion before supplying the constrictor pupillae of the iris. Sympathetic fibres originate in the hypothalamus, pass down the brain stem and cervical spinal cord to emerge at T1, return up to the eye in association with the internal carotid artery and supply the dilator pupillae. Lesions in the sympathetic pathway cause Horner's syndrome (Fig. 26.22). The pupils also constrict as part of the near reflex (in association with accommodation and convergence).

Lesions of the oculomotor nerve, ciliary ganglion and sympathetic supply produce characteristic 'efferent' disorders of pupillary function. 'Afferent' defects

26.25 Common causes of ptosis

Mechanism	Causes	Associated clinical features
3rd nerve palsy	Isolated palsy (see Box 26.24) Central/supranuclear lesion	Ptosis is usually complete Extraocular muscle palsy (eye 'down and out') Depending on site of lesion, other cranial nerve palsies (e.g. 4, 5 and 6) or contralateral upper motor neuron signs
Sympathetic lesion (Horner's syndrome) (see Fig. 26.22)	Central (hypothalamus/brain stem) Peripheral (lung apex, carotid artery pathology) Idiopathic	Ptosis is partial Lack of sweating on affected side Depending on site of lesion, brain-stem signs, signs of apical lung/brachial plexus disease, or ipsilateral carotid artery stroke
Myopathic	Myasthenia gravis Dystrophia myotonica	Extraocular muscle palsies More widespread muscle weakness, with fatigability in myasthenia Progressive external ophthalmoplegia Other characteristic features of individual causes
Other	Pseudo-ptosis (e.g. blepharospasm) Local orbital/lid disease Age-related levator dehiscence	Eyebrows depressed rather than raised May be local orbital abnormality

Fig. 26.22 Right-sided Horner's syndrome due to paravertebral metastasis at T1. There is ipsilateral partial ptosis and a small pupil.

occur as a result of damage to an optic nerve, impairing the direct response of a pupil to light, although leaving the consensual response from stimulation of the normal eye intact. Structural damage to the iris itself can also result in pupillary abnormalities. A summary is given in Box 26.26.

Papilloedema

There are several causes of swelling of the optic disc, but the term 'papilloedema' is reserved for swelling in association with raised intracranial pressure. In raised intracranial pressure from any cause, axoplasmic flow from retinal ganglion cells is held up at the cribriform plate. This results in swollen nerve fibres, which in turn cause capillary and venous congestion, producing papilloedema. The first sign is the cessation of normal venous pulsation seen at the disc, and the disc margins then become red (hyperaemic). The margins become indistinct and the whole disc is raised up, often with haemorrhages in the retina (Fig. 26.23).

Other causes of optic disc swelling are listed in Box 26.27. Some normal variations of disc appear-

26.27 Common causes of optic disc swelling

Raised intracranial pressure

- Cerebral mass lesion (tumour, abscess)
- Hydrocephalus, haemorrhage, haematoma
- Idiopathic intracranial hypertension

Obstruction of ocular venous drainage

- Central retinal vein occlusion
- Cavernous sinus thrombosis

Systemic disorders affecting retinal vessels

- Hypertension
- Vasculitis
- Hypercapnia

Optic nerve damage

- Demyelination (optic neuritis/papillitis)
- Leber's hereditary optic neuropathy
- Anterior ischaemic optic neuropathy
- Toxins (e.g. methanol)
- Infiltration of optic disc
- Sarcoidosis
- Glioma
- Lymphoma

ance can look like pathological disc swelling (pseudo-papilloedema).

Optic atrophy

Loss of nerve fibres causes the optic disc to appear pale, as the choroid becomes visible (Fig. 26.24). A pale disc (optic atrophy) follows optic nerve damage, and causes

26.26 Pupillary disorders

Disorder	Cause	Ophthalmological features	Associated features
3rd nerve palsy	See Box 26.24	Dilated pupil Extraocular muscle palsy (eye is typically 'down and out') Complete ptosis	Other features of 3rd nerve palsy (see Box 26.25)
Horner's syndrome (see Fig. 26.22)	Lesion to sympathetic supply	Small pupil Partial ptosis Iris heterochromia (if congenital)	Ipsilateral failure of sweating (anhidrosis)
Holmes-Adie syndrome (tonic pupil)	Lesion of ciliary ganglion (usually idiopathic)	Dilated pupil Light-near dissociation (accommodate but do not react to light) Vermiform movement of iris during contraction Disturbance of accommodation	Generalised areflexia
Argyll Robertson pupil	Dorsal mid-brain lesion (syphilis or diabetes)	Small, irregular pupils Light-near dissociation	Other features of tabes dorsalis (p. 1213)
Local pupillary damage	Trauma/inflammatory disease	Irregular pupils, often with adhesions to lens (synechiae) Variable degree of reactivity	Other features of trauma/underlying inflammatory disease (e.g. cataract, blindness etc.)
Relative afferent pupillary defect (Marcus Gunn pupil)	Damage to optic nerve (see Box 26.23, p. 1163)	Pupils symmetrical, but degree of dilatation depends on which eye stimulated	Decreased visual acuity/colour vision Central scotoma Papilloedema/optic disc pallor

Fig. 26.23 Mechanism of optic disc oedema (papilloedema). **A** Normal. **B** Disc oedema (e.g. due to cerebral tumour). **C** Fundus photograph of the left eye showing optic disc oedema with a small haemorrhage on the nasal side of the disc.

include previous optic neuritis or ischaemic damage, long-standing papilloedema, optic nerve compression, trauma and degenerative conditions (e.g. Friedreich's ataxia, p. 1203).

Sphincter disturbance

Incontinence and its management are discussed on pages 476 and 915. However, many different symptoms of bladder and bowel disturbance can arise as a result of nervous system dysfunction.

Fig. 26.24 Fundus photograph of the left eye of a patient with familial optic atrophy. Note marked pallor of optic disc.

Bladder dysfunction

The bladder is analogous to skeletal muscle in that neural control can be divided into upper and lower 'motor neuron' components. Conscious control of micturition resides within the pre-frontal cortex. Connections pass from here to the main controlling and coordinating centre in the pons, the pontine micturition centre, and from here down into the spinal cord, where they are found in the lateral columns bilaterally. The sympathetic supply to the bladder leaves from T10–L2 to synapse in the inferior hypogastric plexus, while the parasympathetic supply leaves from S2–4. In addition, a further somatic supply to the distal (voluntary) sphincter arises from S2–4, travelling via the pudendal nerves. Stimulation of sympathetic fibres causes relaxation of the detrusor muscle and contraction of the bladder neck, while stimulation of the parasympathetic fibres causes the reverse effects.

Afferent fibres from the bladder wall pass via the pelvic and hypogastric nerves. In the absence of conscious control (stroke, dementia), distension of the bladder to near-capacity evokes reflex detrusor contraction (analogous to the muscle stretch reflex). Reciprocal changes in sympathetic activation and relaxation of the distal sphincter result in coordinated bladder emptying. Normally, however, conscious control from the medial pre-frontal cortex inhibits bladder emptying until it is socially acceptable.

Damage to the 'lower motor neuron' component (the pelvic and pudendal nerves) gives rise to a flaccid bladder and sphincter with overflow incontinence, often accompanied by loss of pudendal sensation. Such damage may be due to disease of the conus medullaris or sacral nerve roots, either within the dura (as in inflammatory or carcinomatous meningitis) or as they pass through the sacrum (trauma or malignancy), or due to damage to the nerves themselves in the pelvis (infection, haematoma, trauma or malignancy).

Damage to the pons or spinal cord results in an 'upper motor neuron' pattern of bladder dysfunction due to uncontrolled overactivity of the parasympathetic supply. The bladder is small and highly sensitive to being stretched (analogous to spasticity). This results in frequency, urgency and urge incontinence.

Loss of the coordinating control of the pontine micturition centre will also result in the phenomenon of detrusor-sphincter dyssynergia, where detrusor contraction and sphincter relaxation are not coordinated; the spastic bladder will often try to empty against a closed sphincter. This manifests as both urgency and an inability to pass urine, which is distressing and painful, and may last some minutes before partial emptying of the bladder is achieved. There is often a post-micturition residuum of urine which is prone to infection, and the prolonged high bladder pressure may result in renal failure. More severe lesions of the spinal cord, as in spinal cord compression or trauma, can result in urinary retention; this will be painless as bladder sensation, normally carried in the lateral spinothalamic tracts, will be cut off.

Damage to the mesial frontal lobes gives rise to loss of awareness of bladder fullness and consequent incontinence. Coexisting cognitive impairment may result in inappropriate micturition. These features are seen typically in hydrocephalus, frontal tumours, dementia and bifrontal subdural haematomas.

When faced with a patient who has bladder symptoms, it is important to try to localise the lesion on the basis of history and examination, remembering that most bladder problems are not neurological unless there are overt neurological signs. Clinical features are summarised in Box 26.28.

Management of bladder disturbance involves identifying the cause and correcting it if possible. Overactive (spastic) bladders are common in neurological disease, and the unwanted detrusor activity (and hence urgency) can be lessened by anticholinergic drugs such as oxybutynin, tolterodine or imipramine. However, this will not solve the problem of detrusor-sphincter dyssynergia, and it may be necessary to teach the patient how to perform intermittent clean self-catheterisation (ISC); by emptying the bladder regularly, urinary frequency is reduced, as is the likelihood of infection. Bladder ultrasound is often helpful in this regard; a large (> 100 mL) post-micturition residual volume suggests that ISC will be necessary. Flaccid bladders are less common and unfortunately there is no effective drug treatment. These patients therefore need to perform ISC. Long-term cath-

eterisation (urethral or suprapubic) may be necessary in either spastic or flaccid bladders, but this is avoided if at all possible as it is associated with increased infection as well as blockage.

Rectal dysfunction

The rectum has an excitatory cholinergic input from the parasympathetic sacral outflow, and inhibitory sympathetic supply similar to the bladder. Continence depends largely on skeletal muscle contraction in the puborectalis and pelvic floor muscles supplied by the pudendal nerves, as well as the internal and external anal sphincters. Damage to the autonomic components usually causes constipation but diabetic neuropathy can be associated with diarrhoea. Lesions affecting the conus medullaris, the somatic S2–4 roots and the pudendal nerves cause faecal incontinence.

Erectile failure and ejaculatory failure

These related functions are under autonomic control via the pelvic nerves (parasympathetic, S2–4) and hypogastric nerves (sympathetic, L1–2). Descending influences from the cerebrum are important for psychogenic erection, but erection can occur as a purely reflex phenomenon in response to genital stimulation. Erection is largely parasympathetic, mediated by nitric oxide, and is impaired by drugs which have anticholinergic effects and also by some antihypertensive and antidepressant agents. Sympathetic activity is important for ejaculation, and may be inhibited by α -adrenoceptor antagonists (α -blockers). For further information on erectile impotence, see page 477.

HEADACHE SYNDROMES

Headaches are often classified as primary or secondary, depending on the underlying cause (see Box 26.4, p. 1148). There are many causes of secondary headache due to structural, infective, inflammatory or vascular conditions, but these are dealt with elsewhere. The primary

26.28 Neurogenic bladder: clinical features and treatment

	Site of lesion	Result	Treatment
Atonic (lower motor neuron)	Lesions of sacral segments of cord (conus medullaris) Lesions of sacral roots and nerves	Loss of detrusor contraction Difficulty initiating micturition Bladder distension with overflow	Intermittent self-catheterisation In-dwelling catheterisation
Hypertonic (upper motor neuron)	Pyramidal tract lesion in spinal cord or brain stem	Urgency with urge incontinence Bladder sphincter incoordination (dyssynergia) Incomplete bladder emptying	Anticholinergics Oxybutynin (5 mg 8–12-hourly) Imipramine (25 mg 12-hourly) Tolterodine (2 mg 12-hourly) Intermittent self-catheterisation
Cortical	Post-central Pre-central Frontal	Loss of awareness of bladder fullness Difficulty initiating micturition Inappropriate micturition Loss of social control	Intermittent catheterisation

headache syndromes are discussed in the following section.

Tension-type headache

This is the most common type of headache and is experienced at some time by the majority of the population in some form.

Pathophysiology

The cause of tension headaches is incompletely understood. Emotional strain or anxiety is a common precipitant to tension-type headache and there is sometimes an associated depressive illness. Anxiety about the headache itself may lead to continuation of symptoms, and patients often become convinced of a serious underlying condition. Muscular spasms in the head and neck have been suggested to be a cause but there is little direct evidence for this.

Clinical features

The pain of tension headache is usually constant and generalised but often radiates forward from the occipital region. It is described as 'dull', 'tight' or like a 'pressure', and there may be a sensation of a band round the head or pressure at the vertex. In contrast to migraine, the pain may continue for weeks or months without interruption, although the severity may vary, and there is no associated vomiting or photophobia. The patient can usually continue normal activities, and the pain may be less noticeable when the patient is occupied. The pain is characteristically less severe in the early part of the day and becomes more troublesome as the day goes on. Local tenderness may be present over the skull vault or in the occiput but this should be distinguished from the acute pain precipitated by skin contact in trigeminal neuralgia and the exquisite tenderness of temporal arteritis. Typically, the headache does not respond well to treatment with analgesics.

Management

Careful assessment followed by discussion of likely precipitants and explanation of the fact that the symptoms are not due to any sinister underlying pathology is more likely to be beneficial than analgesics. Excessive use of analgesics, particularly of codeine, may actually worsen the headache (analgesic headache). Physiotherapy (with muscle relaxation and stress management) is usually beneficial, and low-dose amitriptyline (10 mg nocte increased gradually to 30–50 mg) sometimes helps. There is evidence that patients benefit from a perception that their problem has been taken seriously and rigorously assessed, but over-investigation can worsen a patient's anxiety.

Migraine

Migraine is a common condition which affects about 20% of females and 6% of males at some point in life. Migraine usually presents before the age of 40 and it has been estimated that 90% of migraine sufferers have their first attack by this time. Although some patients refer to any episodic paroxysmal headache as migraine, there is a characteristic presentation as discussed below.

Pathophysiology

The cause of migraine is incompletely understood but there is increasing evidence that the aura (see below)

is due to dysfunction of ion channels which leads to a spreading front of cortical depolarisation (excitation) followed by hyperpolarisation (depression of activity). This process (the 'spreading depression of Leão') spreads over the cortex at a rate of about 3 mm/minute, corresponding to the spread of the symptoms of the aura. Family history is common in migraine, suggesting a genetic predisposition, and migraine-like phenomena can occur in some rare genetic disorders associated with mutations in calcium channel genes. These data are consistent with the hypothesis that the disorder may be due to abnormal function of ion channels, which in some cases is genetically determined. The great female preponderance and the tendency for some women to have migraine attacks at certain points in their menstrual cycle hint at hormonal influences. The relevance of the contraceptive pill in this context is difficult to establish, but it does appear to exacerbate migraine in many patients, and to increase the small risk of stroke in patients who suffer from migraine with aura. In some patients there are identifiable dietary precipitants such as cheese, chocolate or red wine. When psychological stress is involved, the migraine attack often occurs after the period of stress, so that some patients tend to have attacks at weekends or at the beginning of a holiday. The headache is associated with vasodilatation of extracranial vessels, but may be due to disturbed neuronal activity in the hypothalamus.

Clinical features

Migraine presents with a symptom triad of paroxysmal headache, nausea and/or vomiting, and an 'aura' of focal neurological events (usually visual). Patients with all three of these features are said to have migraine with aura ('classical' migraine). Those with paroxysmal headache (with or without vomiting) but no 'aura' are said to have migraine without aura ('common' migraine). A classical migraine attack starts with a non-specific prodrome of malaise and irritability followed by the aura of a focal neurological event, and then a severe, throbbing, hemicranial headache with photophobia and vomiting. During the headache phase, patients prefer to be in a quiet, darkened room and to sleep. The headache may persist for several days.

The aura most often takes the form of fortification spectra, which are shimmering, silvery zigzag lines which march across the visual fields over a period of about 20 minutes, sometimes leaving a trail of temporary visual field loss. In some patients there is a sensory aura which is a spreading front of tingling followed by numbness which moves, over 20–30 minutes, from one part of the body to another. If the dominant hemisphere is involved, the patient may also experience transient aphasia. Limb weakness can occur in migraine and is termed hemiplegic migraine. However, this is unusual and should be diagnosed with extreme caution. In some patients the focal events may occur by themselves ('migraine equivalent'), but in this case other structural disorders of the brain, or even focal epilepsy, need to be considered in the differential diagnosis. In a smaller number of patients, the symptoms of the aura do not resolve, leaving more permanent neurological disturbance ('complicated migraine').

Management

Identification and avoidance of precipitants or exacerbating factors (such as the contraceptive pill) may prevent attacks. Treatment of an acute attack consists of simple analgesia with aspirin or paracetamol, often combined with an antiemetic such as metoclopramide or domperidone. Long-term use of codeine-containing analgesic preparations should be avoided. Severe attacks can be treated with one of the 'triptans' (e.g. sumatriptan), 5-HT agonists that are potent vasoconstrictors of the extracranial arteries. These can be administered orally, sublingually, by subcutaneous injection or by nasal spray. Ergotamine preparations should be avoided since they easily lead to dependence. This is less likely to happen with the triptans, but it can occur. If attacks are frequent, they can often be prevented with propranolol (80–160 mg daily, in a sustained-release preparation), a tricyclic such as amitriptyline (10–50 mg at night), sodium valproate (300–600 mg/day) or topiramate (50–100 mg/day). Women should be warned that the small risk of ischaemic stroke attributable to taking oral contraception is increased if they have migraine with aura (see above), especially if they also smoke.

Cluster headache

Cluster headaches (also known as migrainous neuralgia) are 10–50 times less common than migraine. There is a 5:1 predominance of males and onset is usually in the third decade.

Pathophysiology

The cause is unclear. There is little evidence for a genetic predisposition, there are no provoking dietary factors and there is a male predominance. Functional imaging studies have suggested abnormal neuronal activity in

the hypothalamus. Patients are usually heavy smokers with a higher than average alcohol consumption.

Clinical features

The characteristic presentation is with periodic, severe, unilateral periorbital pain accompanied by unilateral lacrimation, nasal congestion and conjunctival injection, often with the other features of Horner's syndrome. The pain, whilst being very severe, is characteristically brief (30–90 minutes). Typically, the patient develops these symptoms at a particular time of day (often in the early hours of the morning). The syndrome may occur repeatedly for a number of weeks, followed by a respite for a number of months before another cluster occurs.

Management

Acute attacks can usually be halted by subcutaneous injections of sumatriptan or by inhalation of 100% oxygen, but other migraine therapies are ineffective, probably because of the brevity of the individual attacks. Preventative therapy with the agents used for migraine is often ineffective but attacks can be prevented in some patients by verapamil (80–120 mg 8-hourly), methysergide (4–10 mg daily, for a maximum of 3 months only) or short courses of oral corticosteroids. Patients with severe and debilitating clusters can be helped with lithium therapy, although the usual precautions concerning the use of this drug should be observed (p. 243).

Other headache syndromes

There are a number of rare headache syndromes which produce pains about the eye similar to cluster headaches (Box 26.29). These include chronic and paroxysmal hemicrania, and SUNCT (short-lasting unilateral neuralgiform headaches with conjunctival injection and tearing). The recognition of these syndromes is useful

26.29 Benign paroxysmal headaches

	Character of pain	Duration	Location	Comment
Ice pick	Stabbing	Very brief (split-second)	Variable, usually temporal or parietal	Benign, more common in migraine
Ice cream	Sharp, severe	30–120 seconds	Bitemporal/occipital	Obvious trigger by cold stimuli
Exertional/coital	Bursting, thunderclap	Severe for minutes then less severe for hours	Generalised	Subarachnoid haemorrhage needs exclusion
Cough	Bursting	Seconds to minutes	Occipital or generalised	Intracranial pathology needs exclusion (especially cranio-cervical junction)
Cluster headache (migrainous neuralgia)	Severe unilateral, with ptosis, tearing, conjunctival injection, unilateral nasal congestion	30–90 minutes 1–3 times per day	Periorbital	Usually men, occurring in clusters over weeks/months
Chronic paroxysmal hemicrania	Severe unilateral with cluster headache-like autonomic features (above)	5–20 minutes, frequently through day	Periorbital/temporal	Usually women, responds to indometacin
SUNCT*	Severe, sharp, triggered by touch or neck movements	15–120 seconds, repetitive through day	Periorbital	May respond to carbamazepine

*Short-lasting, Unilateral, Neuralgiform headache with Conjunctival injection, Tearing, rhinorrhoea and forehead sweating.

since they often respond to specific treatments such as indometacin.

Trigeminal neuralgia

This is characterised by lancinating pain in the second and third divisions of the trigeminal nerve territory, usually in patients over the age of 50 years.

Pathophysiology

Trigeminal neuralgia is thought to be caused by an aberrant loop of the cerebellar arteries compressing the trigeminal nerve as it enters the brain stem. Other compressive lesions, usually benign, are occasionally found. When trigeminal neuralgia occurs in multiple sclerosis, there is a plaque of demyelination in the trigeminal root entry zone.

Clinical features

The pain is severe and very brief but repetitive, causing the patient to flinch as if with a motor tic (hence the French term for the condition, 'tic douloureux'). It may be precipitated by touching trigger zones within the trigeminal territory, by cold wind blowing on the face, or by eating. Physical signs are usually absent. Similar symptoms may occur in multiple sclerosis or, rarely, with other brain-stem lesions, in which case there may be sensory changes in the trigeminal nerve territory (and possibly other brain-stem symptoms and signs). There is a tendency for the condition to remit and relapse over many years.

Management

The pain usually responds to carbamazepine in doses of up to 1200 mg daily. It is wise to start with a low dose and increase gradually, according to effect. In patients who cannot tolerate carbamazepine, gabapentin or pregabalin may be effective. Various surgical treatments are available, the simplest of which is injection of alcohol or phenol into a peripheral branch of the nerve. Probably more effective is making a radiofrequency lesion in the nerve near the Gasserian ganglion. Care has to be taken not to cause excessive damage to sensation in the face to prevent the complication of neurogenic pain ('anaesthesia dolorosa') which is worse than the neuralgia. Alternatively, the vascular compression of the trigeminal nerve can be relieved through a posterior craniotomy, often with substantial success. This latter approach is usually favoured in younger patients in whom the other injection treatments may have to be repeated and become less effective.

Post-coital and exercise-induced headache

This usually affects men in their thirties and forties. Patients develop a sudden, severe headache at the climax of sexual intercourse. There is usually no vomiting and no neck stiffness, and it does not persist for more than 10–15 minutes, though a less severe, dull headache may persist for some hours. This type of paroxysmal headache often needs to be distinguished by CT and/or CSF examination from subarachnoid haemorrhage (see Fig. 26.35, p. 1190). A very similar headache may occur during physical exertion, especially if this is attempted with unaccustomed vigour in an unfit person. The pathogenesis is unknown. Though frightening, coital or exer-

tional cephalgia is usually brief and may not need more than ordinary analgesia for the residual headache. The syndrome may not recur but prevention with propranolol or indometacin (75 mg daily) may be necessary.

VESTIBULAR DISORDERS

Vestibular disorders typically present with vertigo (see above) and the majority of patients with an organic cause of vertigo will have labyrinthitis, benign paroxysmal positional vertigo or Ménière's disease.

Labyrinthitis

This condition, also known as vestibular neuronitis, is the most common cause of severe vertigo, but the cause is unknown. It usually presents in the third or fourth decade as severe vertigo, with vomiting but no tinnitus or deafness. It often starts on waking, and patients are usually bedbound by the vertigo for the first few days. The vertigo usually settles over 3–4 days, though head movement may continue to provoke transient symptoms (positional vertigo) for some time and it may take a month or so before the patient feels 'back to normal'. During the acute attack, nystagmus (p. 1165) will be present but this typically disappears after a few days.

Symptomatic relief can be achieved with antihistamines such as cinnarizine, prochlorperazine, and betahistine. These agents should not be used for long-term treatment of persistent vertigo as they are ineffective and actually delay recovery in many patients. Patients with intractable symptoms may need referral to an ENT specialist for assessment, but input from an experienced vestibular physiotherapist is invaluable.

Benign paroxysmal positional vertigo

This is due to the presence of otolithic debris from the saccule or utricle affecting the free flow of endolymph in the semicircular canals (cupulolithiasis). It may follow head injury, but is more common in older patients who complain of paroxysms of vertigo occurring with certain head movements, typically looking up or turning over in bed. Each attack of vertigo lasts seconds but patients often become very distressed and reluctant to move their head, and this can produce a muscle tension-type headache. Secondary hyperventilation attacks and associated depressive features are also common. The diagnosis can be confirmed by the 'Hallpike manoeuvre' to demonstrate positional nystagmus (Fig. 26.25). Although this test is often difficult to perform adequately as patients are frightened by the vertigo, it is useful since it reassures the patient that the doctor knows what is going on. Treatment comprises explanation, along with vestibular exercises designed to send the otolithic debris back from semicircular canal to saccule or utricle (such as the Epley manoeuvre) and/or to re-educate the brain to cope with the inappropriate signals from the labyrinth (such as Cawthorne–Cooksey exercises). The Epley manoeuvre starts with the patient sitting upright on an examination couch. They are asked to lie back with their head turned at a 45° angle to the affected side, and to hold this position for 30–60 seconds. They should then be asked to turn their head 90° to the opposite side and remain in that position for 30–60 seconds. Next, they should be asked to roll on to

A

B

Fig. 26.25 The Hallpike manoeuvre for diagnosis of benign paroxysmal positional vertigo (BPPV). Patients are asked to keep their eyes open and look at the examiner as their head is swung briskly backwards through 120° to overhang the edge of the couch. **A** Perform first with the right ear down. **B** Perform next with the left ear down. The examiner looks for nystagmus (usually accompanied by vertigo). In BPPV, the nystagmus typically occurs in A or B only and is torsional, the fast phase beating towards the lower ear. Its onset is usually delayed a few seconds, and it lasts 10–20 seconds. As the patient is returned to the upright position, transient nystagmus may occur in the opposite direction. Both nystagmus and vertigo typically decrease (fatigue) on repeat testing.

their side in the direction they are facing, so that their face is pointing towards the floor, and hold that position for 30–60 seconds before sitting up once again. Cawthorne-Cooksey exercises involve asking the patient to perform a series of eye, head and whole-body movements whilst lying down, sitting and standing. Antihistamines can be tried if the condition fails to respond to the above measures. (See page 1235 for websites.)

Ménière's disease

This is due to an abnormality of the endolymph which gives rise to paroxysms comprising a sensation of fullness in the ear followed by headache, tinnitus and profound vertigo, each attack typically lasting about 4 hours. In between attacks, patients' hearing may be distorted (typically low-tone deafness). While sensorineural hearing loss may be demonstrable, bedside examination is typically otherwise normal in between attacks, but audiometry is usually abnormal. Management is as described for labyrinthitis.

EPILEPSY

A seizure is any clinical event caused by an abnormal electrical discharge in the brain, whilst epilepsy is the tendency to have recurrent seizures. Epilepsy should be regarded as a symptom of brain disease rather than a disease itself. A single seizure is not epilepsy but an indication for investigation, and medication should generally be withheld until recurrent seizures occur. The recurrence rate after a first seizure is about 70% within the first year, and most recurrent attacks occur within a month or two of the first. Further seizures are less likely if a trigger factor is definable and avoidable (Box 26.30). In some conditions, epilepsy is the

26.30 Trigger factors for seizures

- Sleep deprivation
- Alcohol (particularly withdrawal)
- Recreational drug misuse
- Physical and mental exhaustion
- Flickering lights, including TV and computer screens (primary generalised epilepsies only)
- Intercurrent infections and metabolic disturbances
- Uncommonly: loud noises, music, reading, hot baths

26.31 Classification of epilepsy

Seizure type

- Partial (simple or complex)
- Partial with secondary generalisation
- Absence
- Tonic clonic
- Tonic
- Atonic
- Myoclonic

Physiology (EEG)

- Focal spikes/sharp waves
- Generalised spike and wave

Anatomical site

- Cortex
 - Temporal
 - Frontal
 - Parietal
 - Occipital
- Generalised (diencephalon)
- Multifocal

Pathological cause

- Genetic
- Developmental
- Tumours
- Trauma
- Vascular
- Infections
- Inflammation
- Metabolic
- Drugs, alcohol and toxins
- Degenerative

26.32 Primary generalised epilepsies

	Incidence	Age of onset	Type of seizure	EEG features	Provoking factors	Treatment	Prognosis
Childhood absence epilepsy	6–8/100 000	4–8 yrs	Frequent brief absences	3/s spike and wave	Hyperventilation, fatigue	Ethosuximide Sodium valproate	40% develop GTCS, 80% remit in adulthood
Juvenile absence epilepsy	1–2/100 000	10–15 yrs	Less frequent absences than childhood absence	Poly-spike and wave	Hyperventilation, sleep deprivation	Sodium valproate	80% develop GTCS, 80% seizure-free in adulthood
Juvenile myoclonic epilepsy	25–50/100 000	15–20 yrs	GTCS, absences, morning myoclonus	Poly-spike and wave, photosensitivity	Sleep deprivation, alcohol withdrawal	Sodium valproate	90% remit with AEDs but relapse if AED withdrawn
GTCS on awakening	Common	10–25 yrs	GTCS, sometimes myoclonus	Spike and wave on waking and sleep onset	Sleep deprivation	Sodium valproate	65% controlled with AEDs but relapse off treatment

(GTCS = generalised tonic clonic seizure; AED = anti-epileptic drug)

only feature of underlying disease, whilst in others epilepsy is just one of the manifestations. The annual incidence of new cases of epilepsy after infancy is 20–70/100 000. The lifetime risk of having a single seizure is about 5%, whilst the prevalence of epilepsy in European countries is about 0.5%. The prevalence in developing countries is up to five times higher than in developed countries.

The classification of epilepsy is best achieved by considering the clinical events (the seizures), the abnormal electrophysiology, the anatomical site of seizure genesis and the pathological cause of the problem (Box 26.31).

Primary generalised epilepsy

The primary or idiopathic epilepsies make up some 10% of all epilepsies, including some 40% of those with tonic clonic seizures. Onset is almost always in childhood or adolescence. No structural abnormality is present and there is often a substantial genetic predisposition. Some, like childhood absence epilepsy, are relatively uncommon, whilst others, like juvenile myoclonic epilepsy, are common (5–10% of all patients with epilepsy). The more common varieties of primary generalised epilepsy are listed in Box 26.32, along with their clinical features and management.

Partial epilepsy

Partial seizures may arise from any disease of the cerebral cortex, congenital or acquired, and frequently generalise. With the exception of a few idiopathic partial epilepsies of benign outcome in childhood, the presence of partial seizures signifies the presence of focal cerebral pathology. Common causes are listed in Box 26.33.

Secondary generalised epilepsy

Generalised epilepsy may arise from spread of partial seizures due to structural disease, or may be secondary to drugs or metabolic disorders (Box 26.34). Epilepsy presenting in adult life is almost always secondary generalised, even if there is no clear history of a partial seizure before the onset of a major attack (an 'aura'). The occurrence of epilepsy in those over the age of 60 is frequently

due to cerebrovascular disease and presents specific diagnostic and management problems (Box 26.35).

Pathophysiology

Under normal circumstances, recurrent and collateral inhibitory circuits in the cerebral cortex limit synchronous discharge of neighbouring groups of neurons.

26.33 Causes of partial seizures

Idiopathic

- Benign Rolandic epilepsy of childhood
- Benign occipital epilepsy of childhood

Focal structural lesions

Genetic

- Tuberous sclerosis (p. 1283)
- von Hippel–Lindau disease (p. 1219)
- Neurofibromatosis (p. 1218)
- Cerebral migration abnormalities

Infantile hemiplegia

Dysembryonic

- Cortical dysgenesis
- Sturge–Weber syndrome

Mesial temporal sclerosis (associated with febrile convulsions)

Cerebrovascular disease (p. 1180)

- Intracerebral haemorrhage
- Cerebral infarction
- Arteriovenous malformation
- Cavernous haemangioma

Tumours (primary and secondary) (p. 1216)

Trauma (including neurosurgery)

Infective (p. 1205)

- Cerebral abscess (pyogenic)
- Toxoplasmosis
- Cysticercosis
- Tuberculoma
- Subdural empyema
- Encephalitis
- Human immunodeficiency virus (HIV)

Inflammatory

- Sarcoidosis
- Vasculitis

26.34 Causes of secondary generalised epilepsy

Secondary generalisation from partial seizures

- See Box 26.33 for causes of partial seizures

Genetic

- Inborn errors of metabolism (p. 61)
- Storage diseases (p. 448)
- Phakomatoses (e.g. tuberous sclerosis, p. 1283)

Cerebral birth injury**Hydrocephalus****Cerebral anoxia****Drugs**

- Antibiotics: penicillin, isoniazid, metronidazole
- Antimalarials: chloroquine, mefloquine
- Ciclosporin
- Cardiac anti-arrhythmics: lidocaine, disopyramide
- Psychotropic agents: phenothiazines, tricyclic antidepressants, lithium
- Amphetamines (withdrawal)

Alcohol (especially withdrawal)**Toxins**

- Heavy metals (lead, tin)
- Organophosphates (sarin)

Metabolic disease

- Hypocalcaemia
- Hypoglycaemia
- Hyponatraemia
- Renal failure
- Hypomagnesaemia
- Liver failure

Infective

- Meningitis (p. 1205)
- Post-infectious encephalopathy

Inflammatory

- Multiple sclerosis (uncommon) (p. 1191)
- SLE (p. 1107)

Diffuse degenerative diseases

- Alzheimer's disease (uncommonly) (p. 1198)
- Creutzfeldt-Jakob disease (rarely) (p. 1214)

The inhibitory transmitter gamma-aminobutyric acid

26.35 Epilepsy in old age

- **Incidence and prevalence:** late-onset epilepsy is very common and the annual incidence in those over 60 years is rising.
- **Fits and faints:** the features that usually differentiate these may be less definitive than in younger patients.
- **Complex partial status epilepticus:** can present as confusion in the elderly.
- **Cerebrovascular disease** is the underlying cause of seizures in 30–50% of patients over the age of 50 years. A seizure may occur with an overt stroke or with occult vascular disease.
- **Anti-epileptic drug regimens:** keep as simple as possible and take care to avoid interactions with other drugs being prescribed.
- **Carbamazepine-induced hyponatraemia:** increases significantly with age; particularly important in patients on diuretics or those with heart failure.
- **Withdrawal of anticonvulsant therapy:** late-onset epilepsy often recurs when drug treatment is stopped, so drug withdrawal should not be attempted where it was commenced appropriately.

(GABA) is particularly important in this role, and drugs that block GABA receptors provoke seizures. Conversely, excessive stimulation by excitatory neurotransmitters, such as acetylcholine, glutamate and aspartate, provoke seizure activity. It is likely that both reduction of inhibition and excessive excitation play a part in the genesis of most seizures. The cerebral cortex in epilepsy exhibits hypersynchronous, repetitive discharges involving large groups of neurons, intracellular recordings of which demonstrate bursts of high-frequency action potentials associated with a reduction in the transmembrane potential (paroxysmal depolarisation shift). In animal models, cells undergoing repetitive epileptic discharges undergo morphological and physiological changes which make them more likely to produce subsequent abnormal discharges ('kindling').

Seizures may be partial (focal) in which paroxysmal neuronal activity is limited to one part of the cortex, or generalised when the electrophysiological abnormality involves both hemispheres simultaneously and synchronously (Fig. 26.26). If partial seizures remain localised, the symptomatology depends on which cortical area is affected. If consciousness (the awareness of and ability to respond to the environment) is preserved, the attack is termed a 'simple partial' seizure. If consciousness is lost, this is termed a 'complex partial' seizure and this implies that the seizure activity has involved parts of the brain concerned with awareness (such as the temporal or frontal lobes). Partial seizures may spread into the

Fig. 26.26 The pathophysiological classification of seizures.

A A partial seizure originates from a paroxysmal discharge in a focal area of the cerebral cortex (often the temporal lobe); the seizure may subsequently spread to the rest of the brain (secondary generalisation) via diencephalic activating pathways. **B** In primary generalised seizures the abnormal electrical discharges originate from the diencephalic activating system and spread simultaneously to all areas of the cortex.

diencephalon and thence throughout the rest of the cortex, leading to a 'secondarily generalised' seizure.

In 'primary generalised' seizures, the abnormal activity begins synchronously throughout the cortex without an initial partial onset. It probably originates in the central diencephalic mechanisms controlling cortical activation (see Fig. 26.26). This is recognisable on an EEG as spike and wave discharges (see Fig. 26.10, p. 1141) and quite often hyperventilation and/or photic stimulation will provoke such discharges. There are several possible manifestations of primary generalised epilepsy; some seizures may appear identical to a secondarily generalised ('tonic clonic') seizure, while in others there may be a more restricted clinical manifestation if the abnormal electrical activity fails to affect muscle tone. The latter seizures are termed 'absences'. These are typically brief and involve transient loss of consciousness but the patient remains standing or sitting. Such attacks may be difficult to distinguish clinically from complex partial seizures.

Clinical features

When taking a history from a patient with suspected seizure, it is important to clarify which type of attack is occurring, bearing in mind that there may be more than one occurring in the same patient at different times. Sometimes specific trigger factors can be identified, as discussed above (see Box 26.30, p. 1172). The type of seizure, along with further information from history and investigation, can then be used to determine the epilepsy syndrome, as discussed in the next section. Descriptions of the more common types of seizure follow.

Tonic clonic seizures

A tonic clonic seizure may be preceded by a partial seizure (the 'aura') which can take various forms, described below. However, a history of such an 'aura' is commonly not obtained, probably because the subsequent generalised seizure causes some retrograde amnesia for immediately preceding events. The patient then goes rigid and becomes unconscious, falling down heavily if standing and often sustaining injury. During this phase, respiration is arrested and central cyanosis may occur. After a few moments, the rigidity is periodically relaxed, producing clonic jerks. Some patients do not have a clonic phase and the rigidity is replaced by a flaccid state of deep coma which can persist for some minutes. The patient then gradually regains consciousness, but is in a confused and disorientated state for half an hour or more after regaining consciousness. Full memory function may not be recovered for some hours. During the attack, urinary incontinence and tongue-biting may occur. A severely bitten, bleeding tongue after an attack of loss of consciousness is pathognomonic of a generalised seizure. After a generalised seizure the patient usually feels terrible, may have a headache and will often want to sleep. Witnesses of a seizure are usually frightened by the event, often believe the person to be dying, and may not give a clear account of the episode. This in itself can be a helpful diagnostic pointer since syncope seldom produces such fear in onlookers. Patients may have no tonic or clonic phase, and may not become cyanosed or bite their tongue. However, post-ictal confusion is useful in differentiating seizures from syncope. Psychogenic non-epileptic attacks ('pseudo-seizures') may be accompanied by dramatic flailing of the limbs and arching of

the back; however, these are not usually followed by the same degree of post-ictal confusion and do not usually cause cyanosis (see Box 26.9, p. 1151).

Complex partial seizures

Complex partial seizures involve episodes of altered consciousness without the patient collapsing to the ground, especially if they arise from the temporal or, less frequently, the frontal lobe. Patients stop what they are doing and stare blankly, often blinking repetitively, making smacking movements of their lips, or displaying other automatisms, such as picking at their clothes. After a few minutes, consciousness returns but the patient may be muddled and feel drowsy for a period of up to an hour. Immediately before such an attack the patient may report alteration of mood, memory or perception (such as undue familiarity – déjà vu – or unreality – jamais vu), or complex hallucinations involving sound, smell, taste, vision, emotion (fear, sexual arousal) or visceral sensations (nausea, epigastric discomfort). If these changes of memory or perception occur without subsequent alteration in awareness, the seizure is said to be a 'simple partial' seizure.

Complex partial seizures arising from the anterior parts of the frontal lobe may produce bizarre behaviour patterns including limb posturing, sleep walking, or even frenetic ill-directed motor activity with incoherent screaming. These can sometimes be very difficult to distinguish from psychogenic attacks (which are more common). However, abruptness of onset and relative brevity may help point to frontal seizures, as may a tendency to occur out of sleep.

Absence seizures

Absence seizures (*petit mal*) always start in childhood. The attacks can be mistaken for complex partial seizures but are shorter in duration; they occur much more frequently (20–30 times a day) and are not associated with post-ictal confusion. Absence attacks are caused by a generalised discharge that does not spread out of the hemispheres and so does not cause loss of posture.

Atonic seizures

These are seizures involving brief loss of muscle tone, usually resulting in heavy falls with or without loss of consciousness. They only occur in the context of epilepsy syndromes which involve other forms of seizure. They are not a cause of collapse in patients without epilepsy.

Partial motor seizures

Epileptic activity arising in the pre-central gyrus causes partial motor seizures affecting the contralateral face, arm, trunk or leg. Seizures are characterised by rhythmical jerking or sustained spasm of the affected parts. They may remain localised to one part, or may spread to involve the whole side. Some attacks begin in one part of the body (e.g. mouth, thumb, great toe) and spread (march) gradually to other parts of the body; this is known as a Jacksonian seizure. Attacks vary in duration from a few seconds to several hours (*epilepsia partialis continua*). More prolonged episodes may be followed by paresis of the involved limb lasting for several hours after the seizure ceases (Todd's palsy).

Partial sensory seizures

Seizures arising in the sensory cortex cause unpleasant tingling or 'electric' sensations in the contralateral face or limbs. A spreading pattern similar to a Jacksonian

seizure may occur, the abnormal sensation spreading over the body much faster (in seconds) than the march of a migrainous focal sensory attack, which spreads over 20–30 minutes (p. 1169).

Versive seizures

A frontal epileptic focus may involve the frontal eye field, causing forced deviation of the eyes and sometimes turning of the head to the opposite side. This type of attack often generalises to become a tonic clonic seizure.

Partial visual seizures

Occipital epileptic foci cause simple visual hallucinations such as balls of light or patterns of colour. Formed visual hallucinations of faces or scenes arise more anteriorly in the temporal lobes.

Investigations

After a first seizure, immediate cerebral imaging with CT or MRI is advisable, particularly in patients aged over 20 years, although the yield of structural lesions is low unless there are focal features to the seizure or there are focal signs. Other investigations for infective, toxic and metabolic causes (see Box 26.34) may be appropriate. An EEG performed immediately after a seizure may be more helpful in showing focal features than if performed after a delay.

In a situation where more than one seizure has occurred, an EEG is often useful in establishing the type of epilepsy and to guide therapy. The increasing sophistication of imaging techniques now allows the identification of the cause of epilepsy in an increasing number of patients, especially those with partial seizures. Investigations should be pursued more vigorously if the epilepsy is intractable to treatment. Investigations that may be appropriate in a patient with suspected epilepsy are shown in Box 26.36. The EEG may help to establish a

diagnosis and characterise the type of epilepsy. Inter-ictal records are abnormal in only about 50% of patients with definite epilepsy so the EEG cannot be reliably used to exclude the diagnosis. However, 'epileptiform changes' (sharp waves or spikes) on the EEG are fairly specific for epilepsy (falsely positive in 1/1000). The sensitivity can be increased to about 85% by prolonging recording time and including a period of natural or drug-induced sleep. Ambulatory EEG recording or video/EEG monitoring may provide helpful information when attacks are frequent.

Imaging cannot establish a diagnosis of epilepsy but it is useful in defining or excluding a structural cause. Indications for imaging are summarised in Box 26.37. Imaging is not required if a confident diagnosis of primary generalised epilepsy can be made with an EEG. CT is often sufficient to exclude a major structural cause of epilepsy. MRI of the brain may be indicated if CT shows no abnormality but a subtle structural change is still suspected, as in the case of patients with partial seizures (with or without secondary generalisation) which are resistant to therapy.

Management

It is important to explain the nature and cause of seizures to patients and their relatives, and to instruct relatives in the first aid management of major seizures (Boxes 26.38 and 26.39). Many people with epilepsy feel stigmatised

26.36 Investigation of suspected epilepsy

Are the attacks truly epileptic?

- Ambulatory EEG
- Videotelemetry

From where is the epilepsy arising?

- Standard EEG
- Sleep EEG
- EEG with special electrodes (foramen ovale, subdural)

What is the cause of the epilepsy?

Structural lesion?

- CT
- MRI

Metabolic disorder?

- Urea and electrolytes
- Liver function tests
- Blood glucose
- Serum calcium, magnesium

Inflammatory or infective disorder?

- Full blood count, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP)
- Chest X-ray
- Serology for syphilis, HIV, collagen disease
- CSF examination

26.37 Indications for brain imaging in epilepsy

- Epilepsy starting after the age of 20 years
- Seizures having focal features clinically
- EEG showing a focal seizure source
- Control of seizures difficult or deteriorating

26.38 How to administer first aid for seizures

- Move person away from danger (fire, water, machinery, furniture)
- After convulsions cease, turn into 'recovery' position (semi-prone)
- Ensure airway is clear, but do **NOT** insert anything in mouth (tongue-biting occurs at seizure onset and cannot be prevented by observers)
- If convulsions continue for more than 5 minutes or recur without person regaining consciousness, summon urgent medical attention
- Do not leave person alone until fully recovered (drowsiness and confusion can persist for up to 1 hour)

26.39 Immediate management of seizures

- Ensure airway is patent
- Give oxygen to offset cerebral hypoxia
- Give intravenous anticonvulsant (e.g. diazepam 10 mg) **ONLY** if convulsions are continuous or repeated (if so, manage as for status epilepticus, Box 26.45)
- Take blood for anticonvulsant levels (if known epileptic)
- Investigate cause

by society and may become unnecessarily isolated from work and social life. It should be emphasised that any brain can develop a seizure, that epilepsy is a common disorder which affects 0.5–1% of the population, and that good control of seizures can be expected in more than 80% of patients.

Immediate care

Little can or needs to be done for a person whilst a major seizure is occurring except for first aid and common-sense manoeuvres to limit damage or secondary complications (see Box 26.38).

Lifestyle modification

As soon as possible, patients should be made aware of the riskiness of any activity where loss of awareness would be dangerous until good control of seizures has been established. Such activities include work or recreational activities involving exposure to heights, dangerous machinery, open fires or water. Only shallow baths (or showers) should be taken, preferably with someone else in the house and with the bathroom door unlocked. Cycling should be discouraged until at least 6 months' freedom from seizures has been achieved. Activities requiring prolonged proximity to water (swimming, fishing or boating) should always be in the company of someone who is aware of the risk of a seizure and who is able to rescue the patient if necessary. In the UK and many other countries, legal restrictions regarding vehicle driving apply to patients after a first unprovoked seizure and those with epilepsy, here defined as more than one seizure occurring after the age of 5 years (Box 26.40). The patient should inform the licensing authorities about the onset of seizures, and it is also wise to notify the motor insurance company. Certain occupations, such as nursery nurse or airline pilot, are not open to anyone who has ever had an epileptic seizure; further information is often available from epilepsy support organisations.

26.40 UK driving regulations

Private use

Single seizure

- Cease driving until 1 year has passed without recurrence. Driver and Vehicle Licensing Authority (DVLA) will then restore a full licence

Epilepsy (i.e. more than one seizure over age 5 years)

- Cease driving immediately
- Licence restored when patient is free from all types of seizure for 1 year *or* seizures have occurred *exclusively* during sleep for a period of at least 3 years
- Licence will require renewal every 3 years thereafter until patient is seizure-free for 10 years

Withdrawal of anticonvulsants

- Cease driving during withdrawal period and for 6 months thereafter

Vocational drivers (heavy goods and public service vehicles)

- No licence permitted if any seizure has occurred after the age of 5 years until patient is off medication and seizure-free for more than 10 years, and has no potentially epileptogenic brain lesion

Anticonvulsant therapy

Drug treatment should be considered after more than one seizure has occurred and the patient agrees that seizure control is worthwhile. A wide range of drugs is available. The mode of action of these agents is either to increase inhibitory neurotransmission in the brain or to alter neuronal sodium channels in such a way as to prevent abnormally rapid transmission of impulses. In 80% of patients whose epilepsy is controllable, only a single drug is necessary. The combination of more than two drugs is seldom required. Dose regimens should be kept as simple as possible to promote compliance. Some guidelines are listed in Box 26.41. With the exception of absence attacks and juvenile myoclonic epilepsy, there is no hard evidence indicating that one drug is superior to another in the treatment of epilepsy. The first choice should be one of the established first-line drugs (Box 26.42), with the more recently introduced drugs as second choice. Phenytoin and carbamazepine are not ideal agents for a young woman wishing to use oral contraception, because the drugs induce liver enzymes. Phenobarbital and topiramate have similar effects. Carbamazepine, lamotrigine and sodium valproate are preferable to phenytoin as first-line drugs because of the side-effect profile of the latter and its complicated pharmacokinetics.

Monitoring therapy

With some drugs such as phenytoin and carbamazepine, occasional measurement of the blood level can be a guide to whether the patient is on an appropriate dose and is complying with the medication, but blood levels need to be interpreted carefully. The dose of anticonvulsant drug in an individual patient should primarily be governed by the efficacy of seizure control and the development of side-effects rather than blood levels alone. With sodium valproate, there is a poor relationship between blood levels and anticonvulsant efficacy, and so levels are really only useful to assess compliance. Repeated measurement of blood

26.41 Guidelines for anticonvulsant therapy

- Start with one first-line drug (see Box 26.42)
- Start at a low dose; gradually increase dose until effective control of seizures is achieved or side-effects develop (drug levels may be helpful)
- Optimise compliance (use minimum number of doses per day)
- If first drug fails (seizures continue or side-effects develop), start second first-line drug whilst gradually withdrawing first
- If second drug fails (seizures continue or side-effects develop), start second-line drug in combination with preferred first-line drug at maximum tolerated dose (beware interactions)
- If this combination fails (seizures continue or side-effects develop), replace second-line drug with alternative second-line drug
- If this combination fails, check compliance and reconsider diagnosis (is there an occult structural or metabolic lesion or are seizures truly epileptic?)
- If this combination fails, consider alternative, non-drug treatments (e.g. epilepsy surgery, vagal nerve stimulation)
- Do not use more than two drugs in combination at any one time

26.42 Guidelines for choice of AED

Epilepsy type	First-line	Second-line	Third-line
Partial and/or secondary GTCS	Carbamazepine	Lamotrigine Sodium valproate Levetiracetam Topiramate	Tiagabine Pregabalin Gabapentin Clobazam Phenytoin Primidone Phenobarbital Oxcarbazepine Vigabatrin Acetazolamide
Primary GTCS	Sodium valproate	Lamotrigine Topiramate	Carbamazepine Phenytoin Gabapentin Pregabalin Primidone Phenobarbital Tiagabine Acetazolamide
Absence	Ethosuximide	Sodium valproate	Lamotrigine Clonazepam Acetazolamide
Myoclonic	Sodium valproate	Clonazepam	Piracetam Levetiracetam Lamotrigine Phenobarbital
N.B. Preferably one and no more than two drugs should be used at one time.			

levels is not generally useful and monitoring is of most value in dealing with suspected toxicity (particularly if more than one drug is being taken), in dealing with the pharmacokinetic effects of pregnancy, or in suspected non-compliance.

Withdrawing anticonvulsant therapy

After complete control of seizures for 2–4 years, withdrawal of medication may be considered. Childhood-onset epilepsy, particularly classical absence seizures, carries the best prognosis for successful drug withdrawal. Other primary generalised epilepsies, such as juvenile myoclonic epilepsy, have a marked liability to recur after drug withdrawal. Seizures that begin in adult life, particularly those with partial features, are also likely to recur, especially if there is an identified structural lesion. Overall, the recurrence rate of seizures after drug withdrawal is about 40%. Some adult patients tend to opt for continuation of therapy because they feel that the threat of further attacks (especially the threat to driving) outweighs any drawbacks of continuing with medication. The EEG is generally a poor predictor of seizure recurrence but if the record is still very abnormal, drug withdrawal is unwise. Withdrawal should be undertaken slowly, reducing the drug dose gradually over 6–12 months. In the UK, patients must stop driving whilst withdrawing from their anti-epileptic medication and not drive for 6 months after full withdrawal of the drugs (see Box 26.40).

Contraception

Many anticonvulsant drugs, including carbamazepine, phenytoin, topiramate and barbiturates, induce hepatic enzymes and accelerate the metabolism of oestrogen, causing breakthrough bleeding and contraceptive failure. The safest policy is to use an alternative contraceptive method, but it is sometimes possible to overcome the problem by giving a higher-dose preparation of oestrogen. Lamotrigine and oxcarbazepine have little interaction, and sodium valproate has no interaction with oral contraception.

Pregnancy

Epilepsy presents specific management problems during pregnancy (Box 26.43). With the exception of gabapentin, treatment with almost all anticonvulsant drugs is associated with an increased incidence of fetal congenital abnormalities such as cleft lip, spina bifida and cardiac defects. The risk is greatest when treatment is given during the first trimester, rising from a background risk of 2–4% to about 4–8% with one anti-epileptic drug, and to about 15% with two or more drugs. Folic acid (5 mg daily) taken 2 months before conception may reduce the risk of some fetal abnormalities. Seizures often become more frequent during pregnancy, particularly during the third trimester when plasma anticonvulsant levels tend to fall. Monitoring of blood levels of anticonvulsants can be helpful with adjustment of drug doses. Occasionally, in a well-controlled patient, anticonvulsants can be withdrawn before conception, but if major seizures have occurred in the preceding year this is unwise, since uncontrolled maternal seizures represent a significant risk to the fetus.

Menstrual irregularities and polycystic ovarian disease are more common in women taking sodium valproate, and osteoporosis is more common in women taking one of the enzyme-inducing antiepileptic drugs.

Prognosis

Overall, generalised seizures are more readily controlled than partial seizures. The presence of a structural lesion makes complete control of the epilepsy less likely. The overall prognosis for epilepsy is shown in Box 26.44.

26.43 Epilepsy during pregnancy

- **Fetal malformation:** most anticonvulsants increase the risk—twofold increase in risk with one drug; fourfold increase with two or more drugs. Start folic acid 5 mg daily for 2 months before conception to reduce risk.
- **Haemorrhagic disease of the newborn:** anticonvulsants increase risk. Give oral vitamin K 20 mg daily to the mother during last month. Give i.m. vitamin K 1 mg to the infant at birth.
- **Increased frequency of seizures:** monitor anticonvulsant levels and adjust the dose regimen accordingly.

26.44 Epilepsy: outcome after 20 years

- 50% are seizure-free, without drugs, for last 5 years
- 20% are seizure-free for last 5 years but continue to take medication
- 30% continue to have seizures in spite of anti-epileptic therapy

There is a 40-fold increased risk of sudden unexplained death in epilepsy (SUDEP) and patients may need to be made aware of this in order to help them rearrange their lifestyle and comply with treatment.

Status epilepticus

Status epilepticus is defined as a seizure or a series of seizures lasting 30 minutes without the patient regaining awareness between attacks. Most commonly, this refers to recurrent tonic clonic seizures (major status) and is a life-threatening medical emergency. Partial motor status is obvious clinically, but complex partial status and absence status may be difficult to diagnose because the patient may merely present in a dazed, confused state. Status is never the presenting feature of idiopathic epilepsy but may be precipitated by abrupt withdrawal of anticonvulsant drugs, the presence of a major structural lesion or acute metabolic disturbance. It tends to be more common with frontal epileptic foci. Management is summarised in Box 26.45. It should be remembered that psychogenic or non-epileptic attacks commonly masquerade as 'status epilepticus', so electrophysiological confirmation of the seizures should be obtained as early as possible.

Non-epileptic attack disorder

The episodes characterising this condition are also referred to as 'pseudoseizures' or 'psychogenic attacks'.

Patients may present with attacks that superficially resemble epileptic seizures but which are caused by psychological phenomena and not associated with abnormal epileptic discharges in the brain. Such patients may present in apparent status epilepticus. People with epilepsy may have non-epileptic attacks as well, and this diagnosis should be considered if a patient fails to respond to anti-epileptic therapy, especially in the absence of a structural abnormality. Non-epileptic attacks may be quite difficult to distinguish from truly epileptic attacks. Clues pointing towards non-epileptic attacks include elaborate arching of the back in an attack, pelvic thrusting and/or wild flailing of limbs. Cyanosis and severe biting of the tongue are rare in non-epileptic attacks, but urinary incontinence can occur. The distinction between epileptic attacks originating in the frontal lobes and non-epileptic attacks may be especially difficult, and may require videotelemetry with prolonged EEG recordings. Non-epileptic attacks are three times more common in women than in men and have been associated with a history of sexual abuse in childhood. They are not necessarily associated with formal psychiatric illness. Treatment is often difficult and usually requires psychotherapy and/or counselling rather than drug therapy (p. 239).

DISORDERS OF SLEEP

26

Daytime somnolence

Excessive sleepiness in the day is most commonly due to inadequate night-time sleep related to fatigue and poor sleep hygiene, including the excessive use of caffeine and/or alcohol in the evening. Night-time sleep may also be disturbed by sleep apnoea (p. 722), periodic limb movements and the restless leg syndrome. Somnolence due to disturbed night-time sleep particularly occurs after meals and during dull monotonous activities, such as long car journeys. Such causes of daytime sleepiness need to be distinguished from narcolepsy.

Narcolepsy

This disorder has a prevalence of about 1 in 4000 and is associated with HLA (human leucocyte antigen) DR-1501 and DQB1-0602 in 85% of cases. This has been shown to be due to a deficiency in the hypothalamus of neurons secreting hypocretin, a neuropeptide. There is a familial tendency but a low concordance in monozygotic twins suggesting an additional pathophysiological mechanism, possibly autoimmune in nature. Recurrent bouts of irresistible sleep are experienced, during which the EEG often shows direct entry into rapid eye movement (REM) sleep. Sufferers tend to fall asleep when eating or talking, not just when understimulated. The periods of sleep are usually short and the person can be woken relatively easily. He or she usually feels refreshed after waking. In addition, patients with narcolepsy will report at least one other of the 'narcolepsy tetrad' (Box 26.46). Any of these four symptoms may occur in a given patient; most often, sleep attacks and cataplexy occur together.

Narcoleptic attacks can be treated with central nervous system (CNS) stimulants such as dexamfetamine (5–10 mg 8-hourly) or methylphenidate (10–60 mg per day) but fewer side-effects occur with modafinil

26.45 Management of status epilepticus

Initial

- Ensure airway is patent, give oxygen to prevent cerebral hypoxia, and secure intravenous access
- Draw blood for glucose, urea and electrolytes (including Ca and Mg), and liver function, and store a sample for future analysis (e.g. drug misuse)
- Give diazepam 10 mg i.v. (or rectally) or lorazepam 4 mg i.v.—repeat *once only* after 15 mins
- Transfer to intensive care area, monitoring neurological condition, blood pressure, respiration and blood gases, intubating and ventilating patient if appropriate

Ongoing

If seizures continue after 30 mins

- I.v. infusion (with cardiac monitoring) with one of:
Phenytoin: 15 mg/kg at 50 mg/min
Fosphenytoin: 15 mg/kg at 100 mg/min
Phenobarbital: 10 mg/kg at 100 mg/min

If seizures still continue after 30–60 mins

- Start treatment for refractory status with intubation, ventilation, and general anaesthesia using propofol or thiopental

Once status controlled

- Commence longer-term anticonvulsant medication with one of:
Sodium valproate 10 mg/kg i.v. over 3–5 mins, then 800–2000 mg/day
Phenytoin: give loading dose (if not already used as above) of 15 mg/kg, infuse at < 50 mg/min, then 300 mg/day
Carbamazepine 400 mg by nasogastric tube, then 400–1200 mg/day
- Investigate cause

26.46 The narcolepsy tetrad

Sleep attacks
• Brief, frequent and unlike normal somnolence
Cataplexy
• Sudden loss of muscle tone set off by surprise, laughter, strong emotion etc.
Hypnagogic or hypnopompic hallucinations
• Frightening hallucinations experienced during sleep onset or waking (can occur in normal people)
Sleep paralysis
• Brief paralysis on waking (can occur in normal people)

(200–400 mg per day). Cataplexy responds to clomipramine (25–50 mg 8-hourly) or fluoxetine (20 mg per day).

Parasomnias

Automatic behaviour that is not recalled may take place during light sleep. Sleep talking and sleep walking are innocuous and common in normal children. Sleep walking is uncommon in adults and has no pathological significance. Nightmares are frightening dreams from which the sufferer wakes in a state of fear or agitation. Most normal people have experienced such phenomena and they are not of any significance in terms of organic disease.

Night terrors occur as sudden arousals from deep slow-wave sleep. They are more common in children but may affect adults. The sufferer wakes in a state of agitation, screaming and fearful. Occasionally, violent behaviour occurs. The agitation may last many minutes. Such events may be confused with nocturnal seizures, particularly those arising from the frontal lobe, or their post-ictal effects.

REM sleep behaviour disorder

In this syndrome patients and/or their bed partners notice the often violent acting out of dreams, because there is a loss of the normal muscle atonia during REM sleep. This occurs in Parkinson's disease and Lewy body dementia and can precede the recognition of these neurodegenerative disorders. Treatment is with clonazepam 0.25–2 mg at bedtime.

Restless leg syndrome

This is a common syndrome, also known as Ekbom's syndrome, affecting up to 2% of the population. Unpleasant sensations in the legs that are ameliorated by moving the legs occur when the patient is tired in the evenings and at the onset of sleep. This condition has a strong familial tendency and can present with daytime somnolence due to disturbed night-time sleep. It needs to be distinguished from the daytime sense of restlessness of the limbs known as akathisia that is a side-effect of major tranquillisers, and the related condition of periodic limb movements during sleep. Restless legs can be symptomatic of an underlying peripheral neuropathy or iron deficiency, or other general medical conditions (e.g. uraemia).

Treatment is with clonazepam (0.5–2.0 mg), small doses of levodopa (100–200 mg) or dopamine agonists (p. 1201) at night.

Periodic limb movement syndrome

In this syndrome, sleep is disturbed by repetitive jerky flexion movements of the limbs which occur in the early stages of sleep. The history of abnormal limb movements during sleep may need to be obtained from the patient's bed partner, since the patient may not be aware of the arousals that are occurring as a result of the movements, even though they may be sufficient to cause daytime somnolence. Treatment may be effected with small doses of levodopa (100–200 mg at night) or a dopamine agonist (p. 1201).

CEREBROVASCULAR DISEASE

Cerebrovascular disease is the third most common cause of death in the developed world after cancer and ischaemic heart disease, and is the most common cause of severe physical disability. Stroke is the term used to describe episodes of focal brain dysfunction due to focal ischaemia or haemorrhage. Stroke is the most frequent clinical manifestation of diseases of the cerebral blood vessels, although cerebrovascular disease may present, particularly in the elderly, as a dementia (p. 1197). Whilst subarachnoid haemorrhage (SAH) is a type of stroke based on the above definition, it will be dealt with separately in this chapter since the pathophysiology, clinical manifestations, and management are distinct from ischaemic and haemorrhagic stroke (p. 1190). Stroke is a common medical emergency with an annual incidence of between 180 and 300 per 100 000. The incidence rises steeply with age, and in many developing countries, the incidence is rising because of the adoption of less healthy lifestyles. About one-fifth of patients with an acute stroke will die within a month of the event, and at least half of those who survive will be left with physical disability.

Stroke

Acute stroke is characterised by the rapid appearance (usually over minutes) of a focal deficit of brain function, most commonly a hemiplegia with or without signs of focal higher cerebral dysfunction (such as aphasia), hemisensory loss, visual field defect or brain-stem deficit. Provided that there is a clear history of a rapid-onset focal deficit, the chance of the brain lesion being anything other than vascular is 5% or less. However, care needs to be taken to exclude other differential diagnoses if the symptoms progress over hours or days. Confusion, memory or balance disturbance are more often due to causes other than stroke. Several terms have been used to classify strokes, often based on the duration and evolution of symptoms.

- *Transient ischaemic attack (TIA)*. Describes a stroke in which symptoms resolve within 24 hours—an arbitrary cutoff which has little value in practice apart from perhaps indicating that underlying cerebral haemorrhage or extensive cerebral infarction is extremely unlikely. The term TIA traditionally also includes patients with transient monocular blindness (also known as amaurosis fugax), usually due to a vascular occlusion in the retina. Transient symptoms, such as syncope, amnesia, confusion and dizziness,

26.47 Differential diagnosis of stroke and TIA

- Primary cerebral tumours
- Metastatic cerebral tumours
- Subdural haematoma
- Peripheral nerve lesions (vascular or compressive)
- Cerebral abscess
- Todd's paresis (after epileptic seizure)
- Demyelination
- Hypoglycaemia
- Encephalitis
- Conversion disorder
- Migrainous aura (with or without headache)
- Ménière's disease or other vestibular disorder
- Focal seizures

which do not reflect focal cerebral dysfunction, are often mistakenly attributed to TIA (see Fig. 26.16, p. 1150, and Box 26.47).

- **Stroke.** This is the term reserved for those events in which symptoms last more than 24 hours. The differential diagnosis of patients with symptoms lasting a few minutes or hours is similar to those with persisting symptoms (see Box 26.47).
- **Progressing stroke (or stroke in evolution).** This describes a stroke in which the focal neurological deficit worsens after the patient first presents. Such worsening may be due to increasing volume of infarction, haemorrhagic transformation or increasing oedema.
- **Completed stroke.** This describes a stroke in which the focal deficit persists and is not progressing.

In clinical practice, it is probably most important to distinguish those patients with strokes who, when seen, have persisting focal neurological symptoms, from those whose symptoms have resolved. When assessing a patient within hours of symptom onset, it is not possible to distinguish stroke from TIA unless the symptoms have already resolved. In patients with persisting symptoms, it is necessary to confirm the diagnosis and then consider treatments to reverse the underlying pathology, prevent complications, alleviate the functional consequences of any persisting neurological impairments and reduce the risks of further stroke or other vascular events. In those patients without persisting symptoms, the emphasis should be on confirming the diagnosis and preventing further vascular events.

Pathophysiology

Of patients presenting with a stroke, 85% will have sustained a cerebral infarction due to inadequate blood flow to part of the brain and the remainder will have had an intracerebral haemorrhage. Brain imaging is required to distinguish these pathologies and to guide management. The combination of severe headache and vomiting at the onset of the focal neurological deficits increases the likelihood of a haemorrhagic stroke.

Cerebral infarction

Cerebral infarction is mostly due to thromboembolic disease secondary to atherosclerosis in the major extracranial arteries (carotid artery and aortic arch). About 20% of infarctions are due to embolism from the heart, and a further 20% are due to intrinsic disease of small perforating vessels (lenticulostriate arteries), producing so-called 'lacunar' infarctions. The risk factors for ischaemic stroke reflect the risk factors for the underlying

26.48 Stroke risk factors

Fixed

- Age
- Gender (male > female, except in the very young and very old)
- Race (Afro-Caribbean > Asian > European)
- Heredity
- Previous vascular event, e.g. myocardial infarction, stroke or peripheral embolism
- High fibrinogen

Modifiable

- High blood pressure
- Heart disease (atrial fibrillation, heart failure, endocarditis)
- Diabetes mellitus
- Hyperlipidaemia
- Smoking
- Excess alcohol consumption
- Polycythaemia
- Oral contraceptives
- Social deprivation

vascular disease (Box 26.48). About 5% are due to rare causes, including vasculitis (p. 1112), endocarditis (p. 624) and cerebral venous disease (p. 1191). Cerebral infarction is a process which takes some hours to complete, even though the patient's deficit may be maximal close to the onset of the causative vascular occlusion. After the occlusion of a cerebral artery, infarction may be forestalled by the opening of anastomotic channels from other arterial territories which restore perfusion to its territory. Similarly, reduction in perfusion pressure leads to compensatory homeostatic changes to maintain tissue oxygenation (Fig. 26.27). These changes can sometimes prevent even occlusion of a carotid artery from having any clinically apparent effect.

However, if and when these homeostatic mechanisms fail, the process of ischaemia starts and ultimately leads to infarction unless vascular supply is restored. As the cerebral blood flow declines, different neuronal functions fail at various thresholds (Fig. 26.28). Once blood flow falls below the threshold for the maintenance of electrical activity, neurological deficit appears. At this level of blood flow, the neurons are still viable; if the blood flow increases again, function returns and the patient will have had a TIA. However, if the blood flow falls further, a level is reached at which the process of irreversible cell death starts. Hypoxia leads to an inadequate supply of adenosine triphosphate (ATP), which in turn leads to failure of membrane pumps, thereby allowing influx of sodium and water into the cell (cytotoxic oedema) and the release of the excitatory neurotransmitter glutamate into the extracellular fluid. Glutamate opens membrane channels, allowing the influx of calcium and more sodium into the neurons. Calcium entering the neurons activates intracellular enzymes that complete the destructive process. The release of inflammatory mediators by microglia and astrocytes produces death of all cell types in the area of maximum ischaemia. The infarction process is worsened by the anaerobic production of lactic acid (Fig. 26.29) and consequent fall in tissue pH. There have been attempts to develop neuroprotective drugs to slow down

Fig. 26.27 Homeostatic responses to falling perfusion pressure in the brain following arterial occlusion. Vasodilatation initially maintains cerebral blood flow (A), but after maximal vasodilatation further falls in perfusion pressure lead to a decline in blood flow. An increase in tissue oxygen extraction, however, maintains the cerebral metabolic rate for oxygen (B). Still further falls in perfusion, and therefore blood flow, cannot be compensated; cerebral oxygen availability falls and symptoms appear, then infarction (C).

Cerebral blood flow
mL/100 g/min

Fig. 26.28 Thresholds of cerebral ischaemia. Symptoms of cerebral ischaemia appear when the blood flow has fallen to less than half of normal and energy supply is insufficient to sustain neuronal electrical function. Full recovery can occur if this level of flow is returned to normal but not if it is sustained. Further blood flow reduction below the next threshold causes failure of cell ionic pumps and starts the ischaemic cascade, leading to cell death.

Fig. 26.29 The process of neuronal ischaemia and infarction. (1) Reduction of blood flow reduces supply of oxygen and hence ATP. H^+ is produced by anaerobic metabolism of available glucose. (2) Energy-dependent membrane ionic pumps fail, leading to cytotoxic oedema and membrane depolarisation, allowing calcium entry and releasing glutamate. (3) Calcium enters cells via glutamate-gated channels and (4) activates destructive intracellular enzymes, (5) destroying intracellular organelles and cell membrane, with release of free radicals. Free fatty acid release activates pro-coagulant pathways which exacerbate local ischaemia. (6) Glial cells take up H^+ , can no longer take up extracellular glutamate and also suffer cell death, leading to liquefactive necrosis of whole arterial territory.

the processes leading to irreversible cell death but these have so far proved disappointing.

The final result of the occlusion of a cerebral blood vessel therefore depends upon the competence of the circulatory homeostatic mechanisms, the metabolic demand, and the severity and duration of the reduction in blood flow. Higher brain temperature, as might occur in fever, and higher blood sugar have both been associated with a greater volume of infarction for a given reduction in cerebral blood flow. Subsequent restoration of blood flow may cause haemorrhage into the infarcted area ('haemorrhagic transformation'). This is particularly likely to occur in patients given antithrombotic or thrombolytic drugs, and in patients with larger infarcts.

Radiologically, a cerebral infarct can be seen as a lesion which comprises a mixture of dead brain tissue that is already undergoing autolysis and tissue that is ischaemic and swollen but recoverable (the 'ischaemic penumbra'). The infarct swells with time and is at its maximal size a couple of days after stroke onset. At this stage it may be big enough to exert mass effect both clinically and radiologically; sometimes decompressive craniectomy is required at this time (see Box 26.57, p. 1188). As the weeks go by, the oedema subsides and the infarcted area is replaced by a sharply defined fluid-filled cavity.

Intracerebral haemorrhage

This usually results from rupture of a blood vessel within the brain parenchyma but may also occur in a patient with a subarachnoid haemorrhage (p. 1190) if the artery ruptures into the brain substance as well as into the subarachnoid space. Haemorrhage frequently occurs into an area of brain infarction. If the volume of haemorrhage is large, this may be difficult to distinguish from primary intracerebral haemorrhage both clinically and radiologically (see Fig. 26.31C). The risk factors and underlying causes of intracerebral haemorrhage are listed in Box 26.49. The explosive entry of blood into the brain parenchyma causes immediate cessation of function in that area as neurons are structurally disrupted and white matter fibre tracts are split apart. The haemorrhage itself may expand over the first minutes or hours, or it may be associated with a rim

of cerebral oedema, which, along with the haematoma, acts like a mass lesion to cause progression of the neurological deficit. If big enough, this can cause shift of the intracranial contents, producing transtentorial coning and sometimes rapid death (p. 1215). If the patient survives, the haematoma is gradually absorbed, leaving a hemosiderin-lined slit in the brain parenchyma (see Fig. 26.32D).

Clinical features

The clinical presentation of stroke depends upon which arterial territory is involved and the size of the lesion, both of which will have a bearing on management, such as suitability for carotid endarterectomy. The neurological deficit can be identified from the patient's history and, if the deficit is persistent, from the neurological examination. The presence of a unilateral motor deficit, a higher cerebral function deficit such as aphasia or neglect, or a visual field defect usually places the lesion in the cerebral hemisphere. Ataxia, diplopia, vertigo and/or bilateral weakness usually indicate a lesion in the brain stem or cerebellum. Different combinations of these deficits define several stroke syndromes (Fig. 26.30) which reflect the site and size of the lesion and may provide clues to underlying pathology.

Reduced conscious level usually indicates a large-volume lesion in the cerebral hemisphere but may result from a lesion in the brain stem or complications such as obstructive hydrocephalus, hypoxia or severe systemic infection.

Clinical assessment of the patient with a stroke should also include a general examination (Box 26.50) since this may provide clues to the cause of the stroke, and identify important comorbidities and complications of the stroke.

Investigations

Investigation of a patient presenting with an acute stroke aims to confirm the vascular nature of the lesion, distinguish cerebral infarction from haemorrhage and identify the underlying vascular disease and risk factors (Box 26.51).

26.49 Causes of intracerebral haemorrhage and associated risk factors	
Disease	Risk factors
Complex small vessel disease with disruption of vessel wall	Age Hypertension Low cholesterol
Amyloid angiopathy	Familial (rare) Age
Impaired blood clotting	Anticoagulant therapy Blood dyscrasia Thrombolytic therapy
Vascular anomaly	Arteriovenous malformation Cavernous haemangioma
Substance misuse	Alcohol Amphetamines Cocaine

26.51 Investigation of a patient with an acute stroke

Diagnostic question	Investigation
Is it a vascular lesion?	CT/MRI
Is it ischaemic or haemorrhagic?	CT/MRI
Is it a subarachnoid haemorrhage?	CT/lumbar puncture
Is there any cardiac source of embolism?	Electrocardiogram (ECG) 24-hour ECG Echocardiogram
What is the underlying vascular disease?	Duplex ultrasound of carotids Magnetic resonance angiography (MRA) CT angiography (CTA) Contrast angiography
What are the risk factors?	Full blood count Cholesterol Blood glucose
Is there an unusual cause?	ESR Serum protein electrophoresis Clotting/thrombophilia screen

Risk factor analysis

Initial investigation of all patients with stroke includes a range of simple blood tests to detect common vascular risk factors and markers of rarer causes, an electrocardiogram (ECG) and brain imaging. Where there is uncertainty about the nature of the stroke, further investigations are usually indicated. This especially

26.52 Causes and investigation of acute stroke in young patients

Cause	Investigation
Cerebral infarct	
Cardiac embolism	Echocardiography (including transoesophageal)
Premature atherosclerosis	Serum lipids
Arterial dissection	MRI Angiography
Thrombophilia	Protein C, protein S Antithrombin III Factor V Leiden, prothrombin
Homocystinuria (p. 447)	Urinary amino acids Methionine loading test
Antiphospholipid antibody syndrome (p. 1050)	Anticardiolipin antibodies/lupus anticoagulant
SLE	Antinuclear antibodies
Vasculitis	ESR CRP Antineutrophil cytoplasmic antibody (ANCA)
CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy)	MRI brain Genetic analysis Skin biopsy
Mitochondrial cytopathy	Serum lactate White cell mitochondrial DNA Muscle biopsy Mitochondrial molecular genetics
Fabry's disease	Alpha-galactosidase levels in blood
Neurovascular syphilis	Syphilis serology
Primary intracerebral haemorrhage	
Arteriovenous malformation (AVM)	MRI/angiography
Drug misuse	Drug screen (amphetamine, cocaine)
Coagulopathy	Prothrombin time (PT) and activated partial thromboplastin time (APTT) Platelet count
Subarachnoid haemorrhage	
Saccular ('berry') aneurysm	MRI/angiography
AVM	MRI/angiography
Vertebral dissection	MRI/angiography

applies to younger patients who are less likely to have atherosclerotic disease (Box 26.52).

Neuroimaging

Brain imaging with either CT or MRI should be performed in all patients with acute stroke. Exceptions to this include patients in whom the results would not influence management, such as in the advanced stage of a terminal illness. CT is the most practical and widely available method of imaging the brain. It will usually exclude non-stroke lesions, including subdural haematomas and brain tumours, and will demonstrate intracerebral haemorrhage within minutes of stroke onset (Fig. 26.31). However, especially within the first few hours after symptom onset, CT changes in cerebral infarction may be completely absent or only very subtle. Changes often develop over time (Fig. 26.32), but small cerebral infarcts may never show up on CT scans. For most purposes, a CT scan performed within

Fig. 26.31 CT scans of intracerebral haemorrhage. **A** Basal ganglia haemorrhage with intraventricular extension. **B** Small cortical haemorrhage. **C** Large haemorrhage with mass effect.

26.53 Indications for emergency CT/MRI in acute stroke

- Patient on anticoagulants or with abnormal coagulation
- Consideration of thrombolysis or immediate anticoagulation
- Deteriorating conscious level or rapidly progressing deficits
- Suspected cerebellar haematoma, to exclude hydrocephalus

the first day or so is adequate for clinical care but there are certain circumstances in which an immediate CT scan is essential (Box 26.53). Even in the absence of changes suggesting infarction, abnormal perfusion of brain tissue can be imaged with CT after injection of contrast media (i.e. perfusion scanning). This can be useful in guiding immediate treatment of ischaemic stroke. MRI is not as widely available as CT, scanning times are longer, and it cannot be used in some individuals with contraindications (see Box 26.2, p. 1144). However, MRI diffusion weighted imaging (DWI) can detect ischaemia earlier than CT, and other MRI sequences can also be used to demonstrate abnormal perfusion (see Fig. 26.32). MRI is more sensitive than CT in detecting strokes affecting the brain stem and cerebellum, and, unlike CT, can reliably distinguish haemorrhagic from ischaemic stroke even several weeks after the onset (see Fig. 26.32C and D). CT and MRI may reveal clues as to the nature of the arterial lesion. For example, there may be a small, deep lacunar infarct (Fig. 26.33A) indicating small-vessel disease, or a more peripheral infarct suggesting an extracranial source of embolism (see Fig. 26.33B). In a haemorrhagic lesion, the location might indicate the presence of an underlying vascular malformation, saccular aneurysm or amyloid angiopathy.

Vascular imaging

Many ischaemic strokes are caused by atherosclerotic thromboembolic disease of the major extracranial vessels. Detection of extracranial vascular disease can help establish why the patient has had an ischaemic stroke and may, in highly selected patients, lead on to specific treatments including carotid endarterectomy to reduce the risk of further stroke (p. 1189). The presence or absence of a carotid bruit is not a reliable indicator of the degree of carotid stenosis. Extracranial arterial disease can be non-invasively identified with duplex ultra-

sound, MR angiography (MRA) or CT angiography (see Fig. 26.15, p. 1146). Because of the significant risk of complications, intra-arterial contrast angiography is reserved for patients in whom non-invasive methods have provided a contradictory picture or yielded incomplete information, or in whom it is necessary to image the intracranial circulation in detail: for example, to delineate a saccular aneurysm, an arteriovenous malformation or vasculitis.

Cardiac investigations

Approximately 20% of ischaemic strokes are due to embolism from the heart. The most common causes are atrial fibrillation, prosthetic heart valves, other valvular abnormalities and recent myocardial infarction. These can often be identified by clinical examination and ECG but cardiac sources of embolism can exist without obvious clinical or ECG signs. A transthoracic or transoesophageal echocardiogram can be useful, either to confirm the presence of a clinically apparent cardiac source or to identify an unsuspected source such as endocarditis, atrial myxoma, intracardiac thrombus or patent foramen ovale. Such findings may lead on to specific treatment (Ch. 18).

Management

Management is aimed at minimising the volume of brain that is irreversibly damaged, preventing complications (Box 26.54), reducing the patient's disability and handicap through rehabilitation, and reducing the risk of recurrent episodes.

Supportive care

Early admission of patients to a specialised stroke unit facilitates coordinated care from a specialised multidisciplinary team (Ch. 7) and has been shown to reduce both mortality and residual disability amongst survivors (Box 26.55). Consideration of a patient's rehabilitation needs should commence at the same time as acute medical management. Dysphagia is common after stroke and can be detected by an early bedside test of swallowing. This allows hydration, feeding and medication to be given safely, if necessary by nasogastric tube or intravenously. In the acute phase it may be useful to refer to a checklist (Box 26.56) to ensure that all the factors

Fig. 26.32 Acute stroke seen in CT scans with corresponding MRI appearances. **A** CT may show no evidence of early infarction. **B** Corresponding image seen on MRI diffusion weighted imaging (DWI) with changes in middle cerebral artery (MCA) territory (arrows). **C** Late appearance of haemorrhage on CT (arrow). **D** Corresponding appearance on gradient echo MRI (arrow). **E** Subtle appearance of massive cerebellar infarction on CT (arrows). **F** Corresponding appearance is more obvious on DWI MRI (arrows).

which might influence the patient's outcome have been addressed.

The patient's neurological deficits may worsen during the first few hours or days after their onset. This is most common amongst those with lacunar infar-

tion but may occur in other patients, due to extension of the area of infarction, haemorrhage into it, or the development of oedema with consequent mass effect. It is important to distinguish such patients from those who are deteriorating as a result of complications such

as hypoxia, sepsis, epileptic seizures or metabolic abnormalities which may be more easily reversed. Patients with cerebellar haematomas or infarcts with mass effect may develop obstructive hydrocephalus and some will benefit from insertion of a ventricular drain and/or decompressive surgery (Box 26.57). Some patients with large haematomas or infarction with massive oedema in the cerebral hemispheres may benefit from anti-oedema agents, such as mannitol or artificial ventilation, and surgical decompression to reduce intracranial pressure should be considered in appropriate patients.

Thrombolysis

Intravenous thrombolysis with recombinant tissue plasminogen activator (rt-PA) increases the risk of haemorrhagic transformation of the cerebral infarct with

Airway

- Check that the patient can protect his/her airway and swallow without evidence of aspiration
- Perform a swallow screen and keep patient nil by mouth if swallowing unsafe

Breathing

- Check that the patient is breathing adequately; check oxygen saturation and give oxygen if saturation < 95%

Circulation

- Check peripheral perfusion, pulse and blood pressure adequate and treat with fluid replacement, anti-arrhythmics and inotropic drugs as appropriate

Hydration

- Screen for signs of dehydration and give fluids parenterally or by nasogastric tube if necessary

Nutrition

- Assess nutritional status and provide nutritional supplements if necessary
- If dysphagia persists for a day or two, start feeding via a nasogastric tube

Medication

- If the patient is dysphagic, consider alternative routes for essential medications

Blood pressure

- Unless there is heart failure or renal failure, evidence of hypertensive encephalopathy or aortic dissection, do not lower the blood pressure in the first week since cerebral perfusion may decrease. Blood pressure often returns towards the patient's normal level within the first few days

Blood glucose

- Check blood glucose and treat with insulin when levels are ≥ 11.1 mmol/L (200 mg/dL) (via infusion or glucose/potassium/insulin (GKI)). Monitor closely to avoid hypoglycaemia

Temperature

- Check for pyrexia and investigate and treat underlying cause
- Give antipyretics since raised brain temperature may increase infarct volume

Pressure areas

- Check pressure areas and introduce measures to reduce the risk of bed sores
 - Treat infection
 - Maintain nutrition
 - Provide a pressure-relieving mattress
 - Turn immobile patients regularly

Incontinence

- Check for constipation and urinary retention and treat appropriately
- Avoid urinary catheterisation unless the patient is in acute urinary retention or incontinence is threatening pressure areas

potentially fatal results. However, if given within 3 hours of symptom onset to highly selected patients, the haemorrhagic risk is offset by an improvement in overall outcome (Box 26.58).

Aspirin

In the absence of contraindications, aspirin (300 mg daily) should be started immediately after an ischaemic

EBM 26.57 Decompressive craniectomy after large cerebral infarction

'Early decompressive surgery in patients with large infarctions of the middle cerebral artery reduces mortality and improves functional outcome. NNT = 2 to prevent death or severe disability.'

- Vahedi K, et al. *Lancet Neurol* 2007; 6(3):215–222K.

EBM 26.58 Thrombolysis in acute ischaemic stroke

'rt-PA increases the risk of fatal intracranial haemorrhage, but this risk is offset by an improvement in longer-term outcome amongst survivors. The maximum benefit appears to be when thrombolysis is given within 3 hours of onset. Treating 1000 patients within 3 hours prevents about 60 patients from being dead or dependent at 3 months.'

- Wardlaw JM, et al. (Cochrane Review). *Cochrane Library*, issue 4, 2005. Oxford: Update Software.
- Mielke O, et al. (Cochrane Review). *Cochrane Library*, issue 4, 2005. Oxford: Update Software.

For further information:  www.cochrane.org

stroke unless rt-PA has been given, in which case it should be withheld for at least 24 hours. Aspirin reduces the risk of early recurrence and has a small but clinically worthwhile effect on long-term outcome (Box 26.59); it may be given by rectal suppository or by nasogastric tube in dysphagic patients.

Heparin

Anticoagulation with heparin has been widely used to treat acute ischaemic stroke in the past. Whilst this does reduce the risk of early ischaemic recurrence and venous thromboembolism, these benefits are offset by a definite increase in the risk of both intracranial and extracranial haemorrhage. Furthermore, routine use of heparin does not result in better long-term outcomes, and therefore it should not be used in the routine management of acute stroke. It is unclear whether anticoagulation with heparin might provide benefit in selected patients, such as those with recent myocardial infarction, arterial dissection or progressing strokes. Intracranial haemorrhage must be excluded on brain imaging before considering anticoagulation.

Coagulation abnormalities

Coagulation abnormalities should be reversed as quickly as possible to reduce the likelihood of the haematoma enlarging. There is no evidence that clotting factors are useful in the absence of a clotting defect.

EBM 26.59 Aspirin in acute ischaemic stroke

'After an acute persistent stroke, aspirin started within 48 hours of onset improves long-term outcome. Treating 1000 patients for 2 weeks prevents 13 being dead or dependent by 6 months.'

Management of risk factors

The approaches used are summarized in Fig. 26.34. The average risk of a further stroke is 5–10% within the first week of a stroke or TIA, perhaps 15% in the first year and 5% per year thereafter. The risks are not clearly different for intracerebral haemorrhage. Patients with ischaemic events should be put on long-term antiplatelet drugs (Box 26.60) and statins to lower cholesterol (Box 26.61). For patients in atrial fibrillation the risk can be reduced by about 60% by oral anticoagulation to achieve an INR of 2–3 (Box 26.62). The risk of recurrence after both ischaemic and haemorrhagic strokes can be reduced by blood pressure reduction, even for those with blood pressures in the normal range (Box 26.63).

EBM 26.60 Antiplatelet drugs in secondary prevention of ischaemic stroke

'In patients with ischaemic stroke, aspirin, clopidogrel or a combination of aspirin and dipyridamole reduces the risk of recurrent stroke, myocardial infarction and vascular deaths. Treating 1000 patients for a year prevents about 10 strokes.'

EBM 26.63 Blood pressure lowering in secondary prevention of stroke

'Lowering blood pressure even in the 'normal range' reduces the risk of recurrent stroke, myocardial infarction and vascular deaths in patients who have suffered a stroke. Treating 1000 patients for a year prevents about 22 strokes.'

- PROGRESS Collaborative Group. *Lancet* 2001; 358:1033–1041.

For further information:  www.cochrane.org

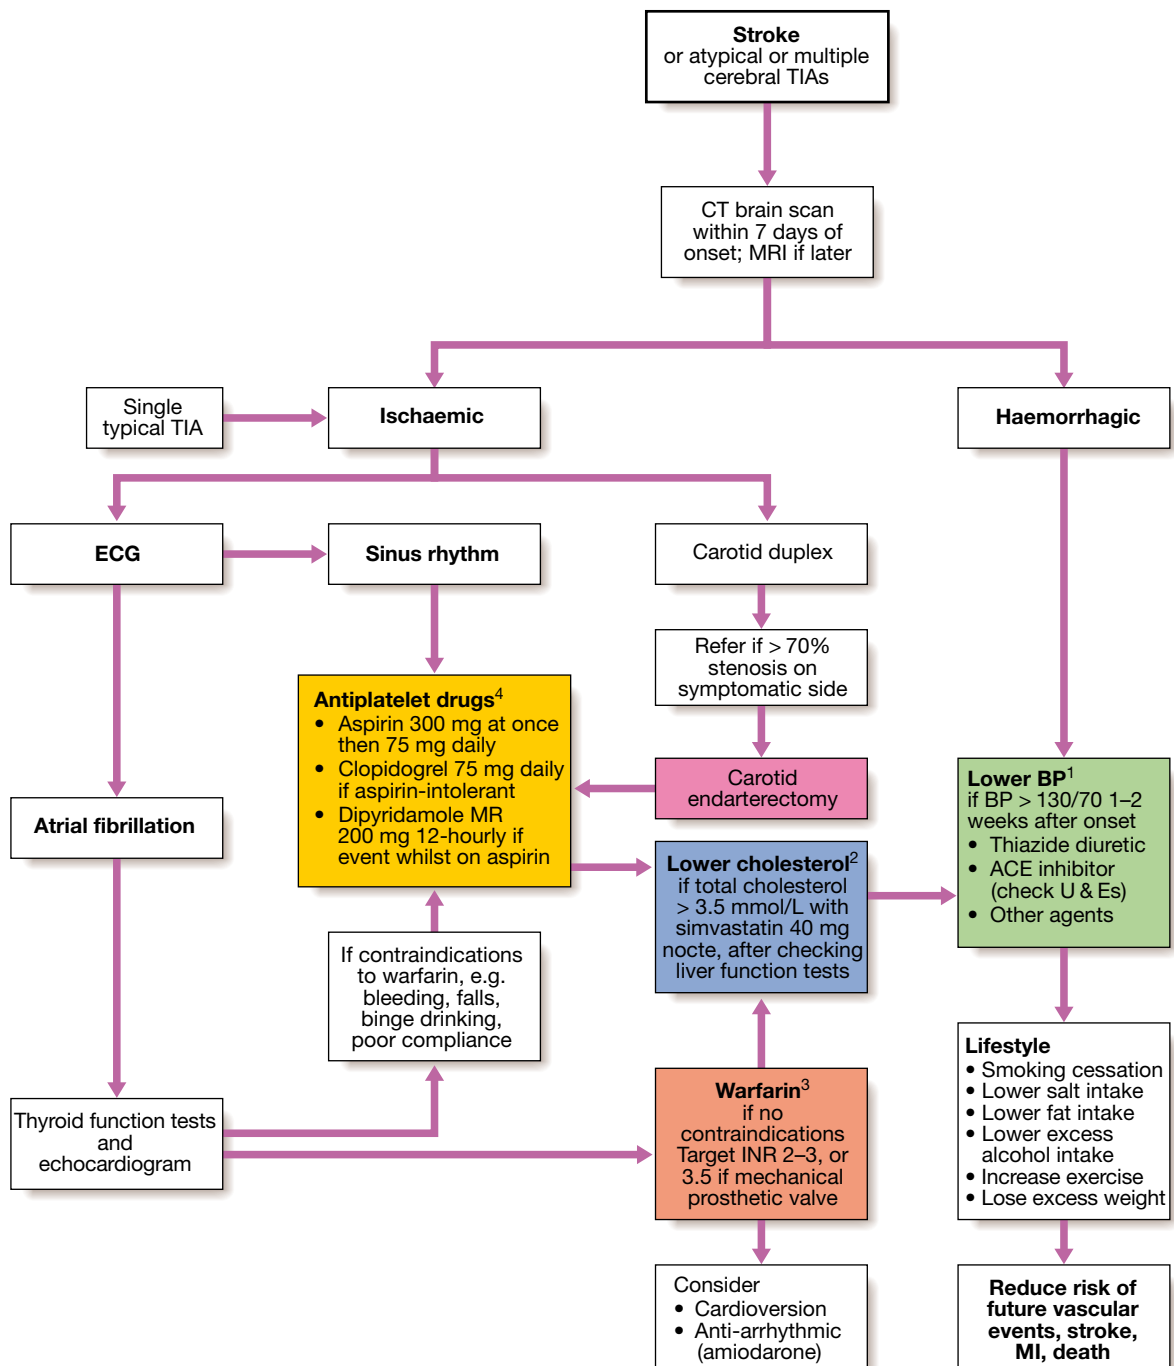

Figure 26.34 Strategies for secondary prevention of stroke. (1) Lower BP with caution in patients with postural hypotension, renal impairment or bilateral carotid stenosis. (2) Pravastatin 40 mg should be considered as an alternative to simvastatin in patients on warfarin or digoxin. (3) Warfarin and aspirin can be used in combination in patients with prosthetic heart valves. (4) The combination of aspirin and clopidogrel is only indicated in patients with unstable angina with ECG or enzyme changes.

Carotid endarterectomy and angioplasty

A small proportion of patients with a carotid territory ischaemic stroke or TIA will have a greater than 50% stenosis of the carotid artery on the side of the brain lesion. Such patients have a greater than average risk of stroke recurrence. For those without major residual disability, removal of the stenosis has been shown to reduce the overall risk of recurrence, although the operation itself carries about a 5% risk of stroke (Box 26.64). The effec-

tiveness of surgery is greatest for those with more severe stenoses (70–99%) and in those in whom surgery can be performed within the first couple of weeks after the TIA or ischaemic stroke. Carotid angioplasty and stenting are technically feasible but have not been shown to be superior to endarterectomy. Endarterectomy of asymptomatic carotid stenosis has been shown to reduce the subsequent risk of stroke, but the small absolute benefit does not justify its routine use.

EBM 26.64 Carotid endarterectomy in ischaemic stroke and TIA

'Carotid endarterectomy reduces the risk of subsequent stroke in patients who have suffered a stroke in the carotid territory, when there is severe ipsilateral stenosis (70%) of the carotid artery. Operating on 1000 patients prevents about 40 strokes over the next year.'

In asymptomatic carotid stenosis, endarterectomy has a smaller benefit. Operating on 1000 patients prevents about 13 strokes over the next year.'

Subarachnoid haemorrhage

Subarachnoid haemorrhage (SAH) is less common than other types of stroke and affects about 6/100 000 of the population. Women are affected more commonly than men and the condition usually presents before the age of 65. The immediate mortality of aneurysmal subarachnoid haemorrhage is about 30% and survivors have a recurrence, or rebleed, rate of about 40% in the first 4 weeks and 3% annually thereafter.

Pathophysiology

Eighty-five percent of SAH are caused by saccular or 'berry' aneurysms arising from the bifurcation of cerebral arteries, particularly in the region of the circle of Willis. There is an increased risk in first-degree relatives of those with saccular aneurysms, and an increased risk of SAH in patients with polycystic kidney disease and congenital connective tissue defects such as Ehlers-Danlos syndrome. In about 10% of cases, SAH are non-aneurysmal haemorrhages (so-called peri-mesencephalic haemorrhages), which have a very characteristic appearance on CT and a benign outcome in terms of mortality and

recurrence. Some 5% of SAH are due to arteriovenous malformations and vertebral artery dissection.

Clinical features

Subarachnoid haemorrhage typically presents with a sudden, severe 'thunderclap' headache (often occipital) which lasts for hours or even days, often accompanied by vomiting. Physical exertion, straining and sexual excitement are common antecedents. There may be loss of consciousness at the onset, so subarachnoid haemorrhage should be considered if a patient is found comatose. About 1 patient in 8 with a sudden severe headache has SAH and, in view of this, all patients with this presentation require investigation to exclude a subarachnoid haemorrhage (Fig. 26.35).

On examination the patient is usually distressed and irritable, with photophobia. There may be neck stiffness due to subarachnoid blood but this may take some hours to develop. Focal hemisphere signs such as hemiparesis or aphasia may be present at onset if there is an associated intracerebral haematoma. A third nerve palsy may be present due to local pressure from an aneurysm of the posterior communicating artery, though this is rare. Fundoscopy may reveal a subhyaloid haemorrhage, which represents blood tracking along the subarachnoid space around the optic nerve.

Investigations

Lumbar puncture is the investigation of first choice and should be performed after 12 hours from symptom onset, if possible. The diagnosis of SAH can be made by CT, but a negative result does not exclude the diagnosis since small amounts of blood in the subarachnoid space cannot be detected by CT (see Fig. 26.35). If either of these tests is positive, cerebral angiography is required to determine the optimal approach to prevent recurrent bleeding.

Management

Insertion of platinum coils into an aneurysm (via an endovascular procedure) or surgical clipping of the

Fig. 26.35 The investigation of sudden severe headache.

aneurysm neck reduces the risk of both early and late recurrence. Coiling is associated with fewer perioperative complications and better outcomes than surgery; where feasible, it is now the procedure of first choice. Arteriovenous malformations can be managed in several different ways including surgical removal, ligation of the blood vessels that feed or drain the lesion, or injection of material to occlude the fistula or draining veins. Nimodipine (30–60 mg i.v. for 5–14 days, followed by 360 mg orally for a further 7 days) is usually given to prevent vasospasm in the acute phase. Treatment may also be required for complications of SAH, which include obstructive hydrocephalus (possibly requiring drainage via a shunt), delayed cerebral ischaemia due to vasospasm (vasodilators), hyponatraemia (water restriction) and systemic complications associated with immobility, such as chest infection and venous thrombosis.

Cerebral venous disease

Thrombosis of the cerebral veins and venous sinuses is less common than arterial thrombosis but has been recognised with increasing frequency over recent years. The causes are listed in Box 26.65.

Cerebral venous sinus occlusion causes raised intracranial pressure and patchy ischaemia, which is often haemorrhagic. The clinical features vary according to the part of the cerebral venous system involved (see below). Anticoagulation is usually beneficial, even in the presence of venous haemorrhage. In selected patients, the use of endovascular thrombolysis has been advocated. Management of underlying causes and complications, such as persistently raised intracranial pressure, is also important.

Cortical vein thrombosis

This may present with focal cortical deficits, such as aphasia and hemiparesis, and epilepsy (focal or generalised), depending on the area involved. The deficit may enlarge if spreading thrombophlebitis occurs.

Cerebral venous sinus thrombosis

The clinical features of cerebral venous sinus thrombosis depend on the sinus involved (Box 26.66). About 10% of cerebral venous sinus thrombosis is associated with infection, particularly thrombosis of the cavernous sinus. Antibiotics are obviously indicated in this situation. Otherwise, the treatment of choice is anticoagulation, as above.

26.65 Causes of cerebral venous thrombosis

Predisposing systemic causes

- Dehydration
- Pregnancy
- Behçet's disease (p. 1114)
- Thrombophilia (p. 997)
- Hypotension
- Oral contraceptive use

Local causes

- Paranasal sinusitis
- Meningitis, subdural empyema
- Penetrating head and eye wounds
- Facial skin infection
- Otitis media, mastoiditis
- Skull fracture

26.66 Clinical features of cerebral venous thrombosis

Cavernous sinus thrombosis

- Proptosis, ptosis, headache, external and internal ophthalmoplegia, papilloedema, reduced sensation in trigeminal first division
- Often bilateral, patient ill and febrile

Superior sagittal sinus thrombosis

- Headache, papilloedema, seizures
- Clinical features may resemble idiopathic intracranial hypertension (p. 1221)
- May involve veins of both hemispheres, causing advancing motor and sensory focal deficits

Transverse sinus thrombosis

- Hemiparesis, seizures, papilloedema
- May spread to jugular foramen and involve cranial nerves 9, 10, 11

Subdural haematoma

This is a collection of blood which forms between the dura and the surface of the brain, due to rupture of veins on the surface of the brain. It usually follows trauma, but may occur spontaneously, particularly in patients on anti-coagulants. It is common in the elderly and in patients who misuse alcohol. There may or may not be a history of trauma. Patients present with subacute impairment of brain function, both globally (obtundation, coma) and focally (hemiparesis, seizures). Headaches may or may not be present. The diagnosis should always be considered in patients presenting with unexplained reduction of consciousness. CT is the investigation of choice, and management entails surgical drainage, usually via a burr hole.

INFLAMMATORY DISEASES

Multiple sclerosis

Multiple sclerosis (MS) is an important cause of long-term disability in adults. The prevalence is about 120 per 100 000 of the population in the UK, with an annual incidence of around 7 per 100 000. The lifetime risk of developing MS is about 1 in 400. The incidence of MS is higher in temperate climates and in Northern Europeans, and the disease is about twice as common in women as men.

Pathophysiology

There is evidence that both genetic and environmental factors play a causative role. The prevalence of MS is low in countries near the equator and increases in the temperate zones of both hemispheres. Most importantly, people retain the risk of developing the disease in the zone in which they grew up, indicating that environmental exposures during growth and development are important. The prevalence has also been found to correlate with various environmental factors, such as sunlight exposure, vitamin D and exposure to Epstein-Barr virus (EBV), although it is currently unclear exactly how all of these factors interact to cause the disease. Genetic factors are also important; the risk of familial recurrence

in MS is 15%, and the highest risk is in first-degree relatives (age-adjusted risk: 4–5% for siblings and 2–3% for parents or offspring). Monozygotic twins have a concordance rate of 30%. The genes that predispose to MS are incompletely defined but inheritance appears to be polygenic, with influences from the HLA region, *IL-7R* (interleukin-7 receptor), *IL-2R* (interleukin-2 receptor), *CLEC16A* (C-type lectin domain family 16 member A) and *CD226* genes. An immune mechanism is suggested by increased levels of activated T lymphocytes in the CSF and increased immunoglobulin synthesis within the CNS.

An attack of CNS inflammation in MS starts with the entry of activated T lymphocytes across the blood–brain barrier. These recognise myelin-derived antigens on the surface of the nervous system's antigen-presenting cells, the microglia, and undergo clonal proliferation. The resulting inflammatory cascade releases cytokines and initiates destruction of the oligodendrocyte–myelin unit by macrophages. Histologically, the characteristic lesion is a plaque of inflammatory demyelination occurring most commonly in the periventricular regions of the brain, the optic nerves and the subpial regions of the spinal cord (Fig. 26.36). Initially, this is a circumscribed area of disintegration of the myelin sheath, accompanied by infiltration by activated lymphocytes and macrophages, often with conspicuous perivascular inflammation. After an acute attack, gliosis follows, leaving a shrunken grey scar.

Much of the initial acute clinical deficit is caused by the effect of inflammatory cytokines upon transmission of the nervous impulse rather than structural disruption of the myelin, and this explains the rapid recovery of some deficits and probably any benefit from corticosteroids. However, the myelin loss that results from an attack reduces the efficiency of impulse propagation or causes complete conduction block, which therefore impairs the efficiency of CNS functions. Inflammatory mediators released during the acute attack (particularly nitric oxide) probably also initiate axonal damage, which is a feature of the latter stages of the disease. In established MS there is progressive axonal loss, probably due to direct damage to axonal integrity by the inflammatory mediators released in acute attacks and the subsequent loss of neurotrophic factors from oligodendrocytes. This axonal loss is the cause of the phase of the disease in which there is progressive and persistent disability (Fig. 26.37).

Clinical features

A diagnosis of MS requires the demonstration of lesions for which there is no other explanation in more than one anatomical site at more than one time (Box 26.67). Around 80% of patients have a relapsing and remitting clinical course of episodic dysfunction of the CNS with variable recovery. Of the remaining 20%, most follow a slowly progressive clinical course, with a tiny minority who have a fulminant variety leading to early death (see Fig. 26.37). The peak age of onset is in the fourth decade and onset before puberty or after the age of 60 years is rare. There are a number of clinical symptoms and syndromes suggestive of MS, some of which may occur at presentation while others may develop during the course of the illness (Box 26.68).

Fig. 26.36 Multiple sclerosis. **A** Photomicrograph from demyelinating plaque showing perivascular cuffing of blood vessel by lymphocytes. **B** Brain MRI in multiple sclerosis. Multiple high-signal lesions (arrows) seen particularly in the paraventricular region on T2 image. **C** In T1 image with gadolinium enhancement recent lesions (A arrows) show enhancement, suggesting active inflammation (enhancement persists for 4 weeks); older lesions (B arrows) show no enhancement but low signal, suggesting gliosis.

Fig. 26.37 The progression of disability in fulminant, relapsing-remitting and progressive multiple sclerosis.

Demyelinating lesions cause symptoms and signs that usually come on subacutely over days or weeks and resolve over weeks or months, although a stroke-like presentation may rarely occur. After a variable interval there may be a recurrence, often within 2 years.

Frequent relapses with incomplete recovery indicate a poor prognosis. In many patients a phase of secondary progression, caused by secondary axonal degeneration, supersedes the phase of relapse and remission. In a minority of patients, there may be an interval of years or even decades between attacks, and in some, particularly if optic neuritis is the initial manifestation, there is no recurrence. Some presentations, such as optic neuritis with purely sensory relapses, have a good prognosis.

The physical signs observed in MS depend on the anatomical site of demyelination. Combinations of spinal cord and brain-stem signs are common, possibly with evidence of previous optic neuritis in the form of an afferent pupillary deficit. Significant intellectual impairment is unusual until late in the disease, when loss of frontal functions and impairment of memory are common.

The prognosis of MS is difficult to predict with confidence, especially early in the disease. About 15% of patients have a single attack of demyelination and do not suffer further events, whilst those with relapsing and remitting MS have, on average, 1–2 events every 2 years. Approximately 5% of patients die within 5 years of onset, whilst others have a benign outcome. Overall, about one-third of patients are disabled to the point of needing help with walking after 10 years, and this rises to about 50% after 15 years.

26.67 The Macdonald criteria for the diagnosis of multiple sclerosis¹

Clinical presentation ²	Additional evidence required for diagnosis of MS
Two or more attacks separated in 'time' (at least 3 months apart) and 'space' (involving different parts of the CNS) with objective clinical evidence of two or more lesions	None
Two or more attacks separated in 'time' and 'space', but with objective clinical evidence for only one lesion	Dissemination in 'space' demonstrated by MRI (multiple lesions in several different sites) or Two or more MRI-detected lesions consistent with MS and oligoclonal bands in CSF or Await further clinical attack at different anatomical site
One attack with objective clinical evidence of two or more lesions in different parts of the CNS (dissemination in 'space')	Dissemination in 'time' demonstrated by serial MRI scans (looking for a new lesion developing at least 3 months after the initial presentation) or Await further (second) clinical attack at different anatomical site
One attack with clinical evidence of only one lesion (clinically isolated syndrome)	MRI demonstration of dissemination in 'space' and 'time' (as above) or Two or more MRI-detected lesions with CSF showing oligoclonal bands and dissemination in 'time', demonstrated by MRI or Await further (second) clinical attack at different anatomical site
Insidious neurological progression suggestive of MS	CSF positive for oligoclonal bands and Dissemination in 'space' and 'time' on MRI and/or abnormal VER ³ or Continued progression for a year

¹Published by the International Panel on MS Diagnosis (Ann Neurol 2001; 50:121–127.) Starting from the clinical presentation in the left-hand column, if the evidence available fulfils the criteria in the right-hand column, the diagnosis is MS. If the criteria are not completely met, the diagnosis is 'possible MS'. If the criteria are fully explored but not met, then the patient does not have MS.

²Assumes other possible causes for CNS inflammation (e.g. sarcoidosis, SLE) have been excluded.

³VER = visual evoked response.

26.68 Clinical features of multiple sclerosis

Common presentations of multiple sclerosis

- Optic neuritis
- Relapsing and remitting sensory symptoms
- Subacute painless spinal cord lesion
- Acute brain-stem syndrome
- Subacute loss of function of upper limb (dorsal column deficit)
- 6th cranial nerve palsy

Other symptoms and syndromes suggestive of CNS demyelination

- Afferent pupillary defect and optic atrophy (previous optic neuritis)
- Lhermitte's symptom (tingling in spine or limbs on neck flexion)
- Progressive non-compressive paraparesis
- Partial Brown-Séquard syndrome (p. 1156)
- Internuclear ophthalmoplegia with ataxia (p. 1164)
- Postural ('rubral', 'Holmes') tremor (p. 1155)
- Trigeminal neuralgia (p. 1171) under the age of 50
- Recurrent facial palsy

Investigations

There is no specific test for MS, and the results of investigation need to be considered in conjunction with the clinical picture to make a diagnosis of varying probability (see Box 26.67). The clinical diagnosis of MS should be supported by investigations to exclude other conditions, provide evidence for an inflammatory disorder and identify multiple sites of neurological involvement (Box 26.69). Following the first clinical event, investigations may help prognostically in confirming the disseminated nature of the disease. Visual evoked potentials (p. 1142) can detect clinically silent lesions in up to 70% of patients, but auditory and somatosensory evoked potentials are seldom of diagnostic value. The CSF may show a lymphocytic pleocytosis in the acute phase and oligoclonal bands of IgG in 70–90% of patients between attacks. Oligoclonal bands are not specific to MS but denote intrathecal inflammation and occur in a range of other disorders. MRI is the most sensitive technique for imaging lesions in both brain and spinal cord (Fig. 26.38) and in excluding other causes of the neurological deficit. However, the MRI appearances in MS may be confused with those of cerebrovascular disease or cerebral vasculitis. Diagnosis depends on the clinical history and examination taken in combination with the investigative findings. It is important to exclude other potentially treatable conditions such as infection, vitamin B₁₂ deficiency and spinal cord compression.

Management

The management of MS involves treatment of the acute episode, prevention of future relapses, treatment of complications and management of the patient's disability.

The acute episode

In a function-threatening exacerbation of MS, pulses of high-dose methylprednisolone, either intravenously (1g daily for 3 days) or orally (500mg daily for 5 days), shorten the duration of the episode (Box 26.70). Pulsed

26.69 Investigations in a patient suspected of having multiple sclerosis

Exclude other structural disease and identify plaques of demyelination

- Image area of clinical involvement (MRI, myelography)

Demonstrate other sites of involvement

- Imaging (MRI)
- Visual evoked potentials
- Other evoked potentials

Demonstrate inflammatory nature of lesion(s)

- CSF examination
 - Cell count
 - Protein electrophoresis (oligoclonal bands)

Exclude other conditions

- Chest X-ray
- Serum angiotensin-converting enzyme (ACE)—sarcoidosis
- Serum B₁₂
- Antinuclear antibodies—SLE
- Antiphospholipid antibodies

steroids may also have some effect in reducing spasticity

Fig. 26.38 Multiple sclerosis: demyelinating lesion in cervical spinal cord, high-signal T2 images (arrow). **[A]** Sagittal plane. **[B]** Axial plane.

EBM 26.70 Pulsed corticosteroids in multiple sclerosis

'In people with multiple sclerosis with acute exacerbations, corticosteroids (methylprednisolone or corticotrophin) improve symptoms compared with placebo within 5 weeks of treatment. The optimal dose, route and duration of treatment are unclear.'

- Filippini G, et al. (Cochrane Review). Cochrane Library, issue 4, 2000. Oxford: Update Software.
- Barnes D, et al. Lancet 1997; 349:902–906.

For further information:  www.clinicalevidence.org

but prolonged administration of steroids does not alter the long-term outcome and should be avoided. Pulses of steroids can be given up to three times in a year but their administration should be restricted to those with significant function-threatening deficits. Prophylaxis to prevent the occurrence of steroid-induced osteoporosis (p. 1116) should be considered in patients who required multiple courses of corticosteroids.

Prevention of relapse

Immunosuppressive agents such as azathioprine appear to reduce the risk of relapses and improve long-term outcome. In relapsing and remitting MS, subcutaneous or intramuscular interferon beta reduces the number of relapses by some 30%, with a small effect on long-term disability (Boxes 26.71 and 26.72); glatiramer acetate has similar effects. Glatiramer is a polymer of four amino acids found in myelin basic protein, which is thought possibly to act as a decoy for the immune response in patients with MS. The recently introduced

EBM 26.71 Interferon beta in multiple sclerosis

'In people experiencing a first demyelinating event, interferon beta decreases the risk of conversion to clinically definite multiple sclerosis over 2–3 years compared with placebo. In people with active relapsing-remitting multiple sclerosis, there is limited evidence that interferon beta reduces exacerbations and disease progression over 2 years compared with placebo.'

agent, natalizumab, is probably somewhat more effective than both, but is usually reserved for patients with particularly aggressive disease, along with less proven therapies such as mitoxantrone and cyclophosphamide (see Box 26.72). Special diets, including a gluten-free diet or linoleic acid supplements, and hyperbaric oxygen therapy are popular with patients but are of no proven benefit.

Treatment of complications and disability

Treatment of the complications of MS is summarised in Box 26.73. It is important to provide patients with a careful explanation of the nature of the disease and its outcome. When and if disability occurs, patients and their relatives need appropriate support. Specialist nurses working in a multidisciplinary team of health-care professionals are of great value in managing the chronic phase of the disease. Periods of physiotherapy and occupational therapy may improve functional capa-

**26.72 Disease-modifying treatments in MS**

Treatment	Mode of action	Comment
Interferon beta	Immune modulation	In widespread use for reducing relapse rate (RCT evidence)
Glatiramer acetate	Immune modulation	Similar efficacy to interferon beta (RCT evidence)
Monoclonal antibody to alpha4-integrin (natalizumab)	Immune modulation (blocks lymphocyte entry into CNS)	Recently introduced. Possibly more effective than interferon beta and glatiramer acetate (RCT evidence)
Monoclonal antibody to CD52 (campath-1H)	Immune suppression (lymphocyte depletion)	Encouraging experimental results
Azathioprine	Immune suppression	Similar efficacy to interferon beta (RCT evidence)
Cyclophosphamide	Immune suppression (cytotoxic)	Occasionally used in aggressive disease. Not recommended for widespread use (no proven benefit in RCTs)
Mitoxantrone	Immune suppression (cytotoxic)	Early trials in aggressive disease (no proven benefit in RCTs)
Plasmapheresis	Immune modulation	Occasionally used in aggressive disease (no proven efficacy in RCTs). Probably more effective in NMO
Intravenous immunoglobulin	Immune modulation	Occasionally used in aggressive disease. Probably more effective in NMO

(NMO = neuromyelitis optica; RCT = randomised controlled clinical trial)

26.73 Treatment of complications of multiple sclerosis	
Complication	Treatment
Spasticity	Physiotherapy Baclofen 15–100 mg* (oral) Dantrolene 25–100 mg* Tizanidine 18–32 mg* Intrathecal baclofen Local (i.m.) injection of botulinum toxin Chemical neurotomy
Ataxia	Isoniazid 600–1200 mg* Clonazepam 2–8 mg*

Impotence	Sildenafil 50–100 mg/24 hours
*In divided doses.	

city in those patients who become disabled, and can provide guidance in the provision of aids at home, reducing handicap. Care of the bladder is particularly important. Urgency and frequency can be treated pharmacologically (see Box 26.28, p. 1168), but this may lead to a degree of retention that promotes the development of infection. Retention can be managed initially by intermittent urinary catheterisation (by the patient, if possible), but an in-dwelling catheter may become necessary. Sexual dysfunction is a frequent source of distress. Sildenafil helps impotence in men, and skilled counselling and prosthetic aids are often useful.

Acute disseminated encephalomyelitis

This is an acute, usually monophasic, demyelinating condition in which there are areas of perivenous demyelination widely disseminated throughout the brain and spinal cord. The illness may apparently occur spontaneously but often occurs a week or so after a viral infection, especially measles and chickenpox, or following vaccination, suggesting that it is immunologically mediated.

Clinical features

Headache, vomiting, pyrexia, confusion and meningism may be presenting features, often with focal or multifocal brain and spinal cord signs. Seizures or coma may occur. A minority of patients who recover have further episodes.

Investigations

MRI shows multiple high-signal areas in a pattern similar to that of MS, although often with larger areas of abnormality. The CSF may be normal or show an increase in protein and lymphocytes (occasionally over 100×10^6 cells/L); oligoclonal bands may be found in the

acute episode but do not persist upon recovery, unlike in MS. The differential diagnosis from a first severe attack of MS may be difficult.

Management

The disease may be fatal in the acute stages but is otherwise self-limiting. Treatment with high-dose intravenous methylprednisolone, using the same regimen as for a relapse of multiple sclerosis, is recommended.

Transverse myelitis

Transverse myelitis is an acute, often monophasic, inflammatory demyelinating disorder affecting the spinal cord over a variable number of segments. Patients may be of any age and present with a subacute paraparesis with a sensory level, often with severe pain in the neck or back at the onset. MRI is needed to distinguish this from a compressive lesion of the spinal cord. CSF examination shows cellular pleocytosis, often with polymorphs at the onset, and oligoclonal bands are usually absent. Treatment is with high-dose intravenous methylprednisolone. The outcome is variable; in some cases, near-complete recovery occurs despite a severe initial deficit. Some patients who present with acute transverse myelitis go on to develop MS in later years.

Neuromyelitis optica

The concurrence of transverse myelitis with bilateral optic neuritis—neuromyelitis optica (Devic's disease)—in some patients has been recognised for many years, and these clinical manifestations are more common in MS which occurs in Asia. Recent work has shown that the majority of these cases are associated with an antibody to a water channel, aquaporin 4, which is found in cells near the ventricular system of the brain. Patients typically have brain MRI scans which are either normal, or have high-signal lesions restricted to the region of the ventricular system. Spinal MRI scans show lesions which are typically longer than three spinal segments (unlike the lesions of MS which are shorter than this). Clinical deficits tend to recover less well than those of MS, and the disease may be more aggressive with more frequent relapses. Treatment with immunosuppressive agents such as steroids, azathioprine or cyclophosphamide and/or plasmapheresis seems to be more effective than in MS.

NEURODEGENERATIVE DISEASES

Many diseases cause degeneration in different parts of the nervous system without an identifiable external cause. Genetic factors are known to be involved in several cases but the cause is still unknown for the majority. Clinical features depend on which structures are affected. Degeneration of the cerebral cortex causes dementia, the most common type being Alzheimer's disease. Degeneration of the basal ganglia results in movement disorder, which may manifest as either too little or too much movement, depending on the structures involved. Examples of these conditions are Parkinson's disease and Huntington's disease. Cerebellar degeneration usually causes ataxia. Degeneration can also occur in the spinal cord or peripheral nerves, giving rise to motor, sensory or autonomic disturbance.

Dementia

Dementia is a common condition affecting up to 5% of the population over the age of 65 years; by the age of 80 the prevalence increases to 20%. Dementia therefore has major implications for health resources. It is a clinical syndrome characterised by a loss of previously acquired intellectual function in the absence of impairment of arousal. There are many underlying causes (Box 26.74) but Alzheimer's disease and diffuse vascular disease are the most common. Rarer causes of dementia should be actively sought in younger patients and those with short histories.

Pathophysiology

Dementias are often divided into 'cortical' and 'subcortical' types, depending upon their clinical features. Many of the primary degenerative diseases that cause dementia have characteristic features that may allow a specific diagnosis during life. Creutzfeldt-Jakob disease is usually relatively rapidly progressive (over months), is associated with myoclonus, and there may be characteristic abnormalities on EEG. Of the more slowly progressive dementias, fronto-temporal dementia presents with rather focal (temporal or frontal lobe) dysfunction often affecting language function early, and Lewy body demen-

tia may present with visual hallucinations. However, it is often difficult to distinguish these dementias from each other or from Alzheimer's disease during life.

Clinical features

The usual presentation is with a disturbance of personality or memory dysfunction. The first step is to exclude a focal lesion by determining that there is cognitive disturbance in more than one area. A careful history is essential and it is important to interview not just the patient but a close family member too. Simple bedside tests such as the Mini-Mental State Examination (MMSE, p. 232) are useful in assessing the cognitive deficit, but more formal help from clinical psychology may be required. General history and examination may give further clues to aetiology.

Investigations

The aim is to discover a treatable cause, if present, and to try to give an idea of prognosis using a standard set of investigations (Box 26.75). Imaging of the brain is important to exclude potentially treatable structural lesions such as hydrocephalus, cerebral tumour or chronic subdural haematoma, though often the only abnormality seen is generalised atrophy. If the initial tests fail to yield

26.74 Causes of dementia

Type	Common	Unusual	Rare
Vascular	Diffuse small-vessel disease	Amyloid angiopathy Multiple emboli	Cerebral vasculitis
Degenerative/inherited	Alzheimer's disease	Fronto-temporal dementia (including Pick's disease) Leucodystrophies Huntington's disease Wilson's disease Dystrophia myotonica Cortical Lewy body disease Progressive supranuclear palsy Others (e.g. cortico-basal degeneration)	Mitochondrial encephalopathies
Neoplastic (p. 1216)	Secondary deposits	Primary cerebral tumour	Paraneoplastic syndrome (limbic encephalitis)
Inflammatory	–	Multiple sclerosis	Sarcoidosis
Traumatic	Chronic subdural haematoma Post-head injury	Punch-drunk syndrome	–
Hydrocephalus (p. 1220)		Communicating/non-communicating 'normal pressure' hydrocephalus	–
Toxic/nutritional	Alcohol	Thiamin deficiency B ₁₂ deficiency	Anoxia/carbon monoxide poisoning Heavy metal poisoning
Infective	–	Syphilis HIV	Post-encephalitic Whipple's disease Subacute sclerosing panencephalitis
Prion diseases (p. 1214)	–	Sporadic Creutzfeldt-Jakob disease (CJD)	Variant CJD Kuru Gerstmann-Sträussler-Scheinker disease

26.75 Initial investigation of dementia

In most patients

- Imaging of head (CT and/or MRI)
- Blood tests
 - Full blood count, ESR
 - Urea and electrolytes, glucose
 - Calcium, liver function tests
 - Thyroid function tests
 - Vitamin B₁₂
 - Venereal Diseases Research Laboratory (VDRL) test
 - ANA, anti-dsDNA
- Chest X-ray
- EEG

In selected patients

- Lumbar puncture
- HIV serology
- Brain biopsy

an answer, more invasive investigations such as lumbar puncture or, rarely, brain biopsy may be indicated. If there is concern that the memory disturbance may be a manifestation of depressive illness, formal neuropsychological evaluation is helpful.

Management

This is directed at removing correctable causes, and providing support for patient and carers if no specific treatment exists. Anticholinesterases, such as donepezil, rivastigmine and galantamine, or NMDA (N-methyl-D-aspartate) receptor antagonists (memantine) appear to improve cognitive function to some extent in Alzheimer's disease (see Box 26.76 below).

Alzheimer's disease

Alzheimer's disease is the most common cause of dementia, which occurs mostly in patients over 45 years.

Pathophysiology

Genetic factors play an important role and about 15% of cases are familial. These fall into two main groups: early-onset disease with autosomal dominant inheritance and a later-onset group whose inheritance is polygenic. Mutations in several genes have been described which cause the disease. In addition, the inheritance of one of the alleles of apolipoprotein ϵ , apo $\epsilon 4$, is associated with an increased risk of developing the disease (2–4 times higher in heterozygotes and 6–8 times in homozygotes). However, its presence is neither necessary nor sufficient for the development of the disease, so screening for its presence is not clinically useful. Macroscopically, the brain is atrophic, particularly the cerebral cortex and hippocampus. On histological examination the disease is characterised by the presence of senile plaques and neurofibrillary tangles in the cerebral cortex. Histochemical staining demonstrates significant quantities of amyloid in the plaques (Fig. 26.39) which typically stain positive for the protein ubiquitin which is involved in targeting unwanted or damaged proteins for degradation. This has led to the suggestion that the disease may be due to defects in the ability of neuronal cells to degrade unwanted proteins. Many different neurotransmitter abnormalities have also been

Fig. 26.39 Alzheimer's disease. Section of neocortex stained with polyclonal antibody against $\beta A 4$ peptide showing amyloid deposits in plaques in brain substance (arrow A) and in blood vessel walls (arrow B).

described. In particular, there is impairment of cholinergic transmission, although abnormalities of noradrenaline, 5-HT, glutamate and substance P have also been described.

Clinical features

The key clinical feature is impairment of the ability to remember information acquired in the past. Hence, patients present with gradual impairment of memory, usually in association with disorders of other cortical functions. Short-term and long-term memory are both affected, but defects in the former are usually more obvious. Later in the course of the disease, typical features include apraxia, visuo-spatial impairment and aphasia. In the early stages of the disease patients may notice these problems, but as the disease progresses it is common for patients to deny that there is anything wrong (anosognosia). In this situation, patients are often brought to medical attention by their carers. Depression is common. Occasionally, patients become aggressive, and the clinical features are made acutely worse by coexistent intercurrent illness.

Investigations and management

Investigation is aimed at excluding other treatable causes of dementia (see Box 26.75), as histological confirmation of the diagnosis usually occurs only after death. There is no known treatment, though recently anticholinesterases such as donepezil, rivastigmine and galantamine, and

EBM 26.76 Anticholinesterases in Alzheimer's disease

'In selected patients with mild or moderate Alzheimer's disease treated for periods of up to a year, donepezil, galantamine, memantine and rivastigmine produce modest improvements in cognitive function. However, the effects on quality of life of both patient and carer are still not clear, and hence the practical importance of these drugs has not been established.'

the NMDA receptor antagonist, memantine, have been shown to be of some benefit (Box 26.76). Management consists largely of providing a familiar environment for the patient, and providing support for the carers. Many patients are depressed, and treatment with antidepressant medication may occasionally be helpful.

Wernicke–Korsakoff disease

This presents with an acute confusional state (Wernicke's encephalopathy) and brain-stem abnormalities such as ataxia, nystagmus and extraocular muscle weakness, particularly affecting the lateral rectus muscle. The condition is caused by deficiency of thiamin (vitamin B₁) and is often associated with alcoholism. However, other causes include generalised malnutrition, malabsorption or protracted vomiting (as in hyperemesis gravidarum). If Wernicke's encephalopathy is inadequately treated, the condition progresses to cause a dementia which is characterised by a profound disturbance of short-term memory associated with a tendency to confabulate, called Korsakoff's syndrome (p. 246). The diagnosis can be made biochemically by the finding of a reduced red cell transketolase, but this test is often difficult to obtain and so the diagnosis is usually made clinically. Because it is potentially treatable, the condition must be consid-

ered in any confused or demented patient; if there is any doubt, it is usually better to treat anyway. Treatment consists of intravenous thiamin (in the form of Pabrinex, 2 vials 8-hourly for 48 hours) initially, followed by oral (100 mg 8-hourly), in addition to treating the underlying cause.

Fronto-temporal dementia

This term encompasses a number of different syndromes, including Pick's disease and primary progressive aphasia. Patients may present with personality change due to frontal lobe involvement or with progressive aphasia. These diseases are much rarer than Alzheimer's disease, and degeneration predominantly affects the frontal and temporal lobes. Histological examination of the brain reveals argyrophilic cytoplasmic inclusion bodies of tau (τ) protein rather than the ubiquitin as in Alzheimer's disease (Fig. 26.40). Memory is relatively preserved in the early stages. There is no specific treatment.

Lewy body dementia

This is a neurodegenerative disorder clinically characterised by dementia and signs of Parkinson's disease. The cognitive state often fluctuates and there is a high incidence of visual hallucinations. Affected individuals are particularly sensitive to the side-effects of anti-parkinsonian medication and also to neuroleptic medication. The condition is associated with accumulation of abnormal protein aggregates in neurons which contain the protein alpha-synuclein in association with other proteins including ubiquitin (see Fig. 26.41). The condition is often inherited and mutations in the alpha-synuclein and beta-synuclein genes have been identified in affected patients. There is no specific treatment for this condition, although there may be clinical benefit with anticholinesterase agents such as rivastigmine.

Parkinson's disease

Parkinson's disease is a neurodegenerative condition which affects the basal ganglia and which presents with differing combinations of slowness of movement (bradykinesia), increased tone (rigidity), tremor and loss of postural reflexes. Parkinson's disease has an annual incidence of about 0.2/1000 and a prevalence of 1.5/1000 in the UK. Prevalence rates are similar throughout the

Fig. 26.40 Fronto-temporal dementia. **[A]** Lateral view of formalin-fixed brain from a patient who died of Pick's disease, showing gyral atrophy of frontal and parietal lobes and a more severe degree of atrophy affecting the anterior half of the temporal lobe (arrow). **[B]** High power ($\times 200$) of hippocampal pyramidal layer, prepared with monoclonal anti-tau antibody. Many neuronal cell bodies contain sharply circumscribed, spherical cytoplasmic inclusion bodies (Pick bodies).

Fig. 26.41 Parkinson's disease. High power ($\times 400$) of substantia nigra of a patient with Parkinson's disease to show classical Lewy body (haematoxylin and eosin).

world, though lower rates have been reported for China and West Africa. Whilst 10% of the patients are under 45 years at presentation, the incidence and prevalence both increase with age, the latter rising to over 1% in those over 60. Sex incidence is about equal. It is less common in cigarette smokers. The outlook for patients with Parkinson's disease is variable, and is related to age at onset. If symptoms start in middle life, the disease is usually steadily progressive and likely to shorten lifespan because of the complications of immobility and tendency to fall. Onset after 70 is unlikely to shorten life or become severe.

Pathophysiology

A small number of cases are familial in nature and mutations in several genes have now been identified as an underlying cause. However, in the majority the cause is unknown, and no strong genetic factors have been identified. The discovery that methyl-phenyl-tetrahydropyridine (MPTP) caused severe parkinsonism in young drug users suggests that the idiopathic disease might be due to an environmental toxin; many candidate toxins have been studied, but there is no strong evidence in favour of any of them. There are several features, including depletion of the pigmented dopaminergic neurons in the substantia nigra, hyaline inclusions in nigral cells (Lewy bodies – Fig. 26.41), atrophic changes in the substantia nigra and depletion of neurons in the locus coeruleus. Reduced dopaminergic output from the substantia nigra to the globus pallidus leads to reduced inhibitory effects on the subthalamic nucleus, neurons of which become more active than usual in inhibiting activation of the cortex. This in turn results in bradykinesia.

Clinical features

The classical syndrome of tremor, rigidity and bradykinesia may be absent initially, when non-specific symptoms of tiredness, aching limbs, mental slowness, depression and small handwriting (micrographia) may be noticed. The presentation is almost always unilateral, a resting tremor in an upper limb being a common presenting feature. The tremor may eventually affect the legs, mouth and tongue. It may remain the predominant symptom for some years. Bradykinesia may develop gradually. Most patients have difficulty with rapid fine

movements, and this manifests itself as slowness of gait and difficulty with tasks such as fastening buttons, shaving or writing. Rigidity, or increased muscular tone, causes stiffness and a flexed posture. Postural righting reflexes are impaired early on in the disease, but falls tend not to occur until later. As the disease advances, speech becomes softer and indistinct. There are a number of abnormalities on neurological examination, and these are listed in Box 26.77.

Although the features are initially unilateral, gradual bilateral involvement is the rule. Muscle strength and reflexes remain normal, and plantar responses are flexor. There is a paucity of facial expression (hypomimia) and the blink reflex may be exaggerated and fail to habituate (glabellar tap sign). Eye movements are normal to standard clinical testing, provided allowance is made for the normal limitation of upward gaze with age. Sensation is normal and intellectual faculties are not affected initially. As the disease progresses, about one-third of patients develop cognitive impairment.

Investigations

The diagnosis is made clinically, as there is no diagnostic test for Parkinson's disease. Sometimes it is necessary to investigate patients to exclude other causes of parkinsonism if there are any unusual features. Patients

26.77 Physical abnormalities in Parkinson's disease

General

- Expressionless face
- Greasy skin
- Soft, rapid, indistinct speech
- Flexed posture
- Impaired postural reflexes

Gait

- Slow to start walking
- Shortened stride
- Rapid, small stride length, tendency to shorten (festination)
- Reduced arm swing
- Impaired balance on turning

Tremor

Resting (4–6 Hz)

- Coarse, complex movements, usually first in fingers/thumb
 - Flexion/extension of fingers
 - Abduction/adduction of thumb
 - Supination/pronation of forearm
- May affect arms, legs, feet, jaw, tongue
- Intermittent, present at rest and when distracted
- Diminished on action

Postural (8–10 Hz)

- Less obvious, faster, finer amplitude
- Present on action or posture, persists with movement

Rigidity

- Cogwheel type, mostly upper limbs
- Plastic (lead pipe) type, mostly legs

Bradykinesia

- Slowness in initiating or repeating movements
- Impaired fine movements, especially of fingers

presenting before the age of 50 are usually tested for Wilson's disease, and imaging (CT or MRI) of the head may be needed if there are any features suggestive of pyramidal, cerebellar or autonomic involvement, or the diagnosis is otherwise in doubt.

Management

Drug therapy

Levodopa combined with a peripheral-acting dopa-decarboxylase inhibitor provides the mainstay of treatment in Parkinson's disease but should only be started to help overcome significant disability. Other agents include anticholinergic drugs, dopamine receptor agonists, selegiline, COMT inhibitors and amantadine (Fig. 26.42).

Levodopa. Although the number of dopamine-releasing terminals in the striatum is diminished in Parkinson's disease, remaining neurons can be driven to produce more dopamine by administering its precursor, levodopa. If levodopa is administered orally, more than 90% is decarboxylated to dopamine peripherally in the gastrointestinal tract and blood vessels, and only a small proportion reaches the brain. This peripheral conversion of levodopa is responsible for the high incidence of side-effects if it is used alone. The problem is largely overcome by giving a decarboxylase inhibitor that does not cross the blood-brain barrier along with the levodopa. Two peripheral decarboxylase inhibitors, carbidopa and benserazide, are available as combination preparations with levodopa (as Sinemet and Madopar, respectively).

The initiation of levodopa therapy should be delayed until there is significant disability, since there is concern

that its use makes long-term side-effects more likely. With this in mind, some authorities suggest that it is advisable to initiate treatment with a dopamine agonist (see below) or a slow-release preparation of levodopa in order to minimise or delay the onset of long-term side-effects, but evidence for this is not strong. The important point is to treat with as little medication as possible consistent with the patient being able to perform the activities of daily living. Levodopa is particularly effective at improving bradykinesia and rigidity. Tremor is also helped but rather unpredictably. The initial dose is 50mg 8- or 12-hourly, increased if necessary. The total levodopa dose may be increased to over 1000mg/day if necessary. Side-effects include postural hypotension, nausea and vomiting, which may be offset by the use of a peripheral dopamine antagonist such as domperidone. Other dose-related side-effects are involuntary movements, particularly orofacial dyskinesias, limb and axial dystonias, and occasionally depression, hallucinations and delusions. Unusual but important side-effects include change in personality with increased (sometimes pathological) gambling, hypersexuality and drug (levodopa)-seeking behaviour.

Late deterioration despite levodopa therapy occurs after 3–5 years in one-third to one-half of patients. Usually this manifests as fluctuation in response. The simplest form of this is end-of-dose deterioration due to progression of the disease and loss of capacity to store dopamine. More complex fluctuations present as sudden, unpredictable changes in response, in which periods of severe parkinsonism alternate with dyskinesia and agitation (the 'on-off' phenomenon). End-of-dose deterioration can often be improved by dividing the levodopa

Fig. 26.42 Mechanisms of drug action in Parkinson's disease. (1) Decarboxylase inhibitors (carbidopa and benserazide) decrease side-effects by reducing peripheral conversion of levodopa to dopamine by aromatic amino acid decarboxylase (AAAD). (2) Active transport of levodopa into the brain may be inhibited by competition from dietary amino acids after a high-protein meal. (3) In the nigrostriatal neurons, levodopa is converted into dopamine. (4) Amantadine enhances the release of dopamine at the nerve terminal. (5) Dopamine agonists act directly on striatal receptors. (6) The monoamine oxidase type B (MAO-B) inhibitor selegiline increases the availability of neuronal dopamine by reducing its metabolism outside the neuron. (7) The catechol-O-methyl-transferase (COMT) inhibitor entacapone prolongs the availability of dopamine by inhibiting the metabolism of dopamine and levodopa outside the neuron.

into smaller but more frequent doses, or by converting to a slow-release preparation. The 'on-off' phenomenon is difficult to treat, but sometimes subcutaneous injections of apomorphine (a dopamine agonist) are helpful to 'rescue' the patient rapidly from an 'off' period.

Involuntary movements (dyskinesia) may occur as a peak-dose phenomenon, or as a biphasic phenomenon (occurring during both the build-up and wearing-off phases). Management is difficult, but involves modifying the way levodopa is administered to obtain constant levels in the brain, and the use of alternative drugs, including amantadine and dopamine agonists. Continuous infusion of apomorphine may be particularly helpful in this situation.

Anticholinergic agents. These have a useful effect on tremor and rigidity, but do not help bradykinesia. They can be prescribed early in the disease before bradykinesia is a problem, but should be avoided in elderly patients in whom they cause confusion and hallucinations. Other side-effects include dry mouth, blurred vision, difficulty with micturition and constipation. Many anticholinergics are available—for example, trihexyphenidyl (benzhexol; 1–4 mg 8-hourly) and orphenadrine (50–100 mg 8-hourly).

Dopamine receptor agonists. Several of these drugs are now available. They all have slightly different activity at the various dopamine receptors in the brain. Apomorphine given alone causes marked vomiting and has to be administered parenterally. The vomiting can be overcome by the concomitant use of domperidone, and parenteral administration achieved through continuous subcutaneous infusion from a portable pump, or by direct injection as needed. This requires considerable nursing support but, used correctly, can be very useful.

More easily administered drugs include bromocriptine, lisuride, pergolide, cabergoline, ropinirole and pramipexole, which can all be taken orally, and rotigotine which can be administered as a transdermal patch. These drugs are less powerful than levodopa in controlling features of parkinsonism, but they are much less likely to cause dose fluctuations or dyskinesia, though they will certainly exacerbate the latter once these have developed. Side-effects include nausea, vomiting, confusion and hallucinations. The dose of bromocriptine is 1 mg initially, increased to 2.5 mg 8-hourly, and thereafter up to 30 mg/day. Pergolide dose starts at 50 µg, increased to 250 µg 8-hourly, and possibly to 3000 µg/day. Dopamine agonists derived from ergot (pergolide and cabergoline) have recently been associated with the development of fibrotic reactions and thickening of heart valves. For this reason, the use of these agents is not advised.

Amantadine. This has a mild, usually short-lived effect on bradykinesia, but may be used early in the disease before more potent treatment is needed. Amantadine can be particularly useful in controlling the dyskinesias produced by dopaminergic treatment later in the disease. The dose is 100 mg 8- or 12-hourly. Side-effects include livedo reticularis, peripheral oedema, confusion and seizures.

Selegiline. Selegiline has a mild therapeutic effect in its own right. An early suggestion that it slows the progression of the disease has been discredited, as has the suggestion that it might be associated with an increased risk of sudden death. The usual dose is 5–10 mg in the morning.

COMT (catechol-O-methyl-transferase) inhibitors Entacapone (200 mg with each dose of levodopa) prolongs the effects of each dose and reduces motor fluctuations when used with levodopa. This allows the levodopa dose to be reduced and given less frequently.

Surgery

Stereotactic thalamotomy can be used to treat tremor, though this is needed relatively infrequently because of the medical treatments available. Other stereotactic lesions are currently undergoing evaluation, in particular the implantation of stimulating electrodes into the globus pallidus to help in the management of drug-induced dyskinesia. The implantation of fetal mid-brain cells into the basal ganglia to enhance dopaminergic activity remains experimental.

Physiotherapy and speech therapy

Patients at all stages of Parkinson's disease benefit from physiotherapy, which helps reduce rigidity and corrects abnormal posture. Speech therapy may help in patients where dysarthria and dysphonia interfere with communication.

Other akinetic-rigid syndromes

There are many conditions which can rarely manifest as parkinsonian syndromes, including other degenerative diseases (Huntington's disease, Wilson's disease) and infective diseases (syphilis). Drug-induced parkinsonism is much more common (particularly with neuroleptic agents and antiemetics). These conditions should always be borne in mind in the differential diagnosis. In particular there are several specific degenerative conditions that can mimic idiopathic Parkinson's disease, particularly in the early stages. These conditions are relatively uncommon, but about 10% of those thought to have idiopathic Parkinson's disease have one of these variants. The variants are notable in causing a more rapid clinical deterioration than idiopathic Parkinson's disease and in being more resistant to treatment with dopaminergic medication.

Multiple systems atrophy

Multiple systems atrophy (MSA) is a sporadic condition seen in middle-aged and elderly patients. Clinical features of parkinsonism, often without tremor, are combined with varying degrees of autonomic failure, cerebellar involvement and pyramidal tract dysfunction. The combination of parkinsonism with autonomic failure was called the Shy-Drager syndrome. The neurodegenerative process in MSA is more widespread than in idiopathic Parkinson's disease, and is associated with deposition of ubiquitin-containing inclusions in neurons. The disappointing response to levodopa and other anti-parkinsonian drugs is probably because of degeneration of post-synaptic neurons in the basal ganglia. Autonomic features include postural hypotension, sphincter disturbance and sometimes respiratory stridor; diagnosis is often assisted by performing tests of autonomic function. Management of postural hypotension includes physical measures such as sleeping with the head end of the bed elevated and wearing compression stockings, and drugs such as fludrocortisone and midodrine (p. 553). Falls are much more common than in idiopathic Parkinson's disease, and life expectancy is considerably reduced.

Progressive supranuclear palsy

This condition presents in middle-aged patients, and is due to more widespread degeneration in the brain than is seen in idiopathic Parkinson's disease. It is caused by accumulation of protein aggregates containing tau (τ) proteins rather than ubiquitin. The clinical features include parkinsonism, though with rigidity in extension rather than flexion, and tremor is usually minimal. In addition, there must be a supranuclear paralysis of eye movements, usually downgaze, for the diagnosis to be made during life. Other features include pyramidal signs and cognitive impairment.

Wilson's disease

This is an inherited disorder transmitted in an autosomal recessive manner, involving a defect of copper metabolism. It is discussed on page 960. It is a treatable cause of various movement disorders, including ataxia and akinetic rigid syndromes, and so must always be considered in the differential diagnosis of these disorders.

Huntington's disease

This is an inherited disorder with autosomal dominant transmission, affecting both males and females, which usually starts in adult life. It is due to expansion of a trinucleotide CAG repeat in the *Huntingtin* gene on chromosome 4 (p. 53). The disease frequently demonstrates the phenomenon of anticipation, in which there is a younger age at onset as the disease is inherited through generations, due to progressive expansion of the repeat. Slightly different features of the disease occur, depending on whether the abnormal gene is inherited from father or mother.

Pathophysiology

The disease is thought to be caused by accumulation of the abnormal Huntingtin protein in neurons, leading to cellular dysfunction and neuronal death.

Clinical features

Symptoms usually begin in middle adult life with the development of chorea, which gradually worsens. This is accompanied by cognitive impairment which often manifests initially as psychiatric symptoms, but later becomes frank dementia. In juvenile-onset disease, there may be parkinsonian features with rigidity (the 'Westphal variant'). Seizures may occur late in the disease.

Investigations

The diagnosis is made clinically but is supported by the finding of atrophy of the caudate nucleus on CT or MRI. Genetic testing can be used to confirm the diagnosis and provide pre-symptomatic testing for other family members after appropriate counselling (p. 60).

Management

Management is symptomatic in nature. The chorea may respond to tetrabenazine or dopamine antagonists such as sulpiride. Long-term psychological support and eventually institutional care are often needed as dementia progresses. Depressive symptoms are common, and may be helped by antidepressant medication. Genetic counselling of relatives is important.

Hereditary ataxia

This is a group of inherited disorders in which degenerative changes occur to varying extents in the cerebellum, brain stem, pyramidal tracts, spinocerebellar tracts, and optic and peripheral nerves. Onset may be in childhood or adulthood, and different disorders demonstrate recessive, sex-linked or dominant inheritance. The genetic abnormalities responsible for some types of spinocerebellar ataxia have been shown to be due to abnormal numbers of trinucleotide repeats in various genes, and these can now be detected by DNA analysis, allowing diagnostic confirmation, pre-symptomatic testing and genetic counselling. Other conditions which may manifest as progressive ataxia, including Friedreich's ataxia, are shown in Box 26.78.

<div> <div>i</div> <div>26.78 Hereditary ataxias</div> </div>			
Type	Inheritance	Onset	Clinical features
Friedreich's ataxia	Autosomal recessive	8–16 years	Ataxia, nystagmus, dysarthria, spasticity, areflexia, proprioceptive impairment, diabetes mellitus, optic atrophy, cardiac abnormalities. Usually chairbound by age 20
Ataxia telangiectasia	Autosomal recessive	Childhood	Progressive ataxia, athetosis, telangiectasia on conjunctivae, impaired DNA repair, immune deficiency, tendency to malignancies
Abetalipoproteinaemia	Autosomal recessive	Childhood	Steatorrhoea, sensorimotor neuropathy, retinitis pigmentosa, malabsorption of vitamins A, D, E, K, cardiomyopathy
Spinocerebellar ataxia (types 1–30)	Autosomal dominant	Childhood to middle age	Progressive ataxia, some types have associated retinitis pigmentosa, pyramidal tract abnormalities, peripheral neuropathy and cognitive deficit
Dentato-rubro-pallido-luysian atrophy (DRPLA)	Autosomal dominant	Childhood to middle age	Children present with myoclonic epilepsy and progressive ataxia; adults have progressive ataxia with psychiatric features, dementia and choreoathetosis
Episodic ataxias (types 1–4)	Autosomal dominant	Childhood and early adulthood	Brief episodes of ataxia, sometimes induced by stress or startle. Some develop progressive fixed ataxia

Motor neuron disease

This is a progressive disorder of unknown cause, in which there is degeneration of motor neurons in the spinal cord and cranial nerve nuclei, and of pyramidal neurons in the motor cortex. Between 5 and 10% of cases are familial, and in 20% of such families the disease is caused by a mutation in the superoxide dismutase (*SOD1*) gene. For the remaining 95%, possible causes include viral infection, trauma, exposure to toxins and electric shock, but no sound evidence exists to support any of these. The prevalence of the disease is about 5/100 000.

Clinical features

Patients present with a combination of lower and upper motor neuron signs without sensory involvement. The presence of brisk reflexes in wasted fasciculating limb muscles is typical. Common presenting features are listed in Boxes 26.79 and 26.80. Rarer variants present with either purely upper motor neuron features (progressive lateral sclerosis) or purely lower motor neuron features (progressive muscular atrophy). Motor neuron disease is relentlessly progressive; the mean time from diagnosis to death is 1 year, with most patients dying within 3–5 years of the onset of symptoms. Younger patients and those with early bulbar symptoms tend to show a more rapid course. Death is usually from respiratory infection and failure, and the complications of immobility. Prognosis is better for progressive lateral sclerosis and progressive muscular atrophy.

Investigations

In many patients the clinical features are highly suggestive but alternative diagnoses need to be carefully excluded. In particular, potentially treatable disorders such as diabetic amyotrophy, spinal disorders and multifocal motor neuronopathy should be excluded. Electromyography helps to confirm the presence of fasciculation and denervation, and is particularly helpful when pyramidal features predominate. Sensory nerve conduction and motor conduction studies are

26.79 Clinical features of motor neuron disease	
Onset	<ul style="list-style-type: none"> Usually after the age of 50 years Very uncommon before the age of 30 years Affects males more commonly than females
Symptoms	<ul style="list-style-type: none"> Limb muscle weakness, cramps, occasionally fasciculation Disturbance of speech/swallowing (dysarthria/dysphagia)
Signs	<ul style="list-style-type: none"> Wasting and fasciculation of muscles Weakness of muscles of limbs, tongue, face and palate Pyramidal tract involvement causing spasticity, exaggerated tendon reflexes, extensor plantar responses External ocular muscles and sphincters usually remain intact No objective sensory deficit No intellectual impairment in most cases
Course	<ul style="list-style-type: none"> Symptoms often begin focally in one part and spread gradually but relentlessly to become widespread

26.80 Patterns of involvement in motor neuron disease

Progressive muscular atrophy

- Predominantly spinal motor neurons affected
- Weakness and wasting of distal limb muscles at first
- Fasciculation in muscles
- Tendon reflexes may be absent

Progressive bulbar palsy

- Early involvement of tongue, palate and pharyngeal muscles
- Dysarthria/dysphagia
- Wasting and fasciculation of tongue
- Pyramidal signs may also be present

Amyotrophic lateral sclerosis

- Combination of distal and proximal muscle-wasting and weakness, fasciculation
- Spasticity, exaggerated reflexes, extensor plantars
- Bulbar and pseudobulbar palsy follow eventually
- Pyramidal tract features may predominate

EBM 26.81 Riluzole and motor neuron disease

'Riluzole 100 mg per day appears to be modestly effective in prolonging survival for patients with motor neuron disease by about 2 months. However, the economics of its use have yet to be fully assessed.'

- Miller RG, et al. (Cochrane Review). Cochrane Library, issue 2, 2004. Chichester: John Wiley.

For further information:  www.cochrane.org

normal but there may be some reduction in amplitude of action potentials due to loss of axons. Spinal imaging and brain scanning may be necessary to exclude focal spinal or cerebral disease. CSF examination is usually normal, though a slight elevation in protein concentration may be found.

Management

The glutamate antagonist, riluzole, has been shown to have a small effect in prolonging life expectancy by about 2 months (Box 26.81). Other agents such as nerve growth factor show promise. Psychological and physical support, with help from occupational and speech therapists and physiotherapists, is essential to maintain the patient's quality of life. Mechanical aids such as splints, walking aids, wheelchairs and communication devices all help to reduce handicap. Feeding by percutaneous gastrostomy may be necessary because of bulbar failure. Non-invasive ventilatory support has been shown to improve the quality of life by alleviating symptoms from weak respiratory muscles and has a small effect on prolonging life; many patients do not choose to proceed to invasive ventilation. Relief of distress in the terminal stages usually requires the use of opiates and sedative drugs (p. 280).

Spinal muscular atrophy

This is a group of genetically determined disorders affecting spinal motor and cranial motor neurons, characterised by proximal and distal wasting, fasciculation and weakness of muscles. Involvement is usually

26.82 Types of spinal muscular atrophy				
Type	Onset	Inheritance	Features	Prognosis
Werdnig–Hoffman	Infancy	Autosomal recessive	Severe muscle-wasting/weakness	Poor
Kugelberg–Welander	Childhood, adolescence	Autosomal recessive	Proximal weakness and wasting, EMG shows denervation	Slowly progressive disability
Distal forms	Early adult life	Autosomal dominant	Distal weakness and wasting of hands and feet	Good, seldom disabling
Bulbospinal	Adult life, males only	X-linked	Facial and bulbar weakness, proximal limb weakness, gynaecomastia	Good

symmetrical but occasional localised forms occur. With the exception of the infantile form, progression is slow and the prognosis better than for motor neuron disease (Box 26.82).

INFECTIONS OF THE NERVOUS SYSTEM

The clinical features of nervous system infections depend upon the location of the infection (the meninges or the parenchyma of the brain and spinal cord), the causative organism (virus, bacterium or parasite), and whether the infection is acute or chronic. The major infections of the nervous system are listed in Box 26.83. The frequency of these varies geographically. Helminthic infections, such as cysticercosis and hydatid disease, and protozoal infections are described in Chapter 13.

26.83 Infections of the nervous system

Bacterial infections

- Meningitis
- Suppurative encephalitis
- Brain abscess
- Paravertebral (epidural) abscess
- Tuberculosis (Ch. 19)
- Neurosyphilis
- Leprosy (peripheral nerves)*
- Diphtheria (peripheral nerves)
- Tetanus (motor cells)

Viral infections

- Meningitis
- Encephalitis
- Transverse myelitis
- Progressive multifocal leucoencephalopathy
- Subacute sclerosing panencephalitis (late sequel)
- Poliomyelitis
- Rabies
- HIV infection (Ch. 14)

Prion diseases

- Creutzfeldt–Jakob disease
- Kuru

Protozoal infections

- Malaria*
- Toxoplasmosis (in immunosuppressed)*
- Trypanosomiasis*
- Amoebic abscess*

Helminthic infections

- Schistosomiasis (spinal cord)*
- Cysticercosis*
- Hydatid disease*
- Strongyloidiasis*

Fungal infections

- Candida meningitis or brain abscess
- Cryptococcal meningitis

*These infections are discussed in Chapter 13.

Meningitis

Acute infection of the meninges presents with a characteristic combination of pyrexia, headache and meningism. Meningism consists of headache, photophobia and stiffness of the neck, often accompanied by other signs of meningeal irritation including Kernig's sign (extension at the knee with the hip joint flexed causes spasm in the hamstring muscles) and Brudzinski's sign (passive flexion of the neck causes flexion of the hips and knees). Meningism is not specific to meningitis and can occur in patients with subarachnoid haemorrhage. The severity of clinical features varies somewhat according to the causative organism, as does the presence of other features such as a rash. Abnormalities in the CSF (see Box 26.3, p. 1147) are very helpful in distinguishing the cause of meningitis. Causes of meningitis are listed in Box 26.84.

26.84 Causes of meningitis

Infective

Bacteria (see Box 26.85)

- *Brucella*

Viruses

- Enteroviruses (echo, Coxsackie, polio)
- Mumps
- Influenza
- Herpes simplex
- Varicella zoster
- Epstein–Barr
- HIV
- Lymphocytic choriomeningitis
- Mollaret's meningitis (herpes simplex virus type 2)

Protozoa and parasites

- *Toxoplasma*
- *Amoeba*
- *Cysticercus*

Fungi

- *Cryptococcus neoformans*
- *Candida*
- *Histoplasma*
- *Blastomyces*
- *Coccidioides*
- *Sporothrix*

Non-infective ('sterile')

Malignant disease

- Breast cancer
- Bronchial cancer
- Leukaemia
- Lymphoma

Inflammatory disease (may be recurrent)

- Sarcoidosis
- SLE
- Behçet's disease

Viral meningitis

Viral infection is the most common cause of meningitis, and usually results in a benign and self-limiting illness requiring no specific therapy. It is a much less serious illness than bacterial meningitis unless there is associated encephalitis (which is rare). A number of viruses can cause meningitis (see Box 26.84), the most common being echoviruses and, where specific immunisation is not employed, the mumps virus.

Clinical features

The condition occurs mainly in children or young adults, with acute onset of headache and irritability and the rapid development of meningism. In viral meningitis, the headache is usually the most severe feature. There may be a high pyrexia, but focal neurological signs are rare.

Investigations

The diagnosis can be made by lumbar puncture. The CSF usually contains an excess of lymphocytes, but glucose and protein levels are commonly normal; the protein level may be raised. It is extremely important to verify that the patient has not received antibiotics (for whatever cause) prior to the lumbar puncture, as this picture can also be found in partially treated bacterial meningitis.

Management

There is no specific treatment and the condition is usually benign and self-limiting. The patient should be treated symptomatically in a quiet environment. Recovery usually occurs within days, although a lymphocytic pleocytosis may persist in the CSF. Meningitis may also occur as a complication of a viral infection primarily involving other organs: for example, in mumps, measles, infectious mononucleosis, herpes zoster and hepatitis. Complete recovery without specific therapy is the rule.

Bacterial meningitis

Many bacteria can cause meningitis, but different organisms tend to affect different age groups (Box 26.85). Bacterial meningitis is usually secondary to a bacteraemic illness, although infection may result from direct

spread from an adjacent focus of infection in the ear, skull fracture or sinus. Bacterial meningitis has become less common but the mortality and morbidity remain significant despite the availability of an increasing range of antibiotics. An important factor in determining prognosis is early diagnosis and the prompt initiation of appropriate therapy. The meningococcus and other common causes of meningitis are normal commensals of the upper respiratory tract. New and potentially pathogenic strains are acquired by the air-borne route, but close contact is necessary. Epidemics of meningococcal meningitis occur, particularly in cramped living conditions or where the climate is hot and dry. The organism invades through the nasopharynx, producing septicaemia that is often associated with meningitis.

Pathophysiology

The meningococcus (*Neisseria meningitidis*) is now second to *Streptococcus pneumoniae* as the most common cause of bacterial meningitis in Western Europe, whilst in the USA *Haemophilus influenzae* remains common. In India, *Haemophilus influenzae* B and *Streptococcus pneumoniae* are probably the most common causes of bacterial meningitis, at least in children. *Strep. suis* is a rare zoonotic cause of meningitis associated with contact with pigs. Hearing loss is a frequent complication. The infection stimulates an immune response causing the pia-arachnoid membrane to become congested and infiltrated with inflammatory cells. A thin layer of pus forms and this may later organise to form adhesions. These may cause obstruction to the free flow of CSF leading to hydrocephalus, or they may damage the cranial nerves at the base of the brain. The CSF pressure rises rapidly, the protein content increases, and there is a cellular reaction that varies in type and severity according to the nature of the inflammation and the causative organism. An obliterative endarteritis of the leptomeningeal arteries passing through the meningeal exudate may produce secondary cerebral infarction. Pneumococcal meningitis is often associated with a very purulent CSF and a high mortality, especially in older adults.

Clinical features

Headache, drowsiness, fever and neck stiffness are the usual presenting features. In severe bacterial meningitis the patient may be comatose and later there may be focal neurological signs. Meningococcal meningitis is associated with a purpuric rash in 70% of cases. When accompanied by septicaemia, it may present very rapidly, with abrupt onset of obtundation due to cerebral oedema, probably as a result of endotoxin and/or cytokine release, and circulatory collapse. Complications of meningococcal septicaemia are listed in Box 26.86. Chronic meningococcal septicaemia is a rare condition in which the patient can be unwell for weeks or even months with recurrent fever, sweating, joint pains and transient rash. It usually occurs in the middle-aged and elderly and those who have previously had a splenectomy. In pneumococcal and *Haemophilus* infections there may be an associated otitis media. Pneumococcal meningitis may be associated with pneumonia and occurs especially in older patients and alcoholics, as well as those without functioning spleens. *Listeria monocytogenes* has recently emerged as an increasing cause of meningitis and rhombencephalitis (brain-stem encephalitis) in the

 26.85 Bacterial causes of meningitis

Age of onset	Common	Less common
Neonate	Gram-negative bacilli (<i>Escherichia coli</i> , <i>Proteus</i>) Group B streptococci	<i>Listeria monocytogenes</i>
Pre-school child	<i>Haemophilus influenzae</i> <i>Neisseria meningitidis</i> <i>Streptococcus pneumoniae</i>	<i>Mycobacterium tuberculosis</i>
Older child and adult	<i>Neisseria meningitidis</i> <i>Streptococcus pneumoniae</i>	<i>Listeria monocytogenes</i> <i>Mycobacterium tuberculosis</i> <i>Staphylococcus aureus</i> (skull fracture) <i>Haemophilus influenzae</i>

26.86 Complications of meningococcal septicaemia

- Meningitis
- Rash (morbilloform, petechial or purpuric)
- Shock
- Intravascular coagulation
- Renal failure
- Peripheral gangrene
- Arthritis (septic or reactive)
- Pericarditis (septic or reactive)

immunosuppressed, people with diabetes, alcoholics and pregnant women (p. 334). It can also cause meningitis in the neonatal period.

Investigations

Lumbar puncture is mandatory unless there are contraindications (p. 1146). Particularly if the patient is drowsy with focal neurological signs or seizures, it is wise to obtain a CT to exclude a mass lesion (such as a cerebral abscess) before lumbar puncture because of the risk of coning, but this should not delay treatment of a presumptive meningitis. If lumbar puncture is deferred or omitted, it is essential to take diagnostic specimens and to start empirical treatment (Fig. 26.43). In bacterial meningitis the CSF is cloudy (turbid) due to the pres-

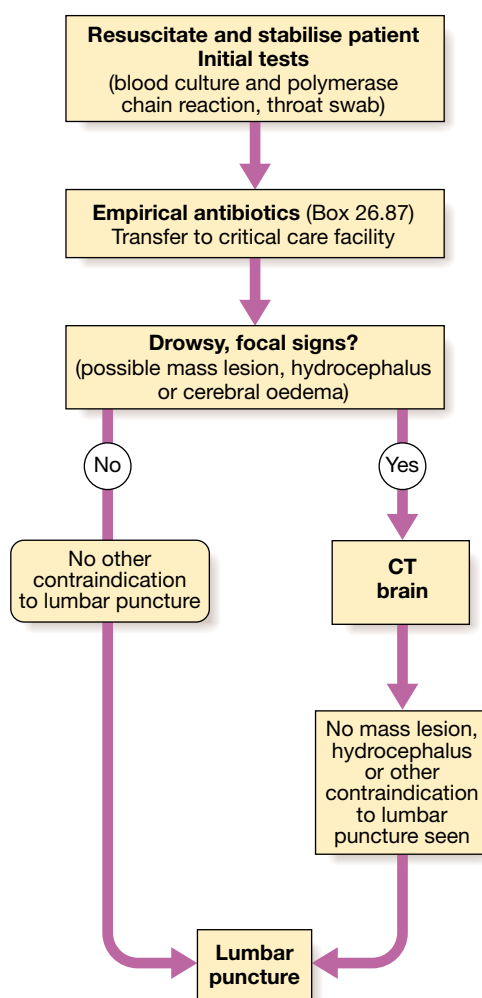

Fig. 26.43 The investigation of meningitis.

ence of many neutrophils (often $> 1000 \times 10^6$ cells/L), the protein content is significantly elevated and the glucose reduced. Gram film and culture may allow identification of the organism. Blood cultures may be positive. Polymerase chain reaction (PCR) techniques can be used on both blood and CSF to identify bacterial DNA. These methods are useful in detecting meningococcal infection and in typing the organism.

Management

If meningococcal or other bacterial meningitis is suspected, the patient should be given parenteral benzylpenicillin immediately (intravenous is preferable to intramuscular) and prompt admission to hospital should be arranged. The only contraindication is a history of penicillin anaphylaxis. Recommended empirical therapy before the cause of meningitis is known is given in Box 26.87. Guidance as to the preferred antibiotic is given in Box 26.88 for when the organism is known after CSF examination. Adjunctive corticosteroid therapy is useful in both children (Box 26.89) and, as demonstrated more recently, adults.

In meningococcal disease, mortality is doubled if the patient presents with features of septicaemia rather than meningitis. Patients likely to require intensive care facilities and expertise include those with cardiac, respiratory or renal involvement, and those with CNS depression prejudicing the airway. Early endotracheal intubation and mechanical ventilation protect the airway and may prevent the development of the acute respiratory distress syndrome (ARDS, p. 187). Adverse prognostic features include hypotensive shock, a rapidly developing rash, a haemorrhagic diathesis, multisystem failure and an age of more than 60 years.

26.87 Treatment of pyogenic meningitis of unknown cause

1. Patients with a typical meningococcal rash

- Benzylpenicillin 2.4 g i.v. 6-hourly

2. Adults aged 18–50 years without a typical meningococcal rash

- Cefotaxime 2 g i.v. 6-hourly *or*
- Ceftriaxone 2 g i.v. 12-hourly

3. Patients in whom penicillin-resistant pneumococcal infection is suspected

As for (2) but add:

- Vancomycin 1 g i.v. 12-hourly *or*
- Rifampicin 600 mg i.v. 12-hourly

4. Adults aged over 50 years and those in whom *Listeria monocytogenes* infection is suspected (brain-stem signs, immunosuppression, diabetic, alcoholic)

As for (2) but add:

- Ampicillin 2 g i.v. 4-hourly *or*
- Co-trimoxazole 50 mg/kg i.v. daily in two divided doses

5. Patients with a clear history of anaphylaxis to β -lactams

- Chloramphenicol 25 mg/kg i.v. 6-hourly *plus*
- Vancomycin 1 g i.v. 12-hourly

<div> <div></div> <div>26.88 Chemotherapy of bacterial meningitis when the cause is known</div> </div>		
Pathogen	Regimen of choice	Alternative agent(s)
<i>N. meningitidis</i>	Benzylpenicillin 2.4 g i.v. 4-hourly for 5–7 days	Cefuroxime, ampicillin Chloramphenicol*
<i>Strep. pneumoniae</i> (sensitive to β-lactams, minimum inhibitory concentration (MIC) < 1 mg/L)	Cefotaxime 2 g i.v. 6-hourly or ceftriaxone 2 g i.v. 12-hourly for 10–14 days	Chloramphenicol*
<i>Strep. pneumoniae</i> (resistant to β- lactams)	As for sensitive strains but add vancomycin 1 g i.v. 12-hourly or rifampicin 600 mg i.v. 12-hourly	Vancomycin plus rifampicin*
<i>H. influenzae</i>	Cefotaxime 2 g i.v. 6-hourly or ceftriaxone 2 g i.v. 12-hourly for 10–14 days	Chloramphenicol*
<i>Listeria monocytogenes</i>	Ampicillin 2 g i.v. 4-hourly plus gentamicin 5 mg/kg i.v. daily	Ampicillin 2 g i.v. 4-hourly plus co-trimoxazole 50 mg/kg daily in two divided doses
<i>Strep. suis</i>	Cefotaxime 2 g i.v. 6-hourly or ceftriaxone 2 g i.v. 12-hourly for 10–14 days	Chloramphenicol*

*For patients with a history of anaphylaxis to β-lactam antibiotics.

EBM 26.89 Adjunctive dexamethasone for bacterial meningitis in children

'Adjunctive dexamethasone therapy prevents severe deafness following *H. influenzae* type B meningitis and, if commenced with or before parenteral antibiotics, in pneumococcal meningitis in childhood. Limiting dexamethasone therapy to 2 days may be optimal.'

- McIntyre PB, et al. JAMA 1997; 278:925–931.
- Coyle PK. Arch Neurol 1999; 56:796–801.

For further information:  www.clinicalevidence.org

Prevention of meningococcal infection

Household and other close contacts of patients with meningococcal infections, especially children, should be given 2 days of oral rifampicin (age 3–12 months 5 mg/kg 12-hourly, > 1 year 10 mg/kg 12-hourly, adults 600 mg 12-hourly). In adults, a single dose of 500 mg of ciprofloxacin is an alternative. If not treated with ceftriaxone, the index case should be given similar treatment to clear infection from the nasopharynx before hospital discharge. Vaccines are available for the prevention of disease caused by meningococci of groups A and C, but not group B which is the most common serogroup isolated in many countries, including the UK.

Tuberculous meningitis

Tuberculous meningitis is now rare in developed countries in previously healthy individuals, but remains common in developing countries and is seen more frequently as a secondary infection in patients with AIDS.

Pathophysiology

Tuberculous meningitis occurs most commonly shortly after a primary infection in childhood or as part of miliary tuberculosis. The usual local source of infection is a caseous focus in the meninges or brain substance adjacent to the CSF pathway. The brain is covered by a greenish, gelatinous exudate, especially around the base, and numerous scattered tubercles are found on the meninges.

Clinical features

The clinical features are listed in Box 26.90. Untreated tuberculous meningitis is fatal in a few weeks but complete recovery is the rule if treatment is started before the appearance of focal signs or stupor. When treatment is started at a later stage, the recovery rate is 60% or less and the survivors show permanent neurological deficit.

Investigations

Lumbar puncture should be performed if the diagnosis is suspected. The CSF is under increased pressure. It is usually clear but, when allowed to stand, a fine clot ('spider web') may form. The fluid contains up to 500×10^6 cells/L, predominantly lymphocytes. There is a rise in protein and a marked fall in glucose. The tubercle bacillus may be detected in a smear of the centrifuged deposit from the CSF but a negative result does not exclude the diagnosis. The CSF should be cultured but, as this result will not be known for up to 6 weeks, treatment must be started without waiting for confirmation. Brain imaging may show hydrocephalus, brisk meningeal enhancement on enhanced CT and/or an intracranial tuberculoma.

Management

As soon as the diagnosis is made or strongly suspected, chemotherapy should be started using one of the regimens including pyrazinamide described on page 693. The use of corticosteroids in addition to antituberculous therapy has been controversial. Recent evidence suggests that it improves mortality but not focal neurological damage, especially if given early. Surgical ventricular drainage may be needed if obstructive hydrocephalus develops. Skilled nursing is essential during the acute phase of the illness, and measures should be put in place to maintain adequate hydration and nutrition.

<div> <div></div> <div>26.90 Clinical features of tuberculous meningitis</div> </div>

Other forms of meningitis

Fungal meningitis (especially cryptococcosis—p. 379) usually occurs in patients who are immunosuppressed and is a recognised complication of HIV infection (p. 400). The CSF findings are similar to those of tuberculous meningitis, but the diagnosis can be confirmed by microscopy or specific serological tests.

In some areas, meningitis may be caused by spirochaetes (leptospirosis, Lyme disease and syphilis—pp. 331, 329 and 417), rickettsiae (typhus fever—p. 345) or protozoa (amoebiasis—p. 362).

Meningitis can also be due to non-infective pathologies. This is seen in recurrent aseptic meningitis due to SLE, Behçet's disease or sarcoidosis, as well as a condition of previously unknown origin known as Mollaret's syndrome in which the recurrent meningitis is associated with epithelioid cells in the spinal fluid ('Mollaret' cells). Recent evidence suggests that this condition may be due to human herpes virus type 2, and is therefore infective after all. Meningitis can also be seen due to direct invasion of the meninges by neoplasm ('malignant meningitis'—see Box 26.84, p. 1205).

Parenchymal viral infections

Infection of the substance of the nervous system will produce symptoms of focal dysfunction (focal deficits and/or seizures) with general signs of infection depending upon the acuteness of the infection and the type of organism.

Viral encephalitis

A range of viruses can cause encephalitis but only a minority of patients have a history of recent viral infection. In Europe, the most serious cause of viral encephalitis is herpes simplex (p. 312), which probably reaches the brain via the olfactory nerves. The development of effective therapy for some forms of encephalitis has increased the importance of clinical diagnosis and virological examination of the CSF. In some parts of the world, viruses transmitted by mosquitoes and ticks (arboviruses) are an important cause of encephalitis. The epidemiology of some of these infections is changing. Japanese encephalitis (p. 323) has spread relentlessly across Asia to Australia, and there have been outbreaks of West Nile encephalitis in Romania, Israel and New York. Acute encephalitis may occur in HIV infection, occasionally at the time of infection, but more commonly as a manifestation of AIDS (p. 399).

Pathophysiology

The infection provokes an inflammatory response which causes inflammation in the cortex, white matter, basal ganglia and brain stem. The distribution of lesions varies with the type of virus. For example, in herpes simplex encephalitis, the temporal lobes are usually primarily affected, whereas cytomegalovirus can involve the areas adjacent to the ventricles (ventriculitis). Inclusion bodies may be present in the neurons and glial cells and there is an infiltration of polymorphonuclear cells in the perivascular space. There is neuronal degeneration and diffuse glial proliferation, often associated with cerebral oedema.

Clinical features

Viral encephalitis presents with acute onset of headache, fever, focal neurological signs (aphasia and/or hemiplegia) and seizures. Disturbance of consciousness ranging from drowsiness to deep coma supervenes early and may advance dramatically. Meningism occurs in many patients. Rabies presents a distinct clinical picture and is described below.

Investigations

Imaging by CT scan may show low-density lesions in the temporal lobes but MRI is more sensitive in detecting early abnormalities. Lumbar puncture should only be performed after brain imaging has excluded a mass lesion. The CSF usually contains excess lymphocytes, but polymorphonuclear cells may predominate in the early stages. Occasionally, the CSF is normal. The protein content may be elevated but the glucose is normal. The EEG is usually abnormal in the early stages, especially in herpes simplex encephalitis, with characteristic periodic slow-wave activity in the temporal lobes. Virological investigations of the CSF, including PCR for viral DNA, may reveal the causative organism but the initiation of treatment should not await this.

Management

Anticonvulsant treatment is often necessary (p. 1177) and raised intracranial pressure is treated with dexamethasone 8mg 12-hourly. Herpes simplex encephalitis responds to aciclovir 10mg/kg i.v. 8-hourly for 2–3 weeks. This should be given early to all patients suspected of suffering from viral encephalitis.

Even with optimum treatment, mortality is 10–30% and significant proportions of survivors have residual epilepsy or cognitive impairment. For details of post-infectious encephalomyelitis, see page 1196.

Brain-stem encephalitis

This presents with ataxia, dysarthria, diplopia or other cranial nerve palsies. The CSF is lymphocytic, with a normal glucose. The causative agent is presumed to be viral. However, *Listeria monocytogenes* may cause a similar syndrome with meningitis (and often a polymorphonuclear CSF pleocytosis) and requires specific treatment with ampicillin 500mg 6-hourly (see Box 26.88).

Rabies

Rabies is caused by a rhabdovirus which infects the central nervous tissue and salivary glands of a wide range of mammals, and is usually conveyed by saliva through bites or licks on abrasions or on intact mucous membranes. Humans are most frequently infected from dogs. In Europe, the maintenance host is the fox. The incubation period varies in humans from a minimum of 9 days to many months but is usually between 4 and 8 weeks. Severe bites, especially if on the head or neck, are associated with shorter incubation periods. Human rabies is a rare disease, even in endemic areas. However, because it is usually fatal, major efforts are directed to limiting its spread and preventing its importation into uninfected countries such as the UK.

Clinical features

At the onset there may be fever, and paraesthesia at the site of the bite. A prodromal period of 1–10 days, during which the patient is increasingly anxious, leads to the characteristic 'hydrophobia'. Although the patient is thirsty, attempts at drinking provoke violent contractions of the diaphragm and other inspiratory muscles. Delusions and hallucinations may develop, accompanied by spitting, biting and mania, with lucid intervals in which the patient is markedly anxious. Cranial nerve lesions develop and terminal hyperpyrexia is common. Death ensues, usually within a week of the onset of symptoms.

Investigations

During life, the diagnosis is usually made on clinical grounds but rapid immunofluorescent techniques can detect antigen in corneal impression smears or skin biopsies.

Management

Established disease

Only a few patients with established rabies have survived. All received some post-exposure prophylaxis, and needed intensive care facilities to control cardiac and respiratory failure. Otherwise, only palliative treatment is possible once symptoms have appeared. The patient should be heavily sedated with diazepam 10 mg 4–6-hourly, supplemented by chlorpromazine 50–100 mg if necessary. Nutrition and fluids should be given intravenously or through a gastrostomy.

Pre-exposure prophylaxis

Pre-exposure prophylaxis is required by those who handle potentially infected animals professionally, those who work with rabies virus in laboratories and those who live at special risk in rabies-endemic areas. Protection is afforded by two intradermal injections of 0.1 mL human diploid cell strain vaccine, or two intramuscular injections of 1 mL, given 4 weeks apart, followed by yearly boosters.

Post-exposure prophylaxis

The wounds should be thoroughly cleaned, preferably with a quaternary ammonium detergent or soap; damaged tissues should be excised and the wound left unsutured. Rabies can usually be prevented if treatment is started within a day or two of biting. Delayed treatment may still be of value. For maximum protection, hyperimmune serum and vaccine are required.

The safest antirabies antiserum is human rabies immune globulin; the dose is 20 U/kg body weight. Half is infiltrated around the bite and half is given intramuscularly at a different site from the vaccine. The dose of hyperimmune animal serum is 40 U/kg; hypersensitivity reactions, including anaphylaxis, are common.

The safest vaccine, free of complications, is human diploid cell strain vaccine; 1.0 mL is given intramuscularly on days 0, 3, 7, 14, 30 and 90. In developing countries, where human rabies globulin may not be obtainable, 0.1 mL of vaccine should be given intradermally into eight sites on day 1, with single boosters on days 7 and 28. Where human products are not available and when risk of rabies is slight (licks on the skin, or minor bites of covered arms or legs), it may be justifi-

able to delay starting treatment for up to 5 days while observing the biting animal or awaiting examination of its brain, rather than use the older vaccine.

Poliomyelitis

Pathophysiology

The disease is caused by one of three polioviruses, which are a subgroup of the enteroviruses. It is much less common in developed countries following the widespread use of oral vaccines but is still a problem in the developing world, especially parts of Africa. Infection usually occurs through the nasopharynx.

The virus causes a lymphocytic meningitis and infects the grey matter of the spinal cord, brain stem and cortex. There is a particular propensity to damage anterior horn cells, especially in the lumbar segments.

Clinical features

The incubation period is 7–14 days. Figure 26.44 illustrates the various features of the infection. Many patients recover fully after the initial phase of a few days of mild fever and headache. In others, after a week of well-being, there is recurrence of pyrexia, headache and meningism. Weakness may start later in one muscle group and can progress to widespread paresis. Respiratory failure may supervene if intercostal muscles are paralysed or the medullary motor nuclei are involved. Epidemics vary widely in their incidence of non-paralytic cases and in mortality rate. Death occurs from respiratory paralysis. Muscle weakness is maximal at the end of the first week and gradual recovery may then take place for several months. Muscles showing no signs of recovery by the end of a month will probably not regain useful function. Second attacks are very rare but occasionally patients show late deterioration in muscle bulk and power many years after the initial infection.

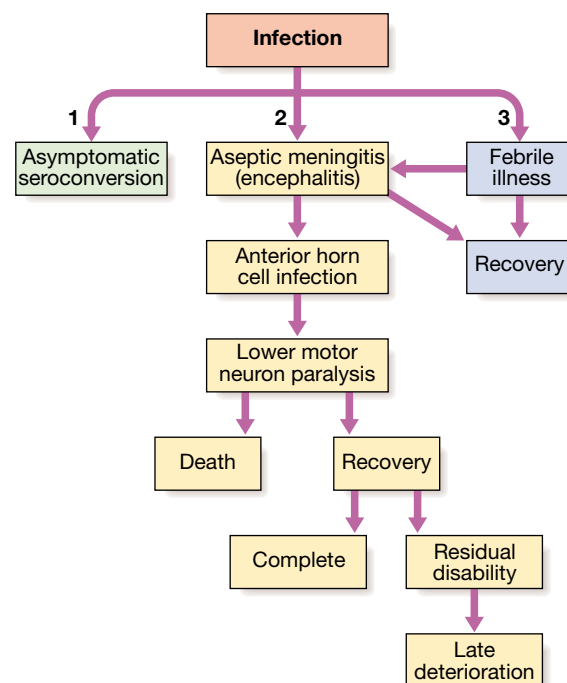

Fig. 26.44 Poliomyelitis. Possible consequences of infection.

Investigations

The CSF shows a lymphocytic pleocytosis, a rise in protein and a normal sugar content. Poliomyelitis virus may be cultured from CSF and stool.

Management

Established disease

In the early stages, bed rest is imperative because exercise appears to worsen the paralysis or precipitate it. At the onset of respiratory difficulties, a tracheostomy and ventilation are required. Subsequent treatment is by physiotherapy and orthopaedic measures.

Prophylaxis

Prevention of poliomyelitis is by immunisation with live (Sabin) vaccine. In developed countries where polio is now very rare, the live vaccine has been replaced by the killed vaccine in childhood immunisation schedules.

Herpes zoster (shingles)

Herpes zoster is the result of reactivation of the varicella zoster virus that has lain dormant in a nerve root ganglion following chickenpox earlier in life. Reactivation may be spontaneous (as usually occurs in the middle-aged or elderly) or due to immunosuppression (as in patients with diabetes, malignant disease or AIDS). Full details are given on page 314.

Subacute sclerosing panencephalitis

This is a rare, chronic, progressive and eventually fatal neurological disease caused by the measles virus, presumably as a result of an inability of the nervous system to eradicate the virus. It occurs in children and adolescents, usually many years after the primary virus infection. The onset is insidious, with intellectual deterioration, apathy and clumsiness followed by myoclonic jerks, rigidity and dementia.

The CSF may show a mild lymphocytic pleocytosis and the EEG is distinctive, with periodic bursts of triphasic waves. Although there is persistent measles-specific IgG in serum and CSF, antiviral therapy is ineffective and death ensues within years.

Progressive multifocal leucoencephalopathy

This was originally described as a rare complication of lymphoma, leukaemia or carcinomatosis. Nowadays it occurs more frequently as a feature of AIDS (p. 398). It is an infection of oligodendrocytes by human polyomavirus JC, which causes widespread demyelination of the white matter of the cerebral hemispheres. Clinical signs include dementia, hemiparesis and aphasia which progress rapidly, usually leading to death within weeks or months. Areas of low density in the white matter are seen on CT but MRI is more sensitive, showing diffuse high signal in the cerebral white matter on T2-weighted images.

Parenchymal bacterial infections

Cerebral abscess

Bacteria may enter the cerebral substance through penetrating injury, by direct spread from paranasal sinuses or the middle ear, or by haematogenous spread from septicaemia. The site of abscess formation and the likely causative organism are both related to the source of infection (Box 26.91). Initial infection leads to local suppuration followed by loculation of pus within a surrounding wall of gliosis, which in a chronic abscess may form a tough capsule. Multiple abscesses may occur, particularly with haematogenous spread.

Clinical features

A cerebral abscess may present acutely with fever, headache, meningism and drowsiness, but more commonly presents over days or weeks as a cerebral mass lesion with little or no evidence of infection. Seizures, raised intracranial pressure and focal hemisphere signs occur alone or in combination. Distinction from a cerebral tumour may be impossible on clinical grounds.

Investigations

Lumbar puncture is potentially hazardous in the presence of raised intracranial pressure, and CT should always precede it. CT reveals single or multiple

26.91 Aetiology and treatment of bacterial cerebral abscess

Site of abscess	Source of infection	Likely organisms	Recommended treatment
Frontal lobe	Paranasal sinuses Teeth	Streptococci Anaerobes	Cefuroxime 1.5 g i.v. 8-hourly <i>plus</i> metronidazole 500 mg i.v. 8-hourly
Temporal lobe	Middle ear	Streptococci	Ampicillin 2–3 g i.v. 8-hourly <i>plus</i> metronidazole 500 mg i.v.
Cerebellum	Sphenoid sinus Mastoid/middle ear	Enterobacteriaceae <i>Pseudomonas</i> spp. Anaerobes	8-hourly <i>plus</i> either ceftazidime 2 g i.v. 8-hourly <i>or</i> gentamicin* 5 mg/kg i.v. daily
Any site	Penetrating trauma	Staphylococci	Flucloxacillin 2–3 g i.v. 6-hourly <i>or</i> cefuroxime 1.5 g i.v. 8-hourly
Multiple	Metastatic and cryptogenic	Streptococci Anaerobes	Benzylpenicillin 1.8–2.4 g i.v. 6-hourly if endocarditis or cyanotic heart disease Otherwise cefuroxime 1.5 g i.v. 8-hourly <i>plus</i> metronidazole 500 mg i.v. 8-hourly

*Monitor gentamicin levels.

Fig. 26.45 Right temporal cerebral abscess (arrows), with surrounding oedema and midline shift to the left. **A** Unenhanced CT image. **B** Contrast-enhanced CT image.

low-density areas, which show ring enhancement with contrast and surrounding cerebral oedema (Fig. 26.45). There may be an elevated white blood cell count and ESR in patients with active local infection. The possibility of cerebral toxoplasmosis or tuberculous disease secondary to HIV infection should always be considered.

Management and prognosis

Antimicrobial therapy is indicated once the diagnosis is made. The likely source of infection should guide the choice of antibiotic (see Box 26.91). Surgical treatment by burr-hole aspiration or excision may be necessary, especially where the presence of a capsule may lead to a persistent focus of infection. Anticonvulsants are often necessary, as epilepsy frequently develops acutely or in the recovery phase.

The mortality rate remains at 10–20% despite an improvement in available surgical and medical treatments, and in some patients this is related to delay in diagnosis and initiation of treatment.

Subdural empyema

This is a rare complication of frontal sinusitis, osteomyelitis of the skull vault, or middle ear disease. A collection of pus in the subdural space spreads over the surface of the hemisphere, causing underlying cortical oedema or thrombophlebitis. Patients present with severe pain in the face or head and pyrexia, often with a history of preceding paranasal sinus or ear infection. The patient then becomes drowsy with seizures and focal signs such as a progressive hemiparesis.

The diagnosis rests on a strong clinical suspicion in patients with a local focus of infection. Careful assessment of a head CT (with contrast) or MRI may show a subdural collection with underlying cerebral oedema. Management requires aspiration of pus via a burr hole and appropriate parenteral antibiotics. Any local source of infection must be treated to prevent re-infection.

Spinal epidural abscess

The characteristic clinical features are pain in a root distribution and progressive transverse spinal cord syndrome with paraparesis, sensory impairment and sphincter dysfunction. Infection is usually haematogenous but a primary source of infection is easily overlooked. The resurgence of staphylococcal infection, often linked to intravenous drug misuse, has contributed to a marked rise in incidence in recent years.

Plain X-rays of the spine may show osteomyelitis but such changes are often late. MRI or myelography should precede urgent neurosurgical intervention. Decompressive laminectomy with draining of the abscess relieves the pressure on the dura. This, together with appropriate antibiotics, may prevent complete and irreversible paraplegia. Organisms may be cultured from the pus or blood.

Lyme disease

See page 329.

Neurosyphilis

Neurosyphilis may present as an acute or chronic process and may involve the meninges, blood vessels and/or parenchyma of the brain and spinal cord. In developed countries, syphilis is now most commonly seen in patients with AIDS. The clinical manifestations are diverse and, although the condition is now rare, early diagnosis and treatment remain important.

Clinical features

The clinical and pathological features of the three most common presentations are summarised in Box 26.92.

Neurological examination reveals signs appropriate to the anatomical localisation of lesions. Delusions of grandeur suggest general paresis of the insane, but more commonly there is simply progressive dementia. The pupillary abnormality described by Argyll Robertson (p. 1166) may accompany any neurosyphilitic syndrome,

26.92 Clinical and pathological features of neurosyphilis		
Type	Pathology	Clinical features
Meningovascular (5 years)*	Endarteritis obliterans Meningeal exudate Granuloma (gumma)	Stroke Cranial nerve palsies Seizures/mass lesion
General paralysis of the insane (5–15 years)*	Degeneration in cerebral cortex/ cerebral atrophy Thickened meninges	Dementia Tremor Bilateral upper motor signs
Tabes dorsalis (5–20 years)*	Degeneration of sensory neurons Wasting of dorsal columns Optic atrophy	Lightning pains Sensory ataxia Visual failure Abdominal crises Incontinence Trophic changes
Any of the above		Argyll Robertson pupils (p. 1166)
*Interval from primary infection.		

but most commonly tabes dorsalis; the pupils are small and irregular, and react to convergence but not directly to light.

Investigations

Routine screening for syphilis is warranted in the great majority of neurological patients. Serological tests (p. 418) are positive in the serum in most patients, but CSF examination is essential if neurological involvement is suspected. Active disease is suggested by an elevated cell count, usually lymphocytic, and the protein content may be elevated to 0.5–1.0 g/L with an increased gamma globulin fraction. Serological tests in the CSF are usually positive, but progressive disease can occur with negative CSF serology.

Management

The injection of procaine benzylpenicillin (procaine penicillin) and probenecid for 17 days is essential in the treatment of neurosyphilis of all types (p. 419). Further courses of penicillin must be given if symptoms are not relieved, if the condition continues to advance or if the CSF continues to show signs of active disease. The cell count returns to normal within 3 months of completion of treatment, but the elevated protein takes longer to subside and some serological tests may never revert to normal. Evidence of clinical progression at any time is an indication for renewed treatment.

Diseases caused by bacterial toxins

Tetanus

This disease results from infection with *Clostridium tetani*, a commensal in the gut of humans and domestic animals which is found in soil. Infection enters the body through wounds, often trivial. It is rare in the UK, occurring mostly in gardeners and farmers but with a recent increase in intravenous drug misusers. By contrast, the disease is common in many developing countries, where dust contains spores derived from animal and human

excreta. If childbirth takes place in an unhygienic environment, *Tetanus neonatorum* may result from infection of the umbilical stump, or the mother may develop the disease. Tetanus is still one of the major killers of adults, children and neonates in developing countries, where the mortality rate can be nearly 100% in the newborn and around 40% in others.

In circumstances unfavourable to the growth of the organism, spores are formed and these may remain dormant for years in the soil. Spores germinate and bacilli multiply only in the anaerobic conditions which occur in areas of tissue necrosis or if the oxygen tension is low as a result of the presence of other organisms, particularly aerobic ones. The bacilli remain localised but produce an exotoxin with an affinity for motor nerve endings and motor nerve cells.

The anterior horn cells are affected after the exotoxin has passed into the blood stream and their involvement results in rigidity and convulsions. Symptoms first appear from 2 days to several weeks after injury – the shorter the incubation period, the more severe the attack and the worse the prognosis.

Clinical features

By far the most important early symptom is trismus – spasm of the masseter muscles, which causes difficulty in opening the mouth and in masticating; hence the name ‘lockjaw’. Lockjaw in tetanus is painless, unlike the spasm of the masseters due to dental abscess, septic throat or other causes. Conditions that can mimic tetanus include hysteria and phenothiazine overdosage, or overdose in intravenous drug misusers.

In tetanus, the tonic rigidity spreads to involve the muscles of the face, neck and trunk. Contraction of the frontalis and the muscles at the angles of the mouth leads to the so-called ‘risus sardonicus’. There is rigidity of the muscles at the neck and trunk of varying degree. The back is usually slightly arched (‘opisthotonus’) and there is a board-like abdominal wall.

In the more severe cases, violent spasms lasting for a few seconds to 3–4 minutes occur spontaneously, or may be induced by stimuli such as moving the patient or noise. These convulsions are painful, exhausting and of very serious significance, especially if they appear soon after the onset of symptoms. They gradually increase in frequency and severity for about 1 week and the patient may die from exhaustion, asphyxia or aspiration pneumonia. In less severe illness, convulsions may not commence for about a week after the first sign of rigidity, and in very mild infections they may never appear. Autonomic involvement may cause cardiovascular complications such as hypertension. Rarely, the only manifestation of the disease may be ‘local tetanus’ – stiffness or spasm of the muscles near the infected wound – and the prognosis is good if treatment is commenced at this stage.

Investigations

The diagnosis is made on clinical grounds. It is rarely possible to isolate the infecting organism from the original locus of entry.

Management

Established disease

Management of established disease should be begun as soon as possible, as shown in Box 26.93.

 26.93 Treatment of tetanus
Neutralise absorbed toxin
<ul style="list-style-type: none"> I.v. injection of 3000 U of human tetanus antitoxin
Prevent further toxin production
<ul style="list-style-type: none"> Débridement of wound Benzyllpenicillin 600 mg i.v. 6-hourly (metronidazole if allergic to penicillin)
Control spasms
<ul style="list-style-type: none"> Nurse in a quiet room Avoid unnecessary stimuli I.v. diazepam—if spasms continue, paralyse patient and ventilate
General measures
<ul style="list-style-type: none"> Maintain hydration and nutrition Treat secondary infections

Prevention

Tetanus can be prevented by immunisation and prompt treatment of contaminated wounds by débridement and antibiotics. In patients with a contaminated wound the immediate danger of tetanus can be greatly reduced by the injection of 1200 mg of penicillin followed by a 7-day course of oral penicillin. For those who are allergic to penicillin, erythromycin should be used. When the risk of tetanus is judged to be present, an intramuscular injection of 250 U of human tetanus antitoxin should be given, along with toxoid which should be repeated 1 month and 6 months later. For those already immunised, only a booster dose of toxoid is required.

Botulism

Botulism is caused by the neurotoxins of *Clostridium botulinum*, which are extremely potent and cause disease after ingestion of even picogram amounts. It is classically described as the acute onset of bilateral cranial neuropathies associated with symmetric descending weakness.

Anaerobic conditions are necessary for the organism's growth. It may contaminate many foodstuffs, from canned meat and salmon to home-produced and preserved vegetables. Contaminated honey has been implicated in infant botulism, in which the organism colonises the gastrointestinal tract of infants. Wound botulism is a growing problem in injection drug-users.

The toxin causes predominantly bulbar and ocular palsies (difficulty in swallowing, blurred or double vision, ptosis), progressing to limb weakness and respiratory paralysis. Criteria for the clinical diagnosis are shown in Box 26.94.

Management includes assisted ventilation and general supportive measures until the toxin eventually dissociates from nerve endings 6–8 weeks following ingestion. A polyvalent antitoxin is available for post-exposure prophylaxis and for the treatment of suspected botulism. It specifically neutralises toxin types A, B and E and is not effective against infantile botulism.

26.94 The US Centers for Disease Control (CDC) definition of botulism

Three main syndromes

1. Infantile
2. Food-borne
3. Wound infection

Clinical features

- Absence of fever
- Symmetrical neurological deficits
- The patient remains responsive
- Normal or slow heart rate and normal blood pressure
- No sensory deficits with the exception of blurred vision

Transmissible spongiform encephalopathies

Transmissible spongiform encephalopathies (TSEs) include a number of conditions affecting both animals and humans which are characterised by the histopathological triad of spongiform change, neuronal cell loss and gliosis in the grey matter of the brain. Associated with these changes, there is deposition of amyloid made up of an altered form of a normally occurring protein, the prion protein. These diseases can be transmitted by inoculation. The precise nature of the infective agent is not yet clear but almost certainly involves the abnormal prion protein. They may also occur spontaneously or as an inherited disorder. Diseases affecting animals include bovine and feline spongiform encephalopathies (BSE and FSE). In humans, the most common TSE is Creutzfeldt-Jakob disease (CJD). This occurs sporadically, with a world-wide incidence of approximately 1/1 000 000, but can also be transmitted by inoculation — for example, through EEG electrodes inserted into the brain, corneal grafts, neurosurgery (especially when cadaveric dura mater grafts were used) and the use of pooled cadaveric growth hormone). Some 10% of cases arise due to a mutation in the gene coding for the prion protein.

Creutzfeldt-Jakob disease

Sporadic Creutzfeldt-Jakob disease (CJD) usually occurs in middle-aged to elderly patients. Clinical features usually involve a rapidly progressive dementia, with myoclonus and a characteristic EEG pattern (repetitive slow wave complexes), although a number of other features such as visual disturbance or ataxia may also be seen. These are particularly common in CJD transmitted by inoculation. Death occurs after a mean of 4–6 months. There is no effective treatment.

Variant Creutzfeldt-Jakob disease

A variant of CJD (vCJD) has been described in a small number of patients, mostly in the UK. The causative agent appears to be identical to that causing BSE in cows, and it has been suggested that the disease appeared in humans as a result of the epidemic of BSE in the UK which started in the late 1980s. Patients affected by vCJD are typically younger than those with sporadic CJD and present with neuropsychiatric changes and sensory symptoms in the limbs, followed by ataxia, dementia and death, progressing at a slightly slower rate than

patients with sporadic CJD (mean time to death is over a year). Characteristic EEG changes are not present but MRI scans of the head show characteristic high-signal changes in the pulvinar in a high proportion of cases. The brain pathology is distinct, with very florid plaques containing the prion proteins. Abnormal prion protein has been identified in tonsil specimens from sufferers of vCJD, leading to the suggestion that the disease could be transmitted by reticulo-endothelial tissue (like TSEs in animals but unlike sporadic CJD in humans). This has caused great concern in the UK, leading to precautionary measures such as leucodepletion of all blood used for transfusion, and the mandatory use of disposable surgical instruments wherever possible for tonsillectomy, appendicectomy and ophthalmological procedures. However, presumably thanks to the public health measures introduced to control BSE, the incidence of vCJD has now declined dramatically.

Other TSE syndromes

Other extremely rare inherited human TSEs include Gerstmann-Sträussler-Scheinker disease, fatal familial insomnia and kuru. Kuru occurred only in members of a cannibalistic New Guinea tribe and was probably transmitted by people eating the brains of dead tribal members. Clinical features include progressive ataxia and dementia.

INTRACRANIAL MASS LESIONS AND RAISED INTRACRANIAL PRESSURE

There are many different types of mass lesion in the head (Box 26.95). In developing countries, tuberculoma is a very common cause, but in developed countries cerebral neoplasms are the most frequent. The clinical features relate to the site of the mass, its nature and its rate of expansion. Symptoms and signs are produced by a number of mechanisms (Box 26.96).

26.95 Intracranial mass lesions

Traumatic

- Subdural haematoma
- Extradural haematoma

Vascular

- Intracerebral haematoma

Infective

- Cerebral abscess (pyogenic, *Toxoplasma* etc.)
- Echinococcosis (as hydatid cysts, p. 375)
- Tuberculoma
- Schistosomiasis (p. 370)
- Cysticercosis (p. 373)

Inflammatory

- Sarcoid mass

Neoplastic

- Cerebral neoplasm (benign and malignant)

Other

- Embryonic dysplastic lesions (craniopharyngioma, hamartoma)
- Arachnoid cyst
- Colloid cyst (in the ventricles)

26.96 Clinical features of intracranial mass lesions

Local effects on adjacent brain tissue (e.g. seizures, focal signs)

- Depends on the site of the lesion (see Box 26.1, p. 1136)

Raised intracranial pressure

- Headache (p. 1148)
- Impairment of conscious level
- Papilloedema
- Vomiting, bradycardia, arterial hypertension

False localising signs

- Pupillary dilatation (ipsilateral to lesion)
- 6th cranial nerve lesion (unilateral or bilateral)
- Hemiparesis (ipsilateral to lesion)
- Bilateral extensor plantar responses

Raised intracranial pressure

Raised intracranial pressure may be caused by mass lesions (especially tumours), cerebral oedema, obstruction to CSF circulation (causing hydrocephalus) or impaired CSF absorption, as in idiopathic intracranial hypertension and cerebral venous obstruction.

Clinical features

The major features of raised intracranial pressure are listed in Box 26.96. Impairment of conscious level is related to the level of intracranial pressure. Cerebral mass lesions will tend to increase intracerebral pressure, but the amount by which the pressure is raised depends on the rate of growth of the mass. If it is slow, various compensatory mechanisms may occur, including alteration in the volume of fluid in CSF spaces and venous sinuses, thereby allowing some tumours to achieve considerable size. More rapid growth (as in highly malignant tumours or abscesses) does not allow the compensatory mechanisms to come into play, so raised intracranial pressure develops early, especially if the CSF circulation is also obstructed. Papilloedema is not always present, either because raised intracranial pressure has developed too recently, or because of anatomic anomalies of the meningeal sheath of the optic nerve. Vomiting, bradycardia and arterial hypertension develop as late features of raised intracranial pressure and usually parallel the other clinical signs; sudden vomiting may be an early feature of tumours of the cerebellum, especially in children. The rise in intracranial pressure from a mass lesion is not usually uniform within the cerebral substance and alterations in pressure relationships within the skull may lead to displacement of parts of the brain between its various compartments. Downward displacement of the temporal lobes through the tentorium due to a large hemisphere mass may cause 'temporal coning' (Fig. 26.46). This may stretch the 3rd and/or 6th cranial nerves, or cause pressure on the contralateral cerebral peduncle (causing ipsilateral upper motor neuron signs). Downward movement of the cerebellar tonsils through the foramen magnum may compress the medulla – 'tonsillar coning' (Fig. 26.47). This coning may result in brain-stem haemorrhage and/or acute obstruction of the CSF pathways. As coning progresses, the patient may adopt a decerebrate posture and, unless rapidly treated, death almost invariably ensues. The process

Fig. 26.46 Cerebral tumour displacing medial temporal lobe and causing pressure on the mid-brain and 3rd cranial nerve.

Fig. 26.47 Tonsillar cone. Downward displacement of the cerebellar tonsils below the level of the foramen magnum.

may be acutely accelerated if the pressure dynamics are suddenly disturbed by lumbar puncture.

Management

The management of raised intracranial pressure is largely dictated by its specific cause (see below). ICU support may be required (p. 200).

Intracranial neoplasms

In the developed world, cerebral tumours account for 2% of deaths at all ages. The majority are metastatic from malignancies outside the nervous system. Meningiomas account for about one-fifth of intracranial tumours. Benign or malignant neoplasms of CNS tissue account for the remainder.

Pathophysiology

Metastases from extracranial primary tumours are usually located in the white matter of the cerebral or cerebellar hemispheres, and common sources are bronchus, breast and gastrointestinal tract. Primary intracerebral tumours are classified by their cell of origin and degree of malignancy, and vary in incidence by age and localisation (Boxes 26.97 and 26.98). Even when malignant, they do not metastasise outside the nervous system.

i

26.97 Primary malignant intracranial tumours

Histological type	Common site	Age
Glioma (astrocytoma)	Cerebral hemisphere	Adulthood
	Cerebellum	Childhood/adulthood
	Brain stem	Childhood/young adulthood
Oligodendroglioma	Cerebral hemisphere	Adulthood
Medulloblastoma	Posterior fossa	Childhood
Ependymoma	Posterior fossa	Childhood/adolescence
Cerebral lymphoma (microglioma)	Cerebral hemisphere	Adulthood

i

26.98 Primary benign intracranial tumours

Histological type	Common site	Age
Meningioma	Cortical dura	Adulthood
	Parasagittal	
	Sphenoid ridge	
	Suprasellar	
	Olfactory groove	
Neurofibroma	Acoustic neuroma	Adulthood
Craniopharyngioma	Suprasellar	Childhood/adolescence
Pituitary adenoma	Pituitary fossa	Adulthood
Colloid cyst	Third ventricle	Any age
Pineal tumours	Quadrigeminal cistern	Childhood (teratomas)
		Young adulthood (germ cell)

Clinical features

The presentation is quite variable. Headache is not an invariable manifestation of cerebral tumour; if present, it may have characteristics of raised intracranial pressure, or be caused by traction on the pain-sensitive intracranial structures (p. 1149). The site of the headache often does not correlate with the site of the tumour, although posterior fossa tumours often cause pain in the occiput or neck. Cerebral tumours may present with focal neurological deficits which are of slow onset and progressive. Tumours may present at an early stage in some areas, such as the brain stem where structural disturbance quickly results in a neurological deficit. In other regions, especially the frontal lobe, a tumour may be quite large before symptoms occur. The clinical features of dysfunction in the various lobes of the brain are outlined in Box 26.1 (p. 1136). Occasionally, localised oedema in the brain tissue surrounding a tumour will cause a rapid progression of symptoms. Rarely, haemorrhage into a tumour can present like an acute stroke. Tumours often present with seizures which are caused by infiltration by tumour cells of an area of cerebral cortex which excites seizure activity. The resulting seizures may be generalised or partial in nature, and the development of focal seizures in adult life should always suggest the possibility of a tumour.

Investigations

Neuroimaging by CT or MRI allows accurate localisation of the tumour and provides some guidance as to the likely histological type (Fig. 26.48). MRI is of particular value in the investigation of tumours of the posterior fossa and brain stem (Fig. 26.49), and in delineating the nature and extent of tumours prior to surgery. Distortion of intracranial structures and the size of the ventricular system can be assessed and may provide accurate evaluation of the extent of the tumour. Plain skull X-rays are rarely of diagnostic value except in pituitary tumours. Chest radiography is an important investigation and may provide evidence of a primary pulmonary tumour or other systemic malignancy.

Management

Medical

Relief of raised intracranial pressure is often required when surgery is not possible or when life is threatened before investigation has revealed the diagnosis. Dexamethasone, 8mg 12-hourly either orally or by injection, is used to lower intracranial pressure by resolving the reactive oedema around a tumour. A striking improvement in conscious level is often produced and focal disabilities may regress. In severe and acutely raised intracranial pressure, 16–20mg of dexamethasone may be given intravenously, or 200mL of a 20% solution of mannitol may be infused. Prolactin- or growth hormone-secreting pituitary tumours (p. 787) may respond to treatment with the dopamine agonists bromocriptine, cabergoline or quinagolide.

Surgical

Surgery is the mainstay of treatment, although only partial excision may be possible if the tumour is inaccessible

Fig. 26.48 MRI showing meningioma in frontal lobe (arrow A) with associated oedema (arrow B).

Fig. 26.49 MRI of an acoustic neuroma (arrows) in the posterior fossa compressing the brain stem. **[A]** Axial image. **[B]** Coronal image.

or if its removal is likely to cause unacceptable brain damage. Biopsy by a direct or stereotactic technique should be considered even if the tumour cannot be removed, since the histological diagnosis has important implications for management and prognosis.

Meningiomas and acoustic neuromas offer the best prospects for complete removal without unacceptable damage to surrounding structures. Meningiomas can recur, particularly those of the sphenoid ridge when partial excision is often all that is possible. Pituitary adenomas can often be removed by a trans-sphenoidal route, thereby avoiding the need for a craniotomy. Ependymomas and medulloblastomas can often be excised with minimal residual disability, but may recur with seeding of the tumour via the CSF.

Gliomas can rarely be completely excised, since infiltration often spreads beyond the radiologically

evident boundaries of the tumour. Recurrence is therefore common, even if the mass of the tumour is apparently removed completely. Partial excision ('debulking') may be useful in alleviating raised intracranial pressure, but survival in highly malignant gliomas is poor even if such a decompressive procedure is attempted. Prognosis is related to histological grade; patients with better grades (I–II) may survive many years, whilst only 20% of patients with grade IV gliomas (glioblastoma multiforme) survive 1 year. Oligodendrogliomas are often slow-growing and relatively benign in the early stages, but may transform to a more malignant form and behave as gliomas.

Radiotherapy and chemotherapy

Radiotherapy and chemotherapy have only a marginal effect on survival in cerebral metastases and malignant gliomas in adults, but their combination has greatly improved the prognosis in medulloblastoma in children. Radiotherapy reduces the risk of recurrence of pituitary adenoma after surgery and may also be helpful as an adjunct to operative treatment in those meningiomas whose anatomical site precludes complete excision or whose histology suggests an increased tendency to recurrence. Ependymomas, some pineal tumours and low-grade gliomas in children and young adults are often radiosensitive.

Neurofibromatosis

This disorder of autosomal dominant inheritance is caused by mutations in the *NF1* gene on chromosome 17 (type 1 neurofibromatosis, NF1) or the *NF2* gene on chromosome 22 (type 2 neurofibromatosis, NF2). Multiple fibromatous tumours develop from the neurilemmal sheaths of peripheral and cranial nerves. Most of the lesions are benign but sarcomatous change may occur. In NF1 (von Recklinghausen's disease) there are characteristic cutaneous manifestations and other extracranial manifestations (Box 26.99). Patients with NF1 are easily recognised because of the cutaneous lesions (Fig. 26.50), which increase in number throughout life. Investigation and treatment are only indicated if there are symptoms of cerebral or spinal involvement, or if malignant change is suspected. Patients with NF2 present with acoustic neuromas, often bilateral, and/or other central neoplasms, and have fewer if any cutaneous lesions. A family history of cerebral or spinal tumours should be noted with care, since relatives of patients with NF2 may require screening for acoustic neuromas.

Fig. 26.50 A café au lait spot (arrow A) and subcutaneous nodules (arrows B) on the forearm of a patient with neurofibromatosis type 1.

Acoustic neuroma

This is a benign tumour of Schwann cells of the 8th cranial nerve, which may arise in isolation or as part of NF2 (see above). As an isolated finding, an acoustic neuroma occurs after the third decade and is more frequent in females. The tumour commonly arises near the nerve's entry point into the medulla or in the internal auditory meatus, usually on the vestibular division. Such lesions make up 80–90% of tumours at the cerebello-pontine angle.

Clinical features

These depend on the site of the tumour along the acoustic or vestibular nerve. Similar tumours arise rarely from the trigeminal nerve. Hearing loss is almost invariable, although it may not be the presenting feature. Sensory symptoms in the face and vertigo are also common at presentation. Distortion of the brain stem and/or cerebellar peduncle may cause ataxia and/or cerebellar signs in the limbs. Distortion of the fourth ventricle and cerebral aqueduct may cause hydrocephalus, which may be the presenting feature (see below). Facial weakness is unusual at presentation, but facial palsy may follow surgical removal of the tumour.

Investigations

MRI is the investigation of choice (see Fig. 26.49).

Management

Surgery is the treatment of choice. If the tumour can be completely removed, the prognosis is excellent. Deafness and facial weakness, if not present before surgery, often result from the operation.

26.99 Types of neurofibromatosis and their clinical features

Type 1 Peripheral form (> 70% of cases)

- Multiple cutaneous neurofibromas
- 'Soft' papillomas
- Café au lait patches
- Axillary freckling
- Iris fibromas (Lisch nodules)
- Plexiform neurofibromas
- Spinal neurofibromas
- Aqueduct stenosis
- Scoliosis
- Endocrine tumours

Type 2 Central form

- Few or no cutaneous lesions
- Cerebral and optic nerve gliomas
- Bilateral acoustic neuromas
- Meningiomas
- Spinal neurofibromas

Von Hippel–Lindau disease

This is a dominantly inherited disease caused by mutations of the *VHL* tumour suppressor gene on chromosome 3. It is characterised by the combination of retinal and intracranial (typically cerebellar) haemangiomas and haemangioblastomas. There may be associated extracranial hamartomatous lesions, which may undergo malignant change. About 10% of posterior fossa tumours are cerebellar haemangioblastomas. Von Hippel–Lindau disease needs to be considered in patients with such lesions, so that screening for other lesions and, if necessary, of family members can be instituted.

Paraneoplastic neurological disease

Neurological disease may occur with systemic malignant tumours in the absence of metastases. Mild degrees of myopathy and neuropathy are quite frequent with the common malignancies. Much rarer are certain disabling, and often fatal, paraneoplastic syndromes which often have an inflammatory basis, with associated autoantibodies which cross-react with neural and tumour antigens (Box 26.100). In the case of the Lambert–Eaton

myasthenic syndrome, the autoantibodies have a functional effect on neuromuscular transmission (p. 1231).

These syndromes are particularly associated with small-cell carcinoma of the lung, ovarian tumours, and lymphomas. In addition to the presence of autoantibodies in the serum and/or CSF, there is usually a lymphocytic infiltrate of the neural tissue affected.

Clinical features

These are summarised in Box 26.100. In most instances the neurological disease progresses quite rapidly over a few months. In 50% of patients with a paraneoplastic syndrome, the neurological disease precedes clinical presentation of the primary neoplasm. Paraneoplastic disease should be considered in the diagnosis of any unusual progressive neurological syndrome.

Investigations

The presence of characteristic autoantibodies in the context of a suspicious clinical picture may be diagnostic (see Box 26.100). The causative tumour may be very small and therefore CT of the chest or abdomen is often necessary to find it. The CSF often shows an increased protein and lymphocyte count with oligoclonal bands.

<div> <div>i</div> <div>26.100 Paraneoplastic syndromes</div> </div>				
Syndrome	Clinical features	Antibody	Associated tumours	Investigations
Retinal degeneration	Painless progressive visual loss	Antiretinal	Small-cell carcinoma of lung Melanoma	Chest X-ray, CT chest Electroretinogram
Opsoclonus-myoclonus	Arrhythmic chaotic rapid eye movements	Anti-Ri	Ovarian, lung Neuroblastoma (in children)	Chest X-ray, CT chest Pelvic ultrasound or CT
Sensory neuropathy	Limb pain, paraesthesia Distal numbness	Anti-Hu	Small-cell carcinoma of lung Hodgkin lymphoma	Chest X-ray, CT chest Nerve conduction studies
Limbic encephalitis	Memory loss, progressive dementia Seizures	Anti-Hu Anti-VGKC	Small-cell carcinoma of lung Hodgkin lymphoma	Chest X-ray, CT chest MRI (head) CSF (pleocytosis, raised protein)
Myelitis	Progressive spinal cord lesion (usually cervical cord)	Anti-Hu	Small-cell carcinoma of lung	Chest X-ray, CT chest MRI (cord, head)
Cerebellar degeneration	Progressive ataxia, nystagmus (down-beating), vertigo	Anti-Yo Anti-Hu	Small-cell carcinoma of lung Ovarian Hodgkin lymphoma	Chest X-ray, CT chest Pelvic ultrasound or CT CSF (raised protein, oligoclonal bands)
Subacute motor neuropathy	Subacute, patchy progressive, usually lower limb weakness and wasting	Anti-Hu	Hodgkin lymphoma Small-cell carcinoma of lung	Chest X-ray, CT chest Nerve conduction studies/EMG
Sensorimotor peripheral neuropathy	Mild, non-disabling peripheral limb numbness and paraesthesia	Not known	Small-cell carcinoma of lung Breast Other carcinoma	Chest X-ray, CT chest Nerve conduction studies/EMG
Lambert–Eaton myasthenic syndrome	Weakness of proximal limb muscles, fatigue with exertion after initial improvement, areflexia	Anti-VGCC	Small-cell carcinoma of lung	Chest X-ray, CT chest EMG
Dermatomyositis/polymyositis	Proximal limb weakness and pain, heliotrope skin rash, Gottron's papules on knuckles	Anti-Jo-1	Lung, breast, ovary	Chest X-ray, CT chest Creatine kinase EMG, muscle biopsy
Guillain–Barré	Ascending weakness, distal paraesthesia	Not known	Hodgkin lymphoma	Nerve conduction studies/EMG

(Anti-VGCC = antibodies to voltage-gated calcium channel; anti-VGKC = antibodies to voltage-gated potassium channels)

Management

This is directed at the primary tumour. Occasionally, successful therapy of the tumour is associated with improvement of the paraneoplastic syndrome. Some improvement may occur following administration of intravenous immunoglobulin.

Hydrocephalus

Obstructive hydrocephalus

This condition occurs as the result of an obstruction to the CSF circulation and causes dilatation of the ventricular system (Fig. 26.51). It is said to be 'communicating' if the obstruction lies outside the ventricular system (usually in the basal cisterns). Obstruction within the ventricles is most common in the narrow channels of the third ventricle and aqueduct, and may be caused by tumour or a congenital anomaly such as aqueduct stenosis (Fig. 26.52). The causes of hydrocephalus are listed in Box 26.101.

Diversion of the CSF by means of a shunt procedure between the ventricular system and the peritoneal cavity or right atrium may result in prompt relief of symptoms in obstructive or communicating hydrocephalus.

Normal pressure hydrocephalus

In this condition the dilatation of the ventricular system is caused by intermittent rises in CSF pressure, which occur particularly at night. It occurs predominantly in old age and is suggested by the combination of gait apraxia (p. 1153) and dementia, often with urinary incontinence as an early feature. This cause of dilatation of the ventricles can be very difficult to distinguish from that occurring due to cerebral atrophy, where the cortical sulci are also dilated. The result of shunting procedures for normal pressure hydrocephalus is unpredictable.

Fig. 26.51 The circulation of cerebrospinal fluid. (1) CSF is synthesised in the choroid plexus of the ventricles, and flows from the lateral and third ventricles through the aqueduct to the fourth ventricle. (2) At the foramina of Luschka and Magendie it exits the brain, flowing over the hemispheres (3) and down around the spinal cord and roots in the subarachnoid space. (4) It is then absorbed into the dural venous sinuses via the arachnoid villi.

Fig. 26.52 MRI of hydrocephalus due to aqueduct stenosis.

A Axial T_2 -weighted image (CSF appears white): note the dilated lateral ventricles. **B** Sagittal T_2 -weighted image (CSF appears black): note the dilated ventricles (top arrow) and narrowed aqueduct (bottom arrow).

26.101 Causes of hydrocephalus

Communicating (obstruction outside ventricular system)

- Bacterial meningitis (especially tuberculous)
- Sarcoidosis
- Subarachnoid haemorrhage
- Head injury
- Idiopathic ('normal pressure')

Non-communicating (obstruction within ventricular system)

- Tumours
- Colloid cyst
- Arnold–Chiari malformation
- Aqueduct stenosis
- Cerebellar abscess
- Cerebellar or brain-stem haematoma

Idiopathic intracranial hypertension

This condition, previously known as 'benign intracranial hypertension' and 'pseudotumour cerebri', usually occurs in obese young women. Raised intracranial pressure develops without a space-occupying lesion, ventricular dilatation or impairment of consciousness. The aetiology is uncertain but there may be a diffuse defect of CSF reabsorption by the arachnoid villi. The condition can be precipitated by drugs, including tetracycline, and vitamin A and its derivatives, the retinoids.

Clinical features

The usual presentation is with headache, sometimes accompanied by transient diplopia and visual disturbance. Clinical examination reveals papilloedema, which may be discovered incidentally at a routine visit to an optician. A palsy of the 6th cranial nerve may also be present.

Investigations

The diagnosis can be confirmed by lumbar puncture which shows raised CSF pressure, but neuroimaging must be performed before a lumbar puncture to exclude the presence of a mass lesion. Patients with idiopathic cranial hypertension have an essentially normal CT with normal-sized or small ventricles. MR angiography or cerebral venography is usually performed to exclude cerebral venous sinus thrombosis or stenosis. True papilloedema may need to be distinguished from other causes of disc swelling clinically and by fluorescein angiography which is indicated in patients where there is any doubt about the diagnosis.

Management

Any precipitating condition should be sought, relevant medication should be withdrawn and a weight-reducing diet instigated, if indicated. The carbonic anhydrase inhibitor, acetazolamide, may help to lower intracranial pressure. Repeated lumbar puncture can be considered, but is often unacceptable to the patient. Patients failing to respond, in whom chronic papilloedema threatens vision, may require optic nerve sheath fenestration or a lumbo-peritoneal shunt. In patients shown to have a fixed stenosis of the transverse venous sinus, stenting of this may be helpful.

DISORDERS OF THE SPINE AND SPINAL CORD

The spinal cord and spinal roots may be affected by intrinsic disease or by disorders of the surrounding meninges and bones. The clinical presentation of these conditions depends on the anatomical level at which the cord or roots are affected, as well as the nature of the pathological process involved. It is important to recognise when emergency surgical intervention is necessary and to plan investigations to identify such patients.

Cervical spondylosis

Cervical spondylosis is the term given to the occurrence of osteoarthritis in the cervical spine. It is characterised by degeneration of the intervertebral discs and osteophyte

formation. This is extremely common and radiological changes of cervical spondylosis are very frequently found in apparently healthy individuals above the age of 50. Whilst cervical spondylosis is often asymptomatic, it may be associated with neurological dysfunction. The C5/6, C6/7 and C4/5 vertebral levels and C6, C7 and C5 roots, respectively, are most commonly affected (Fig. 26.53).

Cervical spondylosis radiculopathy

Compression of a nerve root occurs when a disc prolapses laterally, which may develop acutely, or compression may occur more gradually due to osteophytic encroachment of the intervertebral foramina.

Clinical features

The patient complains of pain in the neck that may radiate in the distribution of the affected nerve root. The neck is held rigidly and neck movements may exacerbate pain. Paraesthesia and sensory loss may be found in the affected segment and there may be lower motor neuron signs, including weakness, wasting and reflex impairment (Box 26.102).

Fig. 26.53 MRI showing cervical cord compression (arrow) in cervical spondylosis.

26.102 Physical signs in cervical root compression			
Root	Muscle weakness	Sensory loss	Reflex loss
C5	Biceps, deltoid, spinati	Upper lateral arm	Biceps
C6	Brachioradialis	Lower lateral arm, thumb, index finger	Supinator
C7	Triceps, finger and wrist extensors	Middle finger	Triceps

Investigations

Plain X-rays, including lateral and oblique views, should be obtained to confirm the presence of degenerative changes and to exclude other conditions, including destructive lesions. If surgery is contemplated, MRI is required. Electrophysiological studies rarely add to the clinical examination, but may be necessary if there is doubt about the differential diagnosis between root and peripheral nerve lesions.

Management

Conservative treatment with analgesics and physiotherapy results in resolution of symptoms in the great majority of patients, but a few require surgery in the form of foraminotomy or disc excision.

Cervical spondylotic myelopathy

Dorsomedial herniation of a disc and the development of transverse bony bars or posterior osteophytes may result in pressure on the spinal cord or the anterior spinal artery which supplies the anterior two-thirds of the cord (see Fig. 26.53).

Clinical features

The onset is usually insidious and painless, but acute deterioration may occur after trauma, especially hyperextension injury. Upper motor neuron signs develop in the limbs, with spasticity of the legs usually appearing before the arms are involved. Sensory loss in the upper limbs is common, producing tingling, numbness and proprioception loss in the hands, with progressive clumsiness. Sensory manifestations in the legs are much less common. The neurological deficit usually progresses gradually and disturbance of micturition is a very late feature.

Investigations

Plain X-rays confirm the presence of degenerative changes, and MRI (see Fig. 26.53) or myelography may be indicated if surgical treatment is being considered. MRI may also show areas of high signal within the spinal cord at the level of compression. Imaging of the cervical spine should be considered if there is diagnostic doubt or if surgery is contemplated.

Management

Surgical procedures, including laminectomy and anterior discectomy, may arrest progression of disability but may not result in neurological improvement. The judgement on whether surgery should be undertaken may be difficult. Manipulation of the cervical spine is of no proven benefit and may precipitate acute neurological deterioration.

Prognosis

The prognosis of cervical myelopathy is variable. In many patients the condition stabilises or even improves without intervention, but if progressive disability does develop, surgical decompression should be considered.

Lumbar spondylosis

This is the term given to the occurrence of degenerative disc disease and osteoarthritic change in the lumbar spine. Pain in the distribution of the lumbar or sacral

roots ('sciatica') is often due to disc protrusion, but can be a feature of other rare but important disorders including spinal tumour, malignant disease in the pelvis and tuberculosis of the vertebral bodies.

Lumbar disc herniation

Acute lumbar disc herniation is often precipitated by trauma, usually by lifting heavy weights while the spine is flexed. The nucleus pulposus may bulge or rupture through the annulus fibrosus, giving rise to pressure on nerve endings in the spinal ligaments, changes in the vertebral joints or pressure on nerve roots.

Pathophysiology

The altered mechanics of the lumbar spine result in loss of lumbar lordosis and there may be spasm of the paraspinal musculature. Root pressure is suggested by limitation of flexion of the hip on the affected side if the straight leg is raised (Lasègue's sign). If the third or fourth lumbar roots are involved, Lasègue's sign may be negative, but pain in the back may be induced by hyperextension of the hip (femoral nerve stretch test). The roots most frequently affected are S1, L5 and L4; the signs of root pressure at these levels are summarised in Box 26.103.

Clinical features

The onset may be sudden or gradual. Alternatively, repeated episodes of low back pain may precede sciatica by months or years. Constant aching pain is felt in the lumbar region and may radiate to the buttock, thigh, calf and foot. Pain is exacerbated by coughing or straining but may be relieved by lying flat.

Investigations

Plain X-rays of the lumbar spine are of little value in the diagnosis of lumbar disc disease, although they may show other conditions such as malignant infiltration of a vertebral body. CT, especially using spiral scanning techniques, can provide helpful images of the disc protrusion and/or narrowing of the exit foramina. MRI is the investigation of choice if available, since soft tissues are well imaged.

Management

Some 90% of patients with sciatica recover following conservative treatment with analgesia and early mobilisation; bed rest does not help recovery. The patient should be instructed in back-strengthening exercises and advised to avoid physical manoeuvres likely to strain the lumbar spine. Injections of local anaesthetic or corticosteroids may be useful adjunctive treatment

26.103 Physical signs in lumbar root compression

Disc level	Root	Sensory loss	Weakness	Reflex loss
L3/L4	L4	Inner calf	Inversion of foot	Knee
L4/L5	L5	Outer calf and dorsum of foot	Dorsiflexion of hallux/toes	
L5/S1	S1	Sole and lateral foot	Plantar flexion	Ankle

if symptoms are due to ligamentous injury or joint dysfunction. Surgery may have to be considered if there is no response to conservative treatment or if progressive neurological deficits develop. Central disc prolapse with bilateral symptoms and signs and disturbance of sphincter function requires urgent surgical decompression.

Lumbar canal stenosis

This is due to a congenital narrowing of the lumbar spinal canal, exacerbated by the degenerative changes that commonly occur with age.

Pathophysiology

The symptoms of spinal stenosis are thought to be due to local vascular compromise secondary to the canal stenosis, rendering the nerve roots ischaemic and intolerant of the demand for increased neural activity that occurs on exercise.

Clinical features

The patients, who are usually elderly, develop exercise-induced weakness and paraesthesia in the legs ('spinal claudication'). These symptoms progress with continued exertion, often to the point that the patient can no longer walk, but are quickly relieved by a short period of rest. Physical examination at rest shows preservation of peripheral pulses with absent ankle reflexes. Weakness or sensory loss may only be apparent if the patient is examined immediately after exercise.

Investigations

The investigation of first choice is MRI, but this is not always possible because of contraindications, and if this is the case CT or myelography can be used as an alternative.

Management

Extensive lumbar laminectomy often results in complete relief of symptoms and recovery of normal exercise tolerance.

Spinal cord compression

Spinal cord compression is one of the most common neurological emergencies encountered in clinical practice and the common causes are listed in Box 26.104. A space-occupying lesion within the spinal canal may damage nerve tissue either directly by pressure or indirectly by interfering with blood supply. Oedema from venous obstruction impairs neuronal function, and ischaemia from arterial obstruction may lead to necrosis of the spinal cord. The early stages of damage are reversible but severely damaged neurons do not recover; hence the importance of early diagnosis and treatment.

Clinical features

The onset of symptoms of spinal cord compression is usually slow (over weeks), but can be acute as a result of trauma or metastases, especially if there is associated arterial occlusion. The symptoms are shown in Box 26.105.

Pain and sensory symptoms occur early, while weakness and sphincter dysfunction are usually late

26.104 Causes of spinal cord compression

Site	Frequency	Causes
Vertebral	80%	Trauma (extradural) Intervertebral disc prolapse Metastatic carcinoma (e.g. breast, prostate, bronchus) Myeloma Tuberculosis
Meninges (intradural, extramedullary)	15%	Tumours (e.g. meningioma, neurofibroma, ependymoma, metastasis, lymphoma, leukaemia) Epidural abscess
Spinal cord (intradural, intramedullary)	5%	Tumours (e.g. glioma, ependymoma, metastasis)

26.105 Symptoms of spinal cord compression

Pain
<ul style="list-style-type: none"> Localised over the spine or in a root distribution, which may be aggravated by coughing, sneezing or straining
Sensory
<ul style="list-style-type: none"> Paraesthesia, numbness or cold sensations, especially in the lower limbs, which spread proximally, often to a level on the trunk
Motor
<ul style="list-style-type: none"> Weakness, heaviness or stiffness of the limbs, most commonly the legs
Sphincters
<ul style="list-style-type: none"> Urgency or hesitancy of micturition, leading eventually to urinary retention

manifestations. The signs vary according to the level of the cord compression and the structures involved. There may be tenderness to percussion over the spine if there is vertebral disease, and this may be associated with a local kyphosis. Involvement of the roots at the level of the compression may cause dermatomal sensory impairment and corresponding lower motor signs. Interruption of fibres in the spinal cord causes sensory loss (p. 1156) and upper motor neuron signs below the level of the lesion, and there is often disturbance of sphincter function. The distribution of these signs varies with the level of the lesion, as shown in Box 26.106.

The Brown-Séquard syndrome (see Fig. 26.18E, p. 1156) results if damage is confined to one side of the cord; the findings are explained by the anatomy of the sensory tracts (see Fig. 26.8, p. 1140). On the side of the lesion there is a band of hyperaesthesia with loss of proprioception and upper motor neuron signs below it. On the other side there is loss of spinothalamic sensation (pain and temperature). With compressive lesions there is usually a band of pain at the level of the lesion in the distribution of the nerve roots subject to compression.

26.106 Signs of spinal cord compression

Cervical, above C5

- Upper motor neuron signs and sensory loss in all four limbs
- Diaphragm weakness (phrenic nerve)

Cervical, C5–T1

- Lower motor neuron signs and segmental sensory loss in the arms; upper motor neuron signs in the legs
- Respiratory (intercostal) muscle weakness

Thoracic cord

- Spastic paraplegia with a sensory level on the trunk

Conus medullaris

- Weakness of legs, sacral loss of sensation and extensor plantar responses

Cauda equina

- Spinal cord ends at approximately the T12/L1 spinal level and spinal lesions below this level can only cause lower motor neuron signs by affecting the cauda equina

26.107 Investigation of acute spinal cord syndrome

- Plain X-rays of spine
- Chest X-rays
- MRI of spine or myelography
- CSF
- Serum B₁₂

Investigations

Patients with a short history of a progressive spinal cord syndrome should be investigated urgently as listed in Box 26.107. The investigation of first choice is MRI (Fig. 26.54); but this is not always possible because of complications; in this situation, myelography can also localise the lesion and, with CT in suitable cases, can define the extent of compression and associated soft-tissue abnormality (Fig. 26.55). Plain X-rays may show bony destruction and soft-tissue abnormalities and are also an essential initial investigation. Routine investigations, including chest X-ray, may provide evidence of systemic disease. If myelography is performed, CSF should be taken for analysis; in cases of complete spinal block this shows a normal cell count with a very elevated protein causing yellow discoloration of the fluid (Froin's syndrome). Acute deterioration may develop after myelography and the neurosurgeons should be alerted before it is undertaken. In patients with secondary tumours, needle biopsy may be required to establish a tissue diagnosis, unless this has already been established.

Management

Treatment and prognosis depend on the nature of the underlying lesion. Benign tumours should be surgically excised, and a good functional recovery can be expected unless a marked neurological deficit has developed before diagnosis. Extradural compression due to malignancy is the most common cause of spinal cord compression in developed countries and has a poor prognosis, although useful function can be regained if treatment is initiated within 24 hours of the onset of severe weakness or sphincter dysfunction. Surgical decompression may be appropriate in some patients, but has a similar out-

Fig. 26.54 Axial MRI of thoracic spine. A neurofibroma (N) is compressing the spinal cord (SC) and emerging in a 'dumbbell' fashion through the vertebral foramen into the paraspinal space.

Fig. 26.55 CT myelogram of cervical spine at the level of C2 showing bony erosion of vertebra by a metastasis (arrow).

come to radiotherapy. Spinal cord compression due to tuberculosis is common in some areas of the world, and requires surgical treatment if seen early. This should be followed by appropriate anti-tuberculous chemotherapy (p. 693) for an extended period. Traumatic lesions of the vertebral column require specialised neurosurgical treatment.

Intrinsic diseases of the spinal cord

There are many disorders which interfere with spinal cord function due to non-compressive involvement of the spinal cord itself. A list of these disorders is given in Box 26.108. The symptoms and signs are generally similar to those that would occur with extrinsic compression (see Boxes 26.105 and 26.106), although a suspended sensory loss (see Fig. 26.18F, p. 1156) can only occur with intrinsic disease such as syringomyelia. Urinary symptoms

26.108 Intrinsic diseases of the spinal cord

Type of disorder	Condition	Clinical features
Congenital	Diastematomyelia (spina bifida)	Features variably present at birth and deteriorate thereafter LMN features, deformity and sensory loss of legs Impaired sphincter function Hairy patch or pit over low back Incidence reduced by increased maternal intake of folic acid during pregnancy
	Hereditary spastic paraplegia	Onset usually in adult life Autosomal dominant inheritance usual Slowly progressive UMN features affecting legs > arms Little, if any, sensory loss
Infective/ inflammatory	Transverse myelitis due to viruses (HZV), schistosomiasis, HIV, MS, sarcoidosis	Weakness and sensory loss, often with pain, developing over hours to days UMN features below lesion Impaired sphincter function
Vascular	Anterior spinal artery infarct Intervertebral disc embolus	Abrupt onset Anterior horn cell loss (LMN) at level of lesion UMN features below it Spinothalamic sensory loss below lesion but spared dorsal column sensation
	Spinal AVM/dural fistula	Onset variable (acute to slowly progressive) Variable LMN, UMN, sensory and sphincter disturbance Symptoms and signs often not well localised to site of AVM
Neoplastic	Glioma, ependymoma	Weakness and sensory loss, often with pain, developing over months to years UMN features below lesion in cord; additional LMN features in conus Impaired sphincter function
Metabolic	Vitamin B ₁₂ deficiency (subacute combined degeneration)	Progressive spastic paraparesis with proprioception loss, absent reflexes due to peripheral neuropathy ± optic nerve and cerebral involvement (p. 113)
Degenerative	Motor neuron disease	Relentlessly progressive LMN and UMN features, associated bulbar weakness, no sensory involvement (p. 1204)
	Syringomyelia	Gradual onset over months or years, pain in cervical segments Anterior horn cell loss (LMN) at level of lesion, UMN features below it Suspended spinothalamic sensory loss at level of lesion, dorsal columns preserved. See Figures 26.18F (p. 1156) and 26.56

(AVM = arteriovenous malformation; HIV = human immunodeficiency virus; HZV = herpes zoster virus; LMN = lower motor neuron; MS = multiple sclerosis; UMN = upper motor neuron)

Fig. 26.56 MRI scan showing syrinx (arrows A), with herniation of cerebellar tonsils (arrow B).

usually occur earlier in the course of an intrinsic cord disorder than with compressive disorders.

Investigation of intrinsic disease starts with imaging to exclude a compressive lesion. If available, MRI provides the most information about structural lesions such as diastematomyelia, syringomyelia (Fig. 26.56), or intrinsic tumours. Non-specific signal change may be seen in the spinal cord in inflammatory (see Fig. 26.38, p. 1194) or infective conditions and others such as B₁₂ deficiency. Other investigations such as lumbar puncture or blood tests are required to make a specific diagnosis.

DISEASES OF PERIPHERAL NERVES

Numerous inherited and acquired pathological processes may affect peripheral nerves, targeting either the nerve roots (radiculopathy), the nerve plexuses (plexopathy) and/or the individual nerves themselves (neuropathy), as summarised in Box 26.109. Cranial nerves 3–12 share the same tissue characteristics as peripheral nerves elsewhere and are subject to the same range of diseases. Nerve fibres of different types (motor, sensory or autonomic) and of different sizes may be variably involved. Disorders may be primarily directed at

26.109 Types and causes of peripheral neuropathy

Neurophysiology	Focal (mononeuropathy)	Multifocal (mononeuropathy multiplex)		Generalised (polyneuropathy)	
		Acute	Chronic	Acute	Chronic
Demyelinating on NCS; slowed conduction ± conduction block	Entrapment*	Diphtheria	Leprosy* Paraproteinaemia MMN HNPP	Guillain-Barré* Suramin toxicity	Hereditary* CIDP Lymphoma Osteoclastic myeloma IgM paraproteinaemia Arsenic toxicity Amiodarone toxicity Diphtheria
Axonal on NCS; reduced or absent action potentials, normal conduction velocities	Severe entrapment*	Diabetes* Vasculitis Lyme disease Cryoglobulinaemia	Diabetes* Neoplastic infiltration HIV Sarcoidosis Amyloid	Alcohol* Guillain-Barré variants Toxins Critical illness Porphyria Paraneoplastic Tick paralysis	Metabolic/endocrine diseases (including diabetes)* Alcohol* Drugs and toxins Vitamin deficiency* Hereditary* IgG paraproteinaemia Paraneoplastic Primary amyloidosis

*Common and/or important causes.

(CIDP = chronic inflammatory demyelinating peripheral neuropathy; MMN = multifocal motor neuropathy with conduction block; HNPP = hereditary neuropathy with tendency to pressure palsies; NCS = nerve conduction studies)

the axon, the myelin sheath (Schwann cells) or the vasa nervorum (see Fig. 26.1, p. 1134). An acute or chronic peripheral nerve disorder may be focal (affecting a single nerve: mononeuropathy), multifocal (several nerves: mononeuropathy multiplex) or generalised (polyneuropathy).

Pathophysiology

Neuropathy can occur in association with many systemic diseases, toxins (Box 26.110) and drugs (Box 26.111) which damage function of the peripheral nerves to cause a neuropathy.

Clinical features

Motor nerve involvement produces features of a lower motor neuron lesion (p. 1152). Symptoms and signs of sensory nerve involvement depend on the type of sensory nerve involved (p. 1156). Autonomic fibre involvement may cause postural hypotension due to disruption of vasomotor control, or disturbance of sweating, cardiac rhythm, and gastrointestinal, bladder and sexual functions.

Investigations

Investigations required in a patient with peripheral neuropathy reflect this wide spectrum of causes (Box 26.112). Neurophysiological tests (p. 1142), and sometimes nerve biopsy, will help determine whether the pathology is primarily affecting the nerve axon (axonal neuropathy), the myelin sheath (demyelinating neuropathy) or the blood vessels (Box 26.109).

Entrapment neuropathy

Focal compression or entrapment is the usual cause of a mononeuropathy. However, some patients present with what initially appears to be a single nerve lesion

and then go on to develop multiple nerve lesions. This is termed mononeuritis multiplex. Symptoms and signs of entrapment neuropathy are listed in Box 26.113. In this situation pressure damages the myelin sheath, and neurophysiology studies show slowing of conduction over the relevant site. Sustained or severe pressure damages the integrity of the axons, demonstrable as loss of the sensory action potential distal to the site of compression. Certain conditions increase the propensity to develop entrapment neuropathies. These include acromegaly, hypothyroidism, pregnancy, any pre-existing mild generalised axonal neuropathy such as diabetes, and osteophytes. Patients with multiple recurrent entrapment neuropathies, especially at unusual sites, should be screened for autosomal dominant hereditary neuropathy with liability to pressure palsies (HNPP) (see Box 26.116, p. 1230). Unless axonal loss has occurred, entrapment neuropathies will recover, provided the pressure on the nerve is relieved, either by avoiding precipitating activities or limb positions, or by surgical decompression. Cranial nerves may also be the target of entrapment neuropathy. Lesions of ocular motor nerves (3rd, 4th and 6th) are reviewed on page 1163. An isolated lesion of one 8th cranial nerve usually indicates compressive pathology such as acoustic neuroma (p. 1218) in or near the cerebello-pontine angle. Isolated lesions of the 9th, 10th, 11th or 12th cranial nerves are uncommon, and anatomical considerations mean that lower cranial nerve lesions tend to occur in groups, sometimes with involvement of the ascending sympathetic innervation to the eye (Box 26.114).

Trigeminal neuropathy

Isolated trigeminal sensory neuropathy is rare. It causes unilateral facial sensory loss and is associated in some patients with scleroderma, Sjögren's syndrome or other

26.110 Systemic disorders and toxins associated with neuropathy

	Metabolic/ endocrine	Toxic	Immune-mediated/ inflammatory	Infective	Neoplastic	Vitamin deficiencies
Common	Diabetes mellitus Chronic renal failure	Alcoholism Chronic liver disease Drugs	–	–	–	–
Unusual	Hypothyroidism	Lead Radiation	Systemic vasculitis SLE Rheumatoid arthritis Sjögren's disease Cryoglobulinaemia Paraproteinaemia	HIV/AIDS	Lymphoma Carcinoma (infiltration and paraneoplastic) Myeloma	Vitamin B ₁₂ Thiamin Pyridoxine Folic acid Vitamin E Pantothenic acid
Rare	Porphyria (p. 456) Acromegaly	Arsenic (p. 221) Mercury Thallium Organophosphates (p. 218) Acrylamide Hexacarbons (glue)	Coeliac disease Sarcoidosis Primary amyloidosis	Lyme disease	–	–

26.111 Drugs causing peripheral neuropathy

Cardiovascular agents		
• Amiodarone	• Statins	• Hydralazine
Chemotherapy agents		
• Cisplatin • Thalidomide	• Paclitaxel	• Vincristine
Anti-infective agents		
• Chloramphenicol • Isoniazid	• Nitrofurantoin • Ethambutol	• Metronidazole • Suramin
Other		
• Gold • Disulfiram	• Pyridoxine • Tacrolimus	• Colchicine • Phenytoin

26.112 Investigation of peripheral neuropathy

	First-line tests	Second-line tests	Occasionally useful tests
Haematology	Full blood count ESR B ₁₂ and folate		
Biochemistry	Urea, electrolytes, calcium Creatinine Liver function tests Blood glucose ± tolerance test/HbA _{1c} Thyroid function tests Plasma protein electrophoresis	Serum lipids, lipoproteins Cryoglobulins Toxic metal and drug screen Prostate-specific antigen Urinary porphyrins Urinary Bence Jones protein Faecal occult blood	Vitamin assays (e.g. vitamin E) Phytanic acid (Refsum's disease)
Immunology	Venereal Diseases Research Laboratory (VDRL) test Serum autoantibodies (antinuclear factor, dsDNA, rheumatoid factor, extractable nuclear antigens)	Antiganglioside antibodies Antineuronal antibodies	
Other	Nerve conduction/EMG	Genetic screening tests (hereditary neuropathies, Friedreich's ataxia) Chest X-ray/CT Mammogram Abdominal imaging	Nerve biopsy

26.113 Symptoms and signs in common entrapment neuropathies

Nerve	Symptoms	Muscle weakness/ muscle-wasting	Area of sensory loss
Median (at wrist) (carpal tunnel syndrome)	Pain and paraesthesia on palmar aspect of hands and fingers, waking the patient from sleep. Pain may extend to arm and shoulder	Abductor pollicis brevis	Lateral palm and thumb, index, middle and lateral half 4th finger
Ulnar (at elbow)	Paraesthesia on medial border of hand, wasting and weakness of hand muscles	All small hand muscles, excluding abductor pollicis brevis	Medial palm and little finger, and medial half 4th finger
Radial	Weakness of extension of wrist and fingers, often precipitated by sleeping in abnormal posture, e.g. arm over back of chair	Wrist and finger extensors, supinator	Dorsum of thumb
Common peroneal	Foot drop, trauma to head of fibula	Dorsiflexion and eversion of foot	Nil or dorsum of foot
Lateral cutaneous nerve of the thigh (meralgia paraesthetica)	Tingling and dysaesthesia on lateral border of the thigh	Nil	Lateral border of thigh

26.114 Syndromes of lower cranial nerve lesions outside the brain stem

Syndrome	Cranial nerves involved	Site of lesion	Cause
Vernet	9, 10 and 11	Jugular foramen (inside skull)	Metastases, neurinoma, meningioma, epidermoid, carotid body tumour
Collet-Sicard	9, 10, 11 and 12	Jugular foramen just outside skull, near foramen lacerum	Metastases, neurinoma, meningioma, epidermoid, carotid body tumour
Villaret	9, 10, 11, 12 and Horner's	Posterior retropharyngeal space, near carotid artery	Carotid dissection, metastases, neurinoma, meningioma, epidermoid, carotid body tumour
Isolated 12th	12	Skull base (hypoglossal canal)	Metastases, neurinoma, meningioma, epidermoid

connective tissue disorder. Patients with trigeminal neuralgia (p. 1171) do not have sensory loss on examination unless there have been operative procedures on the nerve. Reactivation of varicella virus in the trigeminal nerve causes herpes zoster (most frequently in the ophthalmic division) and is followed in about one-third of patients by postherpetic neuralgia (p. 314).

Facial nerve palsy

Idiopathic facial nerve palsy or Bell's palsy is a common condition affecting all ages and both sexes. The lesion is within the facial canal and may be due to reactivation of latent herpes simplex virus 1 infection. Symptoms usually develop subacutely over a few hours, with pain around the ear preceding the unilateral facial weakness. Patients often describe the face as 'numb', but there is no objective sensory loss (except possibly to taste). Hyperacusis can occur if the nerve to stapedius is involved, and there may be diminished salivation and tear secretion. Examination reveals an ipsilateral lower motor neuron facial nerve palsy. Vesicles in the ear or on the palate indicate that the facial palsy is due to herpes zoster (p. 314) rather than Bell's palsy.

Prednisolone 40–60 mg daily for a week speeds recovery if started within 72 hours. Artificial tears and ointment prevent exposure keratitis and the eye should be taped shut overnight. About 80% of patients recover spontaneously within 12 weeks. A slow or poor recovery is predicted by complete paralysis, older age and reduced facial motor action potential amplitude after

the first week. Recurrences can occur but should prompt further investigation. Aberrant re-innervation may occur during recovery, producing unwanted facial movements such as eye closure when the mouth is moved, or 'crocodile tears' (tearing during salivation).

Hemifacial spasm

This usually presents after middle age with intermittent twitching around one eye, spreading ipsilaterally over months or years to affect other parts of the facial muscles. The spasms are exacerbated by talking or eating, or when the patient is under stress. The cause, as with trigeminal neuralgia, is probably an aberrant arterial loop irritating the nerve just outside the pons. The facial nerve should be imaged to exclude a structural lesion, especially in a young patient. Drug treatment is not effective but injections of botulinum toxin into affected muscles help, although these usually have to be repeated every 3 months or so. Occasionally, microvascular decompression is necessary.

Multifocal neuropathy

Multifocal neuropathy (mononeuritis multiplex) is characterised by lesions of multiple nerve roots, peripheral nerves or cranial nerves. It is due either to involvement of the vasa nervorum or to malignant infiltration of the nerves. The clinical expression of a very widespread multifocal neuropathy may become confluent so that the clinical picture eventually resembles a polyneuropathy. In this case neurophysiology may be required to identify

the multifocal nature of the problem. Investigation of patients with an acute multifocal neuropathy should be urgent since vasculitis is a common cause, either as part of a systemic disease (see Box 26.110) or isolated to the nerves.

Polyneuropathy

Polyneuropathy is a generalised pathological process occurring in the longest peripheral nerves first, affecting the distal lower limbs before the upper limbs, with sensory symptoms and signs of an ascending 'glove and stocking' distribution (p. 1156). This is particularly true with axonal neuropathies where the disorder affects the metabolic processes required for axonal transport in the peripheral nerves. In inflammatory demyelinating neuropathies, the pathology may be patchier and variations from this ascending pattern occur.

Guillain-Barré syndrome

This syndrome of acute paralysis develops, in 70% of patients, 1–4 weeks after respiratory infection or diarrhoea (particularly *Campylobacter*). In Europe and North America, acute inflammatory polyneuropathy is most commonly demyelinating (acute inflammatory demyelinating neuropathy, AIDP). Axonal variants, either motor (acute motor axonal neuropathy, AMAN) or sensorimotor (acute motor and sensory axonal neuropathy, AMSAN), are more common in China and Japan. There is a predominantly cell-mediated inflammatory response directed at the myelin protein of spinal roots, peripheral and extra-axial cranial nerves, possibly triggered by molecular mimicry between epitopes found in the cell walls of some microorganisms and gangliosides in the Schwann cell and axonal membranes. The resulting release of inflammatory cytokines blocks nerve conduction and is followed by a complement-mediated destruction of the myelin sheath and the associated axon.

Clinical features

Distal paraesthesia and limb pains (often severe) precede a rapidly ascending muscle weakness, from lower to upper limbs, more marked proximally than distally. Facial and bulbar weakness commonly develops, and respiratory weakness requiring ventilatory support occurs in 20% of cases. In most patients, weakness progresses for 1–3 weeks, but rapid deterioration to respiratory failure can develop within hours. On examination there is diffuse weakness with widespread loss of reflexes. An unusual axonal variant described by Miller Fisher comprises the triad of ophthalmoplegia, ataxia and areflexia. Overall, 80% of patients recover completely within 3–6 months, 4% die, and the remainder suffer residual neurological disability which can be severe. Adverse prognostic features include older age, rapid deterioration to ventilation and evidence of axonal loss on EMG.

Investigations

The CSF protein is elevated at some stage of the illness but may be normal in the first 10 days. There is usually no rise in CSF cell number (a lymphocytosis of $> 50 \times 10^6$ cells/L suggests an alternative diagnosis). Electrophysiological studies are often normal in the early stages but show typical changes after a week or

so, with conduction block and multifocal motor slowing, sometimes most evident proximally as delayed F-waves (p. 1142). Investigation to identify an underlying cause, such as cytomegalovirus, mycoplasma or *Campylobacter*, requires a chest X-ray, stool culture and appropriate immunological blood tests. Antibodies to the ganglioside GQ_{1b} are found in the Miller Fisher variant. Acute porphyria (p. 456) should be excluded by urinary porphyrin estimation, and serum lead should be measured if there are only motor signs.

Management

During the phase of deterioration, regular monitoring of respiratory function (vital capacity and arterial blood gases) is required, as respiratory failure may develop with little warning and require ventilatory support. Ventilation may be needed if the vital capacity falls below 1 L, but intubation is more often required because of bulbar incompetence leading to aspiration. General management to protect the airway and prevent pressure sores and venous thrombosis is essential. Corticosteroid therapy has been shown by RCT to be ineffective. However, plasma exchange and intravenous immunoglobulin therapy shorten the duration of ventilation and improve prognosis, provided treatment is started within 14 days of the onset of symptoms (Box 26.115).

EBM 26.115 Intravenous immunoglobulin (IVIg) and plasma exchange (PE) in Guillain-Barré syndrome

'If used within the first 2 weeks of developing the illness, IVIg and PE are equally effective in reducing the severity and duration of Guillain-Barré syndrome, but there is no advantage in combining the two treatments.'

- Plasma Exchange/Sandoglobulin Guillain-Barré Syndrome Trial Group. *Lancet* 1997; 349:225–230.
- Brit J. Neurology 1996; 46:100–103.

Acute axonal polyneuropathy

There is an axonal variant of Guillain-Barré syndrome, rare in Europe and North America but more common in China and Japan. Circulating antibodies to various peripheral nerve gangliosides are often found. Other causes of acute axonal neuropathy, all rare, include drug or toxin exposure (see Box 26.110).

Chronic polyneuropathy

A chronic symmetrical polyneuropathy, evolving over months or years, is the most frequently seen form of neuropathy. In about 30% of patients no cause can be established, even after thorough investigation. These patients usually have a mild axonal neuropathy which, whilst causing unpleasant symptoms, does not lead to motor disability. Therefore, if a patient with what seems to be an idiopathic polyneuropathy progresses to significant disability, further thought needs to be given to finding a specific cause (usually inflammatory or genetic).

Chronic demyelinating polyneuropathy

This type of chronic polyneuropathy is either hereditary or immune-mediated (including those caused by abnormal paraproteins). Many inherited disorders

cause demyelinating peripheral neuropathies and one of the best known is Charcot-Marie-Tooth disease (CMT). Here the neuropathy produces distal wasting ('inverted champagne bottle' or 'stork' legs), often with pes cavus, and a predominantly motor clinical involvement. In 70–80% the cause is duplication of the *PMP-22* gene on chromosome 17 (autosomal dominant CMT type 1), but similar phenotypes are produced by mutations in other genes with differing modes of inheritance (Box 26.116).

Chronic inflammatory demyelinating peripheral neuropathy (CIDP) presents with a relapsing or progressive generalised neuropathy. Sensory, motor or autonomic nerves can be involved but the signs are predominantly motor; a variant causes only motor involvement (multifocal motor neuropathy, MMN). CIDP usually responds to immunosuppressive treatment, corticosteroids, methotrexate or cyclophosphamide, or to immunomodulatory treatments (plasma exchange or intravenous immunoglobulin, IVIg); MMN is best treated by IVIg.

Some 10% of patients with acquired demyelinating polyneuropathy have an abnormal serum paraprotein, sometimes associated with a lymphoproliferative malignancy.

Chronic axonal polyneuropathy

This is the most common type of chronic polyneuropathy. Where the cause can be found, it is usually a disorder affecting axonal metabolism and transport, either acquired (drugs and toxins) or genetically determined (see Box 26.109, p. 1226 and Box 26.116).

Brachial plexopathy

Trauma usually damages either the upper or the lower parts of the brachial plexus, according to the mechanics of the injury. The clinical features depend upon the anatomical site of the damage (Box 26.117). Lower parts of the brachial plexus are vulnerable to infiltration from breast or apical lung tumours (Pancoast tumour) and may be damaged by therapeutic irradiation. The lower parts of the plexus may also be compressed by anatomical anomalies at the thoracic outlet, which may be accompanied by circulatory changes in the arm due to subclavian artery compression.

An acute brachial plexopathy of probable inflammatory origin may present with 'neuralgic amyotrophy'. In

26.117 Physical signs in brachial plexus lesions			
Site	Root	Affected muscles	Sensory loss
Upper plexus (Erb–Duchenne)	C5/6	Biceps, deltoid, spinati, rhomboids, brachioradialis (triceps, serratus anterior)	Patch over deltoid
Lower plexus (Déjerine–Klumpke)	C8/T1	All small hand muscles, claw hand (ulnar wrist flexors)	Ulnar border hand/forearm
Thoracic outlet syndrome	C8/T1	Small hand muscles, ulnar forearm	Ulnar border hand/forearm/upper arm

26.116 Hereditary peripheral neuropathies				
Type	Inheritance	Molecular pathology	Neurophysiology	Comments
CMT1A	Autosomal dominant	PMP-22 reduplication Chr 17p	Slowed MCV	Common
CMT1B	Autosomal dominant	PO mutation Chr 1q	Marked slowing of MCV	Common
CMTX	X-linked	Connexin-32 mutation Chr Xq	Near-normal conduction velocities	Common, females less affected
CMT2	Autosomal dominant	Not known	Axonal—normal MCV	Rare
CMT3	Dominant (usually new mutation)	PMP-22 mutation or deletion	Severely slowed MCV	Déjerine–Sottas disease, rare
CMT4	Autosomal recessive	Not known	Axonal—normal MCV	Very rare
HNPP	Autosomal dominant	PMP-22 deletion or mutation	Dysmyelination—slowed MCV	Uncommon
HSAN	Autosomal dominant (type 1) and recessive (types 2–5)	Not known	Axonal—normal MVC	Uncommon—lancinating pains, neuropathic feet, recurrent foot ulceration
Refsum's disease	Autosomal recessive	Peroxisome targeting signal 2 mutation Chr 10p	Marked slowing	Very rare, associated retinitis pigmentosa, ataxia and raised blood phytanic acid
Hereditary amyloid neuropathy	Autosomal dominant	Transthyretin mutation (in types 1 and 2) Chr 18q Other mutations (types 3 and 4)	Axonal—normal MCV	Uncommon, associated autonomic neuropathy

(Chr = chromosome; CMT = Charcot–Marie–Tooth; HNPP = hereditary neuropathy with predisposition to pressure palsies; HSAN = hereditary sensory and autonomic neuropathy; MCV = motor conduction velocity; PMP = peripheral myelin protein)

this syndrome, a period of very severe shoulder pain precedes the appearance of a patchy upper brachial plexus lesion, often affecting the long thoracic nerve which produces winging of the scapula. Recovery occurs over months and is usually complete.

Lumbosacral plexopathy

Lumbosacral plexus lesions may be caused by neoplastic infiltration or compression by retroperitoneal haematomas in patients with a coagulopathy. A small vessel vasculopathy can produce a lumbar plexopathy, especially in elderly patients when it may be the presenting feature of type 2 diabetes mellitus ('diabetic amyotrophy') or a vasculitis. This presents with painful wasting of the quadriceps with weakness of knee extension and adduction, and an absent knee reflex.

Spinal root lesions

Spinal root lesions (radiculopathy) are commonly caused by compression at or near their spinal exit foramina by prolapsed intervertebral discs or degenerative spinal disease (p. 1222). Spinal roots may also be infiltrated by spinal and paraspinal tumour masses and inflammatory or infective processes. The clinical features include muscle weakness and wasting and dermatomal sensory loss with reflex changes that reflect the pattern of roots involved. Pain in the

muscles whose innervating motor roots are involved is usually a prominent feature.

DISEASES OF THE NEUROMUSCULAR JUNCTION

Myasthenia gravis

This condition is characterised by progressive fatigable weakness, particularly of the ocular, neck, facial and bulbar muscles.

Pathophysiology

The disease is most commonly caused by autoantibodies to acetylcholine receptors in the post-junctional membrane of the neuromuscular junction. These antibodies block neuromuscular transmission and initiate a complement-mediated inflammatory response which reduces the number of acetylcholine receptors and damages the end plate (Fig. 26.57). A minority of patients have other autoantibodies to epitopes on the post-junctional membrane, in particular autoantibodies to a muscle-specific kinase (MuSK), an agrin receptor which is involved in the regulation and maintenance of the acetylcholine receptors.

About 15% of patients (mainly those with late onset) have a thymoma, and the majority of the remainder have thymic follicular hyperplasia. There is an increased incidence of other autoimmune diseases, and the disease is

26

Fig. 26.57 Myasthenia gravis and Lambert-Eaton myasthenic syndrome (LEMS). In myasthenia there are antibodies to the acetylcholine receptors on the post-synaptic membrane which block conduction across the neuromuscular junction (NMJ). Myasthenic symptoms can be transiently improved by inhibition of acetylcholinesterase (e.g. with Tensilon—edrophonium bromide) which normally removes the acetylcholine. A cell-mediated immune response produces simplification of the post-synaptic membrane, further impairing the 'safety factor' of neuromuscular conduction. In LEMS, antibodies to the pre-synaptic voltage calcium channels impair release of acetylcholine from the motor nerve ending; calcium is required for the acetylcholine-containing vesicle to fuse with the pre-synaptic membrane for release into the NMJ.

linked with certain HLA haplotypes. Nothing is known about factors which trigger the disease itself, but penicillamine can cause an antibody-mediated myasthenic syndrome which may persist even after drug withdrawal. Some drugs, especially aminoglycosides and ciprofloxacin, may exacerbate the neuromuscular blockade and should be avoided in patients with myasthenia.

Clinical features

The disease usually presents between the ages of 15 and 50 years. Women are affected more often than men in the younger age groups while the reverse applies to older age groups. It tends to run a relapsing and remitting course, especially during the early years.

The cardinal symptom is fatigable weakness of the muscles (which is different from a sensation of muscle fatigue); movement is initially strong but rapidly weakens as muscle use continues. Worsening of symptoms towards the end of the day or following exercise is characteristic. There are no sensory signs or signs of involvement of the CNS, although weakness of the oculomotor muscles may mimic a central eye movement disorder.

The first symptoms are usually intermittent ptosis or diplopia, but weakness of chewing, swallowing, speaking or limb movement also occurs. Any limb muscle may be affected, most commonly those of the shoulder girdle; the patient is unable to undertake tasks above shoulder level such as combing the hair without frequent rests. Respiratory muscles may be involved, and respiratory failure is a not uncommon cause of death. Aspiration may occur if the cough is ineffectual. Sudden weakness from a cholinergic or myasthenic crisis (see below) may require ventilatory support. The prognosis is variable and sometimes remissions occur spontaneously. When myasthenia is confined to the eye muscles, the prognosis is excellent and disability slight. Young female patients with generalised disease have high remission rates after thymectomy, whilst older patients are less likely to have a remission despite treatment. Rapid progression of the disease more than 5 years after its onset is uncommon.

Investigations

The intravenous injection of the short-acting anticholinesterase, edrophonium bromide, is a valuable diagnostic aid (the Tensilon test); 2 mg is injected initially, with a further 8 mg given half a minute later if there are no undesirable side-effects. Improvement in muscle power occurs within 30 seconds and usually persists for 2–3 minutes. EMG with repetitive stimulation may show the characteristic decremental response (p. 1142). Anti-acetylcholine receptor antibody (AChRA) is found in over 80% of cases, though less frequently in purely ocular myasthenia (50%). Anti-MuSK antibodies are found especially in AChRA-negative patients with prominent bulbar involvement. Positive anti-skeletal muscle antibodies suggest the presence of thymoma, but all patients should have a thoracic CT to exclude this condition which may not be visible on plain X-ray examination. Screening for associated autoimmune disorders, particularly thyroid disease, is important.

Management

The principles of treatment are:

- to maximise the activity of acetylcholine at remaining receptors in the neuromuscular junctions

- to limit or abolish the immunological attack on motor end plates.

The duration of action of acetylcholine is greatly prolonged by inhibiting its hydrolysing enzyme, acetylcholinesterase. The most commonly used anticholinesterase drug is pyridostigmine, which is given orally in a dosage of 30–120 mg, usually 6-hourly. Muscarinic side-effects, including diarrhoea and colic, may be controlled by propantheline (15 mg as required). Over-dosage of anticholinesterase drugs may cause a cholinergic crisis due to depolarisation block of motor end plates, with muscle fasciculation, paralysis, pallor, sweating, excessive salivation and small pupils. This may be distinguished from severe weakness due to exacerbation of myasthenia (myasthenic crisis) by the clinical features and, if necessary, by the injection of a small dose of edrophonium.

The immunological treatment of myasthenia is outlined in Box 26.118. Thymectomy in the early stages of the disease improves overall prognosis.

Other myasthenic syndromes

There are other conditions which present with muscle weakness due to impaired transmission across the neuromuscular junction. The most common of these is the Lambert-Eaton myasthenic syndrome (LEMS), in which transmitter release is impaired, often in association with antibodies to presynaptic voltage-gated calcium channels (see Fig. 26.57). Patients may have autonomic dysfunction (and a dry mouth) in addition to muscle weakness, but the cardinal clinical sign is absence of tendon reflexes, which can return immediately after sustained contraction of the relevant muscle.

26.118 Immunological treatment of myasthenia

Thymectomy

- Should be considered in any antibody-positive patient under 45 years with symptoms not confined to extraocular muscles, unless the disease has been established for more than 7 years

Plasma exchange

- Removing antibody from the blood may produce marked improvement but, as this is usually brief, such therapy is normally reserved for myasthenic crisis or for pre-operative preparation

Intravenous immunoglobulin

- An alternative to plasma exchange in the short-term treatment of severe myasthenia

Corticosteroid treatment

- Improvement is commonly preceded by marked exacerbation of myasthenic symptoms and treatment should be initiated in hospital
- It is usually necessary to continue treatment for months or years, often resulting in adverse effects

Other immunosuppressant treatment

- Treatment with azathioprine 2.5 mg/kg daily is of value in reducing the dosage of steroids necessary and may allow steroids to be withdrawn (Box 26.119)
- The effect of treatment on clinical disease is often delayed for several months

EBM 26.119 Azathioprine in myasthenia gravis

'Azathioprine as an adjunct to alternate-day prednisolone in the treatment of antibody-positive generalised myasthenia reduces the maintenance dose of prednisolone and is associated with fewer treatment failures, longer remissions and fewer side-effects. However, a small trial suggested that it is probably not useful as an initial immunosuppressive treatment on its own.'

- Palace J, et al. *Neurology* 1998; 50:1778–1783.
- Bromberg MB, et al. *J Neurol Sci* 1997; 150:59–62.

The condition is associated with underlying malignancy in a high percentage of cases, and investigation must be directed towards detecting such a cause. The condition is diagnosed electrophysiologically by the presence of post-tetanic potentiation of motor response to nerve stimulation at a frequency of 20–50/s. Treatment is with 3,4-diaminopyridine.

DISEASES OF MUSCLE

Voluntary muscle is subject to a range of hereditary and acquired disorders of either its structure or the biochemical processes whereby the chemical energy derived from cell metabolism is converted into mechanical energy. These disorders present in a limited number of ways, most commonly a symmetrical weakness of the large,

power-generating proximal muscles (proximal myopathy). This weakness may be fixed or periodic. Other symptoms and signs of muscle disease include myotonia (failure of muscle relaxation) and muscle pain. Diagnosis depends upon consideration of the clinical picture along with the results of EMG studies and muscle biopsy. In some inherited muscular diseases, specific genetic abnormalities can be identified.

Muscular dystrophies

This is a group of inherited disorders characterised by progressive degeneration of groups of muscles, sometimes with involvement of the heart muscle or conducting tissue, and other parts of the nervous system (Box 26.120).

Clinical features

Onset is often in childhood, although some patients, especially those with myotonic dystrophy, may present as adults. Wasting and weakness are usually symmetrical, there is no fasciculation and no sensory loss, and tendon reflexes are preserved until a late stage, except in myotonic dystrophy where there is an associated neuropathy. Differential diagnosis is based on the age at onset, the distribution of affected muscles and the pattern of inheritance. Myotonic dystrophy may be diagnosed clinically by the distribution of muscle weakness and other features, including myotonia (see Box 26.120). Many dystrophies include cardiomyopathy (p. 635) amongst their clinical features. Patients with Duchenne

**26.120 The muscular dystrophies**

Type	Genetics	Age of onset	Muscles affected	Other features
Myotonic dystrophy (DM1)	Autosomal dominant; expanded triplet repeat chromosome 19q	Any	Face (incl. ptosis), sternomastoids, distal limb, generalised later	Myotonia, cognitive dulling, cardiac conduction abnormalities, lens opacities, frontal balding, hypogonadism
Proximal myotonic myopathy (PROMM; DM2)	Autosomal dominant; quadruplet repeat expansion in <i>Zn finger protein 9</i> gene chromosome 3q	Adult	Proximal, especially thigh, sometimes muscle hypertrophy	As for DM1 but cognition not affected Muscle pain
Duchenne	X-linked; deletions in <i>dystrophin</i> gene	First 5 years	Proximal and limb girdle	Pseudohypertrophy of calves Cardiomyopathy
Becker	X-linked; deletions in <i>dystrophin</i> gene	Late childhood/early adult	Proximal and limb girdle	Pseudohypertrophy of calves Cardiomyopathy
Limb girdle	Autosomal dominant (type 1) Autosomal recessive (type 2) Many mutations on different chromosomes	Childhood/early adult	Limb girdle	Some have calf hypertrophy Some have cardiac conduction abnormalities
Facioscapulohumeral (FSH)	Autosomal dominant; tandem repeat deletion chromosome 4q	7–30 years	Face and upper limb girdle Distal lower limb weakness	Pain in shoulder girdle common
Oculopharyngeal	Autosomal dominant and recessive; triplet repeat expansion in <i>PABP2</i> gene chromosome 14q	30–50 years	Ptosis, external ophthalmoplegia, dysphagia, tongue weakness	Mild lower limb weakness
Emery–Dreifuss	X-linked recessive; mutations in <i>emerin</i> gene	4–5 years	Humero-peroneal, proximal limb girdle later	Contractures develop early Cardiac involvement leads to sudden death

dystrophy used to die within 10 years of diagnosis, but with improved general care they are now living into the third decade. The lifespan in limb girdle and facioscapulo-humeral dystrophies is normal. In myotonic dystrophy, there is considerable phenotypic variation and the prognosis is very variable, limited by cardiac and respiratory complications.

Investigations

The diagnosis can be confirmed by specific molecular genetic testing, supplemented with EMG and muscle biopsy if necessary. Creatine kinase is markedly elevated in Duchenne muscular dystrophy, but is normal or only moderately elevated in the other dystrophies. Screening for an associated cardiac abnormality (cardiomyopathy or dysrhythmia) is important.

Management

There is no specific therapy for these conditions, but physiotherapy and occupational therapy help patients cope with their disability. Treatment of associated cardiac failure or arrhythmia (with pacemaker insertion if necessary) may be required; similarly, management of respiratory complications (including nocturnal hypoventilation) can improve quality of life. Genetic counselling is important.

Congenital myopathy

This is rare and presents in infancy with muscular weakness and limpness. Serum muscle enzymes may be normal or slightly elevated and the EMG is usually myopathic. The syndrome may be caused by a number of specific conditions that have a variable inheritance and are defined by the type of structural abnormality present in skeletal muscle fibres. Most patients have a slowly progressive disease and there is no specific therapy.

Inherited metabolic myopathies

A large number of individually rare inherited disorders of the biochemical pathways necessary to maintain the supply of chemical energy (ATP) in muscles may present with muscle pain, weakness and fatigue. These are mostly recessively inherited deficiencies in the enzymes of the glycolytic and fatty acid metabolism pathways (Box 26.121).

Inherited disorders of the oxidative pathways of the respiratory chain in mitochondria cause a group of mitochondrial myopathies which may be associated with a range of other deficits in the nervous system, including episodic stroke-like events and myoclonic epilepsy (Box 26.122). Many of these mitochondrial myopathies (or cytopathies) are inherited via the mitochondrial

26.121 Inherited disorders of muscle metabolism

	Enzyme deficiency	Clinical features	Diagnosis
Carbohydrate metabolism	Myophosphorylase (McArdle's disease)	Exercise-induced muscle cramps, myoglobinuria	CK elevated Muscle biopsy appearance Molecular genetics
	Phosphofructokinase		
	Alpha-1,4-glucosidase (acid maltase)	Proximal limb and diaphragm weakness	CK elevated Myopathic EMG Lymphocyte glycogen storage Muscle biopsy appearance Molecular genetics
Lipid metabolism	Carnitine-palmitoyl transferase (CPT) deficiency	Muscle pain on prolonged exercise, myoglobinuria	CK elevated during attacks of muscle pain, normal in between Muscle biopsy appearance

26.122 Mitochondrial myopathy syndromes

Syndrome	Clinical features
Myoclonic epilepsy with ragged red fibres (MERRF)	Myoclonic epilepsy, cerebellar ataxia, dementia, sensorineural deafness ± peripheral neuropathy and optic atrophy
Mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes (MELAS)	Episodic encephalopathy, stroke-like episodes often preceded by migraine-like headache, nausea and vomiting
Chronic progressive external ophthalmoplegia (CPEO)	Progressive ptosis and external oculomotor palsy, proximal myopathy ± deafness, ataxia and cardiac conduction defects
Kearns-Sayre syndrome	Like CPEO but early age of onset (< 20 yrs), heart block, pigmentary retinopathy
Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE)	Progressive ptosis, external oculomotor palsy, gastrointestinal dysmotility (often pseudo-obstruction), diffuse leukoencephalopathy, thin body habitus, peripheral neuropathy and myopathy

26.123 Muscle channelopathies

Channel	Muscle disease	Clinical features
Sodium	Paramyotonia congenita	Cold-evoked myotonia with episodic weakness provoked by exercise and cold
	Hyperkalaemic periodic paralysis	Brief, frequent episodes of weakness triggered by potassium ingestion
	Hypokalaemic periodic paralysis	Episodic weakness triggered by carbohydrate meal
Chloride	Myotonia congenita (Thomsen's disease)	Generalised myotonia with muscle hypertrophy
Calcium	Hypokalaemic periodic paralysis	Episodic weakness triggered by carbohydrate meal
	Malignant hyperthermia	Hyperpyrexia due to excess muscle activity, precipitated by drugs, usually anaesthetic agents

genome, down the maternal line (p. 50). There is often a characteristic 'ragged-red fibre' change on muscle biopsy.

Channelopathies

Inherited abnormalities of the sodium, calcium and chloride ion channels in striated muscle produce various syndromes of familial periodic paralysis, myotonia and malignant hyperthermia which can be recognised by their clinical characteristics, provocation by exercise or eating, and associated changes in serum potassium concentration (Box 26.123).

Acquired myopathies

Muscle weakness may be caused by a range of metabolic, endocrine, toxic or inflammatory disorders (Box 26.124). Disorders affecting the muscles' structural integrity can be distinguished by EMG from those caused by metabolic derangement. In metabolic disorders, weakness is often acute and generalised, while a proximal myopathy predominantly affecting the pelvic girdle is a feature of some endocrine disorders. This may develop without other manifestations of hormonal disturbance. A wide variety of drugs and toxins may cause myopathy and these are also listed in Box 26.124. Inflammatory myopathy (polymyositis) is described on page 1111.

Terms used to describe skin lesions

Primary lesions

- **Abscess:** a localised collection of pus in a cavity, > 1 cm in diameter
- **Burrow:** a linear or curvilinear papule, caused by a burrowing scabies mite (panel A and Fig. 27.32, p. 1274)
- **Comedone:** a plug of keratin and sebum wedged in a dilated pilosebaceous orifice (panel B)
- **Macule:** a circumscribed flat area of altered colour, e.g. freckle (panel C)
- **Papilloma:** a projecting nipple-like mass, e.g. skin tag (panel D)
- **Papule:** a discrete elevation of skin that may be changed in colour (panel E). Those arising from the subcutis may be felt rather than seen. Larger lesions (> 1 cm) are referred to as nodules
- **Petechiae, purpura and ecchymosis:** petechiae are pinhead-sized flat macules of extravascular blood in the dermis. Purpura are larger and may be palpable. Ecchymosis ('bruise') is where bleeding involves deeper structures (see panel F)
- **Plaque:** a raised area of skin with a flat top, several cm in diameter, e.g. psoriasis (panel G)
- **Pustule:** a visible accumulation of pus in a blister (panel H)
- **Scale:** a flake arising from the stratum corneum, e.g. psoriasis (panel I)
- **Telangiectasia:** visible dilatation of small cutaneous blood vessels (panel J)
- **Vesicle and bulla:** a small (~ several mm) and a larger (~ several cm) fluid-filled blister respectively, e.g. pemphigoid (panel K)
- **Weal:** an evanescent discrete area of dermal oedema, usually white due to masking of local blood supply by fluid, e.g. a nettle sting (panel L)

Secondary lesions

- **Atrophy:** an area of thin, translucent skin due to loss of epidermis, dermis or subcutaneous fat, e.g. excess topical corticosteroids
- **Crust:** dried exudate of blood or serous fluid, e.g. eczema (see Fig. 27.23, p. 1269)
- **Excoriation:** a linear ulcer or erosion resulting from scratching (see Fig. 27.11, p. 1258)
- **Erosion:** an area of skin denuded by complete or partial loss of the epidermis
- **Fissure:** a slit-shaped deep ulcer, e.g. irritant dermatitis of the hands
- **Scar:** replacement of normal structures by fibrous tissue at the site of an injury
- **Sinus:** a cavity or channel that permits the escape of pus or fluid
- **Stria:** a linear, atrophic, pink, purple or white band due to connective tissue changes, e.g. Cushing's syndrome (see Fig. 20.21, p. 771)
- **Ulcer:** an area from which the epidermis and at least the upper part of the dermis have been lost (see Fig. 27.9, p. 1252)

A. Burrow.

B. Comedone.

C. Macule.

D. Papilloma.

E. Papule.

F. Petechiae and purpura.

G. Plaque.

H. Pustule.

I. Scale.

J. Telangiectasia.

K. Vesicle.

L. Weal.

Skin disease is common. European surveys suggest that approximately 1 in 7–10 consultations in primary care are for a skin problem. Skin disease appears to be becoming more common for three reasons:

- a lowered threshold for seeking medical attention
- an increase in the absolute incidence of diseases such as skin cancer and atopic dermatitis
- the availability of new and effective treatments for several skin diseases that were formerly untreatable.

Healthy and attractive skin plays a major role in most individuals' self-esteem, and is a key component of the image they present to the outside world. The appearance, texture and tactile qualities of skin play a significant role in most grooming and sexual behaviours. Patients with skin disease are often stigmatised, sometimes due to the spurious belief that their appearance is the result of a contagious disease. Population prevalence studies reveal an enormous burden of undiagnosed, untreated skin disease.

Skin complaints affect all ages, from the neonate to the elderly, and the general dermatologist sees an even distribution of patients of all ages (Fig. 27.1). This chapter concentrates on the skin conditions that are seen frequently in general practice and general medicine. Skin infections, including those related to the human immunodeficiency virus (HIV), are discussed in Chapters 13 and 14, and connective tissue diseases involving the skin in Chapter 25.

Fig. 27.1 The age distribution of some common skin conditions.

Frequencies of the various rashes are not drawn to scale and are illustrative only.

FUNCTIONAL ANATOMY AND PHYSIOLOGY

The skin of an average adult covers an area of just under 2 m². The epidermis, a stratified squamous epithelium, is the outermost layer and is predominantly composed of keratinocytes. The epidermis is attached to but separated from the underlying dermis by the basement membrane. The dermis supports blood vessels and nerves, and the epidermal-derived structures such as

the appendageal structures (hair follicles, and eccrine and apocrine sweat glands). The predominant cell of the dermis is the fibroblast. Below the dermis is a layer of adipose tissue (the subcutis).

Epidermis

Keratinocytes make up approximately 90% of epidermal cells (Fig. 27.2). The proliferative compartment of the epidermis resides in the basal layer and in the layer immediately adjacent to it. The site of the keratinocyte stem cell is not known, but in hair-bearing skin is likely to be in a specialised region of the hair follicle, close to the insertion of the sebaceous gland.

Keratinocytes synthesise a range of structural proteins, such as keratins, loricrin and filaggrin (**filament aggregating protein**), that play key roles in maintaining normal cutaneous physiology. There are well over 30 different types of keratin and their expression varies by site on the body, by site within the epidermis, and depending on whether the skin is healthy or diseased. Mutations of certain keratin genes result in blistering disorders such as epidermolysis bullosa simplex (p. 1249) and ichthyotic conditions (characterised by scale without dominant inflammation). As keratinocytes move out of the basal layer they differentiate, producing a variety of protein and lipid products. Keratinocytes undergo apoptosis in the granular layer before becoming the flattened anucleate cells that make up the stratum corneum. The epidermis is a site of lipid production, and the ability of the stratum corneum to act as a hydrophobic barrier is the result of its 'bricks and mortar' design; dead corneocytes with a highly cross-linked protein membrane ('bricks') lie within a metabolically active layer of lipid synthesised by the keratinocytes ('mortar'). Terminal differentiation of keratinocytes relies on the keratin filaments being aggregated. This function is in part mediated by filaggrin. It has recently been shown that mutations of the filaggrin gene are common in patients with atopic dermatitis (p. 1257) or ichthyosis vulgaris.

Skin must have considerable physical resilience. Attachments between cells must be able to transmit and dissipate stress, a function performed by desmosomes. Diseases that affect desmosomes, such as pemphigus (p. 1276), result in blistering as the individual keratinocytes separate.

Three other cell types make up most of the remaining 10% of epidermal cells:

- *Langerhans cells* are dendritic, bone marrow-derived cells that circulate between the epidermis and the local lymph nodes. Their prime function is the effective presentation of foreign antigens to lymphocytes. They may also play a part in presentation of tumour antigens. Other antigen-presenting dendritic cells are also present, but in the dermis rather than the epidermis.
- *Melanocytes* are of neural crest origin and are found predominantly in the basal layer. They synthesise the pigment melanin from tyrosine, package it in melanosomes and transfer it to surrounding keratinocytes via their dendritic processes.
- *Merkel cells* are found in the basal layer and are thought to play a role in signal transduction of fine touch. Their embryological derivation is unclear.

Fig. 27.2 Structure of normal skin.

Basement membrane

The basement membrane (see Fig. 27.2) acts as an anchor for the epidermis but allows movement of cells and nutrients between the dermis and epidermis. It consists of several well-defined layers. The cell membrane of the epidermal basal cell is attached to the basement membrane via hemidesmosomes. The lamina lucida is the zone immediately subjacent to the cell membrane of the basal cell, and is composed predominantly of laminin. Anchoring filaments extend through the lamina lucida to attach to the lamina densa. This electron-dense layer con-

sists predominantly of type IV collagen; from it extend loops of type VII collagen, forming anchoring fibrils that fasten the basement membrane to the dermis.

Dermis

The dermis is vascular and supports the epidermis structurally and nutritionally. It varies in thickness from just over 1mm on the inner forearm to 4mm on the back. The epidermis on most sites is only 0.1–0.2mm thick, except on the palms or soles where it can be several millimetres in thickness. The acellular part of the dermis consists

predominantly of fibres, including collagens I and III, elastin and reticulin, synthesised by the major cell type, fibroblasts. Support is provided by an amorphous ground substance (mostly glycosaminoglycans, hyaluronic acid and dermatan sulphate), whose production and catabolism may be influenced by hormonal changes and damage from ultraviolet (UV) radiation. Apart from fibroblasts, other cell types within the dermis include mast cells, mononuclear phagocytes, T lymphocytes, dendritic cells, nerves and vessels. Based on the pattern of collagen fibrils, the superficial part of the dermis is known as the 'papillary dermis', and the deeper and coarser part as the 'reticular dermis'.

Epidermal appendages: hair and sweat glands

Hair follicles, sweat (eccrine) and apocrine glands are epidermal structures which invaginate into the dermis. They are formed during the second trimester and number 3–5 million.

Hair follicles are found throughout the skin, with the exception of palms, soles and portions of the genitalia (glabrous skin). The highest density of hair follicles is on the scalp, which has between 500 and 1000/cm². Newborns are covered with fine 'lanugo' hairs, which are usually non-pigmented and do not have a central medulla (a central cavity). Subsequently, lanugo hair is replaced by vellus hair, which is similar but more likely to contain some pigment. By contrast, scalp hair becomes terminal hair, which is thicker with a central medulla, is usually pigmented and grows longer. At puberty, vellus hair in hormonally sensitive regions such as the axilla and the genital area becomes terminal.

Hairs in humans do not grow continuously but in a cycle with three phases:

- anagen, in which the hair grows
- catagen, a transitional phase
- telogen, a resting stage.

The individual duration of the components of the cell cycle varies by site. On the scalp, anagen will last several years, whereas catagen lasts only a few days and telogen around 3 months. The length of hair at different sites is partly a reflection of the differing lengths of anagen.

Sebaceous glands

Sebaceous glands are epidermal downgrowths, usually associated with hair follicles and comprised of modified keratinocytes. The individual cells of the sebaceous gland (sebocytes) produce a range of lipids before the cell dies, discharging its contents into the duct around the hair follicle. Sebum excretion is under hormonal control, with androgens increasing it (as do progesterones to a lesser degree) and oestrogens tending to diminish it. Sebum plays little physiological role in humans, but it is important in animals for waterproofing of hair.

Eccrine sweat glands

Eccrine sweat glands are found all over the body and their coiled ducts open directly on to the skin surface. They play a major role in thermoregulation and, unusually, are innervated by cholinergic fibres of the sympathetic rather than parasympathetic nervous system. Eccrine glands of the palms and soles are innervated differently and are activated in the 'fight or flight' response, as a small amount of sweat increases frictional forces of the palms.

Blood vessels and nerves

The abundant blood supply of the skin is arranged in superficial and deep plexuses, and is made up of arterioles, arterial and venous capillaries, and venules. The upper plexus is in the papillary dermis and communicates with the lower plexus at the junction between the dermis and the subcutis. Capillary loops arise from terminal arterioles in the horizontal papillary plexus. Blood vessels are supplied by sympathetic and parasympathetic nerves, with the relative contributions of the pathways differing by site. Sympathetic signals are important in mediating autonomic induced vasoconstriction. The blood supply of skin is far greater than that required for normal skin physiology and reflects the important role that skin plays in thermoregulation. Skin is richly innervated by nerves serving a number of different modalities, which penetrate into both the dermis and the epidermis.

Functions of the skin

These are shown in Box 27.1. Skin changes associated with ageing are shown in Box 27.2.

27.1 Functions of the skin	
Function	Structure/cell involved
Protection against:	
Chemicals, particles, desiccation	Stratum corneum
Ultraviolet radiation	Melanin produced by melanocytes and transferred to keratinocytes
Antigens, haptens	Langerhans cells, lymphocytes, mononuclear phagocytes, mast cells
Microbes	Stratum corneum, Langerhans cells, mononuclear phagocytes, mast cells
Maintenance of fluid balance	
Prevents loss of water, electrolytes and macromolecules	Stratum corneum
Shock absorber	
Strong, elastic and compliant covering	Dermis and subcutaneous fat
Sensation	Specialist nerve endings mediating pain leading to withdrawal, and itch leading to scratch and e.g. removal of a parasite
Vitamin D synthesis	Keratinocytes
Temperature regulation	Eccrine sweat glands and blood vessels
Protection, and fine manipulation of small objects	Nails
Hormonal	
Testosterone synthesis and testosterone conversion to other androgenic steroids	Hair follicles, sebaceous glands
Pheromonal (of unknown importance in humans)	Apocrine sweat glands
Psychosocial, grooming and sexual behaviour	Hair, nails, appearance and tactile quality of skin

27.2 Skin changes in old age

- **Photoageing:** most changes are a result of cumulative ultraviolet exposure rather than intrinsic ageing.
- **Typical changes:** include atrophy, laxity, wrinkling, dryness, irregular pigmentation and sparse grey hair.
- **Causes:**
 - Age-related alterations in structure and function of the skin
 - Cumulative effects of environmental insults, especially UV radiation
 - Cutaneous consequences of disease in other organ systems.
- **Immunity:** alterations in immune surveillance and antigen presentation, and reduced cutaneous vascular supply lead to decreases in the inflammatory response, absorption and cutaneous clearance of topical medications.
- **Consequences:** the skin is less durable, slower to heal, and more susceptible to damage and disease.

INVESTIGATIONS AND SPECIALISED EXAMINATION

Diagnosis in dermatology relies almost entirely on clinical skills (pp. 1238–1239), and the role of investigations is limited. The relative contribution of history versus physical signs varies between particular skin disorders, but physical signs are usually the key factor in achieving the correct diagnosis. A number of visual aids are mandatory for proper clinical assessment, the simplest being a magnifying lens.

Dermatoscopy

Also known as dermoscopy or epiluminescence microscopy, this can be performed with a magnifying lens and oil applied to the skin, which reduces specular reflection and allows the observer to 'see through' the epidermis better. This is important in the assessment of pigmented lesions such as melanoma and naevi. Similar effects can be achieved by the use of illumination with polarised light and a lens, allowing non-touch imaging of the skin.

Diascopy

Distinguishing between blood and melanin, the main two pigments (or chromophores) in the skin, can be difficult. Pressing on the lesion with the corner of a glass slide will remove blood from vascular lesions, causing them to blanch. However, failure to remove blood does not reliably exclude a vascular lesion, as the vascular anatomy may sometimes be particularly convoluted. Pressing with a glass slide on some granulomatous lesions (such as cutaneous tuberculosis) gives an appearance known as 'apple jelly' nodules.

Wood's light

Exposure of skin to long wavelength ultraviolet radiation (UVA) with a Wood's light causes collagen in the dermis to fluoresce. In patients with hypopigmentation, Wood's light accentuates the difference in colour between the pigmented and non-pigmented areas because the pigment in the epidermis blocks the UVA photons before they can elicit fluorescence in the dermis. This can be

27.3 Responses to Wood's light

Hypopigmentation accentuated

- Vitiligo
- Albinism
- Tuberous sclerosis

Hypopigmentation less obvious

- Post-inflammatory hypopigmentation
- Pityriasis versicolor
- Leprosy

helpful in mapping out the areas of depigmentation (Box 27.3). Under Wood's light, green fluorescence is seen in scalp ringworm due to *Microsporum canis* (p. 1273), a sporadic ectothrix infection, and pink fluorescence of flexural skin is seen in erythrasma (p. 1269).

Incisional biopsy and histopathology

Histopathological examination of skin biopsies is key, particularly for tumour diagnosis. The purpose of an incisional biopsy is to obtain a sample of tissue for histopathological examination rather than definitive treatment of a lesion, for which excisional biopsy is required. Skin biopsies are usually taken under local anaesthetic. It is best to select an early or typical lesion on a non-exposed site that is not affected by secondary excoriation. An ellipse biopsy, or in certain instances a punch biopsy that removes a cylindrical portion of skin, may be used. Knowing which part of a rash to biopsy, and whether an ellipse or punch biopsy will suffice, is critical to achieving a clear histological diagnosis.

Immunofluorescence

A portion of the biopsy can be frozen in liquid nitrogen for direct immunofluorescence (IF). This allows visualisation of antigens that are present in the skin using specific fluorescein-labelled antibodies. Similarly, indirect immunofluorescence can identify circulating antibodies in the serum by adding the serum to a section of normal skin or other substrate. Immunofluorescence plays a major role in the diagnosis of the autoimmune bullous disorders (p. 1275).

Microbiology

Mycology

Cutaneous scale, nail clippings and plucked hairs can be examined by light microscopy when mounted in 20% potassium hydroxide. The keratin is dissolved, allowing fungal hyphae to be identified. If the potassium hydroxide solution contains Indian ink, the typical 'spaghetti and meatballs' hyphae and spores of the yeast *Pityrosporum orbiculare* can be readily identified in pityriasis versicolor. Samples can also be sent for culture but there is a significant false negative rate for dermatophytes in some laboratories.

Bacteriology

Bacterial swabs may identify a causative infective agent. However, organisms identified from the surface of the skin may not be implicated in the underlying disease, but reflect colonisation of skin damaged by a primary

disease. Conversely, in diseases such as cellulitis, swabs often do not reveal the causative agent. If pustules are present, one should be punctured with a fine sterile needle and the pus exuded gently on to a swab.

Virology

A number of techniques, including immunofluorescence and polymerase chain reaction (PCR), are available to diagnose herpes simplex or herpes zoster viruses (p. 136).

Prick tests

Prick tests are a way of detecting cutaneous type I (immediate) hypersensitivity to various antigens such as pollen, house dust mite or dander. The skin is pricked with commercially available stylets through a dilution of the appropriate antigen solution. Alternatively, specific IgE levels to antigens can be measured in serum. These tests are described in detail on page 88.

Patch tests

Patch tests detect type IV (delayed or cell-mediated) hypersensitivity. A 'battery' of around 20 common antigens, including common sensitizers such as nickel, rubber and fragrance mix, are applied to the skin of the back under aluminium discs for 48 hours. The sites are examined for a positive reaction 48 hours later. An eczematous reaction in the absence of an irritant reaction suggests a type IV hypersensitivity to that particular allergen. The relevant antigens for a particular clinical case may not be in the standard battery of tests so expert advice may be needed. A negative patch test does not exclude a pathogenic role for a particular antigen, nor does a response to an antigen mean that it is necessarily causing the clinical disease.

Phototesting

Diagnostic phototesting is an essential component of the investigation of presumed photosensitive drug reactions and idiopathic photodermatoses such as solar urticaria. It involves exposing skin (often on the back) to a graded series of doses of ultraviolet radiation (UVR) of known wavelength, either on one occasion or repeatedly. In many photodermatoses, erythema will occur at a lower dose of UVR than in the normal population (e.g. drug-induced photosensitivity), or the time course of erythema may be prolonged (as in xeroderma pigmentosum). Alternatively, UVR will provoke lesions with the morphology of the underlying photodermatosis, such as may occur in lupus erythematosus or solar urticaria.

PRESENTING PROBLEMS IN SKIN DISEASE

The major presentations in dermatology are outlined below. Important points of clinical assessment are discussed, but detail about the underlying disorders is given in the disease sections later in the chapter.

New or changing skin lesion

Many patients present with a solitary skin lesion, which may or may not represent a skin cancer. The diagnostic challenge is to distinguish between benign tumours

or hamartomas (e.g. angiomas, melanocytic naevi, seborrhoeic keratoses) and any of the major types of skin cancer such as melanoma, basal cell carcinoma and squamous cell carcinoma (pp. 1277–1281). It is not always possible to distinguish melanocytic lesions clinically from other highly pigmented lesions which are primarily keratinocytic (e.g. seborrhoeic keratosis, p. 1281). A particular concern is when a patient notices new changes in a lesion that has been present for some time, particularly in the case of a melanocytic naevus (mole).

Melanocytic naevus versus malignant melanoma

The following approach helps differentiate these:

- Determine the precise nature of the change. Is it the development of itch, inflammation, bleeding or ulceration, or does it relate to the colour, size, shape or surface of the lesion?
- Subtle changes should not be ignored, as many patients are good observers and 'know' their own moles well. If the change has settled, could it have been due to an insult such as nicking a facial naevus when shaving, plucking hairs from a naevus or the irritant effect of a depilatory?
- Is the patient worried about change in one or many moles? Concern relating to many moles is paradoxically reassuring, as presentation with multiple melanoma is extremely unusual; the patient may thus be needlessly anxious, or have constitutionally unusual but benign naevi.
- Does the patient have other pigmented lesions? The morphology of the other melanocytic naevi may provide useful diagnostic information about the patient's 'constitutional' mole type. Seborrhoeic warts are usually multiple. If a naevus, especially a changing one, appears significantly different in colour, shape or size from others (the 'ugly duckling' sign), it should be treated with suspicion.
- Is there a positive family history of melanoma? Fewer than 10% of melanomas occur in individuals with a strong family history, but in some families, up to 50% of individuals develop melanoma. A suspicious mole on a patient with a first-degree relative with melanoma probably warrants excision.

The ABCDE 'rule' is a guide to the characteristic features of melanoma (Box 27.4 and Fig. 27.3). Loss of normal skin markings is suggestive but not diagnostic of melanoma. Conversely, normal skin markings and fine hairs dispersed evenly over a lesion are reassuring, but do not exclude melanoma.

27.4 ABCDE features of malignant melanoma

- Asymmetry
 - Border irregular
 - Colour irregular
 - Diameter often > 0.5 cm
 - Elevation irregular
- (+ Loss of skin markings)

Fig. 27.3 Malignant melanoma. A changing mole which fails the ABCDE test.

Management

Any changing lesion which is suspected of being a malignant melanoma should be excised with a clear margin, without delay. Depending on the Breslow thickness of the tumour (p. 1281), further excision may be required. Some argue that, if the diagnosis is uncertain and the degree of suspicion low, the patient should be reviewed or the lesion photographed, and then re-assessed in a couple of months and rephotographed. Not all agree, given that melanomas may show only slow or intermittent progression in their early course.

Other new or changing skin lesions

These may be benign (p. 1281), pre-malignant (p. 1279) or malignant (p. 1277) and need careful assessment:

- *History.* Is the lesion of recent onset or has it been present for years? Is it growing fast or slowly? Is there any itch, pain, or bleeding and ulceration?
- *The individual.* What age is the patient (see Fig. 27.1)? Are they fair-skinned? Have they had a lot of sun exposure? Have they always been careful about photoprotection?
- *The site.* Is it in a sun-exposed or covered area? Common areas for sun-induced lesions are the scalp, face, arms and back in men, and the face, hands and lower legs in women.
- *Are there other similar lesions?* If there are many, e.g. actinic keratoses (see Fig. 27.39, p. 1279) on a balding scalp, or seborrhoeic keratoses (see Fig. 27.43, p. 1281) over a person's back, then the lesions are more likely to be benign.
- *Morphology of the lesion.* Assessment with a lens helps identify specific characteristics, e.g. the pearly thread-like border of a superficial basal cell carcinoma (p. 1277) or the poorly defined erythema and scaling of an actinic keratosis.
- *Dermatoscopy.* This is useful in lesions that are not melanocytic, and enhances typical morphological features such as keratin cysts in a seborrhoeic keratosis, or the telangiectasia of a basal cell carcinoma.

In cases of diagnostic doubt, incisional or excisional skin biopsy should be performed, the latter as definitive treatment for malignant lesions.

Itch (pruritus)

Pruritus is defined as an unpleasant sensation that provokes the desire to scratch. Despite being a major symptom of skin disease, it remains poorly understood. Itch can arise from primary cutaneous disease or from systemic disease, which may cause itch via central or peripheral mechanisms. Even when the mechanism is thought to be peripheral, there may be few or no signs of primary skin disease; in a rare condition called aquagenic pruritus, water on the skin induces itch, but there are no other features.

The nerve endings that signal itch lie either within the epidermis or very close to the dermo-epidermal junction. Sensory information is transmitted via C fibres, which have slow conduction speeds, via the spinothalamic tract to the thalamus and on to a cortical representation. There seems to be an antagonistic or inhibitory relationship between pain and itch. Scratching may either cause inhibition of the itch receptors by stimulating ascending sensory pathways which inhibit itch at the spinal cord (Wall's 'gate' mechanism), or interfere with itch fibres lying superficially in skin which may be damaged directly by scratching. In the presence of a focal lesion causing itch, touch on the surrounding areas may be conducted along non-itch fibres but be centrally reinterpreted as itch (a phenomenon known as 'alloknesis', analogous to allodynia in pain).

The mechanism of itch in most systemic diseases is unknown, but in liver disease there is evidence that abnormal circulating opioids stimulate itch centrally.

Clinical assessment

Assessment of the itchy patient is difficult. Helpful pointers from the history include:

- *Time course.* This may be sudden, as in infestations and urticaria, or chronic, as in eczema.
- *Localisation,* including the site of onset. Is the itch confined to certain sites, as in localised skin disease such as lichen planus and lichen simplex, or generalised, as in eczema and scabies? The itch in diabetes is often in the genital region.
- *Exacerbating factors.* Most causes of itch are increased by heat and reduced by cooling. In cholinergic urticaria, exercise or heat dramatically induces itching (and weals on the skin surface); in aquagenic pruritus and aquagenic urticaria, water induces itch and weals respectively. In cold urticaria, cold stimuli such as ice or very cold air may induce weals and itch directly.
- *Involvement of other family members or close contacts,* as in a scabietic infestation. Insect bites usually affect only one member of the family.
- *General health* of the patient. A range of general medical conditions can precipitate itch, the symptoms of which should be sought.

It is important to determine whether there is a primary skin condition or whether the only visible clinical features are secondary to excoriation, but this may be

27.5 Primary skin diseases causing pruritus

Generalised pruritus

- Eczema
- Scabies
- Urticaria/dermographism
- Pruritus of old age and xeroderma

Localised pruritus

- Eczema
- Lichen planus
- Dermatitis herpetiformis
- Pediculosis

difficult. Try to classify the patient into one of the following groups:

- *Pruritus associated with skin disease* (Box 27.5). Atopic eczema and scabies infestation can be difficult to distinguish clinically, particularly in children. Secondary eczematization occurs in scabies, giving rise to an eczematous rash all over the body. Scabietic burrows should be carefully sought, particularly in the finger and toe webs, along the borders of both the hands and the feet and at the wrists, and the mite should be extracted with a needle and examined under a microscope to make a definitive diagnosis. The genitalia and the nipples are particular sites for burrows. Even after successful treatment for scabietic infestation (p. 1274), the itch persists for several weeks or more.
- *Pruritus in pregnancy* (Box 27.6). A number of different conditions cause pruritus in pregnancy, some of which are important to fetal health.

27.6 Causes of pruritus in pregnancy

Condition	Gestation and features	Treatment
Polymorphic eruption (urticarial papules) of pregnancy	3rd trimester, after delivery Polymorphic lesions with urticaria	Chlorphenamine, emollients and topical steroids
Obstetric cholestasis	3rd trimester Associated with abnormal liver function tests and increased risk to the fetus	Emollients Chlorphenamine Colestyramine Early delivery
Pemphigoid gestationis	3rd trimester Pruritus followed by blistering starting around the umbilicus Diagnosed by histology and immunofluorescence	Topical or oral corticosteroids
Prurigo gestationis	2nd trimester Excoriated papules	Emollients Topical corticosteroids Chlorphenamine
Pruritic folliculitis	3rd trimester Aseptic pustules on trunk	Topical corticosteroids

Collaboration between a dermatologist and the obstetrician is important.

- *Pruritus associated with systemic disease* (Box 27.7). Itch is a common symptom in primary biliary sclerosis and may precede other symptoms. Classically, the itch of polycythaemia rubra vera begins soon after stepping out of the bath and lasts for 30–60 minutes. No visible skin signs are present. This can also occur in aquagenic pruritus, in which case follow-up for the development of myeloproliferative disorder is necessary. Although patients with other itchy conditions report worsening with heat or after a bath, the clinical picture is rarely as clear-cut as that seen in aquagenic pruritus or polycythaemia rubra vera. Itch is rarely associated with malignancy. The mechanisms involved are unclear but may be central, or localised secondary to tumour irritation of nerve roots. Lymphoma, particularly Hodgkin's, is important to consider, as the itch may precede other signs of the disease.

27.7 Medical conditions associated with pruritus

Medical condition	Cause of pruritus	Treatment*
Liver disease	Central opioid effect Elevation in bile salts may contribute	Naltrexone Colestyramine Rifampicin Sedative antihistamines UVB
Renal failure	Unknown; unlikely to involve histamine	Oral activated charcoal
Blood disease		
Anaemia	Iron deficiency	Iron replacement
Polycythaemia rubra vera	Unknown	
Lymphoma	Unknown	
Leukaemia		
Myeloma		
Endocrine disease		
Diabetes mellitus	May be associated with genital candidiasis	Clotrimazole
Thyrotoxicosis	Generalised due to dry skin	Emollients
Hypothyroidism	Localised; may be due to <i>Candida</i>	
Carcinoid syndrome (p. 782)	5HT-mediated	
HIV infection	Infection, infestation, e.g. <i>Candida</i> Eosinophilic folliculitis	Treatment of opportunistic infection Local corticosteroids, UVB
	Unknown	UVB
Malignancy	Unknown	
Psychogenic	Unknown	Psychotherapy, anxiolytics, antidepressants

*In addition to specific treatment of primary condition.

In some patients, despite extensive investigations, no cause is found. Rare patients have a true delusional state in which they complain of a sensation of insects crawling across or emerging from the skin. Sometimes they produce scales or other cutaneous matter which they believe to be evidence of the insects. Psychiatric assessment is required.

Management

Treatment of itch depends on the cause and may require several trials of therapy. If there is a reversible cutaneous or systemic cause, this should be treated specifically.

A number of factors are known to exacerbate or precipitate itch. For instance, xerosis (dry skin) can be due to over-frequent bathing, soap and staying in a hot bath too long. Minimising soap and water exposure and using emollients can help. In patients with atopic dermatitis, nails need to be kept short and manicured. Although the evidence is unclear, emollients or cooling creams, such as menthol and aqueous cream, may be helpful.

If histamine is involved in pathogenesis, as in urticaria, then antihistamines are useful. The most appropriate are the non-sedative H_1 antagonists, e.g. fexofenadine, loratadine. If one fails, it is worth trying another. Historically, sedative antihistamines have been used in conditions such as atopic dermatitis which are not mediated via histamine; they act as sedatives which may reduce scratching, but their primary action on itch is unclear.

Phototherapy may help a wide variety of pruritic conditions but is particularly useful in atopic dermatitis and the itch secondary to renal disease. Opiate antagonists are effective in the itch of hepatic disorders. Rifampicin may also have a role in cholestatic pruritus. Capsaicin has been used in some localised causes of itch such as lichen simplex.

Although frequently the subject of ridicule, significant itch may incapacitate, embarrass, disrupt sleep and ruin patients' self-image. Its impact is easily underestimated.

Red scaly rashes (papulosquamous eruptions)

The red scaly rash is a common presenting complaint. The main causes are listed in Box 27.8 and the diagnosis is usually made on the basis of the clinical history and careful assessment of the rash. Key questions are:

- *How long has the rash been present?* Atopic eczema often starts in early childhood. Pityriasis rosea and psoriasis usually occur between the ages of 15 and 40 years. Pityriasis versicolor can persist for many years in one individual. More recent onset is seen in drug eruptions, temporally related to drug ingestion. Secondary syphilis is a transient eruption.
- *Where on the body did it start and how has it evolved?* Atopic eczema usually starts on the cheeks in infancy and spreads to involve the flexures of the limbs. Chronic plaque psoriasis tends to favour the extensor surfaces, but guttate ('raindrop') psoriasis has a rapid onset and is widespread. Facial involvement is uncommon in psoriasis. Drug eruptions evolve over a few days to 3 weeks after starting the culprit drug; they often resolve with desquamation. Fungal infections can affect any

part of the body, including the face, and continue to appear in other sites over time.

- *Is the rash itchy?* Eczema and tinea corporis are always itchy. Psoriasis and drug eruptions can be itchy but pityriasis rosea, pityriasis versicolor and syphilis are rarely so.
- *Was there a preceding illness or systemic symptoms?* Guttate psoriasis is often precipitated by a β -haemolytic streptococcal sore throat. Systemic symptoms, such as fever, malaise and joint pains, are common in drug eruptions. Although the majority of individuals are not allergic to penicillins, almost all patients with infectious mononucleosis (p. 316) treated with amoxicillin will develop

27.8 Causes and clinical features of common scaly rashes

Type of rash	Distribution	Morphology	Associated clinical signs
Atopic eczema (p. 1257)	Face/flexures	Poorly defined erythema and scaling Lichenification	Shiny nails Infra-orbital crease 'Dirty neck' (grey-brown discoloration)
Psoriasis (p. 1260)	Extensor surfaces	Well-defined plaques with a silvery scale	Nail pitting and onycholysis Scalp involvement Axillae and genital areas often affected
Pityriasis rosea (p. 1264)	'Fir tree' pattern on torso	Well-defined erythematous papules and plaques with collarette of scale	
Drug eruption (p. 1286)	Widespread	Maculopapular erythematous scaly areas which merge. Subsequent exfoliation	
Pityriasis versicolor (p. 1265)	Upper torso and upper shoulders	Hypo- and hyperpigmented scaly patches	
Lichen planus (p. 1265)	Distal limbs, especially volar aspect of wrists Lower back	Shiny, flat-topped violaceous papules with Wickham's striae	White lacy network buccal mucosa Nail changes (rare)
Tinea corporis (p. 1273)	Asymmetrical, often isolated lesions	Scaly red plaques which expand with central healing	Nail involvement (see Fig. 27.55, p. 1291)
Secondary syphilis (p. 1264)	Torso and proximal limbs Palms and soles	Red macules and papules which change to a 'gun-metal' grey	Systemic symptoms, e.g. malaise and fever

an erythematous maculopapular eruption. The widespread red scaly eruption of secondary syphilis follows a history of a chancre at the site of inoculation.

The extent and symmetry of the rash should be carefully examined. If symmetrical, it is likely to be due to an endogenous cause, such as eczema, psoriasis, drug eruptions, pityriasis rosea and syphilis. Exogenous eruptions, such as contact allergic dermatitis and tinea corporis, are asymmetrical, initially appearing only in the area where either the allergen or the culprit fungus has affected the skin. The morphology of the rash and the individual lesions is important, particularly whether the lesions are well or poorly defined (Box 27.8). Use of a magnifying lens may help determine this. It is not usually necessary to take a biopsy to confirm the diagnosis of red scaly eruptions, but it may help where there is doubt.

Erythroderma

Eczema, psoriasis, drug eruptions and lichen planus rarely progress to erythroderma, defined as erythema, with or without scaling, affecting almost all the body surface. In dark skin, the presence of pigmentation may mask the erythema, giving a purplish hue. Other causes include cutaneous T-cell lymphoma (Sézary's syndrome, p. 1282), the psoriasis-like condition pityriasis rubra pilaris, and rare types of ichthyosis. Erythroderma may occur at any age and is associated with severe morbidity but rarely mortality. Older people are at greatest risk. It may appear suddenly or evolve slowly.

Erythrodermic patients, especially the elderly, may be systemically unwell with shivering and hypothermia, secondary to excess and uncontrolled heat loss caused by increased blood flow to their skin. However, they may also be pyrexial, and unable to lose heat due to damage to sweat gland function and sweat duct occlusion. Tachycardia and hypotension may be present, due to volume depletion. Peripheral oedema is common in erythroderma, due to low albumin and high-output cardiac failure. Lymph nodes may be enlarged, either reactive to skin inflammation, or rarely due to lymphomatous infiltration.

Urticaria (nettle rash, hives)

Urticaria refers to an area of focal dermal oedema secondary to a transient increase in capillary permeability. On certain body sites such as the lips or hands, the oedema spreads deeper and is referred to as angioedema. By definition, the swelling lasts less than 24 hours. Acute urticaria may be associated with angioedema of the lips, face, throat and rarely wheezing, abdominal pain, headaches and even anaphylaxis (p. 89). Whilst severe angioedema can be life-threatening due to respiratory obstruction, this is extremely rare in a dermatological context.

Although the time frames are somewhat arbitrary, it is useful to ask:

- How long does the individual lesion last?
 < 24 hours (urticaria)
 > 24 hours (urticarial vasculitis)

- How long has the condition been present?
 < 6 weeks (acute urticaria)
 > 6 weeks (chronic urticaria)

Knowing the length of time that an individual weal lasts may be of some use in distinguishing urticaria from urticarial vasculitis. Urticarial vasculitis is much less common than urticaria, and many patients are unable to distinguish the development of new weals and disappearance of old ones, from individual weals which persist for more than 1 day. This may be clarified by drawing around a weal with a pen and examining the patient 24 hours later.

A directed history is the best way to elicit any causes or precipitants of urticaria (Box 27.9). Possible allergens, including drugs, should be determined. The physical urticarias can be identified by asking appropriate questions and subsequent challenge testing. A family history must be sought in cases of angioedema. Examination may reveal nothing as this is a transient eruption, or may uncover the classical weals which vary from papules to large extensive plaques (Fig. 27.4). Pathogenesis, investigations and management are described on page 1266.

27.9 Causes of urticaria

Acute and chronic urticaria

- **Autoimmune** due to production of antibodies that cross-link the IgE receptor on mast cells
- **Allergens** (in foods, inhalants and injections)
- **Drugs** (see Box 27.41, p. 1287)
- **Contact**, e.g. animal saliva, latex
- **Physical**, e.g. heat, cold, pressure, sun, water
- **Infection**, e.g. viral hepatitis, infectious mononucleosis, HIV seroconversion
- **Other conditions**, e.g. systemic lupus erythematosus (SLE), pregnancy, intestinal parasites
- **Idiopathic**

Urticarial vasculitis

- Hepatitis B
- SLE
- Idiopathic

Fig. 27.4 Widespread acute urticaria. In this case urticaria was due to penicillin allergy.

Blisters

Blisters have a limited differential diagnosis (Box 27.10). Loss of adhesion within the skin leads to a potential space which, because of negative extracellular pressure, fills with fluid and forms a blister. Although an artificial distinction, the size (vesicle < 0.5 cm; bulla > 0.5 cm) can be a useful pointer in terms of diagnosis. Much of our understanding of the adhesion mechanisms within the skin has come from the study of a rare group of genetic blistering skin conditions, epidermolysis bullosa (Box 27.11), which, with other genodermatoses, present with blistering at birth.

In acquired blistering disorders, the clinical presentation depends on the site or level of blistering within the skin and this in turn is due to the underlying pathogenesis (p. 1275).

- If blisters occur high up in the epidermis, i.e. below the stratum corneum, the blister is so fragile that it ruptures easily and only an erosion is seen (e.g. pemphigus foliaceus, staphylococcal scalded skin syndrome and bullous impetigo).
- Blisters within the epidermis can be more obvious but may be erosions (e.g. eczema, particularly contact allergic eczema, pemphigus vulgaris, toxic epidermal necrolysis).
- Subepidermal blisters are more robust and can be very tense, as seen in bullous pemphigoid (Fig. 27.5), epidermolysis bullosa acquisita and porphyrias. In dermatitis herpetiformis, an autoimmune blistering disorder (p. 1276), the blisters are deep-seated but so itchy that only excoriations or erosions are seen.

A history of onset, progression, mucosal involvement, drugs and associated systemic symptoms should be taken. Clinical assessment of the distribution, extent and morphology (vesicular/bullous or mixed) of the rash should be made. The Nikolsky sign is useful; sliding pressure from a finger on normal-looking epidermis can dislodge the epidermis in conditions with intra-epidermal defects, e.g. pemphigus and toxic epidermal necrolysis.

27.11 Types of epidermolysis bullosa congenita

Type	Mode of inheritance	Level of blister protein*	Abnormality
Simple	Autosomal dominant	Epidermal basal cell	Keratins 5 and 14
Junctional	Autosomal recessive	Lamina lucida	Laminin-5 and $\alpha_6\beta_4$ integrin
Dystrophic	Autosomal dominant and recessive	Dermis below lamina densa	Collagen VII

*See Fig. 27.2, p. 1241.

Fig. 27.5 Bullous pemphigoid. Large tense and unilocular blisters clustered in and around the axilla.

A systematic approach to diagnosis is required:

1. Exclude blistering as a *less common manifestation of a common skin problem*, e.g. severe peripheral oedema, cellulitis, allergic contact dermatitis, eczema and pompholyx.

27.10 Causes of acquired blisters

	Localised	Generalised	
		Mucosal involvement	No mucosal involvement
Vesicular	Herpes simplex Herpes zoster Impetigo Pompholyx	Eczema herpeticum	Eczema herpeticum Dermatitis herpetiformis Epidermolysis bullosa acquisita
Bullous	Impetigo Bullous cellulitis Bullous stasis oedema Acute eczema Insect bites Fixed drug eruptions	Pemphigus Bullous pemphigoid Bullous erythema multiforme/Stevens-Johnson syndrome Toxic epidermal necrolysis Epidermolysis bullosa acquisita	Acute eczema Erythema multiforme Bullous pemphigoid Epidermolysis bullosa acquisita Bullous lupus erythematosus Pseudoporphyria Porphyria cutanea tarda Drug eruptions, e.g. barbiturates

27.12 Age of onset in immunobullous skin disorders

Disease	Age
Pemphigus vulgaris	40–60 yrs
Bullous pemphigoid	60s and over
Dermatitis herpetiformis	Young, associated with coeliac disease
Linear IgA disease	Any age
Pemphigoid gestationis	Young pregnant female
Epidermolysis bullosa acquisita	All ages
Bullous lupus erythematosus	Young black female

- Exclude *infection*, e.g. viral infections with herpes simplex or varicella zoster or bacterial infections, e.g. staphylococcal bullous impetigo or staphylococcal scalded skin syndrome (SSSS).
- Consider a bullous form of a *reactive skin eruption*, such as drug eruptions (particularly a fixed drug eruption, p. 1286), erythema multiforme (p. 1284) and vasculitis (p. 1112). The morphology and distribution of these eruptions are distinctive. More severe blistering, usually due to drug reactions, is seen in toxic epidermal necrolysis (TEN, p. 1275); the patient is systemically unwell, the skin is shed in large sheets and mortality is significant.
- Consider an *immunobullous skin disorder* (p. 1275). The age of the patient can be a helpful pointer (Box 27.12).

Routine investigations include full blood count, urea and electrolytes, and also:

- swabs for virology and microbiology
- skin snip to differentiate between SSSS and TEN (p. 1270)

- skin biopsy for histology and direct immunofluorescence
- serum sample for indirect immunofluorescence if an immunobullous disorder is suspected.

Treatment is directed towards the underlying cause but significant mucosal involvement and widespread blistering need immediate topical therapy. Skin loss can be painful and fluid loss significant, so analgesia and fluid replacement are important. Blisters can be pierced to release fluid and prevent extension. Topical therapy and dressings may be very soothing (p. 1254). Patients with extensive skin loss may require treatment in an intensive care setting.

Photosensitivity

Ultraviolet radiation is the main cause of skin malignancies in most populations and is responsible for photo-ageing. Whilst UV radiation, by definition, causes a range of photodermatoses, it is also used therapeutically for some of these and for a wide range of other skin diseases, notably psoriasis and cutaneous T-cell lymphoma. It is also necessary for the production of vitamin D in keratinocytes.

UV radiation is divided by convention into three wavebands (Fig. 27.6):

- UVC (280–300 nm)**, which is effectively blocked by the earth's atmosphere
- UVB (300–320 nm)**, which forms a small component of ambient UV radiation but is much more potent biologically and accounts for most of the sunburning activity in natural sunlight
- UVA (320–400 nm)**, the dominant waveband found at the earth's surface, which is biologically less active than UVB.

Both UVB and UVA may induce rashes in sensitive individuals, and in the majority of instances both wavebands

Fig. 27.6 The electromagnetic spectrum. For some conditions the action spectrum is approximate and may vary between patients (e.g. lupus erythematosus, polymorphic light eruption). The action spectrum for non-melanoma skin cancer mirrors that for erythema. The action spectrum for melanoma is not known but certainly involves UVB. (UVR = ultraviolet radiation)

Fig. 27.7 Bullous photosensitive eruption. Note the sharp cut-off at the wrists, due to protection by the shirt sleeves, and sparing of the skin under watch and strap.

are active. In some individuals, pathological sensitivity even extends into the visible spectrum ($> 400\text{ nm}$).

Clinical assessment

The history may clearly indicate that the rash is temporally related to sun exposure. The sites that received the most sunshine will tend to be affected: the face, the nose and the cheeks (but excluding the eyelids, an area under the chin and an area in the shadow of the nose), and the dorsa of the forearm and the hands (Fig. 27.7). Sometimes, however, the diagnosis is not straightforward; the rash may develop on some sun-exposed sites but extend to sun-protected sites, and may not be most prevalent on the areas that have received the maximum ultraviolet exposure. Some rashes, such as solar urticaria, have a clear temporal relation with UV exposure, while others, such as lupus erythematosus, may take up to 10 days to develop following exposure. Common causes are shown in Box 27.13.

Management

If photosensitivity is suspected, an attempt should be made to provoke the rash with phototesting (p. 1244). Only longer wavelength radiation, such as UVA, will pass through normal window glass. If photosensitivity is due to UVB only, individuals will not be at risk when they are behind plain glass, which may be diagnostically useful. Management depends on the diagnosis. In some disorders, such as solar urticaria or polymorphic light eruption, carefully controlled graded exposure to UVR in a phototherapy cabinet seems to lead to a reduction in symptoms. The mechanism is unclear but may involve down-regulation of the cutaneous immune system or skin hardening (increased resistance to the harmful effects of UVR) due to tanning and epidermal thickening. Other therapeutic strategies include sun avoidance, use of sunblocks and antihistamines (useful in solar urticaria), correction of associated metabolic disorders (e.g. porphyria), or removal of an offending drug.

Sunscreens

Chemical sunscreens absorb specific wavelengths of UVR, while physical sunscreens reflect UVR and visible light. Most available products are a combination of UVA and UVB chemical sunscreens. The individual may be sensitive to visible light as well as UVR, but the agents that block visible light are obvious and have limited cosmetic acceptability.

Sunblocks are graded in terms of their sun protection factor (SPF). The SPF is the ratio of the time it takes to induce a certain degree of erythema with and without sunblock. An SPF of 10 means that 90% of the radiation is blocked, and therefore it would take an exposure 10 times as long as that without the sunblock to obtain the same degree of erythema. Thus, for a given unit of time exposure, as the SPF gets larger, the additional benefit is marginal. However, the average individual applies only about one-third of the density of sunblock per unit skin

27.13 The photosensitive dermatoses

Cause	Condition	Clinical features
Drugs	Phototoxic drug eruption	Common; exaggerated sunburn occurs minutes after sun exposure e.g. Phenothiazines, amiodarone, tetracyclines
	Photo-allergic drug eruption	Occurs > 24 hrs after sun exposure Dermatitis or lichen planus-like reaction, may become permanent (persistent light reactor) e.g. Thiazides, enalapril, hydroxychloroquine, quinine, phenothiazines or topical photosensitisers, e.g. fragrances
Metabolic	Porphyrias	Particularly porphyria cutanea tarda (pp. 456 and 1284)
	Pellagra	Dermatitis due to dietary lack of tryptophan (see Fig. 16.17, p. 457)
Exacerbation of pre-existing conditions	Lupus erythematosus	Page 1107
	Erythema multiforme	Page 1284
	Herpes simplex	Page 321
Idiopathic	Polymorphic light eruption	Itchy papulovesicular eruption on exposed sites within hours of UV exposure; more frequent in women
	Solar urticaria	Urticaria within minutes of sun exposure
	Chronic actinic dermatitis	Disabling, itchy dermatitis on sun-exposed sites in elderly men

used in the calculation of SPF figures, so that a sunblock with an SPF of 15 will only actually have an SPF of 5.

Leg ulcers

Ulceration of the skin is due to complete loss of the epidermis and part of the dermis. When present on the lower leg, it is usually due to vascular disease, and around 75% of cases are due in part to venous hypertension. For each cause of leg ulceration there are several different underlying pathologies that have to be considered (Box 27.14). Venous ulcers usually start in middle age. Leg ulcers are more likely to occur and persist in obese people.

Clinical assessment

The history of the onset of the leg ulceration and any underlying predisposing conditions should be sought, and the site and surrounding skin carefully assessed. Varicose veins are often present but are not inevitable. The first symptom in venous ulceration is frequently heaviness of the legs, followed by the development of oedema. Haemosiderin pigmentation and ivory-coloured scarring may then be seen, sometimes associated with venous eczema (p. 1256). This progresses to lipodermatosclerosis – firm induration due to fibrosis of the dermis and subcutis, which may produce the well-known ‘inverted champagne bottle’ appearance. Ulceration, often precipitated by minor trauma or infection, soon occurs. The site of ulceration on the lower leg can give a good indication of the underlying cause (Fig. 27.8). Venous ulcers are seen typically around the medial malleolus but may encircle the ankle (Fig. 27.9). Arterial and vasculitic ulcers may have a punched-out appearance. Neuropathic ulcers appear at maximum pressure points, such as the heel.

Appropriate investigations include:

- *Urinalysis* for glycosuria.
- *Full blood count* to detect anaemia and blood dyscrasias.
- *Bacterial swab* if there is a purulent discharge, rapid extension, cellulitis, lymphangitis or septicaemia.

27.14 Causes of leg ulceration

Venous hypertension

Arterial disease

- Atherosclerosis
- Buerger's disease
- Vasculitis

Small-vessel disease

- Diabetes mellitus
- Vasculitis

Haematological disorders

- Sickle-cell disease
- Spherocytosis
- Cryoglobulinaemia
- Immune complex disease

Neuropathy

- Diabetes mellitus
- Syphilis
- Leprosy

Tumour

- Squamous cell carcinoma
- Malignant melanoma
- Basal cell carcinoma
- Kaposi's sarcoma

Trauma

- Injury
- Artefact

Fig. 27.8 Causes of lower leg ulceration.

- *Doppler ultrasound* to assess arterial circulation. If the ratio of ankle systolic pressure to brachial systolic pressure (ABPI) is < 0.8 , there is significant arterial disease. However, in some patients with diabetes, arterial calcification of the lower limb vessels produces a spuriously high result.
- *Venography*, which is occasionally useful in detecting surgically remediable venous incompetence.
- *Duplex scanning* to delineate arterial disease in those with an ABPI < 0.8 .

Management depends on the cause but usually involves some form of dressing (p. 1288).

Fig. 27.9 A large venous ulcer overlying the medial malleolus.

Abnormal skin colour

Decreased pigmentation

The main disorders to consider are albinism and vitiligo. However, a number of others may produce secondary hypopigmentation:

- pityriasis alba, a type of eczema presenting as depigmented areas on the face, particularly in children, with or without scale
- pityriasis versicolor, a yeast infection characterised by hyperpigmentation early in its pathogenesis but leading to multiple areas of hypopigmentation on the trunk, particularly the back
- idiopathic guttate hypomelanosis, characterised by numerous small areas of depigmentation in areas of skin that have been exposed to the sun
- very rarely, phenylketonuria (p. 447) and hypopituitarism.

Oculocutaneous albinism

Albinism results from a range of genetic abnormalities leading to reduced melanin biosynthesis in the skin and eyes; the number of melanocytes is normal (in contrast to vitiligo). There are a number of different forms of albinism, and considerable variation even within one genetic type. Albinism is usually inherited as an autosomal recessive trait.

Type 1 albinism is due to a defect in the tyrosinase gene, whose product is rate-limiting in the production of melanin. Affected individuals have an almost complete absence of pigment in the skin and hair at birth, with resulting pale skin and white hair, and failure of melanin production in the iris and retina. Patients have photophobia, poor vision not correctable with refraction, rotatory nystagmus, and an alternating strabismus associated with abnormalities in the decussation of nerve fibres in the optic tract.

A second form of albinism is due to a defect in the *P* gene, which encodes an ion channel protein in the melanosome. Patients may have gross reduction of melanin in the skin and in the eyes, but may be more mildly affected than type 1 albinos. Establishing the subtype of albinism requires genetic analysis, as there is considerable heterogeneity in the phenotype of the various subtypes.

Oculocutaneous albinos are at grossly increased risk of sunburn and skin cancer. In equatorial regions, many die from squamous cell carcinoma or, more rarely, melanoma in early adult life. They may, however, show pigmented melanocytic naevi and may freckle in response to sun damage.

Management

Avoidance of sun exposure with protective clothing and hats is important, as is a lifestyle that avoids the mid-day sun in particular, with indoor rather than outdoor occupations. Sunblocks may be useful but can be expensive. Early diagnosis and treatment of skin tumours is essential.

Vitiligo

Vitiligo is an acquired condition in which circumscribed depigmented patches develop; it affects 1% of the population world-wide. Unlike albinism, vitiligo involves focal areas of melanocyte loss. There may be a positive

family history of the disorder in those with generalised vitiligo, and this type is associated with autoimmune diseases such as diabetes, thyroid and adrenal disorders, and pernicious anaemia. Trauma and sunburn may precipitate the appearance of vitiligo. A number of hypotheses have been advanced to explain the pathogenesis, including that the melanocytes are the target of a cell-mediated autoimmune attack, but why only focal areas are affected remains unexplained.

Clinical assessment

Segmental vitiligo is restricted to one part of the body but not necessarily a dermatome. Generalised vitiligo is often symmetrical and frequently involves the hands, wrists, knees and neck, as well as the area around the body orifices. The hair of the scalp and beard may also depigment (Fig. 27.10). The patches of depigmentation are sharply defined, and in Caucasians may be surrounded by light brown 'café au lait' hyperpigmentation. Some spotty perifollicular pigment may be seen within the depigmented patches and is sometimes the first sign of repigmentation. Sensation in the depigmented patches is normal (unlike in tuberculoid leprosy, p. 341). Examination with a Wood's light enhances the contrast between the pigmented and non-pigmented skin. The course of vitiligo is unpredictable but most patches remain static or enlarge; a few repigment spontaneously.

Management

This is unsatisfactory. Protecting the patches from excessive sun exposure with clothing or sunscreen may be helpful in reducing episodes of burning and potential skin cancer. Camouflage cosmetics may also be helpful, particularly in those with dark skin, as can potent topical corticosteroids. Phototherapy with PUVA (psoralen + UVA) or more recently narrow band UVB has been used (p. 1263) but evidence is limited. PUVA therapy increases pigmentation in normal skin, so the cosmetic effect (an increase in contrast) may actually be worse than no treatment, except in very dark-skinned individuals. When repigmentation occurs, it is frequently seen as small foci of dark areas of skin surrounding hair follicles within the vitiliginous area. The absence of whiteness of the hairs in the area of vitiligo is a good prognostic feature. Transplantation, using a range of techniques including split-skin grafts and blister roof grafts, is occasionally used on to dermabraded recipient skin.

Fig. 27.10 Vitiligo. Localised patches of depigmented skin, including some white hairs.

The impact of vitiligo differs markedly between populations. In the Indian subcontinent, the effects of vitiligo are more readily discernible than in pale-skinned individuals in northern Europe. Depigmentation is also seen in leprosy, which means that individuals with vitiligo are often stigmatised. The use of more novel treatments, such as grafting, is often pursued more extensively in such populations.

Increased pigmentation

- **Diffuse hyperpigmentation.** This is mostly due to hypermelanosis but other pigments may be deposited in the skin. Orange discoloration suggests carotenaemia; bronze, haemochromatosis (p. 959); and other hues, drug eruptions.
- **Endocrine pigmentation.** This may occur in a number of conditions. Chloasma describes discrete patches of facial pigmentation which occur in pregnancy and in some women taking oral contraceptives. The basis of the focal increased sensitivity to hormonal control is unknown. Diffuse pigmentation, sometimes worse in the skin creases, may be a feature of Addison's disease (p. 774), Cushing's syndrome (p. 770), Nelson's syndrome (p. 773) and chronic renal failure. This is due to increased levels of pituitary melanotrophic peptides, including adrenocorticotrophic hormone (ACTH, p. 773).
- **Drug-induced pigmentation** (Box 27.15). This is not always due to hypermelanosis but may sometimes be due to deposition of the drug or its metabolite, either of which may be complexed with melanin.
- **Focal hypermelanosis.** This is seen in lesions such as freckles and lentigines, characterised by focal areas of increased pigmentation.

27.15 Drug-induced pigmentation

Drug	Appearance
Amiodarone	Slate-grey; exposed sites
Arsenic	Diffuse bronze pigmentation with superimposed raindrop depigmentation
Bleomycin	Often flexural; brown
Busulfan	Diffuse brown
Chloroquine	Blue-grey; exposed sites
Clofazimine	Red
Mepacrine	Yellow
Minocycline	Slate-grey; scars, temples, shins and sclera
Phenothiazines	Slate-grey; exposed sites
Psoralens	Brown; exposed sites

TOPICAL TREATMENT OF SKIN DISEASE

Topical treatments are a mainstay of the management of many skin conditions. The use of the correct active ingredient (or drug) and the vehicle in which it is applied is important.

Active ingredient

Many topical formulations are available for use in skin disease. Compound formulations are becoming increasingly available. Drugs penetrate the skin according to their molecular weight and their lipid-water coefficients, water-soluble ions and polar molecules being excluded. When the stratum corneum is impaired in disease states, drug absorption increases, but as the skin heals, it diminishes accordingly. If occlusion is applied—for example, under dressings—absorption is increased. Agents may be formulated in different potencies, as with topical corticosteroids, or by different concentrations, as with anthralins, coal tar preparations and first-generation topical retinoids. Most other agents are formulated in one strength, e.g. topical antibiotics, second-generation topical retinoids and vitamin D analogues.

Vehicle (base)

Besides containing the active ingredient, the vehicle of a topical treatment has other roles. It can hydrate and cool the skin, and has antimicrobial and soothing qualities. Creams and ointments are the most common vehicles used. Gels (both non-hydrous and aqueous) and lotions (aqueous) are convenient for use in hair-bearing areas. The properties of different vehicles are listed in Box 27.16. Many active treatments are available in more than one formulation.

Topical corticosteroids

Glucocorticoids are formulated as both ointments and creams. Creams are used in acute exudative conditions, whereas ointments are better in chronic dry skin conditions. Corticosteroids come in a variety of strengths and potencies (Box 27.17), and should be prescribed according to the site of application, the age of the patient and the length of time that the corticosteroids are to be used. Mild topical corticosteroids are used on sensitive sites, such as the face or genital area, in both adults and children. Superpotent corticosteroids are used under occlusion on chronic persistent lesions such as nodular prurigo. Local side-effects of topical corticosteroids include cutaneous atrophy and telangiectasia. These are rarely seen and under-treatment is a more common problem, and can be the cause of apparent treatment failure. There are no rules about the length of time for which a topical corticosteroid may be used safely in a particular individual on any one site, but in general the least potent corticosteroid should be used for the shortest possible time. Corticosteroid-responsive dermatoses should be treated initially with a more potent topical corticosteroid, switching to a less potent one as the condition improves. Long-term treatment is often given intermittently because of tachyphylaxis.

Dressings

An appropriate covering, such as a wound dressing (e.g. Jelonet), a simple tubular bandage (e.g. Tubifast) or a medicated bandage (e.g. Steripaste or Ichthopaste), is known as a dressing. Box 27.18 shows the indications for their use. The choice of dressing should be made according to the active agent, vehicle and covering of the skin. Wet lesions should be treated

27.16 Definition of vehicles used in topical treatments

Vehicle	Definition	Use	Site	Cosmetic acceptability	Risk of contact sensitisation
Creams	Emulsions of oil and water, e.g. aqueous cream	Acute presentations Cooling, soothing and well absorbed Mild emollients	All sites, including mucous membranes and flexures, but not hair-bearing areas	Very good	May contain antimicrobials and preservatives
Ointments	Greasy preparations Insoluble in water, e.g. white soft paraffin Soluble, e.g. Macrogol	Chronic dry areas of skin Mostly occlusive and protective; help rehydrate the skin Mildly anti-inflammatory	Avoid hair-bearing areas and flexures	Moderate	Low risk
Gels	Hydrophilic and hydrophobic bases	For specific sites	Hair-bearing areas and the face	Good	Low risk
Lotions	Water-based	Cooling effect Used to clean the skin and remove exudates Often antiseptic and astringent (e.g. potassium permanganate)	Large areas of the skin and the scalp	Good, but can sting if in an alcoholic base	Rare
Pastes	Semi-stiff preparations containing finely powdered solids suspended in an ointment	Characteristically substantive and bland Used for circumscribed skin lesions, e.g. psoriasis, lichen simplex chronicus	Any area of skin Often used in medicated bandages	Moderate	Moderate

27.17 Strengths of topical corticosteroids*

Mild

- 0.5%, 1%, 2.5% hydrocortisone

Moderate

- Clobetasone butyrate 0.05% (Eumovate)
- Betamethasone 0.025% (Betnovate RD)

Potent

- Mometasone furoate 0.1% (Elocon)
- Betamethasone 0.1% (Betnovate)
- Betamethasone 0.1% and fusidic acid 2% (Fucibet)
- Fluticasone propionate 0.05% and 0.005% (Cutivate)

Very potent

- Clobetasol propionate 0.05% (Dermovate)

*UK trade names are given in brackets.

27.18 Indications for dressings

- Protection
- Symptomatic relief from pain or itch
- Maintenance of direct application of topical treatment
- Acceleration of healing time
- Reduction of exudates

with wet dressings; for example, acute eczema is best treated with potassium permanganate soaks, a topical corticosteroid in a cream formulation and a paste bandage to soothe and cool the skin. In acute blistering, an astringent and antiseptic, such as potassium

permanganate or 2% aqueous eosin, is applied first, followed by a non-adherent dressing such as Jelonet or Alleevyn; antiseptic creams (e.g. Flamazine), topical steroid creams or emollients may also be useful. Chronic dry itchy eczema is best treated with a potent topical corticosteroid in an ointment formulation and a paste bandage to ease itching and scratching. Dressings for venous leg ulcers are described on page 1288. Patients with leg ulcers have an increased risk of contact allergy to medicaments, so potential allergens, such as topical antibiotics, antiseptics and lanolin, should be avoided.

DERMATOLOGICAL SURGERY

A large number of surgical procedures can be carried out under local anaesthetic. Incisional biopsy is described on page 1243. The choice of procedure is important; for example, inappropriate excision of lesions such as seborrhoeic keratoses results in scar formation; these lesions should be treated by cryosurgery or curettage instead.

Excisional biopsy

The lesion is removed and submitted for histopathological examination. The most common indication is the clinical suspicion of malignant disease (e.g. basal cell carcinoma). Most procedures can be carried out under local anaesthetic, but in certain sites local cutaneous blocks are useful (e.g. fingers, plantar aspects of the foot and the nose). Knowledge of local anatomy is important, particularly vessels and nerves. Certain body sites are associated with particular risks:

- biopsies on the upper torso of young persons are likely to lead to keloidal scarring
- biopsies over the scapulae tend to leave unsightly scars
- biopsies on the lower legs of older people are at risk of delayed healing and ulceration.

The lesion and the line of excision should be marked out. Basal cell carcinomas should usually be excised with a 4mm margin, whereas initial biopsies of suspicious pigmented lesions may be excised with a 2mm margin and then further excised with 1 or 2cm margin following histopathological confirmation of melanoma (depending on the Breslow thickness, p. 1281). It is important to excise down to the appropriate anatomical plane. Depending on body sites, a range of procedures can be used to minimise the resulting defect, including undermining, Z-plasties, flaps and grafts. On some concave sites in the elderly, healing by secondary intention can lead to surprisingly good cosmetic results.

Mohs micrographic surgery

Mohs micrographic surgery aims to ensure adequate tumour excision margins, while conserving as much tissue as possible. It is most commonly used for the management of basal cell carcinomas and, to a lesser degree, for squamous cell carcinomas. Initially, the tumour may be debulked with curettage and then an excision is performed, orientated with ink or sutures; horizontal (rather than vertical) cross-sections are cut and examined immediately using the frozen section technique. Any areas of tumour that abut onto the edge can then be orientated back onto the patient and further tissue removal in that particular direction is undertaken. This iteration is continued until the margins are clear of tumour. The procedure is time-consuming and requires particular surgical and pathological skills but is popular. It should be considered especially for morphoeic or otherwise ill-defined basal cell carcinomas, and in sites where tissue conservation is important, such as close to the eye. It is not appropriate for melanoma. Subsequently, appropriate reconstruction can be undertaken in collaboration with oculoplastic/plastic surgery.

Cryotherapy

Cryotherapy is performed as an application of liquid nitrogen either with a cotton wool bud or using a jet gun. Liquid nitrogen can be used to treat a wide range of lesions from viral warts to actinic keratoses, including invasive tumours such as basal or squamous cell carcinomas. The cosmetic effects and morbidity are variable. If neoplasia is suspected, it is wiser to carry out an incisional biopsy first. In general, superficial or 'stuck-on' lesions will require less intense therapy that will be more acceptable to the patient. Melanocytic naevi should not be treated with liquid nitrogen.

Curettage

Curettage involves scraping a small, spoon-shaped implement (curette) across the lesion, not only as a definitive treatment but also as a way of obtaining histological material. The latter, however, may be compromised because epidermal structures are over-represented and the anatomy of the lesion as it descends into the dermis is not preserved; it may therefore be difficult to determine whether a lesion with intra-epidermal dysplasia

shows any evidence of invasion. Curettage is suitable for many seborrhoeic keratoses, actinic keratoses or areas of intra-epidermal carcinoma. Some superficial basal cell carcinomas can be treated with curettage but other variants, such as morphoeic forms, require excision.

Laser therapy

Laser therapy exploits the fact that certain pigments, such as melanin or blood, absorb certain wavelengths of electromagnetic radiation more readily than others. A variety of lasers have been produced which allow selective destruction of structures containing the absorbing pigment. By concentrating the light into short pulses, the damage is restricted to a particular area. Some lasers are better for dealing with primarily vascular lesions, such as port wine stains, while others are more useful for pigmented lesions or for destruction of exogenous pigments, such as tattoo pigments or drug deposits (e.g. minocycline).

By contrast with the vascular laser, the carbon dioxide laser emits infrared light which is absorbed by tissue water. When crudely used, the carbon dioxide laser is therefore similar to a diathermy but the depth of lesion can be controlled to a fraction of a millimetre, and it can therefore be useful for resurfacing and for face lifts. A general anaesthetic is required.

Photodynamic therapy

Photodynamic therapy is based on the pathological processes that underpin the photosensitivity seen in porphyria, i.e. the presence of potent endogenous photosensitisers which results in tissue damage when exposed to light. In photodynamic therapy, topical photosensitisers are applied to the tumour, which is subsequently exposed to visible light. Some tumours may selectively absorb the photosensitiser, thus enhancing the therapeutic ration. Photodynamic therapy is particularly useful for relatively flat lesions, such as some intra-epithelial carcinomas and superficial basal cell carcinomas, and may be preferable to surgery or other treatment. The treatment is time-consuming, as the sensitiser needs to be applied for several hours before exposure to the light source; as with porphyria, exposure may be painful.

Miscellaneous procedures

Keloids (scar tissue that outgrows the original scar) may require corticosteroid injections after freezing or excision. Silicone sheeting may flatten keloids, although the mechanism is obscure. Scars and wrinkles can be filled using collagen or silicone. Liposuction can be used to remove fat, and tissue folds around the eyes can be easily excised. Small acne scars can be excised and larger, more superficial lesions treated with a carbon dioxide laser. Areas of depigmentation in vitiligo or piebaldism may be treated with epidermal grafts from normal skin.

ECZEMA

The terms 'eczema' and 'dermatitis' are synonymous. They refer to distinctive reaction patterns in the skin, which can be either acute or chronic and are due to a number of causes. In the acute stage, oedema of the epidermis (spongiosis) progresses to the formation of

27.19 Classification of eczema

- Atopic
- Seborrhoeic
- Discoid
- Irritant
- Allergic
- Asteatotic
- Gravitational
- Lichen simplex
- Pompholyx

intra-epidermal vesicles, which may enlarge and rupture. In the chronic stage there is less oedema and vesiculation, but more thickening of the epidermis (acanthosis); this is accompanied by a variable degree of vasodilatation and T-cell lymphocytic infiltration in the upper dermis.

Clinical features

There are several patterns of eczema (Box 27.19); some have identifiable environmental causes, whereas others are more complex. The clinical signs are similar in all types and vary according to the duration of the rash. The features of acute and chronic eczema are listed in Box 27.20.

Atopic eczema

Atopy is a genetic predisposition to form excessive IgE, which leads to a generalised and prolonged hypersensitivity to common environmental antigens such as pollen and house dust mite. Atopic individuals manifest one or more of a group of diseases that includes asthma, hay fever, food and other allergies, and atopic eczema. Although any of these conditions tends to be over-represented in families of those with any atopic disease, one particular disease type tends to run more strongly in a particular family. The diagnosis of atopic eczema is made using clinical criteria (Box 27.21). The prevalence of atopic eczema has increased between

27.20 The eczema reaction

Acute

- Redness and swelling, usually with ill-defined margins
- Papules, vesicles and, more rarely, large blisters
- Exudation and cracking
- Scaling

Chronic

- May show all of the above, but usually less vesicular and exudative
- Lichenification, a dry leathery thickening with increased skin markings, secondary to rubbing and scratching
- Fissures and scratch marks
- Hypo- or hyperpigmentation

27.21 Diagnostic criteria for atopic eczema

Itchy skin and at least three of the following:

- History of itch in skin creases (or cheeks if < 4 yrs)
- History of asthma/hay fever (or in a first-degree relative if < 4 yrs)
- Dry skin (xeroderma)
- Visible flexural eczema (cheeks, forehead, outer limbs if < 4 yrs)
- Onset in first 2 yrs of life

twofold and fivefold over the last 30 years, and the disease now affects 1 in 10 schoolchildren.

Aetiology

Genetic factors are important, with concordance in 86% of monozygotic but only 21% of dizygotic twins. Atopic diseases show a degree of maternal imprinting, i.e. they are inherited more often from the mother than the father. A pair of null alleles in the filaggrin gene (R501X and 2282del4), predisposing to atopic eczema and to asthma in association with eczema, have been identified. Filaggrin is an important component of the barrier of the skin (p. 1240) and these findings suggest that this structural defect is important in the development of atopic eczema. Environmental factors, such as exposure to allergens either in utero or during childhood, also have an aetiological role and 60–80% of individuals are genetically susceptible to the induction of IgE-mediated sensitisation to environmental allergens such as food and animal hair.

It is thought that the decreased barrier function of the skin may allow greater penetration of environmental allergens through the epidermis, and so cause stimulation of the immune system in susceptible individuals, precipitating an inflammatory response. In addition, IgE autoantibody production occurs in some individuals, perhaps related to scratching, but whether this is the basis of the 'atopic march' from eczema to food allergies and asthma has yet to be confirmed.

Clinical features

The cardinal feature of atopic eczema is itch, and scratching accounts for many of the signs. Widespread dryness (felt as roughness) of the skin is another feature. The distribution and character of the rash vary with age (Box 27.22; Figs 27.11 and 27.12). Complications are listed in Box 27.23.

Seborrhoeic eczema

This is characterised by a red scaly rash and classically affects the scalp (dandruff), central face, nasolabial folds, eyebrows and central chest. It is due to *Pityrosporum ovale* infection of the skin. When severe, it may resemble psoriasis. Seborrhoeic eczema is a feature of AIDS, in which case it can be very severe.

Discoid eczema

This common form of eczema is recognised from discrete coin-shaped eczematous lesions, particularly on the limbs of young and elderly men. It can occur in children with atopic eczema and may be difficult to treat.

27.22 Atopic eczema: distribution and character of rash

Infancy

- Often acute and involves the face and trunk
- Frequent sparing of the napkin area

Childhood

- Backs of the knees, fronts of the elbows, wrists and ankles (see Fig. 27.11)

Adults

- Face and trunk (see Fig. 27.12) are involved; lichenification is common

Fig. 27.11 Atopic subacute eczema on the fronts of the ankles of a teenager. These are sites of predilection, along with the cubital and popliteal fossae, in atopic eczema.

Fig. 27.12 Nipple eczema. This is frequently bilateral in atopic dermatitis.

Irritant eczema

Strong irritants elicit an acute reaction at the site of contact, whereas weak irritants most often cause chronic eczema, especially of the hands, after prolonged exposure. Detergents, alkalis, acids, solvents and abrasive dusts are common causes. There is a wide range of susceptibility to weak irritants. Irritant eczema accounts for the majority of occupational cases and work loss. The elderly, those with fair and dry skin, and those with an atopic background are especially vulnerable.

27.23 Complications of atopic eczema

Superinfection

Bacterial

- (*Staphylococcus aureus*) most common

Viral

- Herpes simplex virus causes a widespread severe eruption—eczema herpeticum
- Papillomavirus and molluscum contagiosum may be encouraged by use of local corticosteroids

Irritant reactions

- Defective barrier function

Sleep disturbance

- Loss of schooling and behavioural difficulties

Food allergy

- Eggs, cow's milk, protein, fish, wheat and soya may cause an immediate urticarial eruption rather than exacerbation of eczema

Allergic contact eczema

This is due to a delayed hypersensitivity reaction following contact with antigens or haptens. Previous exposure to the allergen is required for sensitisation and the reaction is specific to the allergen or closely related chemicals. Common allergens are listed in Box 27.24.

The eczema reaction occurs wherever the allergen is in contact with the skin and sensitisation persists indefinitely. It is important to determine the original site of the rash before secondary spread obscures the picture, as this often provides the best clue to the allergen. There are many easily recognisable patterns, e.g. eczema of the earlobes, wrists and back due to contact with nickel in costume jewellery, watches and bra clips; or eczema of the hands and wrists due to rubber gloves. Oedema of the lax skin of the eyelids and genitalia is a frequent concomitant of allergic contact eczema (Fig. 27.13).

Asteatotic eczema

This is frequently seen in the hospitalised elderly, especially when the skin is dry; low humidity caused by central heating, over-washing and diuretics are contributory

27.24 Common allergens

Allergen	Present in
Nickel	Jewellery, jean studs, bra clips
Dichromate	Cement, leather, matches
Rubber chemicals	Clothing, shoes, tyres
Colophony	Sticking plaster, collodion
Paraphenylenediamine	Hair dye, clothing
Balsam of Peru	Perfumes, citrus fruits
Neomycin, benzocaine	Topical applications
Parabens	Preservative in cosmetics and creams
Wool alcohols	Lanolin, cosmetics, creams
Epoxy resin	Resin adhesives

Fig. 27.13 Allergic contact eczema. This was caused by the application of an antihistamine cream. The acute eczematous reaction and bilateral periorbital oedema are typical.

factors. It occurs most often on the lower legs as a rippled or 'crazy paving' pattern of fine fissuring on an erythematous background.

Gravitational (stasis) eczema

This occurs on the lower legs and is often associated with signs of venous insufficiency: oedema, red or bluish discoloration, loss of hair, induration, haemosiderin pigmentation and ulceration.

Lichen simplex

This describes a plaque of lichenified eczema due to repeated rubbing or scratching, as a habit or in response to stress (Fig. 27.14). Common sites include the nape of the neck, the lower legs and the anogenital area.

Fig. 27.14 Lichen simplex chronicus on the neck showing increased skin markings and excoriations.

Pompholyx

Recurrent vesicles and bullae occur on the palms, palmar surface of the fingers and soles, and are excruciatingly itchy. This form of eczema can occur in atopic eczema and in irritant and contact allergic dermatitis. It can be provoked by heat, stress and nickel ingestion in a nickel-sensitive patient but is often idiopathic.

Investigation of eczema

Patch tests are performed in suspected cases of contact allergic dermatitis (Box 27.25). Prick tests or IgE and specific IgE tests are occasionally performed to support the diagnosis of atopic eczema and to determine specific environmental allergens, e.g. pet dander, horse hair, house dust mite, pollens and foods. Bacterial and viral swabs for microscopy and culture are useful in suspected secondary infection. Bacteria are invariably present, but antibacterial treatment should be reserved for those cases with evidence of clinical infection. Individuals with atopic eczema have an increased susceptibility to herpes simplex virus (HSV), and are at risk of developing a widespread infection, eczema herpeticum. The presence of small punched-out lesions on a background of worsening eczema suggests the possibility of secondary HSV infection.

General management of eczema

Regular use of bland emollients (e.g. emulsifying ointment) is the mainstay of treatment in all forms of eczema. They prevent excessive water loss from an already dry skin and help to reduce the amount of local corticosteroid used. Emollients are used as a bath additive, a soap substitute and directly onto the skin.

Topical corticosteroids

Lotions and creams are preferable in acute eczema, and ointments in chronic, and are usually applied once or twice daily. Only 1% hydrocortisone should be used on the face, except under expert advice. It is seldom necessary to prescribe more than 200 g of a low-potency corticosteroid (e.g. 1% hydrocortisone), 50 g of a moderately potent corticosteroid (e.g. 0.05% clobetasone butyrate) or 30 g of a potent corticosteroid (e.g. 0.1% betamethasone valerate, 0.1% mometasone furoate) per

EBM 27.25 Contact dermatitis

Patch tests

'Pre-prepared patch tests are significantly more reliable than operator-prepared tests.'

'False negative results occur if a potent topical steroid is applied 2 days or less before testing.'

Management of hand dermatitis

'Second-line treatments, such as psoralen UVA (PUVA), azathioprine and ciclosporin, are useful in steroid-resistant chronic hand dermatitis.'

• Bourke J, et al. *Brit J Dermatol* 2001; 145(6):102–105.

For further information:  www.BAD.org.uk

27.26 Eczema in old age

- **Loss of elasticity:** with advancing age, the skin becomes less pliable and drier. This increases the tendency to irritant dermatitis.
- **Topical corticosteroid usage:** causes more local side-effects, such as purpura or ecchymoses.
- **Prognosis:** widespread eczema is potentially life-threatening, particularly in the presence of comorbidity.

week. Very potent topical corticosteroids (e.g. 0.05% clobetasol propionate) should not be used long-term. The side-effects of strong or extensive local corticosteroid therapy are important when patients are applying these as a long-term measure, and include skin thinning (with striae, fragility and purpura), enhanced or disguised infections, and systemic absorption (causing suppression of the hypothalamic-pituitary-adrenal axis and Cushingoid features). There are no absolute guidelines for the amount of topical corticosteroid that should be used and there is marked variation in sensitivity to their harmful effects, but particular care should be taken on certain sites such as the face and flexures and in the elderly (Box 27.26). The least potent corticosteroid that is effective should be used for the shortest possible time.

Other topical immunosuppressants, including the topical calcineurin inhibitors tacrolimus (a macrolide with immunosuppressant activity) and pimecrolimus (an ascomycin with anti-inflammatory properties), are available. They are expensive but useful in the second-line treatment of facial atopic eczema and contact allergic dermatitis.

Sedative antihistamines (e.g. alimemazine tartrate) are useful if sleep is interrupted, but evidence for their use is limited.

Atopic eczema

Patient information and support are vital and are provided by the health-care system and patient support groups such as the National Eczema Society in the UK. Treatment involves the regular use of emollients and the least possible use of topical steroids. Topical steroids are needed for inflamed areas and can be used with a variety of types of dressing, such as tar and ichthammol paste bandages. Allergen avoidance may have a role in selected patients. Pimecrolimus cream and tacrolimus ointment are used as second-line treatments. Phototherapy is useful as a temporary third-line measure in adolescents and adults, but should never be used in individuals continuing to require topical calcineurin inhibitors. Rarely, systemic treatments are required, including intermittent ciclosporin A, oral steroids, azathioprine or methotrexate. Azathioprine is useful in adult chronic eczema. Baseline measurement of thiopurine methyl transferase (TPMT) levels is useful in determining azathioprine dose and avoiding toxicity.

Seborrhoeic eczema

Antipityrosporal agents, such as ketoconazole shampoo and creams, form the basis of treatment, supplemented with weak corticosteroids if needed. Treatments may need to be repeated at intervals.

Irritant eczema

This is treated by the regular use of emollients, protective clothing (e.g. gloves) and avoidance of irritants.

Contact allergic eczema

Avoidance of the culprit allergen is the most important intervention; this may entail lifestyle modifications, such as a change in occupation or hobbies. Measures used for irritant eczema are also helpful.

Gravitational eczema

Topical corticosteroids should only be applied to eczematous areas and should be avoided on ulcers. Sensitisation to topical antibiotics (neomycin) and preservatives (e.g. chlorocresol) is common. Associated peripheral oedema is treated by elevation of the leg and graded compression bandages.

PSORIASIS AND OTHER ERYTHEMATOUS SCALY ERUPTIONS

Psoriasis

Psoriasis is a non-infectious, chronic inflammatory disease of the skin, characterised by well-defined erythematous plaques with silvery scale, with a predilection for the extensor surfaces and scalp, and a chronic fluctuating course. The prevalence is approximately 2% in European populations but may be lower in African and some Asian populations, e.g. Japanese. Psoriasis may start at any age but is unusual before 5 years. There are two epidemiological patterns of psoriasis, sometimes referred to as type 1 and type 2. The first has an onset in the teenage and early adult years, often with a family history of psoriasis and an increased prevalence of the HLA group Cw6. The onset of the second is in the fifties or sixties, when a family history is less common and HLA Cw6 is not so prominent.

The clinical course of psoriasis is very variable. In general, the earlier the age of onset and the more severe the initial presentation, the more severe is the lifetime course of the disease.

Aetiology

Psoriasis is genetically complex and a large number of genes are thought to be important in its pathogenesis. There is a large familial component. Formal estimates from twin studies suggest a heritability of around 80%, and in monozygotes perhaps one-third will be concordant for psoriasis. Empirical estimates suggest that if one parent has psoriasis, then the chance of a child being affected is in the order of 15–20%; if both parents have the disease, this figure rises to 50%. Both estimates are increased if one sibling already has the disease.

The histological changes of psoriasis are shown in Figure 27.15. There are two key pathophysiological features in psoriatic plaques:

- The keratinocytes hyperproliferate with a grossly increased mitotic index and an abnormal pattern of differentiation, leading to the retention of nuclei in the stratum corneum, not normally present as the stratum corneum cells are dead.
- There is a large inflammatory cell infiltrate.

Fig. 27.15 The histology of psoriasis.

It is uncertain which of these is primary. Traditionally, psoriasis was viewed as a disorder of cell turnover, but it may be that the hyperproliferation is secondary to the inflammatory infiltrate and a consequence of inflammatory cell mediators or signalling.

Disordered cell proliferation in psoriasis is reflected by the increase in the number of mitoses visible in the psoriatic plaque. The transit time, i.e. the time it takes for keratinocytes in the basal layer to leave the epidermis, is shortened in psoriasis from perhaps 28 to 5 days, so that cells that are not fully mature or functional reach the stratum corneum prematurely. The non-plaque skin also shows an elevated rate of proliferation, but this is modest. The nails of patients with psoriasis, even when clinically unaffected, grow more quickly than those of controls.

The evidence implicating a key role for an immune pathogenesis includes the association with HLA Cw6; the success of immunosuppressive drugs, e.g. ciclosporin in treatment; the development of psoriasis in recipients of bone marrow transplants from donors with psoriasis and the precise molecular mechanisms by which the immune system causes the putative cutaneous abnormalities are unclear.

Psoriasis is characterised by variation in both temporal and spatial extent, most of which cannot be explained. At any one time, around 10% of people who have psoriasis have no lesions, and perhaps 15% report remissions of 5 years or more. Factors thought to precipitate exacerbations are listed in Box 27.27. A causal role for stress in exacerbations is not established. Certain studies suggest that alcohol consumption is greater amongst some psoriasis patients, but it is not clear whether this is a cause or result of the disease.

Clinical features

There are several different forms of psoriasis.

Stable plaque psoriasis

This is the most common. Individual lesions are well demarcated and range from a few millimetres to several centimetres in diameter (Fig. 27.16). They are red, with a dry silvery-white scale, which may only be obvious after scraping the surface. The elbows, knees and lower back are commonly involved. Other sites of predilection include:

27.27 Factors causing exacerbations of psoriasis

Trauma

- Lesions appear in areas of skin damage such as scratches or surgical wounds (Köbner phenomenon) when the condition is erupting

Infection

- β -haemolytic streptococcal throat infections often precede guttate psoriasis

Sunlight

- UVR rarely

Drugs

- Antimalarials, β -adrenoceptor antagonists (β -blockers) and lithium
- 'Rebound' after systemic corticosteroids or potent local corticosteroids are stopped

Emotion

- Anxiety

- *Scalp.* This is involved in approximately 60% of patients and it is not clear why this is so common. It typically shows well-demarcated, easily palpable areas, but on occasion a diffuse, fine scaling difficult to distinguish from classical seborrhoeic dermatitis may be present. Temporary hair loss is not uncommon and rarely permanent focal hair loss may occur.
- *Nails.* Involvement is common, with 'thimble pitting', onycholysis (separation of the nail from the nail bed, Fig. 27.17) and subungual hyperkeratosis.
- *Flexures.* Psoriasis involving the natal cleft and submammary and axillary folds is not scaly but red, shiny and symmetrical.
- *Palms.* Individual plaques may be poorly demarcated and barely erythematous, making this type of psoriasis difficult to differentiate from eczema of the palms.

Guttate psoriasis

This is most commonly seen in children and adolescents, and may follow a streptococcal sore throat. In

Fig. 27.16 Psoriasis. [A] Plaques of varying size in a child. [B] Plaques on the flexor surfaces of the knees. [C] Plaque detail.

many, it is the first presentation of the disease. The rash often appears rapidly. Individual lesions are droplet-shaped, seldom over 1 cm in diameter and scaly. Bouts of guttate psoriasis may clear within a few months but respond well to early treatment with phototherapy. The

Fig. 27.17 Coarse pitting of the nail and separation of the nail from the nail bed (onycholysis). These are both classic features of psoriasis.

majority of patients go on to develop plaque psoriasis later in life.

Erythrodermic psoriasis

The skin becomes universally red or scaly, or more rarely just red with very little scale. As in other forms of erythroderma, temperature regulation becomes compromised with a danger of either hypothermia or hyperthermia.

Pustular psoriasis

There are two varieties of pustular psoriasis. The generalised form is rare but serious. The onset is usually sudden, with large numbers of small sterile pustules erupting on a red base. The patient may rapidly become ill with a pyrexia coinciding with the appearance of new pustules, and will usually require urgent assessment and hospital admission. A localised form, which primarily affects the palms and soles, is more common. This is chronic and comprises small sterile pustules which lie on a red base, and resolve to leave brown macules or scaling. The relationship between pustular psoriasis of the palms and the soles (palmoplantar pustulosis) and psoriasis remains disputed, although they commonly coexist.

Arthropathy

Between 5 and 10% of individuals with psoriasis develop a chronic seronegative inflammatory arthropathy which can take on a number of patterns (p. 1095).

Investigations

Biopsy is seldom necessary and contributes little. Throat swabbing for streptococci or other evidence of recent infection may occasionally be useful in suspected guttate psoriasis. Joint symptoms, unless minor, require a formal rheumatology assessment.

General management of psoriasis

Explanation, reassurance and instruction are vital. Patients may be very distressed by their appearance and doctors should be aware of the impact that psoriasis can have. Parents may admit that they cannot take their young children swimming because of the alarm their rash causes to other swimmers. Similarly, blood on bed sheets and the ubiquitous scale on bedclothes and carpets may adversely affect personal relationships.

In the vast majority of cases, psoriasis is not life-threatening and therefore, if the treatment is worse than the disease, it should be stopped. Patients should be encouraged to share decision-making about treatment with their physician.

Treatment

Treatment can be classed in four broad categories (Box 27.28). Traditionally, therapies such as inpatient dithranol, when combined with UVR in Ingram's regimen, were capable of inducing clearance of the disease in most patients. The duration of remission varied considerably from less than 1 month to over a year. By contrast, more acceptable treatments such as calcipotriol rarely clear psoriasis, but do reduce the thickness, scaling and redness of the individual plaques to a varying degree. Depending on the extent of disease, the patient and physician need to choose an appropriate endpoint of treatment, and this may be a compromise between side-effects and practical considerations, such as time available to attend hospital.

Topical agents

A large number of topical agents are used to treat psoriasis. Emollients have a modest effect in reducing scale

and diminishing itch, and many patients feel more comfortable using them.

Dithranol and tar

These were the traditional gold standard of therapy. Both are potent producers of free radicals, which are pro-inflammatory and stimulate hyperproliferation when applied to normal skin but, for reasons that remain unclear, normalise differentiation and inhibit proliferation when applied to psoriatic plaques.

Dithranol is used in two main regimens. In Ingram's regimen, the plaques are covered with low concentrations of dithranol in a zinc oxide paste following a tar bath and UVR exposure, and then covered in talcum powder and bandages, which are left in situ for 24 hours. More recently, short-contact dithranol therapy has been developed, in which higher concentrations are applied for between 15 and 30 minutes and then washed off. The main clinical limitation of dithranol is its pro-inflammatory action on normal skin, which causes 'burning' with pain and erythema that peaks 72 hours after application. Dithranol also results in brown staining of the skin and can cause a purple discoloration in individuals with light hair colour. Use of dithranol or coal tar as an inpatient treatment has drastically diminished over the last 30 years due to low patient acceptability, the increasing use of outpatient phototherapy, and the therapeutic options provided by newer immunomodulatory treatments. Attempts have been made to make dithranol and tar easier to use and more cosmetically acceptable, but efficacy is reduced.

Calcipotriol

Calcipotriol is a vitamin D agonist. It seldom clears plaques of psoriasis but reduces plaque thickness and diminishes scaling. It is applied twice or once daily and, providing no more than 100 g of ointment is used each week, does not cause hypercalcaemia or hypercalciuria. Patients like calcipotriol because it is odourless and colourless, and does not stain. Irritation, usually transient, is the main side-effect. It is a mainstay of primary care management of psoriasis and may be combined with corticosteroids.

Corticosteroids

Corticosteroids may cause local skin atrophy, and when they are stopped the psoriasis tends to return. Nevertheless, they are invaluable for many sites, particularly the flexures, and short bursts of moderately potent corticosteroids can be invaluable. Use of potent topical corticosteroids on the face or hair margins requires close medical supervision.

Ultraviolet and PUVA therapy

UV therapy

Ultraviolet radiation (UVR) is the mainstay of outpatient management of those with moderate to severe psoriasis. The main risks are burning in the short term, and increased skin cancers in the long term.

It has been known for almost a century that ultraviolet B (UVB) administered therapeutically improves psoriasis in many patients, and many sufferers notice a spontaneous improvement in summer. More recently, a particular type of UVB radiation produced by the Philips TL01 lamp (narrowband UVB), delivered 2–5

27.28 Treatment categories in psoriasis

Topical agents

- Emollients, corticosteroids, vitamin D agonists, 'weak' tar or dithranol preparations

UV therapies

- UVB or PUVA

Systemic agents

- Methotrexate, retinoids
- Immunosuppressives, e.g. ciclosporin, mycophenolate
- Newer 'biological' agents, e.g. infliximab, etanercept

Intensive inpatient or day-patient care

- Topical agents and UVR under medical supervision

times a week on an outpatient basis, has become a popular treatment. This lamp peaks at 311 nm, as shorter radiation, while inflammatory, has little therapeutic efficacy. The long-term safety of this lamp is unclear, particularly with regard to whether it is more or less carcinogenic than traditional broadband UVB sources.

PUVA therapy

Psoralens are natural photosensitisers found in a number of plants. Psoralen molecules intercalate between the two strands of DNA and, upon excitation with UVA, photons cross-link the DNA strands. It is thus a pro-drug that is distributed throughout the body after oral administration, but only activated by UVR in skin that is exposed to UVA. Alternatively, psoralens can be applied in a bath before irradiation with UVA ('bath PUVA').

PUVA treatment induces clearance to a similar degree to intensive dithranol therapy. Short-term side-effects are minimal. The therapy can be delivered between 2 and 5 times a week and clearance may be expected in more than 75% of individuals within 8 weeks. Some patients may develop nausea in response to the psoralen. Because the psoralen is present in the eye, patients must wear UVR-resistant sunglasses for 24 hours after therapy. The long-term hazards of PUVA therapy are the result of its mutagenicity; patients who have received a large amount of PUVA therapy, particularly 'maintenance therapy' (continuous PUVA lasting for 6 months to a year), are at increased risk of squamous and basal cell carcinoma. The risk of melanoma may also be increased. Because of this and the increasing availability of other modalities of treatment, the use of PUVA is decreasing in many countries.

Systemic treatment

There are now a large number of systemic agents that can be used for psoriasis. These range from the classical agents, such as methotrexate and hydroxyurea, through standard immunosuppressives such as ciclosporin and mycophenolate to the newer 'biological' therapies.

Methotrexate

Methotrexate is highly effective and is given once weekly. Its mechanism of action is primarily on the immune system (p. 1079) rather than having a direct effect on keratinocyte or epidermal hyperproliferation. The main hazards are immunosuppression and bone marrow suppression, particularly due to interactions with other commonly used drugs such as non-steroidal anti-inflammatories (NSAIDs). Long-term use is associated with hepatic fibrosis and cirrhosis. Because of this, regular monitoring of liver function tests and full blood count is required. An alternative is hydroxyurea, but this is less effective and carries an increased risk of bone marrow suppression.

Oral retinoids

Oral retinoids, such as acitretin, are effective in some patients with psoriasis, particularly pustular psoriasis of the palms and soles, but are also widely used to improve plaque psoriasis. Systemic retinoids are potent teratogens. Following use of acitretin, pregnancy is not safe for at least 2 years. Retinoids may cause raised triglycerides and rarely hepatitis, so regular monitoring of lipids and liver function tests is required.

Ciclosporin

Ciclosporin (p. 1080) is an immunosuppressive used in psoriasis and other inflammatory skin disease. Side-effects include hypertension, nephrotoxicity and immunosuppression, leading to opportunistic infection and an increased risk of skin and other cancers in the long term. Ciclosporin is highly effective in inducing and maintaining clearance of individuals with psoriasis, but continuous use is difficult to justify. It may be used over a 3–4-month period to induce clearance or prior to treatment with other systemic agents.

Biological therapies

Recently, a range of new agents, including monoclonal antibodies, fusion proteins and cytokines, have been shown to have striking activity against psoriasis and appear as effective as classical agents. The long-term role of biological therapies in psoriasis is not yet defined; they are currently extremely expensive and long-term toxicity has still to be established. Of these agents, the anti-tumour necrosis factor (TNF) therapies are the best studied. These include etanercept, which is a human recombinant TNF receptor fusion protein, while infliximab is a human-murine anti-TNF- α monoclonal antibody. Both bind TNF, preventing its action, and both seem highly effective in clearing psoriasis. They have to be given either by infusion or by subcutaneous injection, which may cause adverse reactions. Potential side-effects include reactivation of latent tuberculosis and the development of other opportunistic infections.

Pityriasis rosea

This is an acute, benign, self-limiting exanthem that particularly affects adults and occurs world-wide. It usually occurs during the spring and summer, but although this suggests an infective aetiology, no causal agent has been identified and its aetiology is unknown. It is more common in women than men (1.4:1).

Clinical features and management

Pityriasis rosea is characterised by the appearance of a 'herald patch', an oval lesion (1–2 cm) with a central pinkish (salmon-coloured) centre, a darker periphery and a characteristic collarette of scale. It is followed 1–2 weeks later by a widespread symmetrical papulosquamous eruption which is characteristically arranged in a symmetrical 'fir-tree' pattern on the torso. Individual lesions show a collarette of scale. An inverse variant is recognised with flexural involvement. Mucosal involvement is rare. There is a 3% recurrence rate. No treatment is required, although itch may be helped by emollients and mild topical steroids. Post-inflammatory hyperpigmentation can be a problem, particularly in darker skin types.

Secondary syphilis

Syphilis is caused by the spirochaete *Treponema pallidum*, which is transmitted sexually or in utero. There has been a massive increase in its incidence since 2000 due to HIV co-infection and increasing high-risk sexual behaviour. The initial site of infection is identified by a chancre occurring at the site of inoculation up to 3 months later. Between 4 and 10 weeks after inoculation, the rash of secondary syphilis develops, and 40% of untreated cases progress to tertiary syphilis. Secondary syphilis is a widespread eruption which consists of macules, papules

and occasionally pustules. It affects the trunk and proximal limbs, and characteristically involves the palms, soles and face. The lesions are red, changing to a 'gun-metal' grey as they resolve. Systemic symptoms, such as malaise, fever, myalgia, arthralgia and lymphadenopathy, are usual.

Serological diagnosis and current recommendations for treatment are described on pages 418–420.

Pityriasis versicolor

Pityriasis versicolor is a benign superficial skin condition caused by sensitivity to a common skin commensal, *Malassezia furfur*, the generic term for several yeast-like fungi. It occurs with equal incidence in men and women and in different races. It is more common in warmer months and in areas with higher humidity, and tends to be more severe in the immunocompromised. It is characterised by scaly hypo- and hyperpigmented macules predominantly on the upper torso. Treatment is with selenium sulphide or ketoconazole shampoos, and topical or systemic azole antifungal agents. The change in pigmentation can persist for months after treatment.

Pityriasis lichenoides chronica

This is a rare condition that usually presents within the first three decades of life. The aetiology is unclear but the condition is part of a spectrum, all of which remit spontaneously. The more acute variety (pityriasis lichenoides et varioliformis acuta, PLEVA) presents as papules which rapidly evolve with central necrosis, each attack lasting up to 3 months. The more chronic variety presents as a persistent widespread scaly eruption. Characteristically, the lesions are papules, slightly brown in colour and covered with a mica-like scale (like a stuck-on 'cornflake'). The condition fluctuates but can persist for several months or even years. Treatment with UVB is effective at inducing temporary remissions. Topical emollients and steroids, and long-term oral erythromycin can occasionally be helpful.

Tinea corporis (p. 1273)

This fungal infection may cause a scaly rash.

Maculopapular drug eruptions

These are not common but are an important differential diagnosis in the erythematous scaly eruption (p. 1286). They often evolve with exfoliation ('peeling' of the skin) and may leave post-inflammatory hyperpigmentation.

LICHEN PLANUS AND LICHENOID ERUPTIONS

Lichen planus

Lichen planus is a rash characterised by intensely itchy polygonal papules with a violaceous hue involving the skin and, less commonly, the mucosae, hair and nails.

Aetiology and pathology

The cause is unknown but an immune pathogenesis is suspected, as there is an association with some auto-

immune diseases such as myasthenia gravis (p. 1231) and with thymoma and graft-versus-host disease (GVHD) (p. 1014). There is hyperkeratosis, a prominent granular layer, basal cell degeneration and a heavy T-lymphocyte infiltration in the upper dermis. Degenerating basal cells are seen as colloid (apoptotic) bodies. The T cell–basal cell interaction leaves a 'sawtooth' dermo-epidermal junction, suggesting an immune reaction to an unknown epidermal antigen.

Clinical features

Lichen planus tends to start on the distal limbs, most commonly on the volar aspects of the wrists (Fig. 27.18) and on the lower back. Intensely itchy, flat-topped, pink-purple papules appear and some develop a characteristic fine white network on their surface (Wickham's striae). New lesions may appear at the site of trauma (Köbner phenomenon) and the rash may spread rapidly to become generalised. Individual lesions may last for many months, and the eruption as a whole tends to last about 1 year, often leaving marked post-inflammatory pigmentation. Mucous membrane involvement, comprising an asymptomatic fine white lacy network of pinhead-sized white papules, occurs in about two-thirds of patients (see figure, p. 1238). The nails are affected in 10%, with changes ranging from longitudinal grooving to destruction of the nail fold and bed. Variants of the classic picture are rare but often diagnostically challenging, and include annular, atrophic, bullous, follicular, hypertrophic and ulcerative types.

Diagnosis

This is usually clear-cut clinically but a skin biopsy can be helpful. Other erythematous scaly conditions should be considered, including guttate psoriasis, pityriasis rosea, pityriasis lichenoides and drug eruptions.

Management

The condition is usually self-limiting, although rarely, particularly with oral lichen planus, it may persist for more than 10 years. Potent local corticosteroids may help with the intense itch but systemic corticosteroids may be indicated, and ciclosporin, retinoids or phototherapy may be required. Topical corticosteroids applied to the buccal mucosa may also be needed.

Fig. 27.18 Lichen planus. Glistening discrete papules involving the volar aspects of the forearm and wrist. Note the lesions along scratch marks (Köbner phenomenon).

Lichenoid eruptions

Rashes with clinical and histological features of lichen planus can occur in chronic active hepatitis, in hepatitis B and C infections, and with specific drugs, the most common culprits being gold, proton pump inhibitors, sulphonamides, penicillamine, antimalarials, antituberculous drugs and thiazide diuretics. They also occur in people handling colour developers.

Graft-versus-host disease (GVHD)

In the acute stage of GVHD, there is a distinctive dermatitis associated with hepatitis. After about 3 months, chronic GVHD can present with a lichenoid eruption on the palms, soles, face and upper trunk. Progressive sclerodermatous thickening of the skin can lead to contractures and limited mobility.

URTICARIA

The symptoms and signs of urticaria are due largely to mast cell degranulation with release of histamine and a variety of other vasoactive mediators (Fig. 27.19). More than histamine is clearly involved, as although potent histamine blockers frequently improve the itch of urticaria and the number of weals, they do not abolish them. Causes, clinical features and assessment are described on page 1248. There is an autoimmune pathogenesis for the most common form of disease, chronic idiopathic urticaria, which is defined by the presence of urticarial episodes for more than 6 weeks; self-reacting antibodies appear to cause cross-linking of the surface IgE receptor on mast cells with subsequent cellular degranulation.

Investigations

These should be directed at the possible underlying cause, as elicited from the clinical history. Some or all of the following may be appropriate:

- *full blood count*, including eosinophil count in case of underlying parasites
- *erythrocyte sedimentation rate (ESR)*: may be elevated in cases of vasculitis
- *urea and electrolytes, thyroid and liver function tests*: may reveal an underlying systemic disorder
- *total IgE and specific IgE to possible allergens*, e.g. shellfish or peanuts
- *antinuclear factor*: may be positive in chronic urticaria or urticarial vasculitis
- *CH50*: indicates the level of complement activation; C_3 and C_4 levels may reveal complement consumption
- *C_1 esterase inhibitor*: may be quantitatively reduced or more rarely functionally deficient, as in hereditary angioedema
- *skin biopsy*: helpful if urticarial vasculitis is suspected
- *appropriate challenge test*: to confirm physical urticarias.

Frequently no cause can be found for acute episodes, whereas in chronic urticaria an autoimmune pathogenesis will account for the majority of cases.

Management

Non-sedative antihistamines, such as loratadine, fexofenadine or cetirizine, are effective for perhaps one-third of patients with chronic urticaria; one-third show moderate benefit, whilst the remaining third show minimal benefit. If a patient fails to respond to one of these agents after 2 weeks of therapy, then it may be worth changing to another non-sedative antihistamine and adding in an H_2 -blocker such as cimetidine or ranitidine. Other agents have been used, including mast cell stabilisers or protease and leukotriene inhibitors, but efficacy is not clear. Systemic corticosteroids are widely prescribed for urticaria, although there is little evidence of benefit. Patients with a history of life-threatening angioedema or anaphylaxis, as is seen in allergy to peanuts and wasp stings, should carry a self-administered injection kit of adren-

Fig. 27.19 Pathogenesis of urticaria. Mast cell degranulation occurs in a variety of ways. (1) Type I hypersensitivity causing massive degranulation and sometimes anaphylaxis. (2) Spontaneous mast cell degranulation in chronic urticaria. (3) Chemical mast cell degranulation. (4) Autoimmunity, which accounts for 30% of chronic urticaria.

aline (epinephrine). The management of anaphylactic shock and the treatment and prevention of acute attacks of hereditary angioedema are discussed on pages 89–91.

Urticaria may be precipitated by aspirin or NSAIDs. If there is a clear history of these agents precipitating attacks, they should be avoided, and even in the absence of a clear history it may be advisable to suggest alternatives such as paracetamol. Codeine and opioids can also induce urticaria.

ACNE AND ROSACEA

Acne vulgaris

Acne is almost ubiquitous in the teenage years, individual differences relating to severity and the extent of scarring. Peak severity is in the late teenage years but acne may persist into the third decade and beyond, particularly in females.

Aetiology

The pathogenic factors in acne are shown in Figure 27.20. There is a clear relation between severity of acne and sebum excretion rate, but while increased sebum excretion is necessary for the development of acne, it is not sufficient to cause it alone. The main determinants of sebum excretion are hormonal, accounting for the onset in the teenage years. Androgens are the principal sebotropic hormones, but progestogens also increase sebum excretion, whilst oestrogens reduce it. However, the vast majority of patients with acne have a normal endocrine profile. There is some evidence for a familial component for sebum excretion, but the genetics of acne have been little studied.

In addition to the increased sebum secretion rate, *Propionibacterium acnes* colonises the pilosebaceous ducts and acts on lipids to produce pro-inflammatory factors, and the pilosebaceous unit becomes occluded.

Clinical features

Lesions are usually limited to the face, shoulders, upper chest and back, but may extend to the buttocks. Seborrhoea (greasy skin) is often obvious. Open comedones (blackheads) due to plugging by keratin and sebum of the pilosebaceous orifice, or closed comedones (whiteheads) due to accretions of sebum and keratin deeper in the pilosebaceous ducts, are usually

Fig. 27.20 Pathogenesis of acne.

evident. It is thought that the combination of keratin breakdown products and bacterial products gives rise to the black colour seen in blackheads. Inflammatory papules, nodules and 'cysts' occur (Fig. 27.21), with one or two types of lesion predominating. Scarring may follow.

A number of descriptive terms are applied to clinical variants of acne.

- *Conglobate acne* is characterised by comedones, nodules, abscesses and sinus tracks, often accompanied by keloidal scarring, although true cysts are rare in the acute phases and are more likely to reflect inflamed nodules. Epidermoid cysts are common later on in acne.
- *Acne fulminans* is severe acne accompanied by fever, joint pains and markers of systemic inflammation such as a raised ESR.
- *Acne excoriée* refers to the effects of scratching or picking, principally on the face of teenage girls with acne.

A mild form of acne dominated by the presence of comedones may be due to exogenous substances such as tars, chlorinated hydrocarbons or oily cosmetics. A primarily pustular rash may also be seen in those being treated with corticosteroids, lithium, oral contraceptives

Fig. 27.21 Unpleasant cystic acne in a teenager. [A] Before treatment. [B] After prolonged systemic antibiotic treatment.

and anticonvulsants, but these forms are usually clinically distinct from the usual variety developing in adolescence.

Individuals with moderate or even severe acne very rarely have any other systemic disorder. However, those with polycystic ovary syndrome (p. 760) are more likely to have severe acne, and menstrual irregularities require investigation. If there is associated cutaneous virilism or other features of an androgen-secreting tumour, further endocrine investigation and assessment are warranted.

Investigations

Investigations are rarely required. It is important to enquire about the details of previous treatments and their duration; for example, antibiotics are commonly prescribed for too short a period of time or without the appropriate advice that most tetracyclines need to be taken separately from dairy products. It is also important to establish the patient's expectations.

Management

Mild disease

In individuals with fairly minor disease, particularly dominated by the presence of comedones, topical agents such as benzoyl peroxide or tretinoin should be used. Both may be irritant, which may be important in their therapeutic effect (sunshine or UVB may also be useful therapeutically in some instances for similar reasons). They are initially applied for short intervals of time and the strength and duration gradually increased. Although a number of other topical remedies, including washes, soaps and antiseptics, are recommended, there is little evidence of effectiveness.

Patients with anything but minor degrees of acne require antibiotic therapy, either systemic or local. Topical antibiotics (clindamycin or erythromycin) are used more widely than previously and should be considered prior to systemic antibiotics or in relatively minor disease, and in combination with other topical agents. The principal oral antibiotic is oxytetracycline, taken on an empty stomach without food, in a dose of up to 1.5 g a day if tolerated. Oxytetracycline has a good safety profile, even with long-term use. Minocycline is no longer a first-choice drug, although it may be used if other antibiotics fail, because it is associated with autoimmune hepatitis and requires frequent monitoring.

If an individual has been treated continuously for up to 3 months with little response, the regime should be changed to erythromycin (up to 1 g per day in divided doses). In women, oestrogen-containing oral contraceptives can be a useful adjunct, as they are associated with a small reduction in sebum secretion. Alternatively, oral contraception in the form of a combined oestrogen and anti-androgen (such as cyproterone acetate) may be used. If these topical and systemic agents fail to produce an adequate clinical response within 3–6 months, the patient should be referred for consideration for treatment with isotretinoin (13 cis-retinoic acid).

Moderate–severe disease

Isotretinoin has revolutionised the treatment of severe or moderate acne unresponsive to other therapy. When used at a dose of 0.5–1 mg/kg, it inhibits sebum excretion by > 90% over 4 months. Although sebum excretion

gradually returns to normal over the course of the year after the drug is stopped, the clinical benefit lasts much longer. Many patients will not require any further treatment, but in a significant minority a second or third course of isotretinoin may be required. Sometimes low-dose continuous isotretinoin is used for up to 1 year, in selected patients who have previously been treated with high-dose isotretinoin.

Side-effects, especially drying of the skin and mucous membranes, are common but well tolerated and relate to the drug's effects on the function of modified sebaceous glands on the lips, and on lipid biosynthesis in the interfollicular epidermis. Rarely, abnormalities of liver function occur and limit treatment. Isotretinoin may increase serum triglycerides; levels should be checked before therapy and monitored during it. Depression and suicide have been reported, although it is difficult to disentangle the role of the drug from that of the underlying disease and age groups at risk; it is currently under investigation, but a brief psychiatric history and screening for depressive symptoms should be recorded before prescribing it. Like all systemic retinoids, isotretinoin is highly teratogenic; females must have a negative pregnancy test before treatment and must be checked regularly and following cessation of therapy.

Physical measures

Inflamed nodules can be incised and drained under local anaesthetic, and 'cysts' excised. Intralesional injections of triamcinolone acetonide (0.1–0.2 mL of a 10 mg/mL solution) hasten the resolution of stubborn inflamed nodules. Scarring following acne is uncommon if patients receive adequate care. Small deep acne scars can be excised and other forms of more extensive but shallower scars can be treated by carbon dioxide laser.

Rosacea

Rosacea is a persistent facial eruption of unknown cause. Sebum secretion is normal.

Clinical features and diagnosis

The disorder is most common in middle age. The cheeks, chin and central forehead are affected (Fig. 27.22). Intermittent blushing is followed by fixed erythema and telangiectasia. Dome-shaped papules and pustules, but no comedones, occur. Rhinophyma, with erythema, sebaceous gland hyperplasia and overgrowth of the soft tissues of the nose, is sometimes associated. Blepharitis and conjunctivitis are complications. The diagnosis is often obvious on clinical grounds but must be distinguished from acne, seborrheic eczema, photosensitivity and systemic lupus erythematosus (SLE).

Management

The pustular component of rosacea normally responds well to oral oxytetracycline. Once the disease is controlled (usually within a few months), the dose can be reduced but some patients may need to stay on antibiotics long-term or require repeated courses. Topical metronidazole also shows some efficacy in rosacea, but may cause irritation (Box 27.29). Unfortunately, the erythema and telangiectasia do not respond to antibiotic therapy but vascular laser therapy may be helpful, depending on the extent of the disease.

Fig. 27.22 Rosacea. The colour is distinctive and the typical papulopustular rash involves the cheeks, centre of forehead and chin.

EBM 27.29 Rosacea

'Topical metronidazole and azelaic acid are effective treatments, but the former is more cost-effective.'

- Thomas K, et al. J Dermatol Treat 2008; 21:1–4.

COMMON SKIN INFECTIONS AND INFESTATIONS

Bacterial infections

Impetigo

Impetigo is a common superficial purulent infection of skin caused by either *Streptococcus* or *Staphylococcus*. Two forms exist: non-bullous (Fig. 27.23) and bullous impetigo. Non-bullous impetigo can be caused by either *Staphylococcus aureus* or *Streptococcus* or a combination, and it is not completely clear which is more important. In warmer climates *Streptococcus* is more likely to be the primary organism, but in temperate climates *Staphylococcus* predominates. It affects all age groups but particularly young children, often in late summer. It is contagious and found most commonly in situations of overcrowding and communal living. Other skin diseases, such as eczema and infestations, predispose to it.

The initial lesion is a thin-walled vesicle which rapidly ruptures, with the formation of golden crust on an erythematous base. The sites usually affected are the face and the limbs. Lesions may be single but often become multiple and coalesce. A bacterial swab should be taken prior to starting treatment to determine the culprit organism.

Fig. 27.23 Non-bullous impetigo.

Treatment is usually with a topical preparation such as mupirocin, which is active against both organisms, or fusidic acid. This limits the spread of infection and, together with washing with soap and water, helps the removal of the infected crusts. In severe or extensive cases, an oral antibiotic such as flucloxacillin or erythromycin is indicated. Glomerulonephritis can follow infection with a nephritogenic *Streptococcus* (p. 501). Advice should be given on measures to minimise cross-infection.

Bullous impetigo is primarily caused by *Staphylococcus* and most frequently occurs in children. Bullae (often quite large) are caused by a staphylococcal epidermolytic toxin, and develop and last for 2–3 days, initially clear and then becoming cloudy. Once the blisters have burst, crusts develop and management is the same as for the non-bullous form of the disease.

Erythrasma

Erythrasma is a mild localised infection of the skin with *Corynebacterium minutissimum*, often part of the normal skin flora. It can cause an asymptomatic or mildly itchy eruption between the toes and in the flexures. The lesions tend to be well defined and reddish-brown in colour, with some scale. *C. minutissimum* is identified by coral pink fluorescence with Wood's light. Treatment is with a topical azole cream such as miconazole or a topical antibiotic. Oral erythromycin can be used in cases that fail to respond.

Ecthyma

Ecthyma is a purulent skin infection caused by either *Staphylococcus* or *Streptococcus*, and characterised by ulceration under an exudative crust. It is associated with poor hygiene and malnutrition, and minor trauma can predispose to development of the lesions. It affects any age group and is commonly seen in drug misusers.

Folliculitis, furuncles and carbuncles

Folliculitis can be superficial, involving just the ostium of the hair follicle (folliculitis), or deep (furuncles and carbuncles).

Superficial folliculitis

This extremely common condition can be subacute or chronic. It is often infective, caused by *Staph. aureus*, but can also be caused by physical (e.g. traumatic epilation) or chemical (e.g. mineral oil) injury, in which case the folliculitis is usually sterile. Staphylococcal folliculitis is most common in children and often occurs on the scalp or limbs (Fig. 27.24). The pustules usually heal in 7–10 days but can become more chronic, and in older children and adults can progress to a deeper form of folliculitis.

Deep folliculitis (furuncles and carbuncles)

A furuncle (or boil) occurs most commonly in adolescence and early adult life. Epidemics can occur with a particular staphylococcal strain but infection is more usually sporadic. Males are more commonly affected than females. Any body site can be involved but often it is the neck, buttocks and anogenital area. Predisposing factors include tight clothing, such as neckties. The affected individual may carry the culprit strain of *Staph. aureus* in the nares or perineum. The lesions start as an inflammatory nodule, which becomes pustular and fluctuant and is often very tender. There may be associated constitutional disturbance. The lesions eventually rupture to discharge pus and, because they are deep, leave a scar. They can progress to form a carbuncle, which implies the involvement of several contiguous hair follicles (Fig. 27.25). This usually occurs in middle-aged men, and conditions such as diabetes or immunosuppressive therapy predispose to it. A carbuncle is an exquisitely tender nodule, often on the neck, shoulders or hips, and associated with severe constitutional symptoms. The nodules can be up to 10 cm in size and discharge after several days. Treatment, as for furuncles, is with

Fig. 27.24 Pustular folliculitis.

Fig. 27.25 Staphylococcal carbuncle.

an antistaphylococcal antibiotic, e.g. flucloxacillin, and occasionally incision and drainage.

Staphylococcal scalded skin syndrome (SSSS)

SSSS (Fig. 27.26) is a potentially serious exfoliating cutaneous disease that occurs predominantly in children, particularly neonates. It is caused by blood-borne exfoliative toxins from a focus of infection with *Staph. aureus*, which specifically cleave desmoglein-1 (see Fig. 27.2, p. 1241). The focus of infection may be the umbilicus or urinary tract, or it may stem from colonisation of the nasopharynx. The child presents with fever, irritability, skin tenderness and, in severe cases, erythema, starting in the groin, axilla and around the mouth. Blisters and superficial erosions develop within 24–28 hours, and can rapidly involve large areas of the skin with severe systemic upset. Bacterial swabs should be taken from obvious primary sites of infection, the nose and throat. A skin snip should be taken for rapid histological examination. This is a sample of the superficial peeling skin removed by 'snipping with scissors'. No local anaesthetic is required. It shows a split beneath the stratum corneum, and differentiates it from toxic epidermal necrolysis in which the whole epidermis is affected. Systemic antibiotics (e.g. flucloxacillin) and intensive supportive measures should be commenced at once. Bacterial swabs from nostrils, axilla and groin should be taken from the patient's relatives to exclude staphylococcal carriage.

Cellulitis and erysipelas

Cellulitis (Fig. 27.27) is inflammation, usually infective, of subcutaneous tissue. Erysipelas (Fig. 27.28) is a more superficial involvement of the subcutaneous tissue and lower dermis, but the distinction between the two

Fig. 27.26 Staphylococcal scalded skin syndrome (SSSS).
A Erythema and superficial peeling of the skin. **B** The condition was rapidly diagnosed by examination of a frozen section of skin snip.

conditions can be difficult. The most common organism causing both these conditions is group A *Streptococcus*. Isolating and identifying the organism is difficult but the presence of fever and a raised white cell count usually allow a firm diagnosis. There is often a predisposing portal of entry for infection, e.g. tinea pedis, or underlying predisposition to infection such as varicose leg ulcer or diabetes. Erythema, heat, swelling and pain are constant clinical features. Erysipelas has a characteristic raised erythematous edge, indicating involvement of the dermis. It usually affects the face or the legs, while cellulitis most commonly involves the legs. Blistering occurs in both conditions. Treatment is with an antistreptococcal agent such as phenoxymethylpenicillin, or in cases of penicillin sensitivity, erythromycin or ciprofloxacin. In severe cases, intravenous antibiotics are indicated.

Necrotising soft tissue infections and anthrax

Necrotising soft tissue infections are discussed on pages 300–302 and anthrax on page 341.

Fig. 27.27 Acute cellulitis of the leg. Note that the margin has been marked to assess progression.

Fig. 27.28 Erysipelas. Note the blistering and crusted rash with raised erythematous edge.

Viral infections

Herpes virus infections

There are eight members of the human herpesvirus group and their cutaneous manifestations are described on pages 321–322.

Papillomaviruses and viral warts

Viral warts are extremely common and are due to infection with the DNA human papillomavirus (HPV), of which there are over 90 subtypes on the basis of DNA sequence analysis. Different subtypes appear to be responsible for different clinical wart variants. Genital warts occur most commonly during the sexually active years (p. 423).

Transmission is by direct contact with the virus, in either living skin or fragments of shed skin, and is encouraged by trauma and moisture (e.g. in swimming pools, fishmongers etc.). Genital warts are spread by sexual activity, and show a clear relationship with cervical and intra-epithelial cancers of the genital area. HPV 16 and 18 appear to inactivate tumour suppressor gene pathways and lead to squamous cell carcinoma of the cervix or intra-epithelial carcinoma of the genital skin. Vaccinations are now available against HPV 16 and 18 (e.g. Gardasil) and are recommended for adolescent females before they become sexually active. In contrast, the relation between HPV of the skin and subsequent skin cancer is unclear. Individuals who are systemically immunosuppressed, e.g. after organ transplantation, show greatly elevated risks of skin cancer and a much higher prevalence of infection with HPV, but it is not certain that HPV is causally involved in the development of neoplasia.

Clinical features

Common warts appear initially as smooth, skin-coloured papules. As they enlarge, their surface becomes irregular and hyperkeratotic, producing the typical warty appearance. They are most common on the hands (Fig. 27.29) but may also be seen on the face, genitalia and sun-exposed surfaces of the arm and leg. Multiple warts are common. Plantar warts (verrucae) are characterised by a rough surface protruding only slightly from the skin and are surrounded by a horny collar; they may be painful and disabling. On paring, the presence of capillary loops distinguishes these plantar warts from corns.

Other varieties of wart include:

- *mosaic warts*, mosaic-like plaques of tightly packed individual warts (Fig. 27.30)
- *plane warts*, smooth, flat-top papules seen most commonly on the face and backs of hands which frequently may hyperpigment and consequently be misdiagnosed
- *facial warts*, often filiform
- *genital warts*, which may be papillomatous and protuberant.

Fig. 27.29 Viral wart on finger.

Fig. 27.30 Mosaic plantar wart. A plaque of closely grouped warts on the sole of the foot.

Management

The vast majority of viral warts will resolve spontaneously. However, this may take several years and there is often considerable pressure for treatment from the patient. The majority of treatments are based on destruction of keratinocytes, irrespective of whether they are HPV-infected or not.

Treating warts that are asymptomatic or not causing distress should be avoided. Initial treatment is with salicylic acid or salicylic and lactic acid combinations, together with frequent and regular paring of the hyperkeratotic skin. This needs to continue for several months before convincing effects will be apparent. If this fails, or as an alternative, warts can be treated by cryotherapy using liquid nitrogen. At some sites and in particular individuals, this is accompanied by significant pain, but needs to be repeated at intervals of 2–4 weeks, although the optimum strategy is not defined. Over-aggressive treatment with cryotherapy, particularly on the hands, can lead to significant complications, including tendon rupture. Warts close to or under the nails can be a particular problem. Liquid nitrogen treatment may exacerbate them due to inflammatory swelling, and skilled cutting of the nail and electrodesiccation or another destructive therapy may be necessary.

Viral warts can be a particular problem in individuals who are immunosuppressed following organ transplantation. The prevalence of warts in this group approaches 100% after 5 years and therapy appears less effective than in immunocompetent individuals. Not only are the warts particularly unsightly, but painful verrucae can also limit mobility and require intensive treatment.

Beyond the therapies described above, a number of other treatments have been claimed to be effective; these include systemic retinoids, intralesional injections of bleomycin or interferon, and the application

of contact sensitisers such as diphencyprone or dinitrochlorobenzene to the warts. The topical immunomodulator, imiquimod, is useful in treating stubborn anogenital warts.

Molluscum contagiosum

Molluscum contagiosum is a common cutaneous infection with a poxvirus. It can affect any age group but usually targets children over the age of 1 year. The prevalence is also high in individuals who are immunosuppressed. The classic lesion is a dome-shaped, 'umbilicated', skin-coloured papule with a central punctum (p. 384). The lesions tend to be multiple and are often found in sites of apposition such as the side of the chest and the inner arm; they resolve spontaneously but can take several months to do so. Prior to resolution, they often become inflamed and may leave small, discrete, depressed scars. A wide range of treatments has been tried but none is very effective and they can be painful; no treatment is an acceptable option. Individual lesions can be removed by curettage under local anaesthetic but the lesions are commonly multiple. Gentle squeezing with forceps after bathing can stimulate regression. Topically applied chemicals such as salicylic acid (topical 5% acidified nitrite co-applied with 5% salicylic acid), podophyllin (topical 0.5% podophyllotoxin) and trichloroacetic acid cause marked inflammation and results vary. Cryotherapy can be tried but is not as effective as gentle squeezing. Physical occlusion with duct tape is advocated by some groups. Topical 5% imiquimod cream has recently been shown to be effective.

Orf

Orf is an occupational hazard for those who work with sheep and goats, which transmit a parapoxvirus. Inoculation of the virus, usually into the skin of a finger, causes significant inflammation and necrosis which usually resolve within 2–6 weeks. No specific treatment is available, unless there is evidence of secondary infection. Erythema multiforme (p. 1284) can be provoked by orf infection.

Erythrovirus

This is described on page 311.

Fungal infections

Dermatophytes are fungi capable of causing superficial skin infections known as ringworm or dermatophytosis. The causative fungi belong to three genera (*Microsporum*, *Trichophyton* and *Epidermophyton*). They can originate from the soil (geophilic) or animals (zoophilic), or be confined to human skin (anthropophilic).

Clinical forms of cutaneous infection include tinea corporis (involvement of the body), tinea capitis (scalp involvement, p. 1288), tinea cruris (groin involvement), tinea pedis (involvement of the feet) and onychomycosis (nail involvement, p. 1291).

Tinea corporis

The clinical features of tinea corporis are variable, so the disease should be considered in the differential diagnosis of any red scaly rash. Classically, the lesions are

Fig. 27.31 Tinea corporis in a dark-skinned patient.

erythematous, annular and scaly, with a well-defined edge and often central clearing. They may be single or multiple, and are usually asymmetrical (Fig. 27.31). The degree of associated inflammation depends on the causative fungus and host immunity. *Microsporum canis* (from dogs) and *Trichophyton verrucosum* (from cats) are common culprits. Inadvertent topical corticosteroid application leads to disguising and worsening of the signs (tinea incognito).

Tinea cruris

This common world-wide ringworm affects the groin and is usually caused by *Trichophyton rubrum*. Itchy erythematous plaques extend from the groin flexures on to the thighs.

Tinea pedis (athlete's foot)

This is the most common form of ringworm in the UK and USA; it is usually caused by anthropophilic fungi, such as *Trichophyton rubrum*, *T. mentagrophytes* and *Epidermophyton floccosum*. Clinical features are an itchy rash between the toes, with peeling, fissuring and maceration. Involvement of one sole or palm (in the case of tinea manuum) with a fine scaling is characteristic of *T. rubrum* infection. Vesiculation or frank blistering is more commonly seen with *T. mentagrophytes*.

Diagnosis and management

In all cases of suspected dermatophyte infection, the diagnosis should be confirmed by skin scraping or nail clippings (p. 1243). Treatment can be topical with terbinafine or miconazole cream, or systemic with terbinafine, griseofulvin or itraconazole.

Scabies

Scabies is caused by the Acarus, *Sarcoptes scabiei*, with an estimated global prevalence of 300 million. The infestation causes considerable discomfort and can lead to secondary infection. Scabies spreads in households and environments where there is intimate personal contact. Diagnosis is made by identifying the scabietic burrow (p. 1246 and Fig 27.32) and by extracting the mite using a blunt needle. Inappropriate application of scabietic treatments can cause considerable irritation in other conditions. In small children the palms and soles can be involved with pustule formation (Fig. 27.33).

Fig. 27.32 Scabietic burrow.

Fig. 27.33 Scabies. Pustules at a common site in a child. Burrows were present but cannot be seen at this distance.

Involvement of the genital area in boys is pathognomonic. The main symptom is itch. The clinical features include secondary eczematization elsewhere on the body; the face and scalp are never involved, except in the case of infants. Even after successful treatment, the itch can continue and occasionally nodular lesions persist.

Topical treatment of scabies is required for the affected individual and all asymptomatic family members/physical contacts to ensure eradication. Two applications 1 week apart of an aqueous solution of either permethrin or malathion to the whole body, excluding the head, are usually successful. If there is poor compliance, immunocompromise or heavy infestations (Norwegian scabies), systemic treatment with ivermectin ($200\mu\text{g}/\text{kg}$) as a single dose is appropriate.

Lice

Head lice

Infestation with head louse, *Pediculus humanus capitis*, is common; it is highly contagious, spread by direct head-to-head contact. Itching of the scalp leads to scratching which causes secondary infection and cervical lymphadenopathy. The diagnosis is confirmed by identifying the living louse or nymph on the scalp or on a black sheet of paper after careful fine-toothed combing of wet hair that has had conditioner applied. The empty egg cases ('nits') are easily seen along the hair shaft (Fig. 27.34) and are characteristically difficult to dislodge.

Fig. 27.34 Head lice. 'Nits' (empty egg cases) adhere strongly to the hair shafts.

Treatment is recommended for the infected individual and any infected household/school contacts. Eradication in school populations has proved difficult because of poor compliance and resistance to certain treatments. The standard treatments are malathion, permethrin and carbaryl in a lotion or aqueous formulation, which are applied on two separate occasions at 7–10 days' interval. Many advise rotational treatments within a community to avoid resistance. Regular 'wet-combing' (physical removal of the live lice by regular combing of slippery, conditioned wet hair) seems less effective than pharmacological treatments. Involvement of the eyebrows/eyelashes is treated by topical Vaseline 12-hourly for at least a fortnight.

Body lice

These are similar to head lice but live on clothing, particularly in seams, and feed on the skin. They are found on individuals with poor hygiene and in overcrowded conditions. Itch is the principal symptom. The skin is excoriated and secondary infection is common. It is managed by dry cleaning and high-temperature washing or insecticide treatment of clothes.

Pubic (crab) lice

These are usually sexually acquired and cause pruritus. An aqueous-based treatment of either malathion or carbaryl is the treatment of choice, applied on two occasions to the whole body, as body hair can also be infested. Contacts should also be treated.

BULLOUS DISORDERS

Blistering disorders usually present acutely to the general physician and dermatologist. Better understanding of the mechanisms of adhesion within the skin (pp. 1240–1242) has revealed the pathogenesis of many blistering disorders. In pemphigus, an autoantibody acts on the adhesion protein, desmoglein-1, while in SSSS this is due to a staphylococcal protease directly cleaving desmoglein-1. Blisters can arise at any level within the skin, and the underlying defect and level of blistering accounts for the different clinical presentations (p. 1249). Primary blistering disorders are described here.

Toxic epidermal necrolysis (TEN)

TEN is a life-threatening mucocutaneous blistering eruption that is generally drug-induced, most commonly by anticonvulsants, sulphonyl drugs (e.g. sulphonamides, sulphonylureas), NSAIDs, allopurinol and antiretroviral therapy. Keratinocyte apoptosis is triggered via the Fas receptor. TEN occurs world-wide and has a high mortality rate. Clinically, 1–3 weeks after drug ingestion, the patient develops a systemic illness with pyrexia, erythema and blisters arising centrally and progressing rapidly to involve all the skin. The blisters coalesce and denude, and the underlying skin is erythematous and extremely tender (Fig. 27.35). Mucous membrane involvement is common, with erythema, oedema, blistering and haemorrhage. A standard disease severity score (Box 27.30) is used in assessing prognosis. The main differential diagnosis of this severe blistering disorder is SSSS and early diagnosis is made rapidly by skin snip (p. 1270) or skin biopsy. Initial management includes discontinuation of the possible causative agent and transfer to an intensive care or burns unit. Treatment is primarily supportive, with regular sterile dressings and care-

Fig. 27.35 Toxic epidermolytic necrolysis in an adult. Peeling of the skin involving the whole epidermis is usually secondary to a drug reaction.

27.30 Disease severity score for toxic epidermal necrolysis (TEN): SCORTEN

Factor

- Age > 40 years
- Heart rate >120 beats per minute
- Cancer or haematological malignancy
- Involved body surface area > 10%
- Blood urea > 10 mmol/L (28 mg/dL)
- Serum bicarbonate < 20 mmol/L (20 mEq/L)
- Blood glucose ≥ 14 mmol/L (252 mg/dL)

Mortality rates

- 0–1 factor present = 3%
- 2 factors = 12%
- 3 factors = 35%
- 4 factors = 58%
- ≥ 5 factors = 90%

Bastuji-Garin S, et al. *J Invest Dermatol* 2000; 115:149–153.

ful monitoring for infection and of other organ systems, including for eye involvement. Studies support the use of intravenous immunoglobulins. The use of intravenous steroids is contraindicated, as they are associated with a higher mortality rate.

Immunobullous diseases

In the immunobullous disorders (Box 27.31), the diagnosis is made by taking a skin biopsy from the edge of a fresh blister. This is divided and half is immersed in 10% formalin for histology; the remainder is snap-frozen for direct immunofluorescence studies.

Bullous pemphigoid (BP)

BP is a chronic autoimmune bullous disorder that occurs world-wide and is the most common subepidermal blistering disorder in Europe. The average age of onset is 65 years and the disease affects men and women equally. Autoantibodies BP 230 and BP 180 are directed against the hemidesmosomal BP antigens, BP Ag-1 (intracellular) and BPAg-2 (transmembranous type XVII collagen), respectively. The autoantibodies bind to these, activating complement and inflammatory mediators which damage hemidesmosomes, leading to blistering. There may also be other antibodies to alternative target antigens.

Clinical features and diagnosis

Individuals present with widespread itchy, often urticated skin lesions and tense bullae (see Fig. 27.5, p. 1249). Mucosal involvement affects only 10–25%. Histology shows subepidermal blistering with an inflammatory infiltrate and a predominance of eosinophils. Direct immunofluorescence shows the presence of IgG and C3 at the basement membrane (Fig. 27.36). Differentiating this from epidermolysis bullosa acquisita (see below) requires indirect immunofluorescence studies using the patient's serum on salt split skin. In BP, the immunoreactants localise to the epidermal side (hemidesmosome) of the split skin, whereas in epidermolysis bullosa acquisita they localise to the base of the split (type VII collagen/anchoring fibrils).

Fig. 27.36 Bullous pemphigoid. Direct immunofluorescence on salt-split skin.

27.31 Clinical and investigation findings in immunobullous disorders

Disease	Site of blisters	Nature of blisters	Mucous membrane involvement	Antigen	Circulating antibody (indirect IF)	Fixed antibody (direct IF)
Pemphigus vulgaris	Torso, head	Flaccid and fragile, many erosions	100%	Desmoglein-1 and 3 (120 kD)	IgG	IgG, C ₃ intercellular (epidermal)
Bullous pemphigoid	Trunk (especially flexures) and limbs	Tense	Occasional	BP-230 and 180	IgG (70%)	IgG, C ₃ at BMZ
Dermatitis herpetiformis	Elbows, lower back, buttocks	Excoriated and often not present	No	Unknown	None	Granular IgA in papillary dermis
Linear IgA disease	Widespread	Tense, often annular configuration, 'string of beads'	Frequent	Unknown	50% have low titres of circulating antibody	Linear IgA at BMZ
Pemphigoid gestationis	Periumbilical and limbs	Tense	Rare	Collagen XVII (part of hemi-desmosome BP-180)	Circulating antibody to BPAG2 (type XVII collagen)	C ₃ at BMZ
Epidermolysis bullosa acquisita	Widespread	Tense, scarring	Common (50%)	Type VII collagen	IgG (anti-type VII collagen)	IgG at BMZ
Bullous lupus erythematosus	Widespread	Tense	Rare	Type VII collagen	Anti-type VII collagen	IgG, IgA, IgM at BMZ

(BMZ = basement membrane zone; IF = immunofluorescence)

Management

BP can be managed with very potent topical steroids in frail elderly patients, but in most patients a high-dose systemic corticosteroid or azathioprine is required. With appropriate management, the disease tends to remit within about 5 years.

Pemphigus

Pemphigus is an uncommon autoimmune disorder that can present with mucosal symptoms only, usually in the mouth. It is usually due to IgG1 and IgG4 autoantibodies, directed against desmogleins-1 and 3 and causing intra-epidermal blistering, but it can also be drug-induced (e.g. by penicillamine or captopril) and is rarely associated with an underlying malignancy ('paraneoplastic pemphigus'). In pemphigus foliaceus, a very superficial form, the autoantibodies are directed solely against desmoglein-1, therefore affecting only the most superficial epidermis.

Clinical features and diagnosis

Flaccid blisters occur on the skin, usually on the upper trunk and back. As the blisters are superficial, they are fragile and may look like erosions. The Nikolsky sign is positive. Mucosal involvement can be severe, increasing the morbidity and risk of mortality. Pemphigus can be associated with other autoimmune disorders and full assessment for these is mandatory. In the acute situation, histology from a Tzanck smear (taken from the base of the blister with a scalpel) reveals acantholysis, i.e. separation of the epidermal cells. Disease activity can be monitored by measuring the level of circulating autoantibody in serum by indirect immunofluorescence. Investigations should also include full blood count, ESR, urea and electrolytes, liver function tests, chest X-ray and other imaging, particularly if paraneoplastic pemphigus is suspected.

Management

Systemic treatment with high-dose oral steroids is required, but the disease is more difficult to control than BP and life-long treatment is generally required. Azathioprine and cyclophosphamide are alternatives. Intravenous IgG may be used to gain rapid control in severe cases.

Dermatitis herpetiformis (DH)

DH is an autoimmune blistering disorder associated with coeliac disease. Up to 20% of individuals with coeliac disease have DH. The pathogenesis is unclear.

It presents as an extremely pruritic eruption, usually on the extensor surfaces of the arms, knees and buttocks, but other sites including the face are often involved. Vesicles are occasionally seen but usually it is just excoriations that are apparent, as the disorder is so itchy.

Histology reveals neutrophils and eosinophils in the dermal papillae, which form pustules and vesicles. Granular IgA is found in the papillary dermis. Up to 90% of individuals with DH have coeliac disease (p. 879) and so antiendomysial antibodies and tissue transglutaminase should be checked, and jejunal biopsy should be performed if indicated. Treatment is with a gluten-free diet and dapsone.

Linear IgA disease

This self-limiting autoimmune blistering disorder occurs in both children (chronic bullous disease of childhood) and adults. Several drugs have been implicated in its pathogenesis, notably vancomycin.

Mucosal involvement is common and regular ophthalmic assessment is important in the prevention of long-term scarring. Blisters occur on normal-looking, erythematous and urticated skin and have been described as 'clusters of jewels' (herpetiform) and 'string of beads' (annular/polycyclic). Direct immunofluorescence shows linear IgA at the basement membrane, which localises to either the roof or the floor of salt-split skin.

Treatment is with dapsone, sulphapyridine, prednisolone, colchicine or intravenous immunoglobulin. Most cases remit within a few years.

Epidermolysis bullosa acquisita

This condition is known as the great mimicker because its varied clinical presentation can simulate other autoimmune blistering diseases. It is a chronic blistering disease of the skin and mucous membranes and can be associated with inflammatory bowel disease, rheumatoid arthritis, multiple myeloma and lymphoma. It is due to an IgG autoantibody to type VII collagen and blisters often occur following trauma, with milia formation. Histologically, there is a subepidermal blister with a mixed inflammatory infiltrate in the dermis. The disease can be resistant to treatment with immunosuppressives.

Porphyria cutanea tarda and pseudoporphyria may also cause blistering (p. 1284).

SKIN TUMOURS

The diagnosis and management of skin cancer and lesions that may be confused with skin cancer form a major part of dermatological practice. A number of lesions which are not strictly tumours, but which present clinically as solitary lesions that can be confused with malignant tumours, are included in this section.

Pathogenesis of skin malignancy

In most Caucasian populations, skin cancer is the most common human malignancy. It can be categorised as melanoma and non-melanoma skin cancer (i.e. basal cell carcinomas and squamous cell carcinomas). Melanomas are less common than the non-melanoma skin cancers, but their biological behaviour is more aggressive and they have a higher case fatality rate. Non-melanoma skin cancer is much more common, but can usually be cured.

Ultraviolet radiation is the dominant cause of nearly all forms of skin cancer. The evidence for this is as follows:

- Many skin cancers, such as squamous cell carcinomas and pre-malignant conditions such as actinic keratoses, are most common on sites that receive the most exposure to UVR; for example, squamous cell carcinoma is most common on the heads of bald-headed individuals, on the tops of the ears and on the backs of the hands.
- Individuals who have pale skin, which contains less melanin, are at greatest risk of skin cancer. Melanin is a highly effective sunblock protecting normal skin from the mutagenic load of UVR.
- Skin cancer is most common in those areas which have the greatest ambient UVR (if other factors such as skin colour are kept constant). Dramatically increased tumour rates are seen in those with pale skin who have migrated from areas of relatively low to relatively high UVR exposure.
- There is a grossly elevated risk of skin cancer in patients with xeroderma pigmentosa, a rare autosomal recessive genodermatosis characterised by an inability to repair UVR-induced DNA damage. Affected individuals present in early childhood with

EBM 27.32 Sunscreens and skin cancer

'In a high ambient UVR environment, sunblocks reduce the incidence of actinic keratoses, squamous cell carcinomas and melanocytic naevi in children.'

• Gallagher RP, et al. JAMA 2000; 283:2955–2960.

marked photosensitivity and subsequently develop a range of skin tumours, including squamous cell carcinomas and melanomas.

Although UVR is the major environmental determinant of skin cancer, the various tumour types show different body distribution. While squamous cell carcinomas and actinic keratoses occur at the sites of highest cumulative UVR exposure, basal cell carcinomas tend to be disproportionately common on the face, perhaps reflecting their appendageal origins, and melanoma is relatively more common on areas of skin that may have received intermittent sun exposure, which has led to the suggestion that this or episodes of burning may be important for its pathogenesis.

Whereas squamous cell carcinomas seem to relate to cumulative UVR exposure, there is some evidence that continuous low-grade exposure of the skin, or the maintenance of a tan year-round, is associated with lower melanoma rates. The increase in melanoma incidence with ambient UVR exposure is not as steep as that seen for squamous cell carcinoma. However, it remains agreed that minimisation of UV exposure should reduce skin cancer, at least at the population level (Box 27.32).

Non-UVR causes of skin cancer

Patients on long-term immunosuppression following organ transplantation (especially kidney and heart) are at dramatically increased risk of non-melanoma skin cancer. Any increased risk of melanoma would appear to be marginal. Patients who have received frequent PUVA treatment for psoriasis are also at increased risk of non-melanoma skin cancer and arguably melanoma. Ionising radiation, such as that from radiotherapy, and a variety of xenobiotics including arsenic may also increase the risk of non-melanoma skin cancer.

Malignant tumours

Basal cell carcinoma (BCC)

This is the most common human cancer. Rates are five times higher than for squamous cell carcinoma in European countries. Classically, lesions are slow-growing and ulcerated, with a pearly and telangiectatic edge, and occur on the face of an elderly individual. The tumour invades locally but rarely metastasises. It is managed as though it does not metastasise, unless it is particularly large or has been present for a long time. 'Rodent ulcer' is a term commonly used for slowly expanding ulcerative basal cell carcinoma. The malignant cells resemble basal keratinocytes.

Clinical features

In the nodulo-ulcerative form, the earliest lesion is a small, glistening, skin-coloured papule, often with

Fig. 27.37 Basal cell carcinoma. A slowly growing pearly nodule just below the inner canthus. The central crust overlies an ulcerated area.

fine telangiectatic vessels on the surface, which slowly enlarges. Central necrosis may occur, leaving an ulcer surrounded by a rolled pearly edge (Fig. 27.37). Without treatment, lesions may reach 1–2 cm in diameter over 5–10 years. Slow but relentless growth causes local tissue destruction. Sometimes the tumour becomes cystic or pigmented. The morphoeic variant is a slowly expanding, yellow or grey waxy plaque with an ill-defined edge. Fibrosis often follows ulceration and crusting, and the lesion may appear as an enlarging scar. The superficial (multifocal) variant is seen most often on the trunk; it appears as a slowly enlarging pink or brown scaly plaque with a fine ‘whipcord’ edge and may resemble a patch of intra-epidermal carcinoma (see below). If left, it may grow to 10 cm in diameter.

Management

The majority of BCCs are easily treated with local destruction. Metastasis is extremely rare; nevertheless, problems may arise: for example, in tumours close to the eye margins where local invasion can cause considerable management difficulty, or in tumours which track down nerves such as the infra-orbital.

Possible treatments include surgery, cryotherapy, radiotherapy, photodynamic therapy or the topical immunostimulant imiquimod. Surgery is increasingly used first choice, as it allows proper histological assessment of the tumour and examination of tumour margins (Box 27.33). Curettage and cautery also show good results for some small low-risk lesions, particularly if they are superficial and not close to the eye. Cryotherapy has a significant morbidity when used for anything other than superficial lesions. Radiotherapy is now used rarely.

The importance of control of tumour margins is widely debated. Some tumours can be misleading in terms of clinical assessment of their margins, as they are often more extensive than they first appear. Particular caution is required with morphoeic BCCs. If the primary tumour is not completely excised, it is often suggested that the lesion may just be followed up because not all tumours that appear to be incompletely excised recur. This policy makes sense in many body sites but not for high-risk tumours, such as those close to the eye, or with obviously morphoeic BCCs. Whatever modality

EBM 27.33 Management of non-melanoma skin cancer

Basal cell carcinoma

‘Surgical excision is the preferred treatment. Mohs micrographic surgery is an effective treatment for high-risk primary and recurrent BCC. Topical imiquimod appears effective in the treatment of some primary superficial BCC. Photodynamic therapy is good for primary superficial BCC. BCC in patients with Gorlin’s syndrome should not be treated with radiotherapy.’

Squamous cell carcinoma

‘Clinically well-defined, low-risk tumours less than 2 cm in diameter should be surgically excised with a 4 mm margin around the tumour border. Around 95% of recurrences and metastases of SCCs occur within 5 years; current guidelines suggest patients should be followed up for this period.’

- Telfer NR, et al. *Br J Dermatol* 2008; 159(1):35–48.
- Motley R, et al. *Br J Dermatol* 2002; 146(1):18–25.

For further information:  www.bad.org.uk

of treatment is used, in expert hands the cure rate should be greater than 90%. Tumour recurrences are treated using the same modalities as above.

Squamous cell carcinoma (SCC)

SCC is the second most common skin cancer after BCC and, like other forms of skin cancer, is increasing in age-specific incidence.

Aetiology

As well as the risk factors discussed above, SCC may arise in long-standing areas of inflammation such as around a chronic cutaneous ulcer, or in patients with scarring genetic syndromes of the skin such as dystrophic epidermolysis bullosa, in which up to 50% of patients may develop SCC.

Clinical features

SCC is a proliferative tumour that grows over a few months. Varying clinical presentations include keratotic nodules (Fig. 27.38), exophytic erythematous nodules, infiltrating firm tumours and ulcers with an indurated edge. Histological grade also varies from well differentiated to anaplastic. SCCs of the lip behave more

Fig. 27.38 Squamous cell carcinoma. A warty nodule with induration of the adjacent skin.

aggressively and show a greater frequency of metastasis. It is said that SCCs of the pinnae may also be more aggressive, although this may reflect inadequate primary treatment.

Management

As with BCC, a number of modalities may be used but generally excision is preferred (see Box 27.33). Some small SCCs may be treated with curettage and cautery, or with radiotherapy. Because of the definite but small risk of metastasis, assessment of margins (using standard histology) or Mohs micrographic surgery (p. 1256) is required. For straightforward SCC, excision with a 3–4 mm margin has a cure rate of 90% or more. Poorly differentiated SCC or SCC on the ears or at the site of previous burns should be treated more cautiously. Radiotherapy can be used in selected cases.

Pre-malignant tumours

Actinic keratosis

Actinic keratoses are small, scaly, red areas on sun-exposed sites that show focal areas of dysplasia on histological examination (Fig. 27.39). They are extremely common and frequently multiple; in some surveys over half the population aged over 40 have one or more lesions. The rate of progression to SCC appears low (1:1000 per year per lesion) and a large proportion of actinic keratoses may spontaneously involute. By contrast, many SCCs arise without evidence of a previous actinic keratosis. If an actinic keratosis rapidly increases in size, ulcerates, bleeds or becomes painful, then transformation to SCC should be considered.

Management

Actinic keratoses are treated effectively with liquid nitrogen. If there are a large number of lesions, then the topical cytotoxic 5-fluorouracil may be required; alternatively, topical imiquimod or photodynamic therapy

Fig. 27.39 Numerous actinic keratoses in a white patient who had lived for years in the tropics.

(p. 1256) may be used. Lesions which do not respond to treatment may require curettage or excision and reconsideration of their nature.

Intra-epidermal carcinoma (Bowen's disease)

Clinical features

This usually presents as a slow-growing, red, scaly area with some resemblance to a plaque of psoriasis, on the lower leg of elderly females. Histology reveals full-thickness dysplasia. Lesions may occur at other sites (Fig. 27.40) and occasionally transform into SCC, but with a higher frequency than actinic keratoses.

Investigations and management

An initial incisional biopsy may be required and treatment is by local destruction. Alternatively, the lesions may be managed with curettage and subsequent histology. Curettage, however, does not usually allow an SCC to be positively diagnosed or excluded because the tissue architecture is not preserved. Alternatives are cryotherapy, photodynamic therapy or imiquimod.

Fig. 27.40 Intra-epidermal carcinoma (right cheek). This persistent psoriasis-like plaque recurred after the original (anterior) lesion was treated by freezing.

Keratoacanthoma

This is a striking benign keratinocyte tumour, characterised by a period of rapid growth over a month or two, which develops into a tumour that may be 4 or 5 cm across or even larger. It has a volcano shape with a central keratin plug in a dome-shaped nodule (Fig. 27.41). Spontaneous resolution occurs but may take months. Clinically and histologically, the lesion resembles an SCC but has a different natural history. It is better to excise these lesions because clinically they are frequently hard to distinguish from a fast-growing SCC, and they often leave an unsightly scar which can be improved by surgical removal of the lesion. In order to make a positive diagnosis of keratoacanthoma, a large wedge biopsy or cross-sectional biopsy is required.

Fig. 27.41 Keratoacanthoma.

Melanoma

Malignant melanoma, like other forms of skin cancer, has increased in incidence over recent decades, even when figures are adjusted for changes in the age structure of the population. It has a case fatality rate of approximately 10–20%. Therapy for metastatic melanoma is unsatisfactory and therefore primary prevention and early detection are important. The main risk factors for melanoma are UVR exposure, pale skin, naevi number and family history. Fewer than 10% of melanomas occur in the context of a significant family history, but within this group there are rare kindreds in whom the lifetime risk of melanoma may approach 50%. Melanomas are common on the upper back in men and the lower legs in women.

Clinical features

The classification of invasive malignant melanomas is shown in Box 27.34.

Two-thirds of invasive melanomas are preceded by a superficial and radial growth phase characterised by an expanding, irregularly pigmented macule or plaque. Its margin is usually irregular with reniform projections (Fig. 27.42). Lentigo maligna (in situ changes of malignancy only) and lentigo maligna melanoma occur most often on the exposed skin of the elderly. A speckled macular lentigo maligna may have been present for many years before a nodule of invasive melanoma appears within it. The in situ phase of superficial spreading melanoma, the most common type in Caucasians, seldom lasts for longer than 2 years, usually shows much colour variation and is often palpable. Acral lentiginous melanoma occurs on the palms and soles and the absolute incidence rates are the same in all populations; by contrast, the rates at other body sites are low in African races, the Chinese and the Japanese, which suggests that this variant of melanoma is not related to UVR exposure. Nodular

Fig. 27.42 Superficial spreading melanoma. The radial growth phase was present for about 3 years before the invasive amelanotic nodule developed within it. Note the irregular outline, asymmetrical shape and different hues, including depigmented areas signifying spontaneous regression.

melanoma develops as a pigmented nodule with no preceding in situ phase. All changing pigmented lesions deserve careful examination remembering the 'ABCDE' features of malignant melanoma (see Box 27.4 and Fig. 27.3, p. 1245). About 30–50% of melanomas appear to develop in a preceding melanocytic naevus. A change in any naevus should raise suspicion of malignant transformation.

True amelanotic melanomas occur but are rare; flecks of pigmentation can usually be seen with a lens. Subungual melanomas present as painless, expanding areas of pigmentation under a nail and usually involve the nail fold.

The clinical stages of malignant melanoma are shown in Box 27.35. The diagnosis is established by an initial excision of the lesion with a 2mm margin wherever possible.

Management

Surgical excision is usually required, although very rarely radiotherapy may play a role. The extent of normal tissue that needs to be removed around a melanoma remains a subject of debate. Most would agree that a clear margin needs to be present so that there is little doubt that the tumour is fully excised; the deeper the tumour, the more caution is warranted (Box 27.36). The majority of tumours can be excised without the need

i 27.34 Classification of cutaneous malignant melanoma

Type of invasive melanoma	Presence of preceding in situ/radial growth phase
Superficial spreading	+
Lentigo maligna	+
Nodular	–
Acral lentiginous	+

i 27.35 Clinical stages of malignant melanoma

Stage I	Primary lesion only
Stage II	Regional nodal disease
Stage III	Distant disease (nodal or visceral)

EBM 27.36 Margin of excision of melanoma

'Radical surgery (4–6 cm excision margins) provides no greater benefit for local recurrence or survival than more conservative surgery (1–2 cm excision margins). Recommended excision margins for malignant melanoma depend on their Breslow thickness: melanomas < 1 mm in depth should have a 1 cm margin; melanomas > 1 mm in depth need a 2 cm margin.'

• Roberts DL, et al. on behalf of the Melanoma Study Group. *Br J Dermatol* 2002; 146:7–18.

for grafting. The role of local lymph node dissection in the absence of evidence of tumour spread is uncertain. Recently, attempts have been made to determine whether the local nodes are 'subclinically' involved by sentinel lymph node biopsy. The draining lymph node is identified by injection of radioisotope adjacent to the primary tumour and by radioscinigraphy, and is then removed and examined for 'occult' tumour using histology with or without immunohistology or PCR amplification of melanocyte gene products. Such a biopsy provides some prognostic information, and some would argue that local lymph nodes should be removed if affected. There is, however, no evidence for better outcome in those in whom sentinel node biopsy is performed than in those in whom it is not. Palpable local nodes in stage II patients should be removed by block dissection. Chemotherapy is curative only exceptionally but may play an important palliative role in those with stage III disease or earlier. Interferon-alpha may have a role in individuals at high risk of metastasis.

Prognosis

Fewer than 10% of those with clinical stage III disease survive 2 years; those with stage I disease have a 70% chance of surviving 5 years. The thickness of the tumour can be measured microscopically by Breslow's method, which gives the distance between the granular cell layer and the deepest part of the tumour. This is a reliable predictor of prognosis for patients with stage I disease. Over 90% of those with tumours less than 1 mm thick survive 5 years, but the prognosis worsens with thicker tumours. The 5-year survival of patients with tumours greater than 3.5 mm thick is about 50%. Females generally fare better than males and tumours at certain sites (e.g. lower leg) are less aggressive.

Lesions that may be confused with skin cancers

Although the distinction between melanoma and non-melanoma skin lesions based on cell type would appear clear-cut, in practice it is not always so. For instance, melanocytic naevi which are comprised of melanocytes are frequently but not always markedly pigmented. Seborrhoeic keratosis, even in the hands of experts, can be confused with melanocytic naevi and melanoma. Therefore, in some instances, histology will be required.

Freckle (ephelis)

Freckles are focal increases in melanin in keratinocytes, but with a normal number of melanocytes. They are

common in fair-skinned patients, particularly those with red hair, and there is a familial tendency. In sensitive individuals, freckles may develop at most body sites. Clinically they are flat, tanned brown lesions with irregular borders. They are common on the face and darken in response to UVR.

Lentigines

A lentigo is defined as an area of increased melanocyte proliferation along the basement membrane, but without the formation of the nests that are seen in melanocytic naevi. Confusingly, the solar lentigo is not a true lentigo but a flat form of seborrhoeic keratosis; there is increased undulation of the rete pegs and dermal papillae, associated with a normal number of melanocytes, but increased melanin in the surrounding keratinocytes. These lesions are usually seen in sun-exposed skin, become more common with age and are often referred to as 'liver' or 'age spots'. They can vary in colour from light tan to dark brown. Histopathological examination confirms plain or reticulated seborrhoeic keratoses. Their importance is as a differential diagnosis for a superficial spreading melanoma or a lentigo maligna melanoma.

Haemangiomas

Benign vascular tumours or hamartomas are not uncommon; they include Campbell de Morgan spots which present as bright pink or red smooth papules on the upper half of the body. They can sometimes be difficult to distinguish from melanocytic lesions, particularly if they are thrombosed or occur on particular sites such as the lip or the genitalia.

Seborrhoeic warts (basal cell papilloma)

Seborrhoeic warts (seborrhoeic keratoses) are common benign epidermal tumours (Fig. 27.43). Despite their name and oily appearance, they do not involve the sebaceous glands. They are usually a cosmetic issue but may mimic melanoma. As outlined above, some lesions that are commonly referred to as lentigos are flat seborrhoeic keratoses. The latter, however, may frequently become elevated and are more commonly found on the trunk and the face. Both sexes are equally affected. The lesions take on a myriad of appearances, varying in colour from

Fig. 27.43 Multiple seborrhoeic warts.

light yellow to very dark brown and almost black, and in shape from fairly flat to a protuberant and 'stuck-on' appearance. They may even be pedunculated. The surface often appears greasy and may reveal pinpoint keratin plugs, most easily seen with a lens. If there is no doubt about the diagnosis, they can be readily treated with either cryotherapy or curettage and cautery. Otherwise, an excision biopsy and histology should be performed as, if the lesion is a melanoma, prognostic information, such as the Breslow thickness, is required.

Melanocytic naevi

Melanocytic naevi (moles) are localised benign proliferations of melanocytes, which are clonal. Their cause is unknown but may relate to abnormalities of the normal migratory pattern of melanocytes during development. It is quite normal to have 20–50, but individuals with red hair have fewer. The number reflects both genetic and environmental characteristics. Individuals who have had greater sun exposure have higher numbers of moles, and monozygotic twins show a higher concordance than dizygotes. With the exception of congenital melanocytic naevi (which are present at birth or appear shortly after), most melanocytic naevi appear in childhood and early adult life, or during pregnancy or oestrogen therapy. The onset of a new mole is less common after the age of 25.

Clinical features

Acquired melanocytic naevi are classified according to the microscopic location of the clumps of melanocytes in the skin (Fig. 27.44). Junctional naevi are usually circular and macular; their colour ranges from mid- to dark brown and may vary within a single lesion. Compound and intradermal naevi are similar in appearance; both are nodules of up to 1 cm in diameter, although intradermal naevi are usually less pigmented than compound. Their surface may be smooth, cerebriform or even hyperkeratotic and papillomatous, and are often hairy.

Using a variety of criteria, some naevi have been labelled atypical or dysplastic, suggesting that the individual is at an increased risk of melanoma. Unfortunately, such terms have been poorly defined and used to describe both a clinical and a histological appearance, but these do not coincide. Some individuals have abnormal naevi in the sense that they seem to have larger numbers, or they may have naevi on the scalp and the palmar and plantar surfaces, as well as the buttocks. Some may appear pinkish and even show an inflamed halo. Such naevi are known to occur in some rare families with an inherited predisposition to melanoma. Otherwise, the significance

Fig. 27.44 Classification of melanocytic naevi. Classification is based on microscopic location of the clumps of naevus cells.

of such changes is unclear and criteria for management and follow-up are not agreed.

Whereas it is said that 30–50% of malignant melanomas develop from melanocytic naevi, only a minute percentage of melanocytic naevi become malignant. Malignant change is most likely in large congenital melanocytic naevi (where the risk may correlate with the size or mass of the melanocyte lesion) and possibly in those families who have been diagnosed as showing large numbers of atypical naevi with a history of melanoma. The value of self-examination has not been established in trials. A change in a mole (p. 1244) may be a harbinger of melanoma but is usually not. In the majority of Caucasian populations, any change in a mole requires careful clinical assessment, remembering that the negative specificity of clinical assessment of early melanomas is poor. Excision with histology is therefore frequently recommended.

Management

Melanocytic naevi are normal and do not require excision, except when malignancy is suspected or when they become repeatedly inflamed or traumatised. Some individuals wish to have them removed for cosmetic reasons.

Blue naevi

These are melanocytic naevi in which there is a dermal proliferation of spindled melanocytes relatively deep within the dermis. Light scattering means that the pigment appears blue rather than the usual brown. They may be difficult to distinguish from nodular melanomas.

Dermatofibromas

A dermatofibroma is a firm, often pigmented, raised lesion most common on the lower legs. Its aetiology is unclear and it is uncertain whether it represents a reactive process or a tumour. There is frequently a ring of pigment around the lesion, firmness, and dimpling when the skin is pinched, which reflects the fact that the dermatofibroma is tethered to the epidermis. These lesions are commonly confused with melanocytic naevi.

Acrochordons (skin tags)

These are harmless pedunculated lesions which are common in the skin flexures but can occur at other sites. They may be confused with melanocytic naevi but are easily excised.

Lipomas

These are benign tumours of adipocytes which have a characteristically soft consistency, and are usually easily distinguished from epidermal skin tumours because they arise more deeply within the skin. A variant, called an angiolipoma, is characteristically painful.

Cutaneous T-cell lymphoma (mycosis fungoides)

Cutaneous T-cell lymphoma develops slowly over many (sometimes 20 or 30) years from a plaque stage often resembling psoriasis, through to nodules and finally a systemic stage. B-cell lymphomas, on the other hand, usually present as nodules or plaque-like tumours. The diagnosis of cutaneous T-cell lymphoma requires a high

index of suspicion, particularly in patients thought to have unusual forms of eczema or psoriasis who have failed to respond to treatment. The treatment of cutaneous T-cell lymphoma is symptomatic and there is no evidence that specific modalities of treatment alter prognosis.

In the early stages of cutaneous T-cell lymphoma, either systemic or local corticosteroids may be indicated; alternatively, PUVA or narrow band UVB phototherapy may be employed, although these are of symptomatic benefit only and are not risk-free. Once lesions have moved beyond the plaque stage, electron beam radiation or systemic anti-lymphoma regimens may be required. Management requires careful collaboration between dermatologists, pathologists and haematological oncologists.

SKIN PROBLEMS IN GENERAL MEDICINE

Many skin conditions present to a number of medical specialty clinics. These are listed in Box 27.37 and the most common of those not discussed elsewhere are described below.

Vasculitis

Vasculitis typically presents with palpable purpura (see Fig. 25.42, p. 1113). The causes include drugs, infection, connective tissue disease, malignancy and idiopathic

conditions (e.g. Henoch-Schönlein purpura). The diagnosis is confirmed by skin biopsy, with histology and immunofluorescence examination. Investigation for systemic involvement (particularly renal) and for the precipitating cause is important.

Pressure sores

Pressure sores are caused by prolonged pressure-induced ischaemia, when the interface pressure between the patient's body and its supporting surface exceeds capillary closing pressure. Up to 5% of patients aged over 70 years in hospital develop pressure sores, but this may rise to 30% in those with a fractured neck of femur. The morbidity and mortality of those with deep ulcers are high.

Aetiology

The main risk factors for pressure sores include:

- *immobility*, e.g. coma, neurological disease with paralysis, surgery, pain, overuse of sedatives, depression
- *hypotension*, e.g. shock, dehydration
- *reduced oxygen delivery*, e.g. anaemia, fever, infection
- *peripheral vascular disease*, including diabetic microangiopathy
- *under-nutrition*, e.g. malignant cachexia, alcoholism
- *skin condition*, e.g. atrophy due to age or topical corticosteroids, dry/cracked and moist/chapped.

Clinical features

The sore starts as a localised area of erythema and progresses to a superficial blister or erosion. If the cause is not corrected, deeper damage occurs; a black eschar develops which, when removed or shed, leaves a deep and penetrating ulcer, often colonised by *Pseudomonas aeruginosa*. The skin overlying bony prominences, such as the sacrum, greater trochanter, ischial tuberosity, calcaneal tuberosity and lateral malleolus, is especially susceptible.

Management

This is not easy but the following are important:

- prevention by regular repositioning of immobile patients and use of pressure-reducing mattresses in those at high risk
- treatment of risk factors including undernutrition
- débridement of necrotic tissue either by surgery or by enzymatic necrolysis
- systemic antibiotics for spreading infection
- dressings to keep the wound wet and enhance granulation; regular cleansing with normal saline or 0.5% aqueous silver nitrate; semi-permeable dressings such as OpSite
- consideration of plastic surgical reconstruction when the ulcer is clean.

Tuberous sclerosis complex

This is an autosomal dominant condition with hamartomas affecting many systems. Two genetic loci have been identified: TSC-1 (chromosome 9) encoding hamartin and TSC-2 (chromosome 16) encoding tuberlin.

The classic triad of clinical features comprises learning disability, epilepsy and skin lesions but there is a wide spectrum of clinical expression. The skin signs include small white oval (ash leaf) macules which usually present in early childhood, pink or yellowish

papules on the centre of the face ('adenoma sebaceum' due to angiofibromas) occurring later on in adolescence, periungual and subungual fibromas, and connective tissue naevi (cobblestone-like plaques at the base of the spine, sometimes called shagreen patches). Other features may include hyperplastic gums, retinal phakomas (fibrous overgrowth), renal, lung and heart tumours, cerebral gliomas and calcification of the basal ganglia.

Xanthomas

These deposits of fatty material in the skin, subcutaneous fat and tendons may be the first clue to primary or secondary hyperlipidaemia and are described in detail on pages 452–453.

Amyloidosis

Deposits of amyloid in the skin often appearing as waxy plaques around the eyes; they are prominent in primary systemic amyloidosis (p. 84) and in amyloid associated with multiple myeloma, but uncommon in systemic amyloidosis secondary to rheumatoid arthritis or other chronic inflammatory diseases. 'Pinch purpura' appears where the skin is traumatised due to amyloid infiltration of blood vessels and may be a striking feature. Macular amyloid is a pruritic eruption more common in darker skin types. Clinically, there is macular or patches of grey-brown discoloration, usually on the back. Treatment is difficult but potent topical steroids can be helpful.

Porphyria

The porphyrias are described in detail on page 456.

- *Porphyria cutanea tarda* is the most common porphyria. It usually starts in adulthood and can be inherited or acquired due to alcohol, iron overload, oestrogens, hepatitis C and HIV disease. The cutaneous features are increased skin fragility, blistering (Fig. 27.45), erosions and milia occurring on light-exposed areas such as the backs of the hands. Patients rarely associate their symptoms with acute light exposure. Facial hypertrichosis and hyperpigmentation may also be seen.
- *Erythropoietic protoporphyria* is rare and starts in childhood, with burning and pain on light-exposed areas due to ferrochelatase deficiency. Scars occur, particularly on the nose. Protoporphyrins are found in the red cells, plasma and stool.

Fig. 27.45 Cutaneous hepatic porphyria. Recent skin fragility and blistering on the backs of the fingers.

- *Variegate porphyria* has cutaneous features similar to those of *porphyria cutanea tarda*, and systemic as those of acute intermittent porphyria.
- *Hereditary coproporphyria* is associated with photosensitivity in 30%. Systemic features are as those of acute intermittent porphyria.
- *Pseudoporphyrias* are associated with sunbed usage, NSAIDs (particularly naproxen) and renal failure, which give rise to skin lesions that mimic the photosensitive porphyrias, particularly *porphyria cutanea tarda*. The pathogenesis is unclear.

Sarcoidosis

Skin lesions are seen in about one-third of patients with systemic sarcoidosis (p. 708) and include erythema nodosum (see Fig. 19.54, p. 709), granulomatous deposits in long-standing scars, dusky infiltrated plaques on the nose and fingers (lupus pernio), and scattered brownish-red, violaceous or hypopigmented papules or nodules which vary in number, size and distribution.

Erythema multiforme

This is a reaction pattern of multifiform erythematous lesions. The precipitating factor may not be found in some cases, but attacks are provoked by the factors listed in Box 27.38.

The multifiform erythematous lesions may be urticaria-like and some have obvious 'bull's-eye' or 'target' lesions. Blisters may be seen in the centre or around the edges of the lesions (Fig. 27.46). In some cases blisters

27.38 Provoking factors in erythema multiforme

- Viral infections, e.g. herpes simplex, orf
- Bacterial infections, e.g. *Mycoplasma*
- Drugs, especially sulphonamides, penicillins and barbiturates
- Systemic malignancy
- Radiotherapy

Fig. 27.46 Erythema multiforme with blistering lesions in a young woman.

dominate the picture; the Stevens–Johnson syndrome is severe bullous erythema multiforme with marked mucosal involvement including the mouth, eyes and genitals, and constitutional disturbance.

Usually no treatment is required, although symptomatic relief can be obtained with simple dressings. Stevens–Johnson syndrome can be treated with a short course of intravenous immunoglobulin. Corticosteroids are best avoided.

Erythema nodosum

This characteristic reaction pattern (see Fig. 19.54, p. 709) is due to a vasculitis in the deep dermis and subcutaneous fat. Provoking factors are listed in Box 27.39. Painful, palpable, dusky blue-red nodules are most commonly seen on the lower legs. Malaise, fever and joint pains are common. The lesions resolve slowly over a month, leaving bruise-like marks. The underlying cause should be determined and treated. Bed rest and oral NSAIDs may hasten resolution. Tapering systemic corticosteroid courses may be required in stubborn cases.

27.39 Provoking factors in erythema nodosum

Infections

- Bacteria, e.g. streptococci, mycobacteria, *Brucella*, *Mycoplasma*, *Rickettsia*, *Chlamydia*
- Viruses
- Fungi

Drugs

- e.g. Sulphonamides, oral contraceptives

Systemic disease

- e.g. Sarcoidosis, ulcerative colitis and Crohn's disease

Pyoderma gangrenosum (PG)

PG predominantly occurs in adults between the ages of 25 and 54 years. The eruption starts as an inflamed nodule or pustule which breaks down centrally and rapidly progresses to an ulcer with an indurated or undermined purplish or pustular edge (Fig. 27.47). Lesions may be single or multiple and are classified as ulcerative, pustular, bullous and vegetative. Although PG may arise in the absence of any underlying disease, it is often

Fig. 27.47 Pyoderma gangrenosum. A large indolent ulcer in a patient with rheumatoid arthritis. Note healing in one part.

associated with a systemic disease such as inflammatory bowel disease, arthritis (both rheumatoid arthritis and seronegative arthropathies), immunodeficiency and immunosuppression including HIV disease, monoclonal gammopathies and leukaemia. Investigation for these should be performed. There are no diagnostic features on skin biopsy and the diagnosis is primarily clinical. Local management includes pain relief, prevention of secondary bacterial infection and dressings. Systemic therapy that can be tried includes oral corticosteroids in a tapering dose, dapsone, minocycline, sulfasalazine and ciclosporin. Once the patient is clear of disease, recurrences are only intermittent.

Acanthosis nigricans

This is a velvety thickening and pigmentation of the major flexures, particularly the axillae (see figure, p. 796). There are several types. The most common form is an obesity-associated weight-dependent mild acanthosis nigricans. When the patient loses weight, the cutaneous features regress. It can also be associated with various syndromes, including insulin resistance syndrome (see p. 802 and Box 21.4). Acanthosis nigricans can also be associated with malignancy, particularly gastric (60%). Pruritus is a feature of malignancy-associated acanthosis and regression occurs after the tumour is excised. Acanthosis nigricans sometimes recurs with metastatic disease.

Necrobiosis lipidica

This condition is associated with diabetes mellitus. Less than 1% of people with diabetes have necrobiosis, but more than 85% of patients with necrobiosis will have or will develop diabetes. Typically, the lesions appear as shiny, atrophic and slightly yellow plaques on the shins (Fig. 27.48). Underlying telangiectasia are easily seen. Minor knocks may precipitate slow-healing ulcers. No treatment is very effective. Topical and intralesional corticosteroids are used, as is long-term PUVA.

Fig. 27.48 Necrobiosis lipidica. An atrophic yellowish plaque on the skin of a person with diabetes.

Cutaneous Crohn's disease

Skin involvement in Crohn's disease (p. 896) is rare but can be severely disabling. The skin manifestations can be categorised as specific (perianal, oral and peristomal), non-specific (erythema nodosum, neutrophilic

dermatoses) and secondary to nutritional deficiency. The specific changes include sinuses, fistulae, oedema, oral granulomatous disease and so-called 'metastatic' Crohn's, in which typical non-caseating granulomatous histology is found in a variety of skin eruptions. Treatment is of the underlying disease with mesalazine, steroids, immunosuppressives or anti-TNF- α therapy.

Granuloma annulare

This is a common cutaneous condition of uncertain aetiology; an association with diabetes is now thought to be spurious. Dermal nodules occur singly or in an annular configuration. They are asymptomatic but commonly occur on highly visible sites such as the hands and feet. Histologically, palisading granulomas are found in the dermis. Intralesional corticosteroids can be helpful, but the natural history is spontaneous resolution over a few months to a couple of years.

Morphoea

Morphoea is a localised form of scleroderma that can affect any site at any age. It usually presents as a thickened plaque of skin but can be more generalised or linear. There is no systemic involvement.

DRUG ERUPTIONS

Cutaneous drug reactions are common and almost any drug can cause them. They should be included in the differential diagnosis of most skin diseases. Although the mechanisms are poorly understood, drug eruptions may be classified as shown in Box 27.40.

Clinical features and investigations

Box 27.41 shows the patterns of drug eruptions that may occur. They usually start within a few days or

weeks of taking the culprit drug. The possibility of a drug eruption should be considered particularly when a rash is atypical of a known skin disease (Fig. 27.49). It is essential to take a careful history of medications and preceding illnesses from at least 4 weeks prior to the onset of the rash. Further clues pointing to the diagnosis are included in Box 27.42 but no specific investigations help. While an affected individual will usually have the same reaction to the specific drug or to those chemically related on a further challenge, rechallenging with the suspected drug as a diagnostic test is unwise unless the reaction is mild and there is no suitable alternative.

Management

The first step is to withdraw the suspected drug(s), except in the case of suspected drug-induced photodermatoses, where if possible phototesting should be carried out when the patient is on the drug, and then again at a later date when the drug has been withdrawn. Drug withdrawal may not be easy, or even possible if there is no alternative available. The decision will depend on many factors, including the severity and nature of the drug reaction, its potential reversibility and the probability that the drug caused the reaction. Supportive treatment with antihistamines or a course of systemic corticosteroids may be indicated, depending on the type of skin reaction. The management of anaphylactic shock is described on page 89.

Fig. 27.49 Drug eruption. A bizarre but symmetrical erythematous scaly rash with a distribution suggesting a degree of photosensitivity. The rash persisted until the recently prescribed sulphonylurea was withdrawn.

27.40 Drug eruptions and their mechanisms	
Mechanism	Examples
Non-immunological (non-allergic)	
Pharmacological effect	Striae due to corticosteroids; mouth ulcers due to methotrexate
Drug overdose or failure to eliminate	Morphine rashes with liver disease/failure
Drug interaction	Bruising with warfarin and aspirin
Idiosyncratic reaction	Drug-induced variegate porphyria
Phototoxic reaction	Chlorpromazine-induced light reactions
Altered skin mycology	Tetracyclines and vaginal candidiasis
Exacerbation of pre-existing skin condition	Lithium and β -blocker worsen psoriasis
Immunological (allergic)	
Immediate hypersensitivity	Penicillin-induced urticaria
Immune complex reaction	Drug-induced vasculitis or erythema multiforme
Delayed hypersensitivity	Drug-induced exfoliative dermatitis or photoallergic reactions

27.41 Clinical patterns of drug eruptions

Reaction pattern	Clinical features	Associated drugs
Toxic erythema	Erythematous plaques Morbilliform, sometimes with urticarial or erythema multiforme-like elements	Antibiotics (especially ampicillin) Sulphonamides, thiazide diuretics, para-aminosalicylic acid (PAS)
Urticaria	Itchy weals, sometimes accompanied by angioedema	Salicylates, codeine and NSAIDs Antibiotics, dextran and ACE inhibitors
Erythema and scaling	Small, scaly, pink papules to large, scaly, red papules	Antibiotics (e.g. penicillins, sulphonamides including co-trimoxazole) Gold, penicillamine and NSAIDs, particularly ibuprofen Anticonvulsants, ACE inhibitors, barbiturates, anti-thyroid drugs and cytokine modulators, e.g. adalimumab
Allergic vasculitis	Painful, palpable purpura developing into necrotic ulcers	Sulphonamides, indometacin, phenytoin and oral contraceptives
Erythema multiforme	Target-like lesions and bullae on the extensor aspects of the limbs	Sulphonamides and barbiturates
Purpura	Widespread purpura in the absence of thrombocytopenia or a coagulation defect	Thiazides, sulphonamides, sulphonylureas, adalimumab, infliximab, barbiturates and quinine
Bullous eruptions	May be associated with erythema and purpura May occur at pressure sites in drug-induced coma	Barbiturates Penicillamine Nalidixic acid, vancomycin
Exfoliative dermatitis	Universal redness and scaling, shivering	PAS, isoniazid and gold
Acute generalised exanthematous pustulosis/toxic pustuloderma	Rapid onset of sterile, non-follicular pustules on an erythematous base	Ampicillin/amoxicillin, quinolones, sulphonamides, pristinamycin, terbinafine Diltiazem and hydroxychloroquine
Fixed drug eruptions	Round, erythematous, sometimes bullous plaques developing at same site every time drug is given. Pigmentation on resolution.	Tetracyclines, sulphonamides Quinine and barbiturates
Acneiform eruptions	Rash resembles acne	Lithium and anticonvulsants Oral contraceptive, androgenic or glucocorticoid steroids Antituberculosis drugs, biological therapy (cetuximab)
Toxic epidermal necrolysis	Rash resembles scalded skin (see Fig. 27.35, p. 1275)	Barbiturates, phenytoin, lamotrigine, fluoxetine Penicillin, co-trimoxazole, nevirapine and allopurinol
Hair loss	Diffuse	Cytotoxic agents, infliximab and acitretin Anticoagulants, antithyroid drugs and oral contraceptives
Hypertrichosis	Excessive hair growth in non-androgenic distribution	Diazoxide, minoxidil and ciclosporin
Photosensitivity	Rash limited to exposed skin	Thiazide diuretics and phenothiazines Tetracyclines, sulphonamides and nalidixic acid NSAIDs, retinoids and psoralens
Pigmentation	See Box 27.15 (p. 1254)	
Psoriasiform rash	Rash like psoriasis	Lithium, β -blockers and anti-TNF- α therapy (infliximab)

27.42 Diagnostic clues to drug eruptions

- Past history of reaction to suspected drug
- Introduction of suspected drug a few days before onset of rash
- Recent prescription of a drug commonly associated with rashes (e.g. penicillin, sulphonamide, thiazide, allopurinol)
- Symmetrical eruption which fits with a well-recognised pattern caused by a current drug

LEG ULCERS

Leg ulceration due to venous disease

Damage to the venous system of the leg results in oedema, haemosiderin deposition, eczema, fibrosis and ulceration.

Aetiology

In the normal leg, there is a superficial low-pressure venous system connected to the deep, high-pressure

veins by perforating veins. Muscular activity, aided by valves in the veins, pumps blood from the superficial to the deep system and towards the heart. Incompetent valves in the deep and perforating veins result in retrograde flow of blood to the superficial system, causing a rise in capillary hydrostatic pressure ('venous hypertension'). Fibrinogen is forced out through the capillary walls and fibrin is deposited as a pericapillary cuff. It is thought that growth and repair factors are trapped in the macromolecular cuff so that minor trauma cannot be repaired and ulcers develop.

Incompetent veins leading to venous hypertension may be due to previous deep venous thrombosis (p. 1004), congenital or familial valve incompetence, infection or deep venous obstruction (e.g. by a pelvic tumour). If conditions are favourable, the ulcers will heal by granulation with small epithelial islands at the base and epithelial growth from the edges. Healing is often slow and may never be complete. Recurrent ulceration is common. Clinical assessment and investigations are described on page 1252.

Complications

Chronic venous ulcers are invariably colonised by bacteria. Systemic antibiotic treatment is only required if signs of infection develop. Contact dermatitis to an ointment, dressing or bandage is not uncommon. The usual culprits are preservatives, lanolin and neomycin. Lipodermatosclerosis may cause lymphoedema, leading to hyperkeratosis and the so-called 'mossy foot'. Rarely, an SCC developing in a venous ulcer (Marjolin's ulcer) is responsible for its failure to heal.

Management

- Dietary advice is required in the obese and all should be encouraged to take gentle exercise.
- Oedema is reduced by the regular use of compression bandages, elevation of the legs when sitting and the judicious use of diuretics. In the absence of compromised arterial supply (ABPI > 0.8), graduated compression bandages applied from the toes to the knees enhance venous return and have been shown to be beneficial in healing (Box 27.43). Those individuals with an ABPI < 0.8 should be assumed to have arterial disease and compression bandaging must be avoided.
- Exudate and slough should be removed with normal saline solution, 0.5% aqueous silver nitrate or 5% aqueous hydrogen peroxide. If the ulcer is very purulent, soaking the leg for 15 minutes in 1:10 000 dilution of aqueous potassium permanganate may be helpful.
- Dressings commonly used for venous ulceration include antibiotic-impregnated tulle dressings, non-

adhesive absorbent dressings (alginates, charcoals, hydrogels or hydrocolloids) and dry non-adherent dressings.

- The frequency of dressing changes depends on the state of the ulcer. Very purulent and exudative ulcers may need daily dressings whilst a clean, healing ulcer may only require dressings changed every week.
- Paste bandages, impregnated with zinc oxide or ichthammol, help to keep dressings in place and provide protection.
- Surrounding venous eczema is treated by a mild or moderately potent topical corticosteroid, but it should not be applied to the ulcer itself.
- Short courses of oral antibiotic therapy are only necessary for the treatment of overt infection. An anabolic corticosteroid, stanozolol, may help lipodermatosclerosis but fluid retention and hepatotoxicity limit its use.
- Vein surgery may help some younger patients with persistent venous ulcers. Pinch grafts may hasten the healing of clean ulcers but do not influence their rate of recurrence.

Leg ulceration due to arterial disease

Deep, painful and punched-out ulcers on the lower leg, especially if they occur on the shin and foot and are preceded by a history of intermittent claudication, are likely to be due to arterial disease. Risk factors include smoking, hypertension, diabetes mellitus and hyperlipidaemia. The foot is cyanotic and cold, and the skin surrounding the ulcer is atrophic and hairless. The peripheral arterial pulses are absent or reduced. Doppler studies are required and if arterial insufficiency (ABPI < 0.8) is confirmed, a vascular surgical assessment should be sought (p. 599).

Leg ulceration due to vasculitis

This is described on page 1112.

Leg ulceration due to neuropathy

The most common cause of a neuropathic ulcer is diabetes. The ulcers occur over weight-bearing areas such as the heel. Microangiopathy also contributes to ulceration in diabetes (p. 833).

HAIR DISORDERS

Patients may present with too much hair (hirsutism) or too little hair (alopecia, Box 27.44). Detailed assessment allows a specific diagnosis.

Tinea capitis

Fungal scalp infection is becoming increasingly common in urban areas in the UK, where it is most frequently spread by contact between children. Clinical features are variable due to associated inflammation, with patchy hair loss and some scaling. Affected individuals should have the area scraped and affected hairs plucked for mycological microscopy and culture. Endothrix (within the hair shaft) infections, e.g. *Trichophyton tonsurans*, cause relatively uninfamed patchy baldness with breakage

EBM 27.43 Compression bandaging in leg ulceration

'Compression bandaging is effective in those individuals with an ABPI > 0.8, measured by hand-held Doppler.'

- SIGN. The care of patients with chronic leg ulcer; 2005.

27.44 Classification of alopecia

Localised	Diffuse
Non-scarring	
Tinea capitis	Androgenetic alopecia
Alopecia areata	Telogen effluvium
Androgenetic alopecia	Metabolic
Traumatic (trichotillomania, traction, cosmetic)	Hypothyroidism
Syphilis	Hyperthyroidism
	Hypopituitarism
	Diabetes mellitus
	HIV disease
	Nutritional deficiency
	Liver disease
	Post-partum
	Alopecia areata
	Syphilis
Scarring	
Idiopathic	Discoid lupus erythematosus
Developmental defects	Radiotherapy
Discoid lupus erythematosus	Folliculitis decalvans
Herpes zoster	Lichen planus pilaris
Pseudopelade	
Tinea capitis/kerion	

of the hairs at the skin surface ('black dot'). There is no fluorescence under Wood's light. Ectothrix (outside the hair shaft) species of fungi, such as *Microsporum audouinii* (anthropophilic), show minimal inflammation; *Microsporum canis* (from dogs and cats) infections are more inflamed and can be identified by green fluorescence with Wood's light. Kerions are boggy, highly inflamed areas of tinea capitis and are usually caused by zoophilic (from animals, e.g. cattle ringworm) species of fungi (e.g. *Trichophyton verrucosum*). Accurate diagnosis of the culprit fungus allows treatment and control of the spread of infection.

Treatment is systemic with oral terbinafine, griseofulvin or itraconazole. Topical therapy, such as an antifungal shampoo, is recommended as an adjunct and arachis oil is used to remove crusting. Kerions sometimes require short courses of oral corticosteroids in addition to systemic antifungal therapy to reduce the inflammation.

Alopecia areata

This non-scarring condition appears as sharply defined non-inflamed bald patches, usually on the scalp. During the active stage of hair loss, pathognomonic 'exclamation mark' hairs are seen (broken-off hairs 3–4 mm long, which taper off towards the scalp, Fig. 27.50). An uncommon diffuse pattern on the scalp is recognised. The condition may affect the eyebrows, eyelashes and beard. Pitting and longitudinal wrinkling of the nail may be seen. The hair usually regrows spontaneously in small bald patches, but the outlook is less good with larger patches and when the alopecia appears early in life or is associated with atopy. Alopecia totalis describes complete loss of scalp hair, and alopecia universalis is complete loss of all hair. There is an association of alopecia areata with autoimmune disorders, atopy and Down's syndrome.

Fig. 27.50 Alopecia areata. Marked hair loss with diagnostic exclamation mark hairs (arrows).

Androgenetic alopecia

Male-pattern baldness is physiological in men over 20 years old, although rarely it may be extensive and develop at an alarming pace in the late teens. It also occurs in females, most obviously after the menopause. The well-known distribution (bitemporal recession and then crown involvement) is described as 'male-pattern' but hair loss in females is often diffuse.

Investigations and management

A full blood count, ESR, urea and electrolytes, liver and thyroid function tests, an autoantibody profile and syphilis serology help determine the cause of non-scarring alopecia. Specialised tests, including the hair pluck test in which up to 50 hairs are removed with epilating forceps to determine the anagen:telogen ratio, are seldom necessary. Mycological assessment is advisable in cases of localised hair loss with scaling. In scarring alopecia, scalp biopsy, with direct immunofluorescence, may help to confirm a diagnosis of lichen planus of the scalp or discoid lupus erythematosus.

Successful treatment of alopecia is difficult, and patients require support and reassurance. Any underlying condition should be treated. Alopecia areata sometimes responds to topical or intralesional corticosteroids such as 0.3 mL triamcinolone (10 mg/mL). Some males with androgenetic alopecia may be helped by systemic finasteride or topical 2% minoxidil solution. In females, anti-androgen therapy such as cyproterone acetate is used. A wig may be appropriate for extensive alopecia. Scalp surgery and autologous hair transplants are expensive but sometimes effective in androgenetic alopecia.

Hirsutism

Hirsutism is the growth of terminal hair in a male pattern in a female, and is discussed in detail in pages 759–760. The cause of most cases of hirsutism is unknown and, while it may occur in hyperandrogenism, Cushing's syndrome and polycystic ovary syndrome, only a small minority have a demonstrable hormonal abnormality.

NAIL DISORDERS

The condition of the nails may reflect both local and systemic disease. The nail plate arises from the nail matrix and lies on the nail bed (Fig. 27.51). The keratinous plate is produced by cells of the (dorsal) matrix and, to a much lesser extent, the (ventral) bed. Finger nails grow about 1 cm every 3 months and toe nails at about one-third of this rate.

Examination of the nail folds may reveal the inflammation and swelling of paronychia. Chronic paronychia is seen frequently in those with a poor peripheral circulation, those involved in wet work, those with diabetes mellitus, and in over-enthusiastic manicuring of cuticles. Ragged cuticles and dilated or thrombosed capillaries in the proximal nail folds are important pointers to connective tissue disease (Fig. 27.52).

Fig. 27.51 The nail plate and bed. Arrows indicate the direction of nail growth.

Fig. 27.52 Dermatomyositis. The erythema, dilated and tortuous capillaries in the proximal nail fold and the Gotttron's papules on the digits are important diagnostic features (p. 1111).

Nail plate disorders

Longitudinal ridging and beading of the nail plate is not abnormal and increases with age. Similarly, occasional white transverse flecks (striate leuconychia) are seen frequently in normal nails and are due to airspaces within the plate and not to insufficient calcium.

Congenital disease

Pachyonychia congenita is a rare autosomal dominant condition. Most cases arise due to mutations in a particular group of keratin genes. The nails are grossly thickened, especially at the free edge, and discoloured from birth.

Trauma

- *Splinter haemorrhages* are fine linear dark brown flecks running longitudinally in the plate (see Fig. 18.93, p. 626). They are most commonly due to trauma, particularly when distal, but may be seen in nail psoriasis, and less commonly in infective endocarditis (p. 624).
- *Subungual haematomas* may appear as a crimson, purple or grey-brown discoloration of the nail plate, most frequently that of the big toe (Fig. 27.53). Sometimes but not always, there is a history of trauma. They appear suddenly and the nail folds remain uninvolved. As the nail grows out, a normally coloured band develops proximally. They may be confused with subungual melanoma and biopsy may be necessary.
- *Habit-tic dystrophy* is common, and is due to habitual picking of the proximal nail fold of the thumb. This produces a ladder pattern of transverse ridges and furrows up the centre of the nail.
- *Chronic trauma* from ill-fitting shoes and from sport may cause malalignment and thickening of the nails known as onychogryphosis, and lead to ingrowing toenails.

Fig. 27.53 Subungual haematoma.

The nail in systemic disease

- *Koilonychia* is a concave or spoon-shaped deformity of the plate which is a sign of iron deficiency (Fig. 27.54A). It is seen most often in countries where under-nutrition is prevalent.
- *Beau's lines* are transverse grooves which appear at the same time on all nails a few weeks after an acute illness, moving out to the free margins as the nails grow (Fig. 27.54B).
- *Digital clubbing* in its most gross form is seen as a bulbous swelling of the tip of the finger (Figs 27.54C and D) or toe. The normal angle between the proximal part of the nail and the skin is lost. Causes may be:
 - respiratory – bronchogenic carcinoma, asbestosis (especially with mesothelioma), suppurative lung disease (empyema, bronchiectasis, cystic fibrosis), fibrosing alveolitis
 - cardiac – cyanotic congenital heart disease, infective endocarditis
 - other – inflammatory bowel disease, biliary cirrhosis, thyrotoxicosis, familial.
- *Whitening of the nails* is a rare sign of hypoalbuminaemia. 'Half and half' nails (white proximally and red-brown distally) are seen in

Fig. 27.54 The nail in systemic disease. [A] Koilonychia. [B] Beau's lines. [C] and [D] Digital clubbing. [E] Normal nail.

some patients with renal failure. Rarely, drugs (e.g. antimalarials) may discolour nails.

The nail in common skin diseases

- *Psoriasis* may cause coarse pitting of the nail plate, onycholysis (separation of the nail plate from the nail bed) and subungual hyperkeratosis (see Fig. 27.17, p. 1262).
- *Eczema* may feature shiny nails, which signify frequent rubbing of eczematous skin elsewhere. When eczema involves the distal phalanges, the nail may be deformed, with transverse ridging and thickening of the plate.
- *Lichen planus* and *severe alopecia areata* may cause trachyonychia, a fine roughness and white discoloration of the nail plate.
- *Dermatophyte infection* causes yellow-brown discoloration and crumbling of the plate which usually starts distally and spreads proximally (Fig. 27.55). Usually only a few nails (more commonly toenails than fingernails) are affected and frequently only on one foot or hand. Diagnosis relies on clippings being examined for hyphae and culture, and systemic rather than topical antifungal treatment (e.g. terbinafine) is required.

Fig. 27.55 Dermatophyte infection. This causes discoloration and crumbling of the nail plate.

NOTES ON THE INTERNATIONAL SYSTEM OF UNITS (SI UNITS)

Système International (SI) units are a specific subset of the metre-kilogram-second system of units and were agreed upon as the everyday currency for commercial and scientific work in 1960, following a series of international conferences organised by the International Bureau of Weights and Measures. SI units have been adopted widely in clinical laboratories but non-SI units are still used in many countries. For that reason, values in both units are given for common measurements throughout this textbook and commonly used non-SI units are shown in this chapter. However, the SI unit system is recommended.

Examples of basic SI units

Length	metre (m)
Mass	kilogram (kg)
Amount of substance	mole (mol)
Energy	joule (J)
Pressure	pascal (Pa)
Volume	The basic SI unit of volume is the cubic metre (1000 litres). For convenience, however, the litre (L) is used as the unit of volume in laboratory work.

Examples of decimal multiples and submultiples of SI units

Factor	Name	Prefix
10^6	mega-	M
10^3	kilo-	k
10^{-1}	deci-	d
10^{-2}	centi-	c
10^{-3}	milli-	m
10^{-6}	micro-	μ
10^{-9}	nano-	n
10^{-12}	pico-	p
10^{-15}	femto-	f

Exceptions to the use of SI units

By convention, blood pressure is excluded from the SI unit system and is measured in mmHg (millimetres of mercury) rather than pascals.

Mass concentrations (e.g. g/L, μ g/L) are used in preference to molar concentrations for all protein measurements and for substances which do not have a sufficiently well-defined composition.

Some enzymes and hormones are measured by 'bioassay', in which the activity in the sample is compared with the activity (rather than the mass) of a standard sample that is provided from a central source. For these assays, results are given in standardised 'units', or 'international units', which depend upon the activity in the standard sample and may not be readily converted to mass units.

LABORATORY VALUES

Reference ranges are largely those used in the Department of Clinical Biochemistry and Haematology, Lothian Health University Hospitals Division, Edinburgh, UK. Values are shown in both SI units and, where appropriate, non-SI units. Many reference ranges vary between laboratories, depending on the assay method used and on other factors; this is especially the case for enzyme assays. The origin of reference ranges and the interpretation of 'abnormal' results are discussed in Chapter 1. No details are given here of the collection requirements which may be critical to obtaining a meaningful result. Unless otherwise stated, reference ranges shown apply to adults; values in children may be different.

Many analytes can be measured in either serum (the supernatant of clotted blood) or plasma (the supernatant of anticoagulated blood). A specific requirement for one or the other may depend on a kit manufacturer's recommendations. In other instances, the distinction is critical (e.g. plasma is required for measurement of fibrinogen since it is largely absent from serum; serum is required for electrophoresis to detect paraproteins because fibrinogen migrates as a discrete band in the zone of interest).

28.1 Urea and electrolytes in venous blood

Analysis	Reference range	
	SI units	Non-SI units
Sodium	135–145 mmol/L	135–145 meq/L
Potassium (plasma)	3.3–4.7 mmol/L	3.3–4.7 meq/L
Potassium (serum)	3.6–5.1 mmol/L	3.6–5.1 meq/L
Chloride	95–107 mmol/L	95–107 meq/L
Urea	2.5–6.6 mmol/L	15–40 mg/dL
Creatinine	60–120 μ mol/L	0.68–1.36 mg/dL

28.2 Arterial blood analysis

Analysis	Reference range	
	SI units	Non-SI units
Bicarbonate	21–29 mmol/L	21–29 meq/L
Hydrogen ion	37–45 nmol/L	pH 7.35–7.43
P_{aCO_2}	4.5–6.0 kPa	34–45 mmHg
P_{aO_2}	12–15 kPa	90–113 mmHg
Oxygen saturation	> 97%	

28.3 Hormones in venous blood

Hormone	Reference range	
	SI units	Non-SI units
Adrenocorticotrophic hormone (ACTH) (plasma)	1.5–11.2 pmol/L (0700–1000 hrs)	7–51 pg/mL
Aldosterone		
Supine	30–440 pmol/L	1.09–15.9 ng/dL
Erect	110–860 pmol/L	3.97–31.0 ng/dL
Cortisol	Dynamic tests are required—see Ch. 20	
Follicle-stimulating hormone (FSH)		
Male	1.0–10.0 U/L	0.2–2.2 ng/mL
Female	3.0–9.0 U/L (early follicular, luteal) < 30 U/L (mid-cycle) > 30 U/L (post-menopausal)	0.7–2.0 ng/mL < 6.7 ng/mL > 6.7 ng/mL
Gastrin (plasma, fasting)	< 57 pmol/L	< 120 pg/mL
Growth hormone (GH)	< 0.5 µg/L excludes acromegaly (if IGF1 in reference range) > 6 µg/L excludes GH deficiency Dynamic tests are usually required—see Ch. 20	—
Insulin	Highly variable and interpretable only in relation to plasma glucose and body habitus	—
Luteinising hormone (LH)		
Male	1.0–9.0 U/L	0.11–1.0 µg/L
Female	2.5–9.0 U/L (early follicular, luteal) Up to 90 U/L (mid-cycle) > 20 U/L (post-menopausal)	0.3–1.0 µg/L Up to 10 µg/L > 2.2 µg/L
17β-Oestradiol		
Male	< 160 pmol/L	< 43 pg/mL
Female	110–180 pmol/L (early follicular) 550–2095 pmol/L (mid-cycle) 370–770 pmol/L (luteal) < 150 pmol/L (post-menopausal)	30–49 pg/mL 150–570 pg/mL 101–209 pg/mL < 41 pg/mL
Parathyroid hormone (PTH)	1.0–6.5 pmol/L	10–65 pg/mL
Progesterone		
Male	< 2.0 nmol/L	< 0.63 ng/mL
Female	< 2.0 nmol/L (follicular) > 15 nmol/L (mid-luteal) < 2.0 nmol/L (post-menopausal)	< 0.63 ng/mL > 4.7 ng/mL < 0.63 ng/mL
Prolactin (PRL)	60–500 mU/L	—
Renin activity		
Erect	1.0–4.2 ng/mL/hr	—
Supine	0.5–2.6 ng/mL/hr	—
Testosterone		
Male	10–30 nmol/L	2.88–8.64 ng/mL
Female	0.4–3.0 nmol/L	0.12–0.87 ng/mL
Thyroid-stimulating hormone (TSH)	0.2–4.5 mU/L	—
Thyroxine (free) (free T₄)	9–21 pmol/L	700–1632 pg/dL
Triiodothyronine (T₃)	0.9–2.4 nmol/L	59–156 ng/dL
Notes 1. A number of hormones are unstable and collection details are critical to obtaining a meaningful result. Refer to local laboratory handbook. 2. Values in the table are only a guideline; hormone levels can often only be meaningfully understood in relation to factors such as sex (e.g. testosterone), age (e.g. FSH in women), time of day (e.g. cortisol) or regulatory factors (e.g. insulin and glucose, PTH and [Ca ²⁺]). 3. Reference ranges may be critically method-dependent.		

28.4 Other common analytes in venous blood in adults

Reference range			Reference range		
Analyte	SI units	Non-SI units	Analyte	SI units	Non-SI units
α_1 -antitrypsin	1.1–2.1 g/L	110–210 mg/dL	Ethanol	Not normally detectable Marked intoxication 65–87 mmol/L Stupor 87–109 mmol/L Coma > 109 mmol/L	300–400 mg/dL 400–500 mg/dL > 500 mg/dL
Alanine aminotransferase (ALT)	10–50 U/L	–	Gamma-glutamyl transferase (GGT)	Male 10–55 U/L Female 5–35 U/L	–
Albumin	35–50 g/L	3.5–5.0 g/dL	Glucose (fasting)	3.6–5.8 mmol/L See p. 806 for definitions of impaired glucose tolerance and diabetes mellitus, and p. 781 for definition of hypoglycaemia	65–104 mg/dL
Alkaline phosphatase	40–125 U/L	–	Glycated haemoglobin (HbA_{1c})	4.0–6.0% 20–42 mmol/mol Hb	–
Amylase	< 100 U/L	–	Immunoglobulins (Ig)		
Aspartate aminotransferase (AST)	10–45 U/L	–	IgA	0.8–4.5 g/L	–
Bilirubin (total)	3–16 μ mol/L	0.18–0.94 mg/dL	IgE	0–250 kU/L	–
Calcium (total)	2.1–2.6 mmol/L	4.2–5.2 meq/L or 8.50–10.50 mg/dL	IgG	6.0–15.0 g/L	–
Carboxy-haemoglobin	0.1–3.0%	–	IgM	0.35–2.90 g/L	–
Caeruloplasmin	0.2–0.6 g/L	20–60 mg/dL	Lactate	0.6–2.4 mmol/L	5.40–21.6 mg/dL
Cholesterol (total)	Ideal level varies according to cardiovascular risk (see cardiovascular risk chart, p. 580) so reference ranges can be misleading. The following values were described by the European Atherosclerosis Society: Mild increase 5.2–6.5 mmol/L Moderate increase 6.5–7.8 mmol/L Severe increase > 7.8 mmol/L		Lactate dehydrogenase (total)	208–460 U/L	–
		200–250 mg/dL 250–300 mg/dL > 300 mg/dL	Lead	< 1.0 μ mol/L	< 21 μ g/dL
HDL-cholesterol	Ideal level varies according to cardiovascular risk so reference ranges can be misleading. According to the National Cholesterol Education Programme Adult Treatment Panel III (ATPIII), a low HDL-cholesterol is: < 1.0 mmol/L		Magnesium	0.75–1.0 mmol/L	1.5–2.0 meq/L or 1.82–2.43 mg/dL
		< 40 mg/dL	Osmolality	280–296 mmol/kg	–
Complement			Osmolarity	280–296 mosm/L	–
C3	0.73–1.4 g/L	–	Phosphate (fasting)	0.8–1.4 mmol/L	2.48–4.34 mg/dL
C4	0.12–0.3 g/L	–	Protein (total)	60–80 g/L	6–8 g/dL
Total haemolytic complement	0.086–0.410 g/L	–	Triglycerides (fasting)	0.6–1.7 mmol/L	53–150 mg/dL
Copper	13–24 μ mol/L	83–153 μ g/dL	Troponins	Values consistent with 'myocyte necrosis' or myocardial infarction are crucially dependent upon which troponin is measured (I or T) and on the method employed	
C-reactive protein	< 5 mg/L Highly sensitive CRP assays also exist which measure lower values and may be useful in estimating cardiovascular risk	–	Tryptase	0–135 mg/L	–
Creatine kinase (total)			Urate		
Male	55–170 U/L	–	Male	0.12–0.42 mmol/L	2.0–7.0 mg/dL
Female	30–135 U/L	–	Female	0.12–0.36 mmol/L	2.0–6.0 mg/dL
Creatine kinase MB isoenzyme	< 6% of total CK	–	Vitamin D		
			25(OH)D	25–170 nmol/L	10–68 ng/mL
			1,25(OH) ₂ D	20–120 pmol/L	7.7–46 pg/mL
			Zinc	11–22 μ mol/L	72–144 μ g/dL

28.5 Common analytes in urine

Analyte	Reference range	
	SI units	Non-SI units
Albumin	Definitions of microalbuminuria are given on page 481 Proteinuria is defined below	
Calcium (normal diet)	Up to 7.5 mmol/24 hrs	Up to 15 meq/24 hrs or 3–300 mg/24 hrs
Copper	< 0.6 µmol/24 hrs	< 38 µg/24 hrs
Cortisol Overnight (early morning sample) 24-hr collection	< 20 nmol cortisol/mmol creatinine 25–250 nmol/24 hrs	< 67 µg cortisol/g creatinine 9.1–91 µg/24 hrs
Creatinine	10–20 mmol/24 hrs	1130–2260 mg/24 hrs
5-hydroxyindole-3-acetic acid (5-HIAA)	10–42 µmol/24 hrs	1.9–8.1 mg/24 hrs
Metadrenalines Normetadrenaline Metadrenaline	0.4–3.4 µmol/24 hrs 0.3–1.7 µmol/24 hrs	73–620 µg/24 hrs 59–335 µg/24 hrs
Oxalate	0.04–0.49 mmol/24 hrs	3.6–44 mg/24 hrs
Phosphate	15–50 mmol/24 hrs	465–1548 mg/24 hrs
Potassium*	25–100 mmol/24 hrs	25–100 meq/24 hrs
Protein	< 0.3 g/L	< 0.03 g/dL
Sodium*	100–200 mmol/24 hrs	100–200 meq/24 hrs
Urate	1.2–3.0 mmol/24 hrs	202–504 mg/24 hrs
Urea	170–600 mmol/24 hrs	10.2–36.0 g/24 hrs
*The urinary output of electrolytes such as sodium and potassium is normally a reflection of dietary intake. This can vary widely. The values quoted are appropriate to a 'Western' diet.		

28.6 Cerebrospinal fluid analysis

Analysis	Reference range	
	SI units	Non-SI units
Cells	< 5 × 10 ⁶ cells/L (all mononuclear)	< 5 cells/mm ³
Glucose¹	2.3–4.5 mmol/L	41–81 mg/dL
IgG index²	< 0.65	–
Total protein	140–450 mg/L	0.014–0.045 g/dL
¹ Interpret in relation to plasma glucose. Values in CSF typically approximately two-thirds plasma levels.		
² A crude index of increase in IgG attributable to intrathecal synthesis.		

28.7 Haematological values

Analysis	Reference range	
	SI units	Non-SI units
Bleeding time (Ivy)	< 8 mins	–
Blood volume		
Male	75 ± 10 mL/kg	–
Female	70 ± 10 mL/kg	–
Coagulation screen		
Prothrombin time	10.5–13.5 secs	–
Activated partial thromboplastin time	26–36 secs	–
D-dimers		
To detect disseminated intravascular coagulation	< 200 µg/L	< 200 ng/mL
To detect venous thromboembolism	< 500 µg/L	< 500 ng/mL
Erythrocyte sedimentation rate	Higher values in older patients are not necessarily abnormal	
Adult male	0–10 mm/hr	–
Adult female	3–15 mm/hr	–
Ferritin		
Male	20–300 µg/L	20–300 ng/mL
Female	14–150 µg/L	14–150 ng/mL
Fibrinogen	1.5–4.0 g/L	0.15–0.4 g/dL
Folate		
Serum	5.0–20 µg/L	5.0–20 ng/mL
Red cell	257–800 µg/L	257–800 ng/mL
Haemoglobin		
Male	130–180 g/L	13–18 g/dL
Female	115–165 g/L	11.5–16.5 g/dL
Haptoglobin	0.4–2.4 g/L	0.04–0.24 g/dL
Iron	10–32 µmol/L	56–178 µg/dL
Leucocytes (adults)	4.0–11.0 × 10 ⁹ /L	4.0–11.0 × 10 ³ /mm ³
Differential white cell count		
Neutrophil granulocytes	2.0–7.5 × 10 ⁹ /L	2.0–7.5 × 10 ³ /mm ³
Lymphocytes	1.5–4.0 × 10 ⁹ /L	1.5–4.0 × 10 ³ /mm ³
Monocytes	0.2–0.8 × 10 ⁹ /L	0.2–0.8 × 10 ³ /mm ³
Eosinophil granulocytes	0.04–0.4 × 10 ⁹ /L	0.04–0.4 × 10 ³ /mm ³
Basophil granulocytes	0.01–0.1 × 10 ⁹ /L	0.01–0.1 × 10 ³ /mm ³
Mean cell haemoglobin (MCH)	27–32 pg	–
Mean cell volume (MCV)	78–98 fl	–
Packed cell volume (PCV) or haematocrit		
Male	0.40–0.54	–
Female	0.37–0.47	–
Platelets	150–350 × 10 ⁹ /L	150–350 × 10 ³ /mm ³
Red cell count		
Male	4.5–6.5 × 10 ¹² /L	4.5–6.5 × 10 ⁶ /mm ³
Female	3.8–5.8 × 10 ¹² /L	3.8–5.8 × 10 ⁶ /mm ³
Red cell lifespan		
Mean	120 days	–
Half-life (⁵¹ Cr)	25–35 days	–
Reticulocytes (adults)	25–85 × 10 ⁹ /L	25–85 × 10 ³ /mm ³
Transferrin	2.0–4.0 g/L	0.2–0.4 g/dL
Transferrin saturation		
Male	25–56%	–
Female	14–51%	–
Vitamin B₁₂	251–900 ng/L	–
